backwards, and very considerably curved upon itself. The inner side of the foot is uppermost, the outer side rests upon the ground, the heel is more or less turned inwards and upwards. The integuments of the outer side are thickened by pressure, and there is a sort of provisional cushion, of a somewhat elastic nature, formed under it, while the thickness and hardness of the integuments of the sole are not found to the usual degree. The joints that suffer most in this malformation are, as might be expected from a review of their natural structure, the double articulations between the first and second row of tarsal bones. The scaphoid bone is twisted inwards in such a manner, that the dorsum of it presents forwards and its apex backwards, and the navicular cavity is brought to the inner edge of the astragalus. The cuboid bone generally preserves its relation to the scaphoid, being more or less displaced from the os calcis, and turned under the foot. The cuneiform bones, the metatarsus, and toes, are little altered in their relation to those tarsal bones to which they join, the peculiarity of their position and direction being entirely the result of the alterations in the scaphoid and cuboid, just mentioned. The os calcis is turned, so that its outer side is inclined towards the ground, and further than natural from the outer malleolus; the inner hollow side is inclined upwards and inwards, and nearer to the inner malleolus than natural, and the heel itself is elevated. By this means the articulations between this bone and the astragalus are altered somewhat, particularly if the ankle-joint itself remains natural, the astragalus not having partaken of the general malposition; this bone is then thrown in some degree upon the outer side of the os calcis. The astragalus, we have said, rarely shares in the general deformity; when it does it is tilted outwards, so that its upper surface inclines towards the external malleolus, and the articular portion itself becomes altered in form, as is also the corresponding portion of the tibia; in one instance related by Bouvier, the astragalus, by the pressure of the inner side of the tibia above and of the calcis below, was reduced to a mere thin edge on this side, the whole bone being something in form of a wedge between them.

2. In the *valgus,* (see *fig.* 164), where the foot is turned in the opposite direction to that

Fig. 164.

which has been just described, the whole state of the foot seems to be pretty nearly the exact converse of every thing there mentioned. The same bones are affected, and in the same relative degree; and the same analogy which exists between the one condition and the phenomena of adduction, is found between the other and those of abduction. The dorsum faces more or less directly forwards, the plantar surface backwards, the inner side of the foot rests upon the ground, the outer is uppermost. The tibia frequently here participates in the deformity so far as to have a curve inwards, and the inner ankle consequently approaches to the ground. The double articulation between the first and second row of bones in this case also suffers the most. The astragalus sometimes projects in front, and lower than in the varus. The distortion is sometimes carried to such an extent that the foot is turned nearly upwards and at the side of the fibula. The os calcis is twisted outwards, with the heel elevated, its hollow inclining towards the ground. The scaphoid and cuboid bones are, as we have said, most displaced; the first being nearest the ground, the last placed uppermost, and near the outer malleolus. The cuneiform bones, and the other bones of the foot, retain their relation to the bones to which they are articulated, their unnatural situation being the result of the displacement of these.

Fig. 165.

3. The *pes equinus*, (see *fig.* 165,) so named from the resemblance in the position of the tarsus to that of the horse, differs from either of the others in its anatomical characters. When it has arrived at a considerable pitch, the tibia is found partially dislocated backwards upon the os calcis; the scaphoid and cuboid are carried backwards, towards the sole of the foot, leaving the upper part of the head of the astragalus and cuboides projecting; the cuneiform and metatarsal bones are displaced sometimes in a similar manner. Thus the whole foot is more arched than natural, independently of its altered position; the sole is shortened and hollowed, the dorsum is elongated and projecting.

A very interesting history of yet another form of this disease by M. Holz of Strasburg, is given in the 13th vol. of the Lancet, in which the foot was turned completely back, having the dorsum resting on the ground, the plantar surface being uppermost. The deformity was in both feet. Walking was not painful; the patient rested his weight on the tarsus; the metatarsus and toes did not touch the ground. He wore common half-boots, the toes of which pointed backwards and the heels forwards. The man died, and upon examination of his feet the following state of parts was found. The skin of the dorsum upon which he trod was hard and callous. The bones of the leg were well formed; the astragalus was dislocated forwards; the calcaneum forwards and outwards, and the cuboid downwards on the calcaneum. The dorsal surface of the foot was very convex, excepting at the spot which touched the ground; the plantar surface very concave. The superior articular surface of the astragalus was turned directly forward and a little downward; its posterior surface also looked forward, and the tibia rested on the inferior, in a great degree, and on the small process of the calcaneum. The connexion of the scaphoid with the astragalus was more natural; the scaphoid was, however, turned a little backward. The cuboid rested by its posterior part on the inferior surface of the os calcis. The articular surfaces of the astragalus and os calcis gave attachment to ligamentous fibres. The three cuneiform bones, the metatarsal bones, and the toes had not experienced any sensible change in their position.

The descriptions now given are of extreme cases in each of the species of deformity. Of course the degree of departure from the natural form varies in every case. In the varus, every intermediate shade between the extreme mentioned and the mere state of permanent adduction occurs. The state of fixed abduction may, in the same way, be called the milder extreme of the valgus, while the pes equinus shows its simplest form in the mere fixed extension of the foot.

We also find in some instances a combination of more than one form of the deformity in the same foot. The most frequent of these is the state of permanent extension, of the pes equinus, with the adduction of the metatarsal bones and phalanges, constituting a variety of the varus. (*Fig.* 166.) The same complication of the pes equinus with the valgus is rare, but does sometimes occur. A congenital deformity, so

Fig. 166.

far as we know not mentioned, has once fallen under our notice, namely, a dislocation of the tibia backwards upon the upper and posterior part of the os calcis, so that the prominence of the heel was entirely lost, and the foot flexed to such a degree, as that the dorsum lay in contact with the anterior part of the leg.

The alterations from the normal state of the ligaments, bones, muscles, and articular surfaces, in these cases of deformity, are easily comprehended. The ligaments are of course elongated on the one side of the dislocated joint, and shortened on the other side; the bones are altered in shape, occasionally, where pressure is produced by a neighbouring bone, and sometimes a portion of the bone is twisted, and drawn towards the unnatural situation of that one with which it articulates. The muscles are elongated or shortened, according as their points of attachment are, by the deformity, approximated or further separated. The articular surfaces undergo great alterations: they are altered in shape and situation by the friction of the parts in contact producing a new synovial surface upon its new situation, while a part, or the whole of the natural joint loses its polished surface, and becomes adherent to the integuments, while, in many instances, the altered position of a bone brings it into contact with another, with which naturally it had no such relation, and here again a preternatural synovial articulation will form, in accordance with the same law of the animal economy, by which long-continued pressure will produce a synovial bursa. As a general observation, we may state, that the whole limb is smaller, shorter, and feebler than the sound one, and that this defect increases by comparison with the sound one, as the child grows. M. Cruveilhier has also found that individual bones are sometimes singly defective in their growth, while occasionally only the portion of a bone which is subjected to pressure is checked in its developement.

The deformities described above are generally congenital, but they are also occasionally produced after birth by accidental causes; though in this case there is no difference in the nature of the distortion or in the anatomical condition of the parts, yet they are less frequently cured, because the same carelessness or bad management which has too often occasioned the accidental form of the disease to creep on unheeded, makes the parents indifferent as to the cure, while the deformity, which has not mismanagement for its cause, is immediately remarked on the birth of the child, excites alarm in the mind of the parent, and means are early adopted for its removal.

This part of our subject leads us to notice a deformity, of not uncommon occurrence, but one which has met with little notice from writers, although the inconvenience and suffering occasioned by it, great in degree, and, as far as we have known, permanent in duration, will entitle it to the consideration of the surgeon. We allude to that state of the foot wherein the arch is lost, and the foot rests flat upon the ground. It is met with generally, but not always, in those children of the lower classes who are obliged, in their early youth, to engage in laborious occupations, and particularly in lifting heavy weights, before the powers of the system are developed, though we have known it to occur where none of these causes could be traced. It happens generally, not in the very weak, nor in the firm and robust children, but in those who have the promise of developement on a large scale, and are rapidly growing. It comes on insidiously, and is rarely detected until too far gone to admit of a complete cure. The marks of this disease are an evident alteration in the shape of the foot. The dorsum has comparatively lost its convexity, the concavity of the sole is entirely gone; the scaphoid bone projecting below unnaturally, and the inner malleolus falling considerably inwards. The relative position of all the rest of the foot appears natural. The patient complains of pain and tightness at the upper part of the instep passing through to the sole upon attempting to elevate the heel while standing. Indeed, in aggravated cases, he cannot lift himself at all upon the metatarsus, while every step upon an uneven surface is accompanied with pain. The anatomical characters of this distressing disease consist, as far as a close examination of the living parts can detect, for we have had no opportunity of dissecting them, in a relaxation of that ligament which passes between the os calcis and navicular bone, and on which the fore part of the astragalus rests and moves. It will be quite evident, from an examination of these parts and their connexions, that this supposition is sufficient to account for the symptoms that are apparent, and the idea is borne out by the fact of the point of the scaphoid being further separated than natural from the tubercle of the os calcis, which may be readily ascertained by the touch. We conceive the remote cause to be a certain degree of inflammatory action in the elastic ligament just mentioned, produced by over-exertion, before the part had acquired its full developement and strength. The morbid action being continued by the continuance of the irritation, the elasticity of the ligament is impaired, and it can no more support the weight laid upon it; it consequently yields, and is stretched. This view receives some support from the fact of the tenderness upon pressure constantly found in this precise spot, and from the relief afforded to the more distressing symptoms by the application of leeches and counter-irritations.

Another deformity of the foot occasionally met with is exactly the reverse of the preceding; this is too great a convexity of the arch, by which the foot is considerably shortened, and the bearing, anteriorly, taken from the under side of the heads of the metatarsal bones, and thrown partly upon the bases of the first phalanges and upon the metatarso-phalangeal joint itself. From the tense state of the plantar fascia we must suppose that this structure is shortened, and indeed we have been inclined to consider this contraction of the fascia as in some degree a cause of the deformity, which Dupuytren has proved to be the fact in the parallel case of contraction of the fingers, by shortening of the palmar fascia. With this view, in a case of deformed foot which lately came under our notice, we divided the fascia plantaris, and certainly with considerable temporary benefit. We have not been able to ascertain why the relief was not permanent, as the patient lives at a distance; but it might not improbably arise from his returning to work too soon, and leaving off the extension of the foot which had been adopted.

(A. T. S Dodd.)

FOOT, REGIONS OF THE.—The surgical anatomy of the ankle having already been given, (see ANKLE, REGIONS OF,) it remains for us, in this article, to describe the foot properly so called, that is, all of the lower extremity beyond the ankle. This part comprises much that is practically interesting and important, both in its pathology and surgery, which must be evident when we consider the vast number of ills which are endured in the feet. The foot, considered as an entire region, is naturally and obviously subdivided into dorsal and plantar regions. In the first of these we observe, 1st, the dorsum, or instep, extending from the front of the ankle to the heads of the metatarsal bones; 2d, the toes themselves.

I. *Region of the dorsum.*—We see the instep falling, with a gentle curve, forwards from the ankle, and forming the anterior portion of that arch, which posteriorly runs through the ankle-joint to the heel, and the crown of which, formed by the astragalus, bears the weight of the whole body. This most remarkable provision for the safety and efficiency of the body is well deserving of particular examination, and we shall return to it when describing the plantar region. The curve of the dorsum just mentioned is running forwards to the head of the metatarsal bone of the great toe; there is another arch, a lateral one, running across the foot, of which the inner end is abrupt, as it bends over the inner side of the ossa naviculare and cuneiforme interna; the outer end slopes off more gradually to the os cuboides and metatarsal bone of the little toe. The use of this arch is best seen also in the sole, though it presents itself to the view most strikingly on the dorsum.

The principal points which claim our attention in this region are:—

1. The *integuments,* which are here rather thinner and softer than in other parts of the limb, but varying considerably in texture according to age, sex, and habit: they are also rather thinner on the outer than on the inner side. 2. The *subcutaneous cellular tissue.* This is rather loose, and freer from fat than in other parts of the body, permitting free movement of the superficial parts upon those beneath. This laxity of the cellular tissue is greatest on the middle of the instep; and accordingly we see in children and females, where there is a large quantity of superficial fat, and in effusions of water or other fluids, that the skin of this part rises most, while across the ankle and the roots of the toes there is an appearance like a ligature arising from the comparative closeness and shortness of this cellular web. In this layer also we find several large veins and some branches of nerves. The dorsal veins of the foot run in very irregular directions, varying in size in different subjects, but mostly collected into two plexuses, which form in front of the inner and outer ankles, the *saphena major* and *minor* veins. The course of these veins, though various, is generally as follows:—The *saphena major* begins to shew itself pretty conspicuously on the middle and inner side of the instep, and running to the inner ankle receives in its course numerous additions, and then passes over the internal malleolus. The *saphena minor* is seldom found in a notable trunk on the foot; we see only on the outer side of the dorsum several small branches communicating with the inner plexus, and taking their course towards the outer ankle; there they form sometimes one, but generally two branches, which pass sometimes over, generally behind the outer malleolus. It is the first of these veins that is principally important in surgery, as it occasionally, and we think it might with advantage be more frequently, opened for the detraction of blood. It is immediately brought into view by a ligature placed above the ankle, and in opening it we must bear in mind that, from its superficial situation, from the looseness of the enveloping tissue, and from the greater distance of the ligature from the point to be punctured, the vein is much more liable to roll and to foil our attempts than the vein at the elbow: we must, therefore, take the precaution of putting the fore-finger above, and the thumb below the spot where the lancet is to enter, which will retain with facility the vein in its place.

The varicose distention to which the trunks of the saphena veins in the leg are peculiarly liable, is often found extending to their minute commencing branches on the dorsum of the foot; so much so that the whole of this region is irregularly distended, and covered with the knots and ramifications of the distended veins. This morbid state is dependent upon the same causes as the varicose affection of the veins of the leg, and can be remedied only by the same means, but with this additional disadvantage, that the mechanical means adopted for their relief by pressure, owing to the more conical form of the foot, can with greater difficulty be retained.

Besides the veins, we find imbedded in this same layer of cellular tissue a number of nervous filaments, which should be remembered as occasionally interfering with operations on this part. The last portion of the saphenus or long cutaneous nerve runs so near to the saphena major vein that some of its twigs pass in front of and some behind it, and have been occasionally punctured in opening this vein; but this should form no stronger an objection to this operation than a similar arrangement of the nerves, and a similar accident in bleeding, which occasionally happens, should be allowed as an objection to venesection at the bend of the arm.

3. The next layer brought into view by dissection is a thin expansion of fascia, continuous with the anterior annular ligament of the ankle, and formed of fibres running in various directions, principally transverse and spreading over the whole of the dorsal region, but principally at the upper part. The observations which have been made on this same fascia when covering the ankle may be applied also to the part just described, (see ANKLE-JOINT, REGION OF,) with this exception, that as the dorsal fascia is much thinner and more incomplete than that over the ankle, matter would here not be so tightly bound down, nor would it present so strong an obstacle to the pointing of it outward.

4. On removing the layer of aponeurosis a muscular and tendinous stratum is exposed, comprehending the entire muscle of the extensor brevis digitorum and the tendons of several of the long muscles situated on the leg. The first of these has a thick fleshy belly, and occupies the outer part of the dorsum of the foot, sending its tendons down, like so many rays, to the bases of the toes. The tendons are spread over the foot in the following order:—on the inner side the tibialis anticus passing to be inserted, by a broad attachment, into the internal cuneiform bone and base of the first metatarsal bone; next the extensor proprius pollicis runs forwards and inwards, along the fibular edge of the first metatarsal bone; then the tendons of the extensor longus digitorum run diverging towards the bases of the four outer toes, crossing over the tendons of the extensor brevis; and lastly, the tendon of the peroneus tertius, diverging from the extensor longus, sends its small flat tendon to the base of the fifth metatarsal bone. Each of these tendons runs in its own synovial sheath, and these are, from their superficial situation and from their proximity to the bones over which they pass, peculiarly liable to be affected by pressure, as from tight boots. The consequence of this is not unfrequently seen in a small round swelling, situated generally over the tarsal bones, and upon one of the tendons of the extensor digitorum longus. It is first discovered generally by its tenderness, and when this is relieved by taking off the pressure which was its first cause, the swelling itself still remains, soft and elastic to the touch, and having all the characters of an enlarged bursa, and which has received the name of *ganglion*. The cure may generally be accomplished easily and expeditiously: a smart blow with some hard body, as the back of a book, while the swelling is rendered tense by the forcible extension of the foot, will be all that is necessary; the cyst is thus burst, and its synovial contents, when extravasated among the adjacent cellular tissue, soon become absorbed, while the empty cyst itself shrinks and contracts to its natural size. Should, however, this plan not be approved, or, which may happen, not succeed, the introduction of a cataract needle in an oblique direction under the skin, and the puncture of the cyst, will evacuate the fluid into the surrounding cellular tissue, and thus effect a cure.*

A tumour is sometimes formed upon the instep, which is also the result of pressure, and which bears a near relation to a corn. It is met with in young men who wear tight boots, and the usual situation of it is over the articulation between the internal cuneiform bone and the metatarsal bone of the great toe. The tumour is under the skin, hard and immovable; so that it seems to a superficial observer to be an enlargement of the bone itself. The skin over it is in a natural state, except in cases of long standing, in which the cuticle becomes thickened. This swelling is described by Sir B. Brodie in a clinical lecture in the Medical Gazette, vol. xvii. He is uncertain in what precise situation this tumour exists, whether in the ligaments of the joint, or periosteum, or in the ultimate fibres of the tendon of the tibialis anticus muscle, not having had an opportunity of dissecting it.

In this view also are exposed the course and situation of the dorsal artery of the foot. This, which is merely the continuation of the anterior tibial artery, commences its course from the anterior annular ligament of the ankle, a little to the inner side of the middle of the foot; from thence it runs obliquely towards the first interosseal space of the metatarsal bones, at the commencement of which it dips into the sole of the foot, leaving only a branch to continue its course to the great toe. In the course just mentioned this artery rests upon the bones of the tarsus, separated from them and their ligaments only by a small quantity of cellular tissue. It is accompanied by its vein and a branch of a nerve, and will readily be found running along the outer or fibular edge of the tendon of the extensor proprius pollicis, which partly overlaps it. Notwithstanding the superficial situation of this artery, its close connexion with the above-mentioned tendon renders it peculiarly ineligible for the application of a ligature, and fortunately it is very rarely that we are called upon to perform an operation upon it; but its course and situation are important to the surgeon, as affording a valuable diagnostic mark, negative at

* See a paper on Ganglion by C. A. Key, Esq. in the 1st vol. of Guy's Hospital Reports.

least, if not positive, in the examination of an injury to some of the larger vessels, as the femoral or the anterior tibial. For though, owing to occasional varieties in the course and distribution of the dorsal arteries of the foot, the absence of pulsation in the situation of the arteria dorsalis pedis, just indicated, would not be a positive proof of injury to the larger vessels, (though even this might be received as valuable corroborative evidence,) yet the clear and full pulsation of this vessel would of course be undoubted evidence that the larger arteries were safe and sound. (See Tibial Arteries.)

II. *Region of the toes.*—In the natural state the toes are covered by a skin, soft and pliable, except the extreme phalanx, the dorsal surface of which is defended by the nail, for the structure and arrangement of which we refer to the article Tegumentary system. Under the skin and subcutaneous tissue we find the tendon of the long extensor, lying close upon the bone adhering to it and to the synovial membranes of the joints, by short but free cellular tissue, sufficiently loose to allow of the free movements of the subjacent joints. We observe that the length of the toes, by the construction of the bones, much shorter and smaller than the fingers, appears shorter still in the metatarsal phalanx by the greater depth of the integumental web between the toes. The operator will do well to remember this in amputating at the metatarso-phalangeal joint, or he will surely be foiled in his attempt to open it, particularly as this joint, lying deeper and being composed of smaller bones than the corresponding joint of the hand, is much less readily perceptible, even to the touch. Lastly, these organs, the toes, more universally, and in greater degree perhaps than any other part of the body, pay the penalty of hyper-refinement and civilization in the distortion and disfigurement of their entire structure from pressure. The skin suffers most acutely; it becomes entirely altered in structure. The soft cuticle which covered it is, by the irritation of pressure, increased in thickness by successive additional layers. This increase is greatest just at the point where there is most pressure, namely, at the upper and lateral parts of the projecting joints; nature thus providing a defence for the tender cutis, pressed between the bone and the shoe. The cause of irritation being still continued, the defence itself is converted into an additional enemy; the accumulated layers of hardened cuticle form a hard corn, and irritate and inflame the subjacent cutis. Another effort of nature is made to relieve the suffering parts; a small bursa is formed under the most prominent part of the corn, and this again is made an additional cause of suffering by this part also becoming inflamed, the original source of evil not being removed. The same process taking place between the toes by the pressure of one toe against the other, produces the soft corn by the moisture of this part not allowing the thickened cuticle to become hard and dry. The same process on a larger scale over the joints of the great toe occasions the bunion,* the bursal cysts of which form a beautiful illustration of the powers of nature in accommodating herself to accidental circumstances.

Nor is the mischief arising from this opposition to nature confined to the results now mentioned. The toes, from being constantly kept in a distorted position, acquire permanently an unnatural form, sometimes being bent laterally under or over each other, the ligaments become stretched, the articular cartilages absorbed, the ends of the bones altered in form, and anchylosis is not unfrequently the result. If the shoe be too short, a permanent contraction of the joint of the toe is produced, which is sometimes so distressing in walking as to be a serious impediment to this exercise, and even to demand amputation of the toe as the only means of deliverance. This, when it does occur, is almost always found in the second toe, because it projects beyond the others.

Plantar region.—The plantar region, like the dorsal, may be divided into the plantar region, strictly so called, and the region of the toes.

I. *Proper plantar region.*—The skin upon the sole of the foot is covered by a cuticle remarkable both for its general density and for the great difference of its density in different parts. In the hollow of the sole it is thinnest, next along the outer side, and thickest of all under the heel and heads of the metatarsal bones. This great thickness of the cuticle, though partly arising from pressure, is yet partly natural, being found in some degree even in the fœtus, and is one of those marks of Provident Wisdom of which every part of our structure furnishes instances. The cutis itself is still more striking for the strength and density of its structure, which we observe particularly in dissecting this part. The scalpel must be sharp indeed to cut through it with ease. This, in fact, with its horny cuticle is nature's provision against the injuries to which the important parts of the sole are exposed, and the only defence, the only sandal worn to this day by multitudes. Its structure, as shewn by removing carefully the cellular tissue from its inner surface, is composed of a number of whitish glistening fibres crossing each other in every direction, and enclosing in their meshes portions of that granular fat which forms the layer immediately subjacent to the skin. These meshes are closer and smaller as we approach the outer surface, where the cells entirely disappear. When the cuticle is separated from it, the cutis exhibits a vast number of exhalent pores, the source of that profuse perspiration which is given off from this part of the feet under exercise; these are pretty equally distributed over the sole, but the great thickness of the epidermis at the heel must impede the transpiration through it

* See an excellent paper by Mr. Key in Guy's Hospital Reports. Vide Clinical Lecture on Corns and Bunions, by Sir B. C. Brodie, Bart. in the Med. Gazette, vol. xvii.

to a considerable degree. The sensibility of this part of the integuments is not at all in relation to its apparent want of delicacy in structure; no part of the body possesses a covering more acutely sensitive. The effects of pricking, of titillation, of cold or heat applied to the sole of the foot, exemplify this. Its sympathies also are as remarkable for their liveliness as for their extent. Not even the arm-pits or sides of the ribs are at all equal to it in this respect. The bladder, the urethra, the stomach and intestines, in fact almost all the mucous membranes, together with the whole voluntary system of nerves, and through them the whole system of voluntary muscles, may be said especially to sympathize with and to be influenced by this one part. Of this no one can doubt when we see the effects of sudden cold applied to it in relaxing spasm of the urethra or bowels, in checking vomiting, or in rousing the whole nervous and muscular system during fainting, &c. The effect also of hot applications of stimulants and irritants applied to this part familiarly illustrate its extensive sympathies. The most sensitive part of the sole is the hollow, that part where the cuticle is least dense.

When the cutis is removed, we expose a stratum of cellular tissue remarkable for its density and toughness, and for the granular fat with which its cells are filled; it lies immediately under the true skin, and over the plantar fascia. We may here observe that a similar integument, and the same kind of cellular web under it, is spread over the heel, and, from the peculiarity of its texture, is probably more likely to inflame under the effects of pressure than the skin of other parts of the body; at any rate, it very frequently does inflame, and even slough, when long subjected to pressure; and inattention to this point is often the source of great misery in the treatment of fractures and dislocations of the lower extremity. The heel resting upon some hard portion of the apparatus often so torments the patient as to be a serious impediment to the successful treatment of the case.

The *fascia plantaris* demands our particular attention. It is a strong tendinous structure forming a covering to the muscles and important structures of the sole. It is very thick and dense at its posterior part, and becomes thinner, though still of the same consistence, at the anterior part. The cellular web just mentioned strongly adheres to it externally, while the muscles which it covers are not only adherent to its inner side, but many of their fibres arise directly from it. It not only forms a layer of separation between these muscles and the more external parts, but it sends processes of a similar tendinous structure between the principal muscles, which also afford origin to many of their fibres. It divides itself into three portions, one covering each of the three principal groups of muscles found here. These three portions are, however, united behind where they arise in common from the under projecting part of the os calcis, while anteriorly the layer becomes quite incomplete from the subdivision into five slips, each of these again splitting to pass to be fixed into each side of the heads of the metatarsal bones. The situation, structure, and connexions of this fascia, of the dense stratum of cellular tissue, and of the peculiar skin covering this, are highly important to the surgeon. The knowledge of these points teaches why phlegmonous inflammation must be difficult of treatment, and often dangerous in its results, whether it occurs immediately under the skin or under the fascia, but particularly in the latter situation, the dense unyielding structure of which prevents the swelling from pressing outward, thus greatly aggravating the pain and irritation, and when matter has formed, equally prevents its pointing outwards, and calls for the early application of the lancet to give it free vent, and thus prevent its spreading along the foot. The structure of the parts just described is, as far as it goes, an objection to the partial amputation of the foot recommended by Chopart, wherein the flap is formed from these parts in the sole, together with the muscles and tendons found there. But this objection is by no means fatal to operations upon these parts, which have often been successfully performed, and when they are so, often give a limb much more useful than a wooden one.

We now come to the deep-seated parts of the foot. These consist, 1. of the muscles and tendons; 2. of veins and arteries; 3. of nerves; 4. of absorbents. The muscles and tendons compose three principal groups destined to accomplish the movements of the great toe, of the three middle toes, and of the little toe, and according to their destination and use, so is their situation in the sole. On the inner side the abductor, the adductor, the flexor brevis, and tendon of the flexor longus pollicis form a pretty considerable mass, and have a separate slip of the fascia plantaris lying under them, in contact with the most superficial of them, viz. the abductor. On the outer or fibular side of the sole, a similar mass of muscles, but smaller, lie underneath the metatarsal bone of the little toe, composed also of an abductor and a short flexor, while one slip both from the long and short common flexors joins them anteriorly. The space between these two masses of muscles is occupied, most superficially, and immediately in contact with the plantar fascia, by the flexor brevis digitorum, next by the tendons of the flexor longus digitorum, accompanied by their accessories; posteriorly, the accessories or massa carnea Jacobi Sylvii; and anteriorly, the lumbricales, while deeper still than all there are the interossei interni.

Amidst this number of small muscles, the plantar arteries take their course in the following manner. The posterior tibial artery, as we have elsewhere seen (vide Ankle-joint, Regions of), passing down behind the inner malleolus, gets into the hollow of the os calcis, lying pretty close to this bone, and covered only by the integuments, cellular tissue, and fascia. It now passes between the origins of the adductor pollicis, and in doing so divides into external and internal plantar. The first of these, which is much the larger of the two, runs in a somewhat semicircular course, first forwards and outwards till it has reached the base of the metatarsal bone of the little toe, and then winds round across the other metatarsal bones, till at that of the great toe it terminates by uniting with the anterior tibial. In this course it runs first between the superficial and deep muscles, viz. first covered by the abductor pollicis, then between the flexor brevis digitorum and the long flexor tendons; it then becomes more superficial, lying between the flexor digitorum brevis and the abductor minimi digiti; then in crossing back to the inner side of the foot, it runs deep under all the muscles and tendons, except the interossei. Thus this artery forms an arch, called the plantar arch, having its convexity forwards and outwards, its concavity inwards and backwards. The branches which it supplies in this course are, first, a number of large muscular branches before it reaches the outer side of the foot; then from the convexity of the arch itself, the digital arteries, one to each metatarsal space, which, dividing at the first joint of the toes, run one on each side of the toe to its termination; and lastly, those from the upper and inner sides, being generally very insignificant muscular branches and communicating branches, these last going upwards between the metatarsal bones to anastomose with the metatarsal branches of the anterior tibial artery. It is right, however, to state that in this, as in every other part of the arterial system, great variety is occasionally found. The internal plantar artery is a comparatively small artery, merely going to supply the muscles and integuments of the great toe, and for this purpose passes forwards along the under and inner side of the tarsus, covered by the abductor pollicis as far as the first phalanx of the great toe, where it divides into several branches, supplying both sides of the great toe, and the inner side of the second. The veins which accompany the plantar arteries are, like all deep-seated veins, two in number, one on each side of the artery, and they terminate in the hollow of the os calcis by forming the posterior tibial veins. The plantar arteries are accompanied also in their course by corresponding nerves, the termination of the posterior tibial nerve, which divides in the hollow of the os calcis. The internal plantar nerve, contrary to the order of the arteries, is the larger of the two; it runs in company with the inner plantar artery, and sends branches to the three inner toes, and to the inner side of the fourth, while the external plantar nerve running the course of the corresponding artery is distributed only to the fifth toe and outer side of the fourth. The lymphatics of the sole of the foot, like the rest of this system, are composed of a superficial and a deep set, the former collecting from all parts towards the inner ankle; the latter accompanying the plantar arteries and veins, and passing up also with them behind the inner ankle, go with the tibial veins to the ham. There are several synovial bursæ in this region which it is necessary here to mention. They are surrounding the tendons as they pass into the sole along the hollow of the os calcis, viz. the flexor longus pollicis and flexor longus digitorum. Their anatomical description has been already given (see Ankle, Region of). Another synovial sheath is surrounding the tendon of the peroneus longus as it obliquely crosses the sole to its insertion. This bursal cavity is situated close upon the bone, and under the principal ligaments.

II. *Plantar region of the toes.* — Of the toes we observe that the integuments of the under part are always soft and pliable, compared with the rest of the integument of the sole, and possessing peculiarly the sense of touch; that under the skin at the extremity of the toes there is a soft elastic cushion of cellular tissue, analogous to that at the tip of the fingers, and in this and in the cutis the extremity of the digital arteries and nerves is minutely ramified. The digital arteries themselves, with their accompanying nerves and veins and absorbents, are running along the edges of this under surface of the toes. Lastly, the tendinous thecæ, in which the flexor tendons are lying, are situated along the under surface of the phalanges of the toes, and are particularly attached to the sharp edges of these bones (see Foot, Joints of). They have a smooth synovial lining which prevents the effects of friction upon the tendons, and facilitates their movements.

From the description which has now been given of the organization of the plantar region of the foot, we readily perceive, 1st, Why deep wounds of this part are both followed by considerable hæmorrhage, and why this is at the same time very difficult to stop. The arterial branches are numerous and lie deep. Before we can get at them either to press upon or to tie them, we must do so through a thick integument, a dense tendinous fascia, and deep-seated layer of muscles. If we dilate the opening in all these parts we wound many more branches, while it is impossible at such a depth, and through such part, to discover the bleeding vessel, if the opening is small. We are, therefore, compelled in such a case, if pressure will not stop the hæmorrhage, to tie the posterior tibial artery, either behind the ankle or at the lower third of the leg. But even this is sometimes not sufficient to stop the hæmorrhage, owing to the free anastomosis of the arteria dorsalis pedis with the plantar arteries; and we are then compelled also to tie the anterior tibial. 2d, We see why inflammation and suppuration in these parts, whose parietes as well as contents are in great measure tendinous, are threatening both in their present symptoms and in their consequences. Not only is the ready detection of suppuration prevented, but the efforts of nature to bring it to the surface are resisted. The inflamed parts are bound tight; if matter has formed, it is obliged to burrow laterally, in contact with nerves, arteries, tendons, &c. The inflammation spreading to the synovial sheaths either impairs or destroys the movements of the tendons in them, or, going still further, communicates the inflammation to the tendon, and occasions it to slough. Moreover, the tendinous structure which envelopes some of these bursal cavities is the cause of those violent and alarming symptoms of constitutional irritation, by no means uncommon when only a very small quantity of matter has formed within them, a state sometimes almost instantaneously relieved by a judicious opening made with the lancet, and giving exit to even so small a quantity of pus. 3d, Why severe contusions or lacerations are here so often followed by bad consequences, the power of repair in tendinous structures, which so largely enter into the composition of the parts about the foot, being small, and consequently the inflammation frequently proving the destruction either of the structure or the functions of the parts affected.

The study of the nature and position of these joints of the foot is of great interest and importance to the surgeon, and it will not be inappropriate in this article to offer some observations upon some of the operations in which they are concerned. Modern surgery, whose greatest triumphs have been in the saving of limbs, not in removing them, in discovering the least possible quantity of loss by which the disease might be eradicated, rather than the readiest method of taking off the entire limb, has taught us not to be deterred by the intricacies of the numerous joints of the foot, but fearlessly to lead the knife through any part of them, so that we may only save a serviceable portion, which may be more convenient than a wooden substitute. The removal of the toes at their joints is comparatively easy, though it should be remembered, in amputating at the metatarso-phalangeal joint, that this articulation is situated much deeper than the corresponding one of the hand, owing to the greater length of the web and greater thickness of the member itself. The metatarsal bones may be removed separately or altogether from their junction with the tarsus, as first done by Hey of Leeds, and described in his Surgical Observations. The removal of a single bone is, except it be either the first or the fifth, more difficult and even more dangerous, in regard to the liability to after inflammation, than the removal of the whole metatarsus. In performing this last operation, the guide for entering the whole row of joints is the projecting tubercle of the fifth metatarsal bone, immediately behind which the joint may be opened, and on coming to the projection of the inner cuneiform bone, (see *fig.* 167,) most surgeons recommend the cutting

Fig. 167.

off its projecting part, rather than to finish by opening the joint. The tarsal bones have been extracted, both with and without the attached metatarsal bones. Of the former kind a very remarkable instance is given by Mr. Key in the second number of Guy's Hospital Reports, in which the only bones of the tarsus left were the os calcis, astragalus, scaphoid, and internal cuneiform bones as a support to the great toe. (See *figs.* 167 and 168, in the first of which the dotted line represents the portion of the bones of the foot which was removed in *fig.* 168.)

Fig. 168.

Should disease or accident have destroyed all, or most of the bones in the front row of the tarsus, they may all be readily removed by amputation at the astragalo-scaphoid and calcaneo-cuboid joints, an operation generally known as that of Chopart, who first practised it. How far, however, such a portion of the foot preserved is preferable to the use of a short wooden leg applied to the end of the limb, amputated a little above the ankle, (a plan which we have used with perfect success,) certainly admits of a doubt. At any rate its advantages cannot be put in competition with the principle so admirably illustrated by Mr. Key in the before mentioned case, of saving, if possible, a portion of the metatarsus and toes, though at the risk of a more painful, and perhaps more dangerous operation.

Upon a general survey of the structure and form of the foot, we are struck with the difference between this organ in man and in all other animals. The most striking peculiarities consist in the great breadth of the foot, its shortness in proportion to the leg, the large size of the bones of the tarsus, the relative shortness and smallness of the four outer toes, and the great size of the inner one, the great strength of the calcaneum, and lastly, in those arches produced by the arrangement and form of the tarsal and metatarsal bones. The only animal that nearly approaches to the form of man, the monkey, yet differs from him in all these points. Its foot is narrower and longer in proportion to the leg, its tarsal bones are smaller, its four outer toes are long like the fingers, while the first is small, and separated from the rest. The calcaneum is relatively small, and inclines upwards at its posterior projection, while the peculiarities already specified necessarily occasion that the arches of the foot are much less distinct than in man. Indeed, in supporting itself erect, the monkey rests very much on the outer side of the foot, probably on this account. In all other animals these differences are still more marked. What now can be more evident or more beautiful than the design manifested in this simple arrangement of the foot! Man is physically as well as morally intended to carry himself erect. The breadth of his base was necessary for his continued support; the strength of it is called for on account of the great weight which erect progression throws upon it. Its arches were essential not only to give lodgment and defence to the vessels and nerves of the plantar region, but, by the peculiarity of their construction, to admit of a certain degree of elastic yielding, which greatly diminishes the shocks from violent efforts in leaping, running, &c. The shortness of the toes, augmented by the depth of the webs, shows that prehension forms no part of the design of the foot, while the size of the first toe, and its connexion with the others, points it out as the principal instrument of progression, to which the rest are auxiliary. The analogies between the foot and the hand are striking; they have the same general arrangement of bones and muscles, and even the arteries and nerves, the joints and ligaments, are in many respects similar, but in the particulars just mentioned the difference is strikingly obvious and important, and just in these respects it is that the feet of the Quadrumana also differ from those of man, showing a difference in their intended action, the erect position, at the utmost being only occasional, not being the natural habit, but the foot being prepared and adapted for grasping and clinging, for which the human foot is quite unfit.

The construction of the arches of the foot requires a few words. They are two in number, a transverse and a longitudinal one. The latter of these is principally found along the inner edge of the foot, and as we pass towards the outer side the longitudinal arch gradually shortens and becomes more flattened, until at the outer side the arch is entirely lost, the bones of the tarsus and metatarsus resting through their whole length upon the ground. This is to a certain degree necessary from the construction of the toes, these being weaker and shorter, as well as their metatarsal bones, as they are further from the great toe; as their strength therefore diminishes, the corresponding part of the arch is shortened and flattened, and, consequently, less strain is thrown upon them, until, at the line of the little toe, the arch is obliterated, and what weight is resting here comes at once upon the ground. But from this construction it follows that the longest and the highest line of this arch falls upon the strongest metatarsal bone and longest toe, and that whatever yielding there is occurring in the entire longitudinal arch is greatest in this part of it. This is, indeed, proved by the fact that the length of the foot in a sound state is increased in the line of the great toe to the extent of several lines, by resting the weight of the body upon the foot, whereas it is not at all increased in the line of the little toe. When, therefore, the arch yields to the superincumbent pressure, it does so chiefly along the inner side, and the foot is thus, to a certain degree, twisted, the inner malleolus approached nearer to the ground, while the outer is very little, if at all, lowered. This explains to us the reason of the scaphoid and inner cuneiform bones projecting as they do in the flat foot, and of the pain experienced on the inner side of the foot in the same deformity in all efforts to raise the heel in walking. It may also in some degree account for the fact of the more frequent occurrence of dislocation of the tibia at the ankle-joint inwards than outwards, the arch of the foot yielding first to the force of the accident on the inner side, and thus tilting the whole ankle-joint inwards. The utility in walking of the form and relation of the various parts of the foot now mentioned is readily seen when we unite the consideration of the structure of this arch with the combined action of the gastrocnemii upon the heel, and of the peroneus longus upon the outer side of the foot. The united action of these muscles throws and sustains the whole weight upon the strongest and most elastic part.

Whatever has been said of the utility of the longitudinal arch applies equally to the transverse arch, which is supplementary and auxiliary to the former in all its uses.

(A. T. S. Dodd.)

FOOT, MUSCLES OF THE.—In speaking of the muscles of the foot we necessarily understand not merely those muscles which are situated upon the foot, but those muscles peculiarly belonging to it, which are concerned in producing its motions wherever situated. The muscles of the foot, in this sense, are partly situated upon the leg and partly upon the foot, and should, in a physiological view, be considered together, that we may the better understand their separate and combined functions. We shall therefore, in this, as in other anatomical articles, first give the descriptive anatomy of the muscles situated upon the foot, and then examine their functions in connexion with those others whose action is upon the joints of the foot, and which are therefore strictly muscles of the foot, but which are anatomically described elsewhere. (See Leg, Muscles of the.)

The proper muscles of the foot are, 1. those on the dorsum; 2. those on the sole.

The muscles on the dorsum pedis are the *extensor brevis digitorum* and the *dorsal interossei.*

1. The *extensor brevis digitoram* (Fr. *pedieux*).—This is a short flat muscle, situated upon the outer side of the tarsus and metatarsus. It arises by fleshy and tendinous fibres from the upper and anterior part of the os calcis, in the hollow between that bone and the astragalus *(creux astragalo-calcanien)*, also partly from the os cuboides. It immediately forms a broad fleshy belly, the fibres of which pass forwards and inwards, and divide into four portions, from each of which proceeds a slender tendon. These four tendons, of which the two internal are the strongest, cross under those of the long extensor of the toes, opposite the heads of the metatarsal bones. Of these tendons the internal is inserted into the base of

the first phalanx of the great toe, the others are united to the outer edge of the long tendons, with which they form the aponeurosis which covers the dorsum of each toe. The obliquity of this short muscle counteracts the obliquity of the long extensor, and it serves to extend and to spread the toes, and to pull them away from the great toe.

2. *Interossei dorsales vel externi.*—These are four in number, and arise by double heads, that is, they arise from both the contiguous metatarsal bones, here occupying the whole of the interosseal space, and thus concealing the internal interossei, which are seen only in the sole. Their flat tendon unites with that of the long and short extensors, and is inserted into the side of the bases of the first phalanges of the toes in such a manner that, with internal interossei, every toe has one of these little muscles on each side of it, except the first toe, which has two distinct muscles of its own for the same action, and the little toe, which is provided with a separate abductor. Their use is to separate the toes, and perhaps to assist in extending them.

In the sole of the foot the inner side is occupied by the muscles of the great toe, constituting what some French writers call the *thenar eminence*. These muscles are as follows:—

1. *Abductor pollicis pedis.*—This commences, by a tendinous and fleshy origin, from the tubercle on the under and fore part of the os calcis, from the ligament extending between the os calcis and os naviculare, and from the fascia plantaris. Its tendon unites with the flexor brevis pollicis, and is inserted into the internal sesamoid bone, and inner side of the base of the first phalanx of the great toe. It draws the great toe from the others.

2. *Flexor brevis pollicis.*—Lies between the abductor and adductor, in contact with the metatarsal bone. It arises, by two portions, from the under and fore part of the os calcis, and from the external cuneiform bone. It is united, on each side, to the abductor and the adductor, and is inserted with these, by a union of tendons, into the two sesamoid bones and base of the first phalanx of the great toe, having the tendon of the long flexor passing between the two insertions.

3. *Adductor pollicis.*—This muscle, which is situated the most externally, or fibulad, of the muscles of the great toe, commences by a tendinous origin, from the calcaneo-cuboid ligament, and from one or two of the metatarsal bones. It is double at first, and then uniting, sends a tendon to be fixed into the external sesamoid bone and outer or fibular side of the base of the first phalanx of the great toe, in close connexion with the flexor brevis. It draws the toe towards the others. The muscles of the little toe are situated on the outer edge of the foot, and form, in that situation, a corresponding eminence, which has been called the hypothenar eminence.

1. *Abductor minimi digiti.*—This arises from the outer, under, and fore part of the os calcis, and from the fascia plantaris. It forms a long slender belly, and is fixed by its tendon into the base of the first phalanx of the little toe, and head of its metatarsal bone. It flexes and abducts the little toe, and, by its attachment to the metatarsal bone, it strengthens the arch of the foot, which indeed may be said of almost all the muscles of the foot.

2. *Flexor brevis minimi digiti* commences from the os cuboides and base of the metatarsal bone of the little toe, and lying close to this bone, it is inserted into the base of the first phalanx. It is a very small muscle, and its use is to flex the toe.

The middle of the plantar region is occupied by six muscles common to all the smaller toes.

1. *Flexor brevis digitorum*, called also *perforatus.*—This muscle arises, fleshy, from the anterior part of the protuberance of the os calcis, also from the inner surface of the plantar fascia, both from its central thick portion and from the septa, which run between this muscle and those of the great and little toes. Under the metatarsus it sends off four small tendons, which, entering the sheath on the under side of the four outer toes, are inserted into their second phalanx. Before these tendons arrive at the point of insertion each of them splits, to allow the passage of the tendon of the long flexor, in a manner similar to what takes place in the hand, and they thus have a double insertion into the toe. The action of this muscle is to flex the second joint of the four lesser toes.

2. *Flexor digitorum accessorius*, or *massa carnea Jacobi Sylvii.*—This is a short muscle, somewhat square in form, covered by the flexor brevis digitorum. It arises, fleshy, from the sinuosity of the os calcis, and tendinous from the outer side of the same part; it is attached anteriorly to the tendon of the flexor longus digitorum, just before it divides. Its use is, evidently, to assist the action of the long flexor.

3. *Lumbricales.*—These slender round muscles are found between the tendons of the long flexor of the toes; they arise from these tendons just after their division, and fix their own tendon into the inner or tibial side of the first phalanges of the four outer toes; they act by bending the first joint of these toes.

4. *Interossei plantares vel interni.*—These are three in number, smaller than the external, and having their origin each from only one metatarsal bone. Their insertion and action have been mentioned when speaking of the external interossei.

5. *Transversalis pedis.*—This little muscle is situated across the heads of the metatarsal bones, passing from the fibular side of the great toe to the tibial side of the little one, and attached to them all as it passes over them. It goes under the tendons of the long flexors and the lumbricales, or rather between them and the bones. Its action is to draw the metatarsal bones together, thus to consolidate, as it were, and strengthen that antero-posterior arch, which, were its parallel portions allowed to spread out unchecked, would be materially weakened, and be less able to encounter the violent movements to which the foot is liable in leaping, running, &c.

We shall now enumerate the muscles which are employed in the movements of the foot and its several portions, and classify them according to the joints upon which they act and the movements they produce.

The motions of the ankle-joint are	1. Flexion accomplished by	1. Tibialis anticus. 2. Peroneus tertius. 3. Extensor longus digitorum. 4. Extensor proprius pollicis.
	2. Extension performed by	1. Gastrocnemius externus. 2. Gastrocnemius internus. 3. Plantaris. 4. Flexor longus digitorum. 5. Flexor longus pollicis. 6. Tibialis posticus. 7. Peroneus longus. 8. Peroneus brevis.
The motions between the first and second row of tarsal bones* are . . .	1. Downwards and inwards accomplished by .	1. Tibialis posticus. 2. Extensor proprius pollicis. 3. Flexor longus digitorum. 4. Flexor longus pollicis.
	2. Upwards and outwards by	1. Peroneus Longus. 2. Peroneus brevis. 3. Peroneus tertius. 4. Extensor longus digitorum.
The motions of the toes are	1. Flexion performed by .	1. Flexor longus pollicis. 2. Flexor brevis pollicis. 3. Flexor longus digitorum. 4. Flexor brevis digitorum. 5. Flexor accessorius digitorum. 6. Lumbricales. 7. Flexor brevis minimi digiti.
	2. Extension by . . .	1. Extensor proprius pollicis. 2. Extensor longus digitorum. 3. Extensor brevis digitorum.
	3. Abduction by . . .	1. Abductor pollicis. 2. Abductor minimi digiti. 3. Interossei: Prior indicis. Prior medii digiti. Prior tertii digiti.
	4. Adduction by . . .	1. Adductor pollicis. 2. Transversalis. 3. Interossei: Prior minimi digiti. Posterior indicis. Posterior medii digiti. Posterior tertii digiti.

In this table we are struck with the proportion which the antagonist muscles bear to each other, both in numbers and in individual as well as collective power. This proportion is of course regulated by the demand for muscular force in the ordinary movements of the joints. The extension of the ankle, in the most ordinary mode of its performance, implies the lifting of the whole weight of the body by the elevation of the heel, the toes resting upon the ground. This, owing to the unequal length of the two levers, requires an immense power, while the shortness of the moveable lever allows of very little extent of motion. The gastrocnemii are accordingly thick short muscles, with a long and powerful tendon. These are assisted by the plantaris and five other muscles. Flexion, on the contrary, which generally implies merely the elevation of the foot, without any other force to overcome, is adequately provided for by only four muscles, and these not large, indeed one of them very small. The assistance rendered by the five auxiliary muscles, which pass behind the malleoli, though considerable on the whole, yet is small individually in proportion to their size, owing to the disadvantageous situation which their tendons occupy at so very short a distance from the centre of motion; for this reason,—when the tendo Achillis is ruptured, the patient is as incapable of walking as if all the extensor muscles were divided, yet when the body is resting the antagonism of the extensors is not entirely lost. The foot is not permanently bent upwards, and the simple act of extension can be accomplished without great difficulty. One of the most remarkable of all the extensor muscles, both as to its course and its function,

* It is remarkable that so original and accurate an observer as Dr. Barclay should attribute this motion to the ankle-joint, and should deny any motion, more than a mere yielding, to any of the tarsal bones. But it is still more surprising that he should make the same observation of the carpus, when so very considerable a part of the ordinary motion at the wrist is obviously between the two rows of carpal bones. See Barclay on Muscular Motion, pp. 404, 447.

is the peroneous externus. (See LEG, MUSCLES OF.) The tendon of this muscle passes behind the outer malleolus, then, running downwards and forwards, it enters a groove formed in the os calcis, close behind the prominence of the base of the fifth metatarsal bone. It then runs across the sole of the foot, in contact with the bones, to be fixed to the inner cuneiform bone and metatarsal bone of the great toe. The course and situation of the tendon well deserve particular attention in the dissection of the foot. Without some study, it is impossible fully to understand its office, or how essential its action is to the mechanism of progression. If we examine the general form of the foot, we see that the anterior end of it is not square, owing to the comparative length of the toes. These are not of equal length, but are each shorter than the other as we proceed outwards, the outermost of all being the shortest. This part of the foot then is like the end of an oblong, with one angle greatly rounded off. When, therefore, the weight of the body is, by the elevation of the heel, thrown forwards upon the toes, there is necessarily a tendency, in this shape of the foot, to tilt the pressing force outwards, whereas if all the toes had been of equal length, the elevation of the heel would simply have thrown the weight directly forwards, the support being equal on both sides of the foot. This tendency outwards, occasioned by the difference in length of the toes, is still further increased by the difference in strength, the largest, the most unyielding support, being on the inner side of the foot, the smallest and the most yielding being on the outer. This then being the construction of the basis of support, some means of counteracting this tendency was necessary to enable us to carry the body directly forwards, even in the simple act of walking, and still more in the more violent exertions. This is accomplished by the peroneus longus, whose tendon, like a girt, passes under the outer edge of the sole, and thus, lifting this, and in some degree turning the sole outwards, throws the weight of the body upon the great toe. This action of the muscle is particularly exemplified in the movements of skaiting.

The movements of the bones of the tarsus are so distinct and constant that we have classified the muscles which act upon them separately from those of the ankle. (See FOOT, JOINTS OF.)

The muscles of the great toe are remarkable, as might be expected, for their size and strength. The long flexor is considerably larger than that common to the other toes, and gives to this a slip of its tendon, so that the flexor longus pollicis does in fact assist in flexing all the toes.

The general arrangement of all the muscles and tendons in the sole is very curious, and has a further object than the mere flexion of the toes. The great toe is, as we see, well provided, and it needs this, since it bears the greatest share of the burden of the body in walking, &c. The muscular provision for the other toes is as considerable, and indeed more so, in proportion to the size of the toes. There is, 1st, the flexor brevis digitorum; 2d, the flexor longus

Fig. 169.

1 Flexor accessorius.
2 Flexor pollicis longus.
3 Flexor digitorum longus.

5 Lumbricales.
6 Tendon of long flexor.

digitorum; 3d, this tendon receives an auxiliary tendon from the long flexor of the great toe; 4th, the massa carnea; 5th, the lumbricales. There can be little doubt that the use of all these muscles is to give a powerful support to the antero-posterior arch of the foot, to which purpose the mere ligaments would be little equal. But we must admire not only the number and force but the arrangement of these muscles, which are so placed as to act, almost all of them, from the same centre, and therefore with greater advantage for the object of strengthening the arch. Thus the flexor brevis digitorum lies pretty nearly central in this region, while immediately under it the flexor longus digitorum, running from within outwards, is crossed in the opposite oblique direction by the flexor longus pollicis, and these again are still further checked outwards by the flexor accessorius, so that the centre of action of all these muscles and of the lumbricales also, which arise from the long flexor tendon, is in the same line as the flexor brevis, which lies over them, and as a support to the great arch of the foot this arrangement of the muscular chords must have a peculiarly advantageous effect.

(A. T. S. Dodd.)

For the BIBLIOGRAPHY, see ANATOMY (INTRODUCTION).

FORE-ARM, (Surgical anatomy), (*Antibrachium*; Fr. *Avant-bras*; Germ. *der Vorderarm*). This term is applied to that portion of the upper extremity which is situated between the elbow and wrist-joint.

In the well-formed male all the muscles of this region, but especially the supinators, from the fascia which covers them being extremely thin, when thrown into action stand out in strong relief, giving an appearance of great power concentrated within a small space. In the female, on the contrary, the fore-arm, from the great preponderance of adipose tissue, presents a swelling outline and rounded form, not the less beautiful, perhaps, from indicating deficiency of muscular energy, and conveying the idea of softness and dependence.

The usual and least constrained position of the fore-arm is with the hand between pronation and supination, that is, with the palm of the hand inwards and the dorsum outwards; but for the purpose of anatomical description the palm of the hand is supposed to face forwards and the dorsum backwards, the fore-arm being extended. In this position the fore-arm obviously differs from the arm in being wider from side to side than from before backwards. Superiorly it presents in front a very slightly convex surface, but inferiorly there is formed by the flexor tendon a distinct central projection, which is bounded by the flexor carpi radialis on the radial side, and by the flexor carpi ulnaris on the ulnar.

The posterior surface of the fore-arm is more irregularly convex than the anterior; the greatest convexity is nearer the ulnar than the radial edge, and is formed by the olecranon above and the shaft of the ulna below, which is covered only by the skin superiorly. A considerable depression may be observed, bounded on the inner side by the olecranon, and on the outer by the supinators; in this depression the outer condyle may be felt. To the inner side of the olecranon there is a corresponding but much smaller depression, in which the inner condyle is situated. For about three inches above the wrist-joint the fore-arm posteriorly is slightly concave in the centre in consequence of the marked projection of the ulna and radius on either side. In the motions of pronation and supination the shape of the fore-arm is considerably changed; but as no practical advantage can attend a detailed account of the changes undergone, we shall not dwell upon them here.

The parts composing the fore-arm are as follow: the radius and ulna, the muscles of the hand and fingers, the radial and ulnar arteries with their branches, the venæ satellites of these arteries and the subcutaneous veins, the radial, ulnar, median, and cutaneous nerves, the absorbent vessels, a quantity of cellular and adipose tissue, various aponeuroses, and the common integuments.

The configuration, relative position, and connection of the bones of the fore-arm have been described in the article EXTREMITY. They move together in the flexion and extension of the fore-arm on the os humeri at the elbow-joint, under the influence of the biceps flexor cubiti and brachialis anticus, and the triceps extensor cubiti and anconeus.

In the motions of supination and pronation the radius is always rolled upon the ulna, the latter remaining perfectly fixed, though this fact has been disputed in consequence of the thick sacciform ligament of the wrist and the tendon of the extensor carpi ulnaris being felt to roll under the finger when placed on the inferior extremity of the ulna during the motion of rotation and supination, and thus communicating the sensation of a motion in the ulna itself.

The skin of the fore-arm differs considerably on the dorsal and anterior aspects. On the former it is coarse and comparatively rough, containing numerous small hairs; on the latter it is smooth and more delicate, and the adipose tissue being more abundant on the anterior, the whole surface is more even, while on the posterior the extensor muscles of the hand and fingers, being slightly covered, project considerably. Neither of the regions, however, contain so much fat as most other parts of the body.

The superficial veins which are subject to the greatest variety, are usually more distinct and numerous on the dorsal aspect, particularly at the lower part.

The subcutaneous nerves, which are very numerous, are derived from the following sources: 1st, the internal cutaneous nerve, which is one of the divisions of the axillary plexus; 2dly, the cutaneous branch of the radial; 3dly, the musculo-cutaneous.

The internal cutaneous nerve divides into two branches in the upper arm, in which region it accompanies the basilic vein. These two branches penetrate the fascia separately above the elbow-joint, and the one, the *anterior* branch, descends on the front of the fore-arm, the other, the *posterior*, on the back of it. The anterior branch usually passes behind the basilic vein, sending a small twig or two anterior to it. Its course is continued to the wrist-joint, supplying the skin on the anterior and inner side throughout; the posterior division accompanies the basilic vein, and may be always traced to the back part of the wrist.

The small branches of this nerve, which cross in front of the basilic or median basilic vein, are occasionally wounded in the operation of venesection; an accident which generally excites considerable inflammation, with severe constitutional irritation, symptoms which are sometimes erroneously attributed to the action of a foul lancet.

The skin on the anterior surface of the outer half of the fore-arm is supplied with nerves by the external cutaneous nerve, a division of the axillary plexus: it is a deep-seated muscular nerve in the upper arm and penetrates the fascia, becoming subcutaneous anterior and a little below the elbow-joint. In this situation it is posterior to the median cephalic vein; its branches are numerous throughout its course, which terminates at the wrist-joint in the supply of branches to the skin on the dorsum and ball of the thumb, which inosculate with the cutaneous of the radial.

This last-mentioned branch, the *cutaneous of the radial*, is derived from its trunk on the outer side of the middle of the arm; immediately after that nerve has emerged from between the triceps extensor and the bone, a series of branches is distributed to the skin of the arm. The remainder of the nerve, which is a descending branch of some size, passes down behind the elbow-joint, and becoming subcutaneous supplies the skin of the posterior surface of the outer half of the fore-arm, and corresponds to the musculo-cutaneous on the anterior. Thus it will be seen that the skin on the inner side of the fore-arm, both anteriorly and posteriorly, is supplied by the internal cutaneous, while that on the outer side is supplied in front by the musculo-cutaneous, and behind by the radial nerve.

The superficial veins of the fore-arm, though subject to the greatest variety, are usually distinguished by the names of the cephalic, basilic, and median. The two first commence on the back of the hand; the cephalic on the external, and the basilic on the internal side. They freely anastomose at the lower part of the fore-arm, after which they separate, and reaching the anterior surface below the elbow, are joined by the median vein, as described in the article ELBOW.

The superficial absorbents take nearly the same course as the veins, though they are far more numerous, and on the whole pursue a straighter direction. The course of these vessels is occasionally demonstrated in the living subject by active inflammation of their coats following the absorption of irritating matter.

Aponeurosis.—The aponeurosis of the fore-arm is simply a continuation of the same structure, which surrounds and supports the muscles of the upper arm; it varies very much in density and appearance in different situations; this difference arises from the fact that both the triceps extensor and biceps flexor cubiti send to it many fibres, which not merely give additional strength to its texture, but also act as a medium through which these muscles possess the power of making tense the fascia. This provision for tightening and supporting the fascia of the fore-arm is analogous to those arrangements which we meet with in the thigh and leg.

The fascia of the fore-arm is strongest at the posterior part of the limb, on each side of the olecranon. The fibres derived from the tendon of the triceps on the external side pass transversely outwards to be inserted into the outer condyle, intermingling with the radial extensors at their origin, at the same time firmly connected to the olecranon process, posterior and internal edge of the ulna, thus forming a dense and firm covering to the anconeus, between which muscle and the extensor carpi ulnaris a process of fascia is met with which forms a dense septum between the two. The fibres from the internal edge of the triceps at the upper part also pass transversely, reaching the inner condyle, intermingle with the origin of the flexor muscles; others again, descending at the back part of the arm, form an aponeurosis over the flexor carpi ulnaris; while those which pass forwards intermingle with the aponeurotic fibres of the biceps. These fibres from the biceps are uniformly strong and distinct, and give a great firmness and density to the fascia on the inner side of the arm covering the flexor muscles, which is not met with on the outer side of the arm supporting the supinators. The fascia in front of the fore-arm which covers the supinators receives its last fibrous connexion from the tendon of the deltoid. The fascia of the fore-arm on reaching the posterior part of the wrist-joint has interwoven with its texture many beautifully distinct fibres, taking a slightly oblique course from without to within, and from above to below; these fibres, which are firmly attached to the radius on the outer side and the ulna on the inner, become insensibly lost in the fascia on the back part of the hand, which resembles in its homogeneous appearance the fascia on the lower part of the fore-arm; these supplementary fibres to the fascia, though presenting a distinct edge neither above nor below, act as a ligament to the extensor tendons in their passage behind the wrist-joint, which has been called by some anatomists the posterior annular ligament; between these tendons and the ligament there is a large and distinct bursa, not unfrequently the seat of inflammation. The fascia on the lower and fore part of the fore-arm, consisting principally of transverse fibres, becomes gradually thinner, and in front of the wrist-joint is inseparably interwoven with the fibres of the annular ligament.

The aponeurosis of the fore-arm forms many septa between the muscles. Commencing with the description of the septa in the back part of the arm, we find a dense and strong one separating the anconeus from the extensor carpi ulnaris, and from which the latter muscle takes part of its origin. A second dips between the extensor carpi ulnaris and extensor communis digitorum, giving origin to both. A third is found between the common extensors of the fingers and radial extensors. The radial extensors and supinators are not thus separated from each other. A fourth process, distinct though comparatively thin, separates the supinator radii longus from the brachialis anticus, the tendon of the biceps, pronator radii teres, and flexor carpi radialis. There is also another process which unites the tendon of the supinator radii longus on the outer side to the flexor carpi ulnaris on the inner side, and forms a firm and dense covering to the radial artery. The pronator radii teres is scarcely separated from the flexor carpi radialis by a distinct septum, though the last-mentioned muscle is completely separated from the palmaris longus by a dipping in of the fascia. Between the flexor communis digitorum sublimis and flexor carpi ulnaris there is a very perfect and distinct septum.

Of the different morbid growths which arise in the cellular tissue of the fore-arm, those which are superficial and those which are beneath the fascia require careful distinction, the removal of the former being easily effected, while all operations on the latter require great consideration and care.

The superficial tumour projects under the skin, creating some deformity; it may be moved with facility, for its attachments are loose; while, on the other hand, the deep-seated or sub-fascial tumour has frequently a flattened surface, and often appears, on superficial examination, insignificant and of small extent, while in fact its mass is considerable, burrowing deeply between the muscles. It is to be distinguished from the supra-fascial tumour by its comparative immobility, by the various effects produced upon it by the fascia when in a state of tension or relaxation, by the pain produced by pressure on nerves, or impediment to the circulation from pressure on the vessels. In the removal of the sub-fascial tumour the operator must call to mind the direction and relative position of the muscles in the neighbourhood of it, as the roots or under surface of these generally follow the interspace between the muscles, and are thus guided to a great depth among the vessels and nerves of the fore-arm.

The same principles apply to the diagnosis and treatment of superficial and deep-seated abscesses. The superficial abscess is less circumscribed; the matter is diffused without limit through the subcutaneous tissue; from its position the absorption of the superincumbent tissues takes place rapidly, the skin either giving way entirely without the aid of the surgeon, or else pointing at some particular spot indicates where the abscess lancet may be employed with advantage.

The sub-fascial abscess, on the contrary, proceeds slowly in many cases, and even insidiously, bound down by the unyielding fascia; it tells us of its presence, in the first instance, rather by the constitutional disturbance which it rouses than any striking indications of local mischief. These abscesses are occasionally the consequence of inflammation commencing in the theca of the flexor tendons, and the burrowing of the matter upwards in the course of the tendons. The septa of the fascia, which have been described passing down between the muscles to the bone, limit the passage of the pus in different directions.

The fascia itself is not much subject to disease, though it seems peculiarly disposed to slough as a consequence of phlegmonous erysipelas.

Vessels.—The main arteries of the fore-arm are the radial and ulnar, into which the brachial artery divides just below the bend of the elbow. The brachial artery at this spot has on its outer side the tendon of the biceps; on its inner side, one of the venæ comites, the median nerve, and the pronator radii teres muscle. Behind the brachial artery is the brachialis anticus muscle, and in front of it the fascial insertion of the biceps muscle.

The radial artery, which is the smaller of the two divisions, pursues nearly the same direction as the brachial, and in the lower part of the upper third of the fore-arm is found exactly midway between the radial and ulnar surfaces, overlapped by the supinator radii longus, and lying upon the tendon of the pronator radii teres muscle, with the radial nerve about a quarter of an inch to its outer side, and separated by fat and cellular membrane. From this point the radial artery descends towards the wrist-joint, and at the lower part of the upper half of the fore-arm quits the pronator radii teres, and passes on to the anterior surface of the flexor longus pollicis, having the flexor carpi radialis to its inner side. A little lower down, that is, at the upper part of the lower third, the vessel emerges from beneath the supinator radii longus muscle, and is covered only by the fascia. In its further course to the wrist-joint the flexor carpi radialis maintains its position on the inner side, to which the tendon of the supinator radii longus corresponds on the outer. The radial nerve no longer accompanies the vessel, for it has now slid under the supinator radii longus, and reached the posterior face of the arm. As the radial artery just above the wrist-joint is covered only by the fascia, and lies upon the bone, its pulsations are easily felt, and in consequence of its convenient situation is generally selected by the medical practitioner to ascertain the general state of the circulation. We should, however, always bear in mind the great variety both in size and distribution to which this vessel is liable, and take the precaution of at least examining the radial artery in both arms.

The inner edge of the supinator radii muscle is a certain guide to the situation of this artery should the surgeon be required to secure it, and this should always be effected by two ligatures, as its free anastomosis below will certainly produce secondary hemorrhage if this precaution is neglected. As the nerve lies on the outer side of the artery, the needle must be passed from without inwards.

The ulnar artery has a deep course, first passing beneath the median nerve, which separates it from the pronator radii teres muscle, next beneath the flexor digitorum sublimis, the two last muscles separating it from the flexor carpi radialis and palmaris longus, and upon the flexor digitorum profundus, and when it reaches the tendon of this muscle midway between the wrist and elbow-joints, it comes into contact with the ulnar nerve, by which it is separated from the flexor carpi ulnaris muscle on its inner side. In its further descent to the wrist-joint it is situated between the flexor communis digitorum sublimis and flexor carpi ulnaris. Gradually sliding behind, the tendon of the latter remains covered by it for about two inches above the annular ligament of the wrist, in front of which it passes into the palm of the hand. The third branch worthy of mention in this division of the fore-arm is the anterior interosseal. This vessel is a branch of the ulnar artery, and not unfrequently is of large size, though usually of a calibre about intermediate to the two last mentioned. It arises from the ulnar artery where that vessel is covered by the pronator radii teres, and descending towards the interosseal ligament reaches that structure a little below the tendon of the biceps. It is accompanied by a branch of the median nerve in its course downwards; lies between the interosseous ligaments and the external edge of the flexor communis digitorum profundus; it terminates by dividing into two branches, of which one passes backwards through the interosseal ligament, anastomosing with the posterior interosseal, and the other, a small branch, descends over the wrist-joint into the palm of the hand, where it anastomoses with the deep palmar arch.

In the posterior region of the fore-arm we meet with only one vessel of any size; this is the *posterior interosseal artery*, a branch from the anterior interosseal, which passes through the interosseal ligament opposite the tubercle of the radius; its course is not so straight and uniform as the anterior, its distribuent branches are larger and more numerous, and it may be said to ramble down between the extensor muscles and the interosseal ligament, though it does not lie so immediately in contact with the ligament as the anterior interosseal. It terminates by anastomosis with the vessels about the wrist-joint.

Such is the usual distribution of these vessels; they are, nevertheless, subject to every kind of variety, and the operator previously to the commencement of an operation ought always carefully to examine the course of these vessels in order to detect any anormal arrangement either in relation to their size or distribution.

The arteries of the fore-arm are more exposed to accidents from cutting instruments than most other vessels in the body; and the usual plan of securing the vessel in these cases is to apply two ligatures on the wounded trunk, one above and the other below the orifice, the latter being required in consequence of the free anastomosis of the vessels in the hand.

But the fore-arm is occasionally wounded by sharp penetrating instruments, which passing deeply into the fleshy mass, the vessel which has been wounded is not immediately indicated, and the surgeon is consequently at a loss to discover which of the three main trunks requires the application of a ligature.

An examination through the wound would tend to aggravate the mischief, and besides, the search is often attended with difficulty, and often unsatisfactory.

In such cases it will be found far more advantageous to arrest the hemorrhage by pressure on the brachial artery, at the same time allaying the local inflammation by due attention to the position of the arm, and the usual antiphlogistic remedies, a plan which I have seen adopted with great success by Mr. Tyrrell, at St. Thomas's Hospital.*

* See St. Thomas's Hospital Reports, edited by John F. South, No. i. p. 25.

There are some cases, however, which imperatively require the application of ligatures, as for instance, when either of these vessels is opened by sloughing of the tissues from phlegmonous inflammation, or from aneurism in the fore-arm or hand. In the first of these cases, patients have frequently been lost from the temporary suspension of the hemorrhage by the use of cold applications or accidental circumstance, and its occurring again suddenly during the absence of the surgeon.

In the performance of the operation of tying the radial artery the supinator radii longus muscle affords an unerring guide throughout the fore-arm, but the surgeon must remember that the inner edge of this muscle is not on the outer side of the fore-arm, but as nearly in the centre as possible. The needle must be passed from without inwards, in order to avoid wounding the nerve.

The ulnar artery cannot be secured in the upper third of the arm, it lies so completely covered by most of the flexors arising from the inner condyle; as soon as the vessel has gained its position between the flexor carpi ulnaris and the flexor digitorum communis, it may be easily reached, the former muscle overlapping it, and therefore forming an excellent guide. The needle in this operation must be passed from within outwards, as the nerve lies to the ulnar side of the artery.

The bones of the fore-arm are not unfrequently fractured, either singly or together, but the radius, from its external position and strong connection with the bones of the hand, is more frequently fractured than the ulna. The injury generally takes place a little above the middle of the bone.

When both bones are fractured, the accident is frequently occasioned by the passage of a heavy weight over the limb, the violence acting immediately on the injured portions. In childhood these bones are sometimes bent instead of being broken, and as the deformity is slight, though the effect altogether very serious, the nature of the accident is not very readily detected.

"When these bones are fractured near their inferior extremities," says M. Boyer,* "the inflammatory swelling might render the diagnosis difficult, and cause the fracture to be mistaken for a luxation of the hand. But the two cases may be distinguished by simply moving the hand; by the motion, if there be luxation without fracture, the styloid processes of the radius and ulna will not change their situation; but if a fracture do exist, these processes will follow the motion of the hand."

If the radius be fractured a little below the head and above the tubercle, that is, through the neck, and the annular ligament remain entire, the deformity is so slight that there is great difficulty in detecting the nature of the injury, especially if there be much swelling and effu-

* Lectures of Boyer upon Diseases of the Bones, arranged by M. Richerand, translated by M. Farrell, vol. i. p. 161.

sion. Unless the surgeon can distinctly feel the head of the radius, so that he can clearly ascertain on rotating the lower portion with the hand, that the upper does follow but remains perfectly unmoved, he has no equivocal guide as to the real nature of the injury.

If the ulna is fractured separately from the radius, which seldom occurs, the injury generally happens to the lower third of the bone, which is much smaller and more exposed than the upper; the accident is easily detected by running the finger down the posterior edge of the bone. When the radius is fractured near its centre, the pronator quadratus muscle obtains entire power over the bone, and drawing the lower portion across towards the ulna, causes a considerable projection in the anterior interosseous space. If this be not corrected by the use of a pad, as recommended a little further on, the two bones will unite, and all motion of pronation and supination be entirely lost.

In all these cases of fracture of the bones of the fore-arm, nearly the same plan of treatment is required, namely, 1st, two pads, increasing in thickness from the elbow to the wrist, and not wider in any place than the arm itself, sufficiently soft to be pushed well into the interosseal spaces, applied anteriorly and posteriorly; a long linen roller enveloping the hand and the whole of the fore-arm, and pressing the pads between the two bones, so as to counteract the action of the two pronator muscles which have a tendency to bring them together. Splints extending from the elbow to the hand.

When the radius alone is fractured, it is advisable not to support the hand, but to allow it to hang down, and by this plan the hand acting as a weight, will draw the lower fractured portion, which has a tendency to overlap the upper, downwards, and thus bring them into apposition.

(Samuel Solly.)

FORE-ARM, MUSCLES OF THE.— When we consider how varied and complex are the motions of the arm and hand, it is no matter of surprize that so many as nineteen muscles should be found composing the fleshy mass of the fore-arm.

These muscles may be classified in reference to their action, and are briefly enumerated as follows:—

In the first place there is one muscle physiologically belonging to the upper arm, the anconeus; the rest are connected with the hand; for instance, there are three flexors of the hand; *flexor carpi radialis, flexor carpi ulnaris, palmaris longus.* Three extensors of the hand, *extensor carpi radialis longior, extensor carpi radialis brevior, extensor carpi ulnaris.* Three long flexors of the thumb and fingers; *flexor communis digitorum sublimis, flexor communis digitorum profundus, flexor longus proprius pollicis.* Five extensors of the thumb and fingers, *extensor ossis metacarpi pollicis, extensor primi internodii, extensor secundi internodii, extensor communis digitorum, extensor indicis.* Two supinators, *supinator radii longus, supinator radii brevis.* Two pronators, *pronator radii teres, pronator quadratus.*

In proceeding to describe the attachments and relations of the foregoing muscles, it will be found convenient to examine them as they are met with in the following regions of the fore-arm. 1. The anterior region, which contains a superficial and a deep set of muscles. 2. The posterior region, which likewise has its superficial and its deep layers of muscles. These regions again may be conveniently subdivided into radial and ulnar sections, between which a very natural line of demarcation is observable after the skin and adipose tissue have been removed.

Exactly on this line, and one-third from the elbow and two-thirds from the wrist-joint, two long muscles will be found in contact, the *supinator radii longus* in the radial section, the *flexor carpi radialis* in the ulnar. Above and below this point these muscles diverge. The flexor carpi radialis, at its origin from the internal condyle, is distant, from the boundary line referred to, at least one-third of the transverse diameter of the arm, and the space thus left, triangular in its figure, contains a large portion of the pronator radii teres. The radial edge of the pronator radii teres is in contact with the supinator radii longus to the extent of about an inch and a half; this muscle descending in like manner obliquely from its origin in the ulnar section towards the radial leaves above a similar though small triangular space, in which the tendon of the biceps flexor cubiti is lodged. Below the point referred to above, between the elbow and wrist, the flexor carpi radialis runs in contact with and on the ulnar side of the boundary line till within an inch and a half of the wrist-joint, where it gradually slides into the radial section, so that at the annular ligament the tendon of the flexor carpi radialis will be found entirely in the radial region with its internal edge in contact with the boundary line.

Thus it will be seen that a line drawn from the elbow to the wrist and dividing the fore-arm into two portions, of which the internal or ulnar section is exactly two-thirds, while the external or radial section is only one-third of the transverse width, not merely forms an artificial division into radial and ulnar sections, but also points out the exact situation of the tendon of the biceps, the outer edge of the pronator radii teres, and the flexor carpi radialis, and in addition, as we shall presently see, the supinator radii longus. The fleshy belly of this muscle lies exactly parallel with this boundary line in the upper half of the arm.

In consequence of the supinator radii longus becoming tendinous about the middle of the fore-arm, and the tendon being narrower in its transverse diameter than the muscle, a space is left at the lower part of the arm between it and the flexor carpi radialis, and the supinator radii longus is no longer met in contact with the boundary line. In this space is lodged the radial artery, lying midway between these two tendons, separated from the flexor longus pollicis by a deep layer of fascia, which is united to the edge of the supinator radii longus on the outer side, and the flexor carpi ulnaris on the inner side

Muscles in the anterior region of the fore-arm.—*a. Superficial layer of muscles.*—On the radial side we observe two, *supinator radii longus* and *extensor carpi radialis longior.*

1. *Supinator radii longus, (grand supinateur,* Cloq., *brachio-radialis,* Soëmm.,) arises by a broad, flat, fleshy origin from the rough ridge, on the outer side of the lower extremity of the os humeri, which gradually terminates in the outer condyle; it is connected at the apex of its origin with the deltoid : it arises likewise from the intermuscular ligaments of the upper arm ; passing over the elbow-joint, its surfaces, which in the upper arm face outwards and inwards, are converted into anterior and posterior in the fore-arm ; opposite the tubercle of the radius it becomes tendinous on its under surface, and the fleshy fibres on its anterior face entirely disappear about the middle of the fore-arm in a flat tendon, which, narrowing as it descends, is inserted into the external edge of the base of the radius.

This muscle at its origin has to the inner side of it the brachialis anticus muscle and the radial nerve and superior profunda artery; to its outer side and posteriorly the triceps extensor cubiti ; a little lower down and just above the elbow-joint it has the extensor carpi radialis longior to its outer side, which maintains a uniform relation to it in its whole course; in passing over the elbow-joint the tendon of the biceps flexor cubiti separates it from the brachialis anticus; below the tendon of the biceps muscle, we meet with, first, the pronator radii teres in apposition with its internal edge ; and, next, the flexor carpi radialis. In contact with its posterior face superiorly is the supinator radii brevis ; below this muscle the tendon of the pronator radii teres; and still lower down the flexor longus pollicis.

The supinator radii longus, in addition to its action as a supinator of the hand, is a flexor of the fore-arm upon the arm.

2. *Extensor carpi radialis longior, (radialis externus longior,* Soëmm., *humero sus-metacarpien,* Chauss., Dumas,) arises from the lower extremity of the ridge above referred to, and from the outer condyle. Advancing forward it passes over the front of the elbow-joint, and soon becoming tendinous on its anterior surface descends on the anterior part of the fore-arm, partly overlapped by the tendon of the supinator radii longus—its tendon gradually seeks the posterior part of the arm, and running through a broad shallow depression appropriated to it and the second radial extensor, finishes its course by being inserted into the back part of the metacarpal bone supporting the index finger. This muscle, as its name implies, is an extensor of the hand, possessing also a slight power in effecting its abduction.

In the ulnar section of the anterior superficial antibrachial region we find five muscles.

1. *Pronator radii teres* arises tendinous, above the elbow-joint from the intermuscular ligament of the upper arm, from the front part of the internal condyle of the os humeri, from the process of fascia separating it from the flexor carpi radialis, and from the ulna close to the insertion of the brachialis anticus. This muscle, though tendinous at its origin, soon becomes fleshy, and from its rounded form, which causes a distinct projection beneath the skin at the front and upper part of the fore-arm, derives its name. Its fleshy fibres terminate in a tendon as it enters the radial section, which gradually becomes wider as it descends, and sliding behind the supinator radii longus and extensor carpi radialis and in front of the radius, is inserted into the outer and back part of that bone. The *pronator radii teres* has to its outer side, superiorly, the tendon of the biceps muscle; below the tubercle of the radius it has the internal edge of the supinator radii longus in apposition with it, and as it slides in a spiral direction round the radius, and behind this muscle, it has the supinator radii brevis superior and external to it ; to its inner side it has throughout its course the flexor carpi radialis.

In the ulnar section the anterior surface of this muscle is in contact with the fascia; in the radial it is covered by the supinator radii longus, the two radial extensors, and crossed by the radial artery and nerve. The posterior surface of this muscle is in contact with the anterior ligament of the elbow-joint, the brachialis anticus, the median nerve, ulnar artery, the flexor communis digitorum sublimis and radius. This muscle, while presenting a smooth and tendinous face to the under surface of the supinator longus and radial extensors, continues fleshy on its under surface to the very point of its connexion with the radius, the muscle beneath, whose surface is in contact with its fleshy fibres, being clothed in a similar manner with tendon ; this admirable contrivance for preventing friction is by no means peculiar to this situation, though its utility is frequently overlooked.

The name of this muscle indicates its action as a pronator of the hand, and when that effect has been produced, if its contractile power be still further excited, it will flex the fore-arm upon the upper. In case of fracture of the radius, this power is excited injuriously in bringing the radius across the ulna, and thus obliterating the interosseal space, and if not corrected by the surgeon, causing unnatural union of the two bones.

2. *Flexor carpi radialis (M. radialis internus,* Winslow, Albinus, Lieutaud, Sabatier, Soëmm.; *grand palmaire,* or *radial anterieur,* Cloquet;) arises from the internal condyle of the humerus in common with the last-mentioned muscle; at the point where these two muscles are connected with the humerus there exists no natural separation between them. About an inch and a half from their origin a separation is effected by the dipping in of the fascia forming

one of the muscular septa previously referred to. At the lower part of the upper third of the fore-arm their separation is complete. The flexor carpi radialis first changes its muscular fibres for tendinous on its anterior face, and a rounded tendon is the result at the upper part of the lower third of the arm. This tendon passes in front of the wrist-joint and through a groove in the os trapezium, is ultimately inserted into the base of the metacarpal bone supporting the fore-finger.

This muscle has on its outer edge, in the superior third of the fore-arm, the pronator radii teres, in the two inferior thirds the supinator radii longus; the palmaris longus to its inner edge, both at its origin and throughout its whole course in the fore-arm. Anterior to it there is simply the fascia, its posterior face is in contact with the superficial flexor of the fingers above and the long flexor of the thumb below. The tendon of this muscle projects distinctly through the skin at the lower part of the arm.

The flexor carpi radialis, besides flexing the whole hand on the fore-arm, bends the second row of carpal bones upon the first. It will also act as an abductor of the hand, in consequence of its being fixed on the outer side of the hand in the pulley-like groove of the trapezium through which it passes. It slightly assists the pronator muscles in their influence over the hand.

3. The *palmaris longus*, Soëmm., *epitrochlo-palmaire*, Chauss. The origin of this muscle, which is in common with the other flexors, is from the inner condyle, also from a tendinous intermuscular septum which separates it from the flexor carpi radialis on the outer side and the flexor communis digitorum on the inner. This muscle, the smallest of those situated in the fore-arm, becomes tendinous midway between the elbow and wrist-joint. This tendon, which is narrow and slender, descends to the annular ligament, and is ultimately connected with the palmar fascia. This fascia has sometimes been considered as a mere expansion of the tendon of the palmaris longus, but as the muscle is occasionally wanting and the fascia never, we regard it rather as another instance of that useful connexion of muscles with fasciæ which we have already had occasion to admire. This muscle, except at its origin where it has the flexor carpi radialis to its inner side and the flexor communis to the outer, maintains a position completely superficial to the other muscles, its posterior face lying upon the flexor communis sublimis.

This muscle flexes the hand, and makes tense the palmar fascia and annular ligament, and thus takes off from the palmar vessels and nerves and the tendons of the digital flexors the pressure to which they are exposed when the hand grasps a solid body firmly; as, for instance, when the whole weight of the body is sustained, as in the case of the sailor climbing the rigging of a vessel, by the power of the flexors of the fingers and hand.

4. *Flexor communis digitorum sublimis perforatus*. (*Musculus perforatus*, Soëmm., *epitrochlo-phalanginien commun*, Chauss.) This muscle also arises from the inner condyle in common with the other muscles, and from a strong tendinous septum separating it from the flexor carpi ulnaris. About the middle of the fore-arm this portion of the muscle is joined by muscular fibres which arise from the radius immediately below the insertion of the supinator radii brevis, and on the inner side of the pronator radii teres. Between these two origins of the flexor communis digitorum is placed the median nerve. The tendinous fibres, into which the muscle is gradually transformed, become first apparent on the anterior surface, and next being collected ultimately split into four cords, which passing behind the annular ligament of the wrist, enter the palm of the hand; opposite the first phalanx of the four fingers these cords, splitting into two portions and allowing the passage of the deep flexors, terminate by being inserted in the rough edge on the sides of the second phalanges. The tendons of this muscle as well as the deep flexor are bound down to the phalanges by smooth tendinous sheaths or thecæ which are dense and firm between the articulations, but insensibly disappearing opposite the joint, where their presence would interfere with the motion of the parts; they are lined by synovial membrane to prevent unnecessary friction.

Although the lateral width of this muscle is considerable, only a very narrow edge is in contact with the fascia, the remainder being covered by the last-mentioned muscles, so that some anatomists have described it as constituting a middle layer.

On the internal edge is placed the flexor carpi ulnaris, which maintains the same relative position to it throughout the fore-arm. In contact with its posterior face we have the flexor digitorum profundus, the flexor longus pollicis, and the ulnar artery, vein, and nerve.

This muscle flexes the second phalanx on the first, and the first on the metacarpus, and the whole hand on the fore-arm.

5. *Flexor carpi ulnaris*, (*musculus ulnaris internus*, Soëmm, *cubital interne*, Portal, *cubito-carpien*, Chauss.) This muscle arises from the internal extremity of the internal condyle of the humerus from the tendinous intermuscular septum, between it and the flexor carpi digitorum sublimis, and from the olecranon process of the ulna; between these two heads the ulnar nerve is situated; its origin from the ulna is not limited to the olecranon process, for it continues its connexion with that bone nearly as low down as the origin of the pronator quadratus. This muscle, which arises tendinous and fleshy, merges into tendinous fibres on its anterior surface at the upper part of the lower third of the fore-arm. The tendon by degrees becomes more rounded, but does not cease to receive fleshy fibres until it terminates by becoming inserted into the annular ligament and os pisiforme.

The flexor carpi ulnaris, forming the inner margin of the muscles of the fore-arm, is in contact with the fascia: its external edge touches the flexor communis digitorum sublimis. The relation of this muscle to the ulnar artery has induced some anatomists to denominate it *muscle satellite de l'artère cubitole.*

In addition to its power as a flexor of the hand on the fore-arm, this muscle adducts the hand, drawing it towards the mesial line.

b. The deep layer of muscles.—These are three in number, the *flexor longus proprius pollicis, flexor communis digitorum profundus perforans,* and the *pronator quadratus.* A portion of the supinator radii brevis is also found in it.

1. *The flexor longus proprius pollicis,* Sœmm. (*Radio-phalangettien du pouce,* Chauss.) This muscle, situated most externally, arises by two heads; one, narrow, rounded, tendinous, and fleshy, from the inner condyle of the humerus; the other, broad and fleshy, from the front of the radius, below the insertion of the biceps and supinator radii brevis, and from the interosseal ligament, extending as low down as the insertion of the pronator quadratus. Its tendon, first formed on its internal and anterior edge, descends behind the annular ligament of the wrist-joint, and taking its course between the two heads of the flexor brevis pollicis, is inserted into the last phalanx of the thumb.

This muscle is covered anteriorly by the supinator radii longus and extensor carpi radialis longior, except at the lower part, where it is simply covered by the deep fascia on which the radial artery lies. To its inner side is the flexor digitorum profundus.

This muscle is a flexor of the last phalanx of the thumb, a powerful and important muscle in grasping objects.

2. *Flexor communis digitorum profundus perforans.* (*M. perforans,* Sœmm. *M. cubito-phalangettien commun,* Chauss.) arises tendinous from the front of the ulna immediately below the insertion of the brachialis anticus into the tubercle of that bone, and from the same as low down as the pronator quadratus; also from the interosseous ligament. It becomes tendinous on its anterior face about the middle of the fore-arm, thus presenting a smooth and polished surface to the muscles in front of it: like the superficial flexor, it forms its four tendons, which, after traversing the palm of the hand and piercing the split tendons of the superficial flexor, are ultimately inserted into the third phalanx of each of the fingers.

This muscle has the flexor longus pollicis to its outer side; the flexor carpi ulnaris to its inner; and the flexor carpi radialis, flexor communis digitorum sublimis and palmaris longus, anterior to it.

To flex the fingers on the hand, commencing with the flexion of the last phalanx on the others, and the whole hand on the fore-arm, constitutes the principal action of this muscle.

3. *Pronator quadratus,* Sœmm. (*Cubito-radial,* Chauss.) This muscle, entirely covered by those mentioned above, presents a beautiful appearance on their removal, from the tendinous surface admitting by its transparency the colour of the muscle to shine, as it were, through it.

It arises from the ulna about an inch and a half above the wrist-joint, occupying exactly that extent of the surface of the bone with its attachments: it is inserted fleshy into the lower part of the radius.

This muscle, simple as its action appears, that of rolling the radius over the ulna, performs a most important part in those easy motions of the hand which the artist unconsciously produces when he is engaged sketching in bold and flowing lines the subject of his picture.

To the surgeon a knowledge of the attachments of this muscle is peculiarly important, for in those cases in which the radius is fractured near its lower extremity it draws the injured bone into the field of the flexor tendons, and by bringing it into close contact with the ulna, produces a deformity which great care will alone obviate.

Posterior antibrachial region.—If we now look to the posterior part of the fore-arm, we shall find that though it may be divided into radial and ulnar sections like the anterior, the proportions between them will be very different; for one-fifth of the transverse diameter of the arm alone can be correctly allotted to the radial region in the upper part, and two-fifths close to the wrist-joint. The line of demarcation between these two regions is accurately formed in the dissected arm by the radial edge of the extensor communis digitorum. This muscle, like those on the anterior surface of the arm, is wide and muscular above, tendinous and comparatively narrow below; and hence we find the radial section wider below than it is above. In the ulnar section, we have the extensor communis digitorum to the outer side; in contact with this muscle, on its ulnar side, is the extensor carpi ulnaris. This muscle, at its origin at the upper part of the arm, is narrow, and the space, thus yielded as it were by its form, is occupied by the anconeus, which forms the boundary of this region on the ulnar side. The space left at the lower part of the arm, from the divergence of the tendons of the extensor carpi ulnaris and extensor communis digitorum, permits a view of the indicator. The radial section contains at its upper part solely the extensor carpi radialis brevior; but at the upper part of the middle of the arm, we have sliding into it from behind the extensor communis digitorum, the extensor ossis metacarpi pollicis, and extensor primi internodii pollicis. These pursue their course obliquely across the radial section till they reach the outer edge of the arm. Lower down than these muscles and scarcely in contact with their inferior edges, we discover the tendon of the extensor secundi internodii pollicis likewise emerging from beneath the extensor communis digitorum.

a. Superficial muscles of the posterior antibrachial region. — 1. *Anconeus* (*epicondylo-cubital,* Chauss.) though usually described as a distinct muscle, is, in reality, a continuation of the triceps extensor cubiti: the fibres of each are perfectly continuous, and there is no line of demarcation between them. An artificial boundary may be made by drawing a line horizontally inwards when the fore-arm is extended on the upper arm, between the outer condyle of the os humeri and the olecranon process of the ulna. With this view of the limit of the upper edge of the anconeus, it may be described as a triangular muscle, the base above and the apex below. This muscle arises tendinous from the back part of the outer condyle, its external and anterior edge continuing tendinous almost to its insertion; its superior fleshy fibres pass transversely inwards and backwards, to be inserted into the fascia of the fore-arm and also into the olecranon; the middle and inferior fibres pass backwards to the ulna with various degrees of obliquity, and occupy by their insertion about one-third of the bone from its superior extremity.

This muscle is a simple extensor of the fore-arm.

2. *Extensor carpi ulnaris, (ulnaris externus*, Sœmm.; *cubito sus-metacarpien*, Chauss.) arises from the back part of the outer condyle between the anconeus and the extensor communis digitorum, with which latter muscle it is so intimately connected that, more strictly speaking, it ought to be said to arise in a common tendon. Connected by a narrow origin to the humerus it gradually expands, and about the middle of the fore-arm, a tendon being formed in the centre, it exhibits in its further course a well-marked specimen of the double penniform muscle. The tendon of this muscle, in its passage towards the wrist-joint, runs in an especial groove appropriated for its reception in the back part of the ulna; it terminates by being inserted in the metacarpal bone supporting the little finger. The extensor carpi ulnaris is more or less connected with the fascia throughout the whole of the upper arm.

This muscle extends the first row of carpal bones on the second and the whole hand on the fore-arm; it is likewise an adductor of the hand.

3. *Extensor communis digitorum (epicondylo sus-phalangettien commun*, Chauss. Dumas) arises from the back part of the outer condyle in common with the extensor carpi ulnaris on its outer side, and the extensor carpi radialis brevior on its inner side. The connexion of this muscle to the os humeri is extremely narrow in comparison with the width of the muscle in the centre of the fore-arm. In its ample attachment to the fascia it resembles the flexor ulnaris, and, like it, is a penniform muscle. We not unfrequenly find a portion of this muscle so entirely distinct from the rest that anatomists have occasionally described it as a separate muscle, under the name of the extensor proprius minimi digiti; for being inserted into the little finger, it possesses the power of extending that portion of the hand. It passes behind the posterior annular ligament of the wrist-joint, splits into four tendons, which, expanding on the back part of the phalanges of the four fingers, convey the power of the muscle to each phalanx in an equal degree. The tendons of this muscle in their passage behind the annular ligament of the wrist-joint are clothed by a synovial membrane (reflected like all other synovial membranes) so as to form a perfect purse or bursa. Both these muscles are intimately connected upon their under surface at the upper part of the arm, with the aponeurosis covering the supinator radii brevis.

This muscle is an extensor of the fingers and the hand on the fore-arm.

4. *Extensor carpi radialis brevior, (radialis externus brevior*, Sœmm. *Epicondylo sus-metacarpien*, Chauss. Dumas), with a small portion of the extensor carpi radialis longior, occupies the radial division of the posterior superficial antibrachial region. This muscle arises from the outer condyle by a flattened narrow origin, in common with the extensor communis digitorum, being overlapped on its outer side by the extensor carpi radialis longior. This muscle, like most we have described in the fore-arm, swells out towards the centre, where, gradually becoming tendinous, it again diminishes in size. It passes the same groove in the radius as the extensor carpi radialis longior, and terminates by an insertion into the metacarpal bone of the middle finger. The under surface of this muscle is tendinous at the upper part of the arm, which permits it to play without friction upon the smooth and tendinous face of the supinator radii brevis with which it is in contact.

This muscle acts as an extensor of the hand on the fore-arm and an abductor.

b. Deep muscles of the posterior antibrachial region.—The muscles in this region commencing above, are the *supinator radii brevis, the extensor ossis metacarpi pollicis, the extensor primi internodii pollicis, the extensor secundi internodii*, and *the indicator*.

1. *Supinator radii brevis, (epicondylo-radial*, Chauss.) arises tendinous from that portion of the outer and back part of the ulna, unoccupied by the insertion of the anconeus; it arises also from the back part of the outer condyle, covered at its origin from the outer condyle by the extensor communis digitorum and by the extensor carpi radialis brevior. Its posterior and external surface is tendinous, its internal fleshy, and it embraces so much of the upper extremity of the radius, as to form an imperfect tube. Anteriorly we find it partly overlapping the tubercle of that bone, with the tendon of the biceps which is inserted into it. Between these and the under surface of the muscle is a large and distinct bursa mucosa; it covers rather more than the upper third of the radius by its insertion, extending as low down as the pronator radii teres.

This muscle is the main agent in effecting the supination of the hand.

2. *Extensor ossis metacarpi pollicis, (abductor longus pollicis manus*, Sœmm. *cubito-radi sus-metacarpien*, Dumas,) arises from the ulna, interosseous ligament, and the back part of the radius, opposite the insertion of the pronator radii teres, having to its outer side the supi-

nator radii brevis, to its inner the extensor primi internodii pollicis. It is covered posteriorly by the extensor communis digitorum and extensor carpi ulnaris. Gliding downwards and outwards from beneath these muscles and becoming tendinous on its under surface, it slips over the lower third of the posterior face of the radius, and then running in a groove on the outer side of that bone, common to it and the next mentioned muscle, is ultimately inserted into the metacarpal bone of the thumb.

The action of this muscle is to extend the metacarpal bone of the thumb, which corresponds as regards its capacity for motion, with the phalanges of the fingers.

3. *Extensor primi internodii (extensor minor pollicis manus*, Sœmm.; *cubito sus-phalangettien du pouce*, Chauss.) is a very small muscle compared with the last, though varying much in size in different subjects. It lies between the extensor ossis metacarpi pollicis and the extensor secundi internodii, passing through the same groove in the radius as the extensor ossis metacarpi pollicis, it becomes inserted into the first phalanx of the thumb.

4. *The extensor secundi internodii pollicis (extensor major pollicis manus*, Sœmm.; *cubito sus-phalangettien du pouce*, Chauss.)—This muscle is usually larger than the former; it arises fleshy from the ulna and interosseous ligament; becoming tendinous in its centre, it presents the same penniform appearance referred to above. The groove in the radius which is narrow and deep, this tendon alone being lodged in it. It is situated between that for the two radial extensors and the broad and hollow one for the common extensors and indicator. Crossing on the back of the wrist the radial extensors it is finally inserted into the second phalanx of the thumb. This muscle is entirely covered in the fore-arm by the common extensors of the fingers.

5. *The indicator (cubito sus-phalangettien de l'index)* occupies the remaining portion of the posterior interosseal space. Like the three last described muscles it is penniform, and arises fleshy from the ulna and interosseous ligament, it descends to the hand and passes through the same groove at the back of the radius as that of the extensor communis digitorum, it is inserted into the posterior surface of the three phalanges of the index finger. This muscle is entirely concealed by the extensor carpi ulnaris and extensor communis digitorum.

The names of this and the two preceding muscles indicate their actions.

(*Samuel Solly.*)

FOURTH PAIR OF NERVES (*nervus trochlearis*, s. *patheticus*).—The fourth pair is the most slender of the encephalic nerves. They are intermediate in the order of succession to the third or motor oculi and the fifth nerves, and hence the name. Each nerve is attached at its encephalic extremity to the lateral part of the superior surface of the anterior medullary velum or valve of Vieussens, immediately behind the testes or the posterior of the tubercula quadrigemina. It is divided at its attachment, for the most part, into two roots, inserted at a little distance from each other, one close to the testes, the other posterior to it. Occasionally it has but one root and sometimes even three. Gall and Spurzheim* are of opinion that the nerve might be traced to a more remote point, and according to Mayo† "its fibrils appear to pass through the filaments of the pillar of the valve, and in part to arise from the back part of the medulla oblongata."

The nerve is concealed at its insertion by the superior vermiform process of the cerebellum, and it is not immediately provided with neurilemma, and hence, as also because of its delicacy, it is very easily broken off.

Its course within the cranium is circuitous and long, longer than that of the other nerves. It passes outward, downward, and forward: it first descends external to the superior peduncle of the cerebellum (the processus a cerebello ad testes), between it and the vermiform process, then becomes invested with arachnoid membrane and free, and runs round the lateral part of the crus cerebri, above the superior margin of the pons Varolii, and beneath the free edge of the tentorium cerebelli, until it reaches the posterior clinoid process of the sphenoid bone; it then enters the outer wall of the cavernous sinus between the points of attachment of the tentorium, and is transmitted through a canal in the dura mater, by which the wall is formed, forward to the foramen lacerum of the orbit. It does not enter the sinus, being contained in a canal in its outer wall.

At the posterior part of the sinus the nerve is situate beneath the third, between it and the first division of the fifth nerve; but at the anterior, and as they are about to pass into the orbit, the fourth and frontal branch of the fifth are both above the third, the fourth internal and a little superior to the frontal.

The nerve lastly enters the orbit through the superior part of the foramen lacerum in company with the frontal, above the levator palpebræ muscle, and immediately beneath the roof of the region. Having entered, it runs forward and inward, gains the surface of the superior oblique muscle, and attaching itself to it upon its superior aspect, about its middle, it divides into filaments, which are all distributed to the muscle.

The fourth nerve does not give off any branch during its course to the oblique muscle, unless, at times, first a filament described by Cruveilhier, and, according to him, distributed to the tentorium cerebelli. This filament arises from the nerve while traversing the wall of the cavernous sinus, runs backward into the substance of the tentorium, and divides into two or three branches: Cruveilhier calls it "the branch of the tentorium." Secondly, according to both Swan and Cruveilhier, the fourth nerve gives off a fila-

* Anatomie du Systeme nerveux.

† Physiology.

ment to the lachrymal branch of the fifth. Before its entrance into the orbit the nerve receives a filament from the sympathetic,* and at or immediately after entering, it receives one also from the frontal branch of the fifth, by the accession of which it is sensibly increased in size. It is very closely connected to the frontal itself at the back of the orbit.

Upon the fourth nerve the power of the superior oblique muscle is considered to depend. It is remarkable that this muscle should be provided with an especial nerve, differing, apparently, so much in its encephalic relations from those by which the others are supplied; but the theories which have been advanced upon the subject are as yet so unsubstantial, that we think it better to leave them untouched. (See Orbit, muscles of the).

The nerve exists with similar relations in all the vertebrata.

(B. Alcock.)

GANGLION, (Gr. γαγγλιον; Germ. *Nerven Knoten.*)—This term is applied to several distinct structures: to the nodules placed on certain nerves, to the lymphatic glands or ganglions, to certain bodies, as the thyroid, the thymus, &c., which have been called by some anatomists vascular ganglions, and lastly, in surgical language, to the enlargement of the synovial bursæ. It is, however, most generally applied to the ganglions of the nerves; but of late years many anatomists, who conceive that the various masses of grey matter met with in the encephalon and spinal chord are, together with the ganglia of the nerves, sources of nervous power, have extended to those masses the general term of ganglion. Although there can be no doubt that the analogy has a real foundation, and that this application of the word is both convenient and correct, it is nevertheless proposed, in obedience to custom, to retain the old and more limited sense of the term ganglion, and to devote the present article to the structure of the ganglions of the spinal and sympathetic nerves, referring the reader for an account of the functions of these bodies to the articles Nervous System and Sympathetic Nerve.

The nervous ganglions consist of a number of oval or roundish organs connected with certain nerves, and placed deeply in the trunk of the body, to which they are confined, being situated, with the exception of those of the head, in the immediate vicinity of the vertebral column. Their number and size are subject to variation, not only in different persons, but even on the two sides of the same individual; the following is the enumeration which approaches nearest to the truth: thirty on each side of the body, placed on the posterior roots of the spinal nerves; one on each side, situated on the larger origin of the fifth pair; the ganglions of the great sympathetic consisting of the following, connected on each side of the body with what is regarded as the trunk of this nerve, viz. three cervical, twelve dorsal, three to four or five lumbar, three to five sacral; to these we must add some large masses placed near the mesial plane, viz. two semilunar, three or four cœliac ganglions, and one cardiac ganglion, first described by Wrisberg, but which is occasionally deficient; and lastly, forming a part of the great sympathetic, the ophthalmic, the spheno-palatine, the otic, and the submaxillary ganglions, and a small body usually met with in the cavernous sinus, the cavernous ganglion. M. Hip. Cloquet has described in rather vague terms a small reddish mass placed in the anterior palatine canal, which he calls the *naso-palatine* ganglion; but Arnold, Cruveilhier, and others deny, and with good reason, the existence of this body. A gangliform enlargement is constantly seen on the commencement of the nervus vagus, and a second lower down; a similar swelling is also placed on the glosso-pharyngeal nerve (g. petrosum).

Professor Müller of Berlin has discovered above this enlargement a *true ganglion on the the glosso-pharyngeal* (ganglion jugulare nervi glosso-pharyngei), occupying half or two-thirds of the trunk of the nerve, and being precisely to that nerve what the intervertebral ganglion and the Gasserian are to the spinal nerves and the fifth pair. My colleague Mr. Walker has shown me this ganglion, which is placed in the upper part of the foramen lacerum basis cranii posterius, and corresponds to the above description.*

Arnold has further noticed that at the junction of the superior twig of the Vidian nerve, or nervus innominatus, with the facial nerve, there is a gangliform swelling.†

Mayer has discovered a minute posterior root of the sublingual nerve, with a ganglion on it, in some mammalia (ox, dog, pig), and *in one instance in man.*

Thus the total number of ganglions in the human body amounts to about one hundred and twenty-seven, exclusive of the gangliform enlargements on the pneumo-gastric, glosso-pharyngeal, and the facial nerves.

These bodies have been variously arranged by writers on this subject; thus by Weber‡ they are divided into ganglions of reinforcement, such as those on the spinal nerves, and into ganglions of origin, of which those of the sympathetic, the ophthalmic, and the spheno-palatine are examples; whilst Wutzer,§ classing them according to their situation and relations, considers that there are three orders, 1. the cerebral; 2. the spinal; 3. the vegetative: the first comprises the Gasserian ganglion, the ophthalmic, and the ganglion of Meckel, to which must be added the otic ganglion of Ar-

* See Pauli in Müller's Archiv. for 1834.

* This very interesting discovery confirms the opinion that the glosso-pharyngeal is, like the spinal and the fifth, a compound nerve of motion and sensation. See Medizinische Vereins-Zeitung, Berlin, 1833.

† Icones Nerv. Corp. p. 2. tab. ii. and vii.

‡ Anat. Compar. nervi sympath.

§ De corp. hum. ganglior. fabrica atque usu, p. 52.

nold; in the second order are enumerated the thirty spinal ganglions and the ganglionic enlargement of the nervus vagus and glosso-pharyngeus; in the third division are included the ganglions of the sympathetic nerve.

The former of these arrangements is objectionable, because offices are assigned to the ganglions the existence of which has not been ascertained; and the latter is so far erroneous that in this classification the ganglion of the fifth pair is separated from the spinal, to which it is undoubtedly similar; whilst the ophthalmic and spheno-palatine are as incorrectly divided from the system of the sympathetic.*

In endeavouring to detect that which constitutes the essential difference among these numerous bodies, we ought to pay special attention to the character of the nerves which are attached to the ganglions. Taking this as the only rational guide, I should refer them to two classes. 1. Those which are placed on sentient nerves, comprising the Gasserian, the ganglion of the glosso-pharyngeus, and the spinal ganglions The gangliform enlargement of the nervus vagus should be referred to this order, inasmuch as there can be little doubt, although this at present is not proved, that this nerve is compounded, like the spinal nerves, of motor and sentient fibrils, a surmise supported by the distribution of the vagus, and still more by the interesting discovery of my friend Mr. Solly, of the existence of certain motor fibrils in the exact part of the medulla oblongata, whence this nerve arises.†

2. Those which have connected with them both motor and sentient nerves, and are, as I believe, always in relation with contractile and sensitive structures:‡ those, namely, of the great sympathetic nerve, comprising the cervical, the dorsal, lumbar, and sacral, together with the cardiac, the semilunar and cœliac, also the ophthalmic, the spheno-palatine, the otic, submaxillary, and cavernous.

These classes nearly correspond with the *simple* and *compound* ganglions of Scarpa* and Meckel.†

There are occasionally found ganglia on other nerves; thus, Mr. Swan‡ has noticed one on the posterior spinal nerve, where it is placed under the extensor tendons of the wrist. My friend Mr. Pilcher has also found in two subjects a gangliform enlargement on the internal nasal nerve, where it is lodged on the æthmoidal bone.

It is necessary to remark that although the ganglia of the first class are placed on certain of those nerves which are commonly regarded as being subordinate simply to sensation, yet the highly important observations of Dr. M. Hall,§ which have, I conceive, opened an entirely new field in physiology, render it doubtful that those bodies are essential to the exercise of sensation.

Organization.—Although the cerebro-spinal and sympathetic ganglia present some important peculiarities when contrasted with each other, particularly as regards the proportions of the grey and fibrous substances, still as both classes possess essentially the same structure, they may with propriety be considered in a collective manner.

Every ganglion contains two totally distinct substances which have a close relation to, and are, I believe, identical with the grey and fibrous matters, constituting the encephalon and other parts of the nervous system. It is true that the appearance of these bodies is in many respects dissimilar to that of the brain; but at length it is universally admitted that differences in mere physical properties are unimportant, and do not constitute any test as to the essential structure of an organ. In the present instance the diversity may very readily be understood when the difference of situation is considered. The cerebral organ is enclosed in a cavity, the cranium, formed of some of the strongest bones of the skeleton, and hence, being effectually defended from the effects of motion and external pressure, all its parts are soft and delicate; whilst the ganglia, placed on bones which move on each other, slightly it is true, are exposed to external compression, and consequently a much firmer texture is required. It is for this reason that these bodies are invested in a dense fibrous capsule, which is to them what the cranium is to the encephalon, and which furnishes in addition a number of internal processes surrounding each fibril, and sustaining the spherical masses of grey matter. The difficulty of detecting the intimate texture is by these means greatly increased; but as it is so similar to that of the cerebrum, it is desirable to examine the constituent parts according to the order observed in investigating that organ.

I. *Reddish grey matter.*—The quantity of this substance, often called the peculiar matter of the ganglions, but which, as I have stated,

* The following is the classification of Müller: 1. Ganglia of the posterior roots of the spinal nerves, of the larger portion of the nervus trigeminus, of the nervus vagus, and ganglion jugulare nervi glosso-pharyngei. 2. Ganglia of the great sympathetic. 3. Ganglia which occur at the points of junction of the cerebro-spinal nerves with the branches of the sympathetic, comprising ganglion petrosum nervi glosso-pharyngei, intumescentia gangliformis nervi facialis, ganglion spheno-palatinum, ciliare, oticum (probably). To which should be added ganglion submaxillare. Handbuch der Physiol. der Menschen. Erster Band. p. 588.

† According to the present opinion, the whole of the fibres belonging to the nervus vagus enter into the ganglion; and Bischoff imagines that this nerve derives its motor portion from the spinal accessory. The intimate relations between these two nerves require further investigation.

‡ It cannot be too often repeated that sensibility, or, to speak more correctly, the capability of being excited by the contact of a physical agent, may exist without being accompanied with consciousness: the inner surface of the heart, of the blood-vessels, and intestine are as capable of being excited as the skin or the retina; but the impressions which they receive are not *usually* perceived by the mind.

† Man. d'Anat. t. i. p. 231.

‡ On the Nerves, pl. xxii. fig. 3.

§ Lect. on the Nerv. Sys. 1836.

is possessed by those bodies in common with the brain and spinal chord, is very considerable, constituting apparently the largest, and certainly the most essential part of the ganglion. It is so intimately connected with the fibres that these latter appear as if they were incrusted, being surrounded in every direction by this greyish matter; but although this intimate intermixture is very evident, no fibrils can be perceived actually terminating in or arising from the grey matter. A section of one of the sympathetic ganglia, the first cervical for example, displays this incrustation of the fibres and the interposition between them of rounded masses of the grey matter; but the Gasserian is in many respects the most favourable for examination.

Much difference of opinion exists concerning the true nature of this substance. Scarpa contends that it is not analogous with the grey matter of the brain, but that it consists of a flocculent tissue loaded with a mucilaginous fluid, which becomes oily in obesity, and watery and abundant in anasarca. The accumulation of fat in the true ganglionic tissue has, however, been denied by Béclard, Wutzer, and others. According to Bichat, whose opinions must always command our respect, "the ganglions have a colour very different from that of the nerves. They present a soft spongy tissue, somewhat similar to the lymphatic glands, but which has nothing in common either with the cerebral substance or with that of the nerves." It is stated by Lobstein, who has published one of the latest and most minute accounts of the structure and diseases of the sympathetic nerve,* that he has observed lying contiguous to the white and filamentous tissue another substance presenting a flocculent appearance, with globules interspersed *(materies vel substantia orbicularis tomentosa)*, and which he regards as the second material of the ganglia.

Fig. 170.

Semilunar ganglion, twice the natural size.

a, a, Fasciculi of splanchnic nerve.
b, b, Fibres running through the ganglion.
c, c, Branches collected from the former, and emerging.
d, d, Flocculent or orbicular substance placed between and applied to fibres.
e, e, Foramina perforating the ganglion.

This juicy or gelatinous substance, which is met with in the spinal as well as in the sympathetic ganglia, does not, however, according to Lobstein, appear to be an essential part of the organization, as it varies in its proportion in different ganglia, and may even be absent; nor, it is said, can it be assimilated with the grey matter of the brain.

Ehrenberg also controverts the opinion that the ganglia resemble the grey part of the brain; but although he has found by microscopical inspection, that these bodies contain an overwhelming proportion of large varicose tubes, similar to those of the fibrous portion of the brain, yet he has also shewn that they possess *minute varicose fibres like those of the grey substance;* and what particularly is deserving of notice, he has detected in the muscles of the fibres *granules similar to those which are found in the cervical portion of the brain.*†

* De Nervi Sympath. Humani, fabrica, usu, et morbis, p. 66.

† Structur des Seelenorgans bei Menschen und Thieren, Berlin, 1836, p. 31.

Notwithstanding these and other high authorities, the researches of many recent writers, which have thrown so much new and valuable light on the mutual relations of the component parts of the nervous system, leave little room for doubting the identity of these two substances. The analogy of the whole nervous system tends to prove that this peculiar matter is nothing else than the grey substance; in the Gasserian ganglion, indeed, the resemblance is so striking that no doubt of their identity can be entertained. This view of the subject was taken by Winslow, Johnstone, and others; and lately the existence of grey matter has been admitted by Dr. Fletcher, an assumption, indeed, which is the basis of his hypothesis, that the ganglionic system of nerves is the immediate seat of irritability.*

II. *Fibres.*—This is a most important branch of the present inquiry, because a knowledge of the connexions of these bodies with the other parts of the nervous system and with each other, as well as of the internal disposition of their fibres, is indispensable to the investigation of their functions. The subject may be resolved into two questions. *a. What is the arrangement of the fibres in the ganglia? b. What is the nature of the fibres which are connected with the ganglia?*

a. The internal disposition of the nervous filaments, owing to the very intimate relations subsisting between them and the grey matter, is difficult to determine; and hence it has happened that great difference of opinion prevails on this point. I shall in the first place describe the arrangement in the most simple of these organs, and for that purpose shall select that of the portio major of the fifth pair. On inspection it is seen that the large coarse fibrils of the nerve on approaching the ganglion begin to spread out from each other, and although in its interior they are, as we have already observed, encrusted by the grey matter, yet, on scraping this away, the fibres may be seen still passing on uninterruptedly, but becoming more and more separated from each other. It is this disposition which Scarpa has aptly enough compared to a rope the two ends of which remain twisted, whilst in the middle the component threads are unfolded and pulled asunder. A similar, but less distinct arrangement exists in the spinal ganglia.

Although the continuity of the fibres through the ganglion is easily demonstrated, yet it would be wrong to conclude that this passage is all that happens; for in the first place the three branches of the trigeminal nerve which emerge from, are decidedly larger than the trunk of the same nerve which passes into the ganglion. Their physical qualities are also altered, especially as relates to their colour, which, instead of having the whitish aspect common to the proper fibres of the cerebro-spinal axis, is for some distance of the reddish hue proper to the ganglionic system; and again it would be in opposition to all our notions of the properties of the grey matter to imagine that the fibres do not maintain intimate connexions with that substance, by which means its influence, whatever it may be, is communicated to those threads.

In the sympathetic ganglions the internal formation is much more intricate; and it is especially in reference to these bodies that so much diversity of opinion prevails among anatomists. The researches of Monro,* Scarpa,† and Lobstein,‡ as well as ocular inspection, prove that *some* fibres undoubtedly pass without interruption through the ganglion.

On making a section of the first cervical ganglion, previously hardened by alcohol, fibres will be perceived, which, although separated from each other by irregular interstices filled with grey matter, are still continued uninterruptedly from one to the other extremity. There are, however, besides these, other fibres, which are so complex that it is almost impossible to demonstrate their exact disposition. I believe, however, that, independently of those fibrils which run through the ganglion, there are some which terminate in, and others which arise from the grey matter in its interior.

b. What is the nature of the fibres which are connected with the ganglia? The very interesting inquiries of Brown, Darwall, Teale, Stanley, and others into the nature of those frequent affections now generally known under the term of neuralgic diseases, by which a new and unexpected light has been thrown on a most obscure branch of pathology, render this part of the present investigation of pre-eminent importance. The mutual influence exerted by the cerebro-spinal axis and the great sympathetic on each other, in consequence of which disease of the brain and spinal chord may cause morbid actions and conditions of the organs of digestion, circulation, and secretion, and vice versa, can only be experienced by a reference to the relations which exist between these two great divisions of the nervous system. Unfortunately, however, this question, so important both as regards physiology and pathology, is not easily resolved on account of the difficulty in the present state of our knowledge of distinguishing from each other the different species of fibres which enter into these organs. I shall in the first place speak of the fibres which are perceptible to the naked eye, and afterwards point out the information that has been afforded by microscopical examination.

The intervertebral ganglia (and these observations may be applied to those of the fifth pair, of the glosso-pharyngeal, and of the pneumo-gastric) receive fibres only from the posterior roots of the spinal nerves, which, since the researches of Bell, Magendie, and Mayo, have been regarded as being subordinate to sensation. But if the important principles announced by Dr. M. Hall be susceptible, as I believe they are, of that confirmation from anatomical examination of which at present they stand in need, then to the true sensiferous fibrils which enter these ganglia we must add what are called by Dr. Hall *incident* filaments. It is also a question which yet remains to be decided, whether the twigs that are known to run between the posterior roots of the spinal nerves and the sympathetic ganglions pass in reality from the former to the latter or from the latter to the former; if, as appears most probable, these threads are furnished by the sympathetic, then it is to be presumed they are subsequently continued to the intervertebral ganglions.

With respect to the sympathetic ganglions, the following are the only facts that are at this time established.

1. There are longitudinal commissural filaments by which the ganglia are joined to each other, and by which they are formed, however remote they may be from one another, into one great and extensive system.

2. There are fibrils which extend between the motiferous part of the cerebro-spinal axis and the sympathetic, but whether they are derived from the former or the latter is not decided.

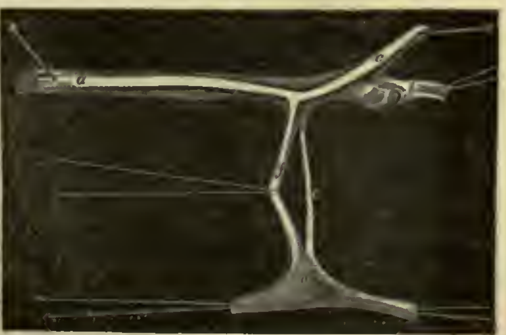
3. There are sentient fibrils observing a similar disposition.

As the anatomical facts by which these facts are established will be found under the head Sympathetic Nerve, only a few remarks are required in this place.

1. With respect to the longitudinal commissural fibres, they are as necessary here as in other parts of the nervous system; and although Bichat speaks of this connexion of the ganglions being occasionally absent, such deficiencies are extremely rare, and if they do really exist, must be regarded as an abnormal state. The importance of this connexion is rendered apparent by the union of the several nodules placed on the trunk of the sympathetic, which is so constant that anatomists were for a long time so far misled by it as to compare this gangliated cord with the common nerves of the body; but it is perhaps still more striking in the commissural fibres, which are so invariably noticed passing from the sympathetic to the small ganglia of the head.

2 and 3. In consequence of the motor and sentient nerves of the head usually forming distinct trunks, the ophthalmic ganglion offers a natural analysis, as it were, of the connexion between the great sympathetic and the cerebro-spinal axis. One twig passes between this small body and the nasal nerve of the fifth pair (sentient); a second extends between it and the lower division of the third pair (motor). The dissections of Arnold prove that a similar connexion exists in the spheno-palatine, the otic, and the submaxillary ganglia.* Mayo has also ascertained that the branches placed between the ganglia of the great sympathetic and the compound nerves of the spine are of a twofold character, one set being attached to the sentient and the other to the motor root. The adjoining figure (*fig.* 172), copied from a dissection I made for this purpose, shows the mode of communication in the thorax.

Fig. 172.



a, Anterior root. *c*, Ditto. *b*, Posterior root entering the ganglion. *d*, Sympathetic ganglion. *e*, Filament of communication to posterior root. *f*, Filament of communication to anterior root.

* These connexions are very beautifully represented in his work, Icones Nerv Capit. Tab. 5, 6, 7, and 8. On some points relative to the otic ganglion it has been proved by the dissections of Schlemm that Arnold was in error, especially as relates to the branch supposed to be furnished from the ganglion to the tarsor tympani.

Notwithstanding so many important points have been established, it must be confessed that much remains to be decided. Thus, for example, we perceive that the ganglion of Meckel, like the ganglions of the sympathetic in the neck, has connected with it a motor fibril; but this fibril, as Arnold has observed, presents the whitish character and firm texture common to the cerebro-spinal nerves, and therefore, it must be presumed, passes from the portio dura to the ganglion, whilst the twigs uniting the cervical nerves and the sympathetic are reddish and soft, rendering it probable, as Fletcher supposes, that they are furnished by the ganglia.

Such being the imperfect results of ocular inspection, we are naturally anxious to obtain more exact information, especially in reference to the character of the different orders of fibres which are connected with the ganglia. The microscopical observations which are being carried on at this time with so much zeal in Germany, and from the prosecution of which the most valuable evidence may be anticipated respecting the undecided points of minute anatomy, have already thrown some light on this interesting question. Thus Ehrenberg* has detected in the sympathetic not only the varicose fibres which some imagine are proper to that system, but also some of the cylindrical fibres of which the cerebro-spinal nerves are principally composed. According to Lauth and Remark, the nerves of organic life (i. e. of the sympathetic) consist for the most part of varicose fibres mixed up with a small proportion of cylindrical; whilst those of animal life consist principally of cylindrical mingled with a few varicose fibres. This is the exact appearance which must have been anticipated, if the mutual interchange of fibres described by Bichat,† W. Philip,‡ Mayo,§ Fletcher,‖ and others, really exist.

It may here be remarked that although the accuracy of Ehrenberg's researches, confirmed as they have been by Müller, Purkinje, Valentin and others, is called in question by Krause, Berres, and Treviranus, yet the essential fact of there being a decided difference in the physical character of different orders of nervous fibres, and, consequently, a test for their successful analysis, is universally admitted.¶

Lastly, it is a question of great interest whether there are not, independently of the relations which exist between the sympathetic and the cerebro-spinal axis, fibres proper to the former,

* L. c. p. 31.

‡ On Vital Functions, and Gulstonian Lect.

§ Out. of Phy. 4th edit. p. 259.

‖ Rud. of Phy. part ii. a. p. 76.

¶ Since the above was written I have learnt that the doubts expressed by Treviranus, Arnold, and others, as to the correctness of the views of Ehrenberg, have been confirmed. Professor Müller attributes the appearance of the varicose fibres to artificial causes; and it is said that Ehrenberg himself doubts if such fibres exist in the normal condition.

which establish between them and the organs they supply with nerves most important connexions. Our present knowledge does not afford the means of solving this question; and, although my attention has been particularly directed to this subject, still, as my observations are as yet incomplete, I shall satisfy myself by expressing my conviction that such a system of nervous fibres does exist.

Covering.—Every ganglion possesses two coverings: the outer one in the spinal ganglions is very firm, being derived from the vertebral dura mater, whilst in the sympathetic ganglions it is composed of condensed cellular tissue. On raising very carefully the external capsule, a more delicate tunic is exposed, which adheres to the proper ganglionic tissue.

Bloodvessels.—These bodies, like all other parts of the nervous system, are amply supplied with arterial blood. After a successful injection, two, three, or more arteries, derived from the neighbouring vessels, may be readily observed running to the ganglion. Each vessel, having perforated the coverings of the ganglion, forms according to Wutzer a plexus on the inner surface of the capsule, and at length sends delicate branches into the pulpy matter, which, with the aid of the microscope, may be observed to run in the same direction with the nervous filaments. The exact mode in which these vessels terminate is unknown, but it is probable, as in the cerebro-spinal system, that each nervous fibre is accompanied by a minute artery and vein. No lymphatics have been demonstrated, but analogy tends to prove their existence, and Lobstein states that he has often seen them forming networks around the ganglions.

Chemical composition.—The experiments performed by Bichat* and Wutzer† would tend to show that the substance of the ganglions is distinct in its qualities from the cerebral matter and also from that of the nerves. By boiling, it is at first hardened, but soon becomes softened; maceration in cold water renders it more soft and pulpy, and if sufficiently prolonged, the water being frequently changed, it is converted into adipocire. It is liquefied by the alkalies, and is rendered crisp and hard by the acids and alcohol.

GASTEROPODA, (*γαστηρ, venter, πους, pes;* Eng. *Gasteropods;* Fr. *Gastéropodes;* Germ. *Bauchfüsser; Mollusca Repentia,* Poli.)

Definition.—An extensive class of the Molluscous division of the animal kingdom distinguished by the structure and position of their locomotive apparatus, which consists of a muscular disc attached to the ventral surface of the body, serving either as an instrument by means of which the animal can crawl, or in rarer instances compressed into a muscular membrane useful in swimming.

Characters of the class.—*Body* soft, enclosed in a muscular covering, which, from its contractility in every direction, produces great variety in the external form of the animal: the back is covered with a mantle of greater or less extent, which in most of the genera secretes a shell either enclosed within its substance, or, as is more frequently the case, external and sufficiently large to conceal and protect the whole body, in which case it is often provided with an operculum capable of closing its orifice when the animal is lodged within it. The *head* is anterior, distinct, and generally furnished with two, four, or six tentacles, which are placed above the oral aperture, and merely serve as instruments of touch. The *eyes* are two in number, and are placed sometimes on the head itself, but more generally at the base, at the side or at the extremity of the tentacles; they are always very small, and not unfrequently wanting. The muscular disc which is subservient to locomotion is called the *foot*, and is generally broad and fleshy, forming a powerful sucker, but in some instances it takes the shape of a deep furrow, or is compressed into a vertical lamella. The *respiratory apparatus* varies in structure; in some genera it is composed of vascular ramifications which line a cavity into which the respired medium is freely admitted. Others are provided with branchiæ, adapted to the respiration of water, variously disposed upon the exterior of the body, or concealed internally. The *heart* generally consists of an auricle and ventricle, and is systemic, or, in other words, receives the blood from the organs of respiration, and propels it through the body. The *sexual organs* vary in their structure in different orders; in the greater number each individual is possessed both of an ovigerous and impregnating apparatus, but copulation is essential to fecundity: in many the sexes are distinct, and some are hermaphrodite and self-impregnating. Some species are terrestrial and others aquatic.

In separating the Gasteropoda into orders, the naturalist finds in the position and structure of the branchial apparatus a character sufficiently obvious; and as the arrangement of these organs is modified by the circumstances of each individual, and is generally in relation with the peculiarities met with in the internal organization of the animal, the branchiæ are at present universally referred to as affording a convenient basis of classification. We shall in this article follow the arrangement adopted by Ferussac, of which, as well as of the systems of other zoologists, an outline is contained in the following table.

Order I. *NUDIBRANCHIATA,** (Cuv.)
Syn. Polybranchiata,† and genus *Doris,* Blainville; *Gasteropodes Dermobranches,‡* Dumeril; *Gasteropodes Tritoniens,* Lamarck.

In these the branchiæ are symmetrical, assuming a variety of forms, but always placed upon some part of the back, where they are unprotected by any covering; the animals may be provided with a shell or naked, but they are all hermaphrodite with mutual copulation, and marine.

1st Sub-order, *Anthobranchiata,§* Goldfuss; *Cyclobranchiata,‖* Blainville.
1st Fam. *Doris.*
2d Sub-order, *Polybranchiota,* Blainville.
2d Fam. *Tritonia, fig.* 173.
3d Fam. *Glaucus, fig.* 174.

Fig. 173.

Fig. 174.

Order II. *INFEROBRANCHIATA,* (Cuv. and Blain.)
Syn. Gast. Dermobranches, Dumeril; *Gast. Phyllidiens,* Lamarck.

In the Inferobranchiate Gasteropods the branchiæ are arranged under the inferior border of the mantle on both sides of the body, or upon one side only: the mantle sometimes contains a calcareous lamella. All the genera

* *Nudus,* naked; *branchiæ,* gills.
† Πολυς, *many;* branchiæ.
‡ Δερμα, *skin.*
§ Ανθος, *a flower.*
‖ Κυκλος, *a circle.*

are hermaphrodite with reciprocal impregnation, and marine.

1st Sub-order, *Phyllidiadæ*, Cuv.
 1st Fam. *Phyllidia*, *fig.* 175.
2d Sub-order, *Semi-phyllidiadæ*, Lam.
 2d Fam. *Gastroplax*, Blainville.
 3d Fam. *Pleurobranchus*, Cuv.

Fig. 175.

Order III. *TECTIBRANCHIATA*,* (Cuv.)

Syn. Chismobranches, Blainville; *Gast. Adelobranches*,† Dumeril; *Gast. Phyllidiens* and *Laplysiens*, Lamarck.

In this order the branchiæ are placed upon the dorsal aspect of the body, but are protected by a fold of the mantle which almost always contains a shell presenting a rudimentary spire. They are all hermaphrodite like the preceding, and marine.

1st Fam. *Dikera*.
2d Fam. *Akera*.

Order IV. *PULMONALIA INOPERCULATA*, (Ferussac)

Syn. Pulmones, Cuv.;‡ *Pulmobranches*, Blainville; *Gast. Trachelipodes*,§ Lamarck.

The respiratory apparatus is here adapted to the respiration of atmospheric air, and instead of being composed of branchial tufts or laminæ, consists of a cavity lined by the ramifications of the pulmonary vessels, the entrance to which can be opened or closed at the pleasure of the animal. Almost all the species are provided with a shell either turbinated or concealed within the mantle, but are never furnished with a calcareous operculum. Every individual is hermaphrodite, but mutual copulation is essential to fertility. Some are terrestrial, others inhabit fresh water, and some are marine.

1st Sub-order, *Geophilidæ*,* Ferussac.
 1st Fam. *Limax*.
 2d Fam. *Helix*.
2d Sub-order, *Gehydrophilidæ*,† Ferussac.
 3d Fam. *Auricula*.
3d Sub-order, *Hygrophilidæ*,‡ Ferussac.
 4th Fam. *Limnæus*.

Order V. *PULMONALIA OPERCULATA*, (Ferussac.)

Syn. Pectinibranchiata,§ Cuv.; *Siphonibranchiata*,|| Blain.

The respiratory organs of the animals forming this order are similar in structure to those found in the last, but they differ materially in other points. In all the operculated division the shell is closed by a calcareous operculum not found in the last, and instead of that hermaphrodite condition of the sexual organs common to the inoperculated order, the sexes are distinct, the male and female parts existing in different individuals. They are all terrestrial.

1st Fam. *Helicina*.
2d Fam. *Turbicina*.

Order VI. *PECTINIBRANCHIATA*, (Cuv.)

Syn. Trachelipodes, Lamarck; *Monopleuribranches*, Blain.; *Gast. Adelobranches* and *Siphonibranches*, Dumeril.

This extensive order, which comprises most of the univalve mollusks whose shells enrich our cabinets, is characterized by a respiratory apparatus adapted to an aquatic medium. The branchiæ are pectinated, consisting of ranges of fringes disposed like the teeth of a comb, and generally enclosed in a dorsal cavity which opens externally at the side of the body or above the head. The shell is always turbinated, and sometimes provided with an operculum. The sexes are separate, and the animals fluviatile or marine.

1st Sub-order, *Pomastomidæ*,¶ Ferussac; *Chismobranches*, Blainville.
 1st Fam. *Turbo*, Lin.
 2d Fam. *Trochus*, Lin.
2d Sub-order, *Hemipomastomidæ*, Ferussac.
 3d Fam. *Cerithium*, Adanson.
 4th Fam. *Buccinum*, Lin.
 5th Fam. *Murex*, Lin.
 6th Fam. *Strombus*, Lin.
 7th Fam. *Conus*, Lin.
3d Sub-order, *Apomastomidæ*, Ferussac.
 8th Fam.
 9th Fam. *Voluta*, Lin.
 10th Fam.
4th Sub-order, *Adelodermidæ*, Ferussac.
 11th Fam. *Sigaretus*, Adanson.

* *Tectus*, covered.
† Αδηλος, *concealed*.
‡ Pulmo, *lungs*.
§ Τραχηλος, *the neck*; πους, *foot*.

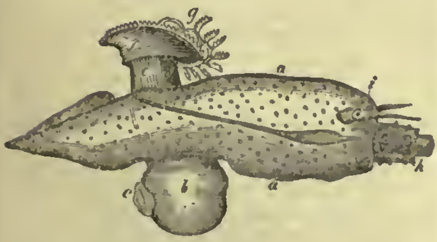
* Γη, *the earth*; φιλεω, *to love*.
† Γη, *the earth*; υδωρ, *the water*; φιλεω.
‡ Υγρος, *moist*; φιλεω.
§ Pecten, -inis, *a comb*.
|| Σιφων, *a canal*.
¶ Πωμα, *operculum*; στομα, *mouth*.

Order VII. *SCUTIBRANCHIATA,** (Cuv.)

Syn. Cervicobranches, Blain.; *Chismobranches,* Blain.; *Gast. Dermobranches,* Dum.; *G. Trachelipodes,* Lam.

Fig. 176.

Fig. 177.



In this order the structure of the branchiæ is analogous to what has been described in the Pectinibranchiata; but the shell, which in the latter was always turbinated, in the Scutibranchiata is a mere shield, in which the indications of a spire are very slight or totally deficient. There is never an operculum. The organs of both sexes are united in every individual, but there is no necessity for copulation, each animal being self-impregnating. The species are all aquatic.

1st Sub-order, *Anthophora.*†

1st Fam. *Haliotis, fig.* 176.

2d Sub-order, *Calyptracidæ,*‡ Lam.

2d Fam. *Capulus.**

3d Sub-order, *Heteropoda*† *Nucleobranches,* Blainville.

3d Fam. *Pterotrachea, fig.* 177.

Order VIII. *CYCLOBRANCHIATA,* (Cuv.)

Syn. Dermobranches, Dum.; *Gast. Phyllidiens,* Lam.; *Gast. Chismobranches,* Blain.

In this order the branchiæ are arranged under the margin of the mantle around the circumference of the body; the shell is a simple shield, either composed of one piece, which is never turbinated, or else made up of several divisions. They are all hermaphrodite and self-impregnating.

1st Sub-order, *Chismobranchiata,* Blain.; *Cyclobranchiata,* Goldfuss.

1st Fam. *Patella.*

2d Sub-order, *Polyplaxiphora,*‡ Blain.

2d Fam. *Oscabrion.*

Cuvier detaches the genera *Vermetus, Magilus,* and *Siliquaria* from the Pectinibranchiata on account of the irregular form of their shell, which is only spiral at its commencement, and is usually firmly attached to some foreign body, a circumstance which involves as a necessary consequence the hermaphrodite type of the sexual organs, so that these genera are self-impregnating. He has, therefore, arranged them in a separate order, to which he applies the name of *Tubulibranchiata.*

Tegumentary system.—The skin which invests the Gasteropoda varies exceedingly in texture, not only in different species but in different parts of the same animal; its structure being modified by a variety of circumstances connected with the habits of the creature, the presence or absence of a calcareous covering, or the mode of respiration. In the naked Gasteropods, especially in the terrestrial species, it is thick and rugose, serving as a protection against the vicissitudes consequent upon the changeable medium which they inhabit. In such as are aquatic the integument is proportionably thinner, and its surface more smooth and even; in both, however, it differs much in texture in different parts of the body; thus in the dermobranchiate species it becomes attenuated into a thin film, where it invests the vascular appendages subservient to respiration, and such portions as cover the organs of sense assume a transparency and delicacy adapted to the sensibility of the parts beneath. In those orders which are provided with shells, the integument which protects such parts of the body as are exposed when the animal partially emerges from its abode, is thick and spongy, and very different from the thin fibrous membrane which invests the mass of viscera contained within the shell. We are led by various circumstances to presume that the skin of all the Gasteropods is in structure essentially analogous to that of higher animals, and in de-

* *Scutum,* a shield.

† Ανθος, *a flower*; φερω, *to carry.*

‡ Καλυπτρα, *a covering.*

* Many of the Capuloid Gasteropods are thought by Cuvier to be diœcious.

† Ετερος, *different*; πους, *foot.*

‡ Πολυς, *many*; πλαξ, *a scale*; φερω, *to carry.*

scribing it we shall avoid obscurity by applying to its different parts the names ordinarily made use of by anatomists to distinguish the tissues enumerated as composing the human integument.

The *dermis* is an extremely lax and cellular texture, eminently elastic, and so intimately blended with the contractile layers beneath it, that it is difficult to recognise it as a distinct structure: its great peculiarity consists in the power which it possesses of secreting calcareous matter, which being deposited either in a cavity within its substance, or as is more frequently the case, upon its outer surface, forms a concealed or external shell: from this circumstance, and from the abundant quantity of mucus which it constantly furnishes, we may infer its great vascularity, while the high degree of sensibility which it evidently possesses unequivocally demonstrates that it is plentifully supplied with nerves, although the existence of a true papillary structure cannot be satisfactorily distinguished. *The colouring pigment* likewise exists, as is evident from the brilliant markings which are often met with in some of the more highly coloured species; but there is a circumstance in connection with this rete mucosum which requires particular mention, as it will enable us afterwards more clearly to explain the formation of shells; the pigment is not merely a layer which serves to paint the surface of the body generally, but appears rather to be an infiltration of the lax tissue of the cutis with coloured fluid, which is poured out in great abundance at particular points, especially around the margin of the shell, and there being mixed up with the calcareous matter secreted by the collar, its tints are transferred to the exterior of the shell itself, tinging it with similar hues. *The epidermis* is evidently deficient, its place being supplied by the viscid matter with which the surface of the body is continually lubricated. The muciparous crypts destined to furnish the copious supply of glairy fluid with which the skin is so largely moistened, have not been detected, but the pores through which it exudes are sufficiently distinct. It is in connexion with the needful diffusion of this secretion over the entire animal, that the skin of the terrestrial species, as the Slugs and Snails, is observed to be deeply furrowed by large anastomosing channels, formed by the rugæ of the surface, and serving as canals for its conveyance by a species of irrigation to every point. No pilous system, properly so called, exists in any of the Gasteropods, the hairy covering of many shells being, as we shall presently see, of a widely different nature.

From the modifications observable in the structure of the integument, it is not to be wondered at that names have been applied to different portions, which it will be useful to notice, especially as they are not unfrequently used in a confused and unprecise manner. That portion of the skin which is more immediately connected with the secretion of the shell, in such Gasteropoda as are provided with a defence of that description, has been termed the *mantle*, and in certain instances, from the mode in which it seems to form a special covering to a part of the body, it has some claim to the name; the mantle is, however, extremely variable, both in position and arrangement. In the Nudibranchiata, which have no shell, it cannot be said to exist, as no fold of the integument or defined margin indicating a portion deserving of a distinct appellation can be detected. In the *Tectibranchiata* the mantle is a small triangular fold of the integument on the right side of the body, inclosing a rudimentary shell, and serving as a covering to the subjacent branchiæ. In the Inferobranchiata it invests the whole of the back, and forms a fold around the margins of the body, beneath which the branchiæ are found; whilst in all the conchiferous Gasteropods it lines the interior of the shell, whatever its shape, forming a distinct fold or thickened rim around its aperture, to which when much developed, as in Helix, the name of *collar* is not improperly applied.

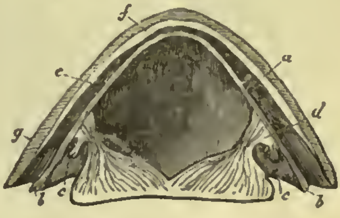
In the naked terrestrial species the mantle consists of a thickened portion, occupying a variable position on the back, and more or less defined by a distinct margin; it is here not unfrequently termed the corselet, and generally contains a calcareous plate. In *Vaginula* it covers the whole of the back; in *Limax* it occupies only its anterior portion; in Parmacella it is found in the middle of the dorsal region, whilst in Testacella it is placed quite posteriorly in the vicinity of the tail; yet whatever its situation, shape, or size, it is the immediate agent in the formation of the shell, and as such we have deemed it necessary to be thus precise in describing the different aspects which it assumes.

Growth of shell.—The varied and beautiful shells that form so important a part of the integument of many individuals belonging to this order, however they may differ in external form and apparent complication, are essentially similar in composition and in the manner of their growth. These calcareous defences, although serving in many cases as a support to the animal, from which important muscles take their origin, differ widely from the internal skeletons of vertebrate animals, being mere excretions from the surface of the body, absolutely extra-vital and extra-vascular, their growth being entirely carried on by the addition of calcareous particles deposited in consecutive layers. The dermis or vascular portion of the integument is the secreting organ which furnishes the earthy matter, pouring it out apparently from any part of the surface of the body, although the thicker portion, distinguished by the appellation of the mantle, is more especially adapted to its production. The calcareous matter is never deposited in the areolæ of the dermis itself, but exudes from the surface, suspended in the mucus which is so copiously poured out from the muciparous pores, and gradually hardening by exposure; this calciferous fluid forms a layer of shell, coating the inner surface of the pre-existent layers to increase the size of the original shell, or else is furnished at particular points for the reparation of injuries which accident may have occasioned. It is to the investigations of Reaumur that we are indebted for our knowledge concerning this interesting process, and subsequent writers have added little to the information derived from his researches; in order, however, to lay before the reader the principal facts connected with this subject, we shall commence with the simplest forms of the process, and gradually advance towards such as are more complicated and less easily understood.

The shells of the Gasteropoda are of two kinds, some being entirely concealed within the substance of the mantle, and consequently internal, whilst others are placed upon the surface of the body external to the soft integument. In the former case the shell is uniform in texture and colourless; in the latter, its developement is much more elaborate, and it is not unfrequently moulded into a great diversity of forms, and painted with various tints, which are sometimes of great brilliancy. The internal or dermic shells are found in many of the *pulmonary* and *tectibranchiate* orders, and possess but little solidity; although inclosed in the substance of the mantle, they are so little adherent, that when exposed by an incision they readily fall out of the cavity in which they are lodged, and from which they are apparently quite detached. Their substance is generally calcareous, but in many instances, as in *Aplysia*, the shell is of a horny texture, being transparent, flexible, and elastic, as is the gladius of many of the Cephalopod Mollusca. In all cases horny or calcareous plates of this description are found to be composed of superposed lamellæ, which are successively secreted by the floor of the cavity in which they are contained, the inferior layer being always the largest and most recent. These shells, therefore, may be considered as merely formed by the deposition of successive coats of varnish, which become indurated, and the simple manner of their growth will best exemplify the mode in which more complicated shells, whatever be their form, are constructed. External shells present an endless diversity of figure, and some classification of their principal forms will facilitate our contemplation of the peculiarity observable in each. The concealed shells, which are merely the rudiments of what we are now considering, are so small in comparison with the size of the body, that they can only be looked upon as serving for the protection of the more important organs, namely, the heart and respiratory apparatus, which are placed beneath them, but the external shells, from their great developement, are not merely a partial protection to the animal, but in most cases constitute an abode into which the creature can retract its whole body. The external shell consists generally of one piece, the form of which may be symmetrical, in which case it is a cone or disc simply covering the back of the animal; or, as is generally the case, the shell may be more or less twisted around a central axis, forming a convoluted, turbinated, or spirivalve shell. In one genus only, *Chiton*, Lin., the shell is formed of several pieces articulated with each other, and covering the surface of the back.

The shell of the Patella, a section of which is represented in *fig.* 178, is a simple cone placed upon the back of the creature, which it completely covers, and upon which it is evidently moulded. On making a section of the animal, as in the figure, the shell is found to be entirely lined by the mantle *a*, *b*, by which it is secreted.

Fig. 178.

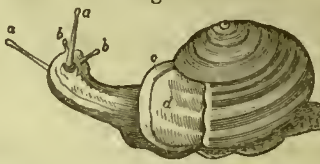


That the whole surface of the mantle is capable of secreting the calcifying fluid from which the shell is formed, is distinctly proved by the manner in which a fracture or perforation in any part is speedily repaired by the deposition of a patch of calcareous matter beneath it, but in the ordinary growth of the animal the different portions of the mantle execute different functions. It is obvious that the enlargement of the body of the patella, as its age increases, must necessitate a corresponding enlargement of its habitation, and this is principally effected by additions of calcareous matter in successively larger rings around the mouth of the shell only; the great agent therefore in forming the shell is the margin of the mantle, *b*, *b*. This hangs loosely as a fringe near the mouth of the shell, and being moveable at the will of the animal, the calcareous matter which it pre-eminently furnishes may be laid on in successive layers to extend the mouth of its abode; and these consecutive additions are indicated externally by concentric lines running parallel with the circumference of the shell, the number of which necessarily increases with age. Whilst the abode of the creature is thus enlarged by the deposition of shell from the vascular and spongy margins of the mantle, the office of the rest of that membrane is reduced to the increase of its thickness, depositing successive coatings of calcareous particles, which are laid on to its inner surface, and when a section of the shell is made *(f)*, these last-formed strata are readily distinguishable by their whiteness and different arrangement. So far the production of an external shell is entirely similar to what we have met with in the formation of the internal defences of the naked Gasteropoda, yet in other respects the former are much more elaborately organised. In the first place many of them are adorned externally with colours, not unfrequently arranged with great regularity and beauty; these tints belong exclusively to the outer layers of the shell, that is, to those formed by the margins of the mantle, and are produced by a glandular structure appropriated to the secretion of the colouring matter, which only exists in the vascular circumference of the calciferous membrane. The colouring matter becomes thus incorporated at definite points, with the cement by which the shell is extended, and is arranged in various manners according to the position of the secreting organs which furnish it. Another peculiarity which distinguishes external shells is that their outer surface is often invested with a membranous layer, called the epidermis, which having been regarded by some authors as a part of the true integument of the body, has given rise to the supposition that all shells being placed between two layers of the skin were in fact internal, the difference between the one and the other consisting merely in the extent of development. In support of this opinion reference has been made to the great thickness of this epidermic coat, which not unfrequently is such as to give to the surface of the shell a felted or pilous appearance; but if such an idea were correct, it is evident that the epidermis must be formed prior to the deposit of calcareous matter beneath it, which observation has disproved, inasmuch as those shells in which the epidermic covering is most dense and shaggy are found whilst in ovo to be without such an investment. The so-called epidermis, therefore, whatever may be the aspect which it presents, whether it be, as is usually the case, a brittle lamella encrusting the shell, or a flocculent and pilous covering, is evidently inorganic, being merely a crust of inspissated mucus, originally secreted with the calcareous particles, and forming when dry a layer encrusting the surface of the shell.

There is yet another structure common to shells of this class, of which it remains to speak, namely, the enamel or pearl, which lines such portions of them as are immediately in contact with the body of the animal; this polished material may be likened to the glazing of an earthenware vessel, and is a varnish produced from the general surface of the mantle, by some modification of its secretion the nature of which is unknown, and spread in successive coatings over the more coarse calcareous matter, wherever such a polish becomes needful.

Having thus briefly described the origin of the different parts of a shell in the simple form which we have chosen as an example, we shall now proceed to examine the structure and mode of growth in others of a more complicated aspect. The majority of the Gasteropoda are furnished with a shell which has been denominated spirivalve. Let the reader imagine the shell of the Patella to be lengthened into a long cone, which, instead of preserving its symmetrical form, is twisted around a central axis, and he will immediately understand the general arrangement of the parts in shells of this description. The cause of such an arrangement is owing to the shape of the body of the animal inhabiting the shell, which, as it grows, principally enlarges its shell in one direction, thus of course making it form a spire modified in shape according to the degree in which each successive turn surpasses in bulk that which preceded it. The axis around which the spire revolves is called the *columella*, and the mode of revolution around this centre gives rise to endless diversity in the external form. In the spirivalve-shelled Gasteropoda, as in those last described, we find a difference in structure between that part of the mantle which envelopes the viscera, and is always concealed within the cavity of the shell, and the more vascular portion placed around its aperture: the former is thin and membranous, its office being merely that of thickening the shell by the deposition of successive calcareous strata applied to its inner side, and of producing the pearly lining which smooths and polishes the interior; the latter part of the mantle is thick, spongy, and coloured, secreting largely the calcareous particles with which the progressive amplification of the shell is effected: this portion (*fig.* 179, *c*,) from its thickness, and the

Fig. 179.



manner in which it usually surrounds the entrance to the shell, is generally termed the collar. In such species as inhabit coloured shells we may observe upon the surface of the collar (*fig.* 179, *d*,) patches of different colours corresponding in tint with the various hues seen upon the exterior. These spots supply the pigment, which being mixed up with the earthy cement serving for the enlargement of the shell stains it with a corresponding tint. In many instances, as in the figure, the colours are continually secreted by the dark spaces, *d*, causing the painted bands which they produce to wind uninterruptedly in the direction of the convolutions of the spire, and they may be seen gradually to increase in breadth as the size of the animal enlarges: but more frequently it happens that the colouring matter is only furnished at stated periods, and in such cases of course the shell will be marked with spots, the intervals between which will be regulated by the frequency of the supply. It will be seen that by a combination of these circumstances it is easy to explain how every variety of marking may be produced.

The most conspicuous exception to the general process by which shells are painted, is met with in the porcellaneous Couries (*Cypræa*), which at various periods of their growth could scarcely be recognised as belonging to the same genus. In the young animal the enlargement of the shell is effected in the ordinary manner, and its colours are supplied from the surface of the collar: in the mature state, however, these shells are coloured in a very different manner, and acquire at the same time a great increase of thickness; this is effected by the enormous development of the alæ of the mantle, which in the full-grown animal become so much extended, that when the creature is in motion they are laid over the external surface of the shell so as entirely to conceal it. These alæ contain patches of pigment which secrete colours entirely different from those contained in the collar, and from their whole surface exudes a calcareous varnish, which being laid over the exterior of the old shell completely conceals the original markings; these, however, may be again exposed on removing with a file the outer crust: a line, which is generally very distinctly seen running longitudinally along the back of the shell, indicates the spot where the edges of the two alæ of the mantle met during the completion of this singular process. Such shells are therefore remarkable from the circumstance of having their thickness increased by additions to the outer as well as to the internal surface.

In terrestrial shells it is only when they have arrived at their full growth that a rim or margin is formed around the aperture, which serves to strengthen the whole fabric; but in marine shells, which attain to much larger dimensions, the growth is effected at distinct periods, each of which is indicated by a well-defined margin, and these ridges remaining permanent, the successive stages of increase may be readily seen. At each suspension of development, it is not unusual to find spines or fringes, sometimes differently coloured from the rest of the shell, and not unfrequently of considerable length. In *fig.* 180, which represents the shell of *Murex*

Fig. 180.

cornutus, the nature and arrangement of such spines is well exemplified. They are all formed by the margin of the mantle which shoots out into long fringes, encrusting themselves with a shelly covering; each spine therefore is at first hollow, and if in many species they are found solid, it is because the original cavity has been gradually filled up by the deposition of earthy matter within it. The syphon with which many Conchiferous Gasteropoda are provided is produced in precisely the same manner, and its identity in form with the other spines covering the surface of the shell is in the annexed figure sufficiently obvious. In many species, as in the beautiful *Turbo scalaris*, (*fig.* 181,) the epocha of growth are only indicated by ridges surrounding the shell at regular intervals, each of which originally terminated a fresh augmentation of its size. It is difficult to imagine by what influence these creatures are induced to enlarge their habitations at such regular intervals, terminating each operation by a similar margin; some authors imagine that each time the creature emerges from its abode a fresh addition is made; others that it is dependent upon the temperature or state of the seasons, but without sufficient grounds for either of these assertions; it seems more probable therefore that the growth of the body gradually rendering the former dimensions of the shell incommodious from time to time renders these periodical enlargements necessary.

Fig. 181.

Although shells are evidently inorganic and extra-vascular structures, it is now universally conceded that their inhabitants have the power of removing portions which may obstruct their growth, or needlessly infringe upon the limits of their abode. In the Murices we have indisputable evidence of this fact in the removal of such spines as would interfere with the revolutions of the shell around the columella, and in Conus and similar genera a like faculty enables the animals to thin the walls which bound the inner whirls when their original thickness is rendered unnecessary by the accession of new turns. Such a solvent power indeed is not only exercised upon their own habitations, but many Gasteropods are able gradually to bore holes in other shells, or perforate the rocks upon which they reside to a considerable depth. The mode in which this is effected is, however, still a mystery; some authors ascribe it to a power of absorbing their shells, an expression the vagueness of which is sufficiently evident; others ascribe it to some acid secretion at the disposal of the animal; yet although this explanation is certainly plausible, when we reflect that the very structure which secretes this supposed acid is itself the matrix of such abundant alkaline products, it is not easy to imagine how the same structure can at the same time furnish such opposite materials.

As we should expect from the mode of its growth, the shell throughout all the Conchiferous class is composed of earthy matter, cemented together by an animal substance easily separable by the action of acids. In the porcellaneous shells the animal matter exists in much less quantity than in those of a fibrous texture; in the former, indeed, Mr. Hatchett found that when the carbonate of lime, of which the earthy portion is almost entirely formed, is dissolved even by very feeble acids, little or no vestige of any membranous structure could be perceived, nor indeed could any be detected, but by the small portion of animal coal which was formed when these shells had been exposed for a short time to a low red heat; in others however, as the Patellæ, a substance was left untouched by the acids which had the appearance of a yellowish transparent jelly, by means of which the earthy matter had been, as it were, cemented together.

On examining minutely the mechanical arrangement of the layers of which these shells are composed, it is found to vary in different kinds, and from this circumstance the fossil conchologist may derive important information in examining mutilated remnants sometimes so plentifully met with in calcareous strata. The simpler shells (Patella, Fissurella) are formed of very thin, compact, and parallel layers, whilst in others three distinct strata of fibres, each of which assumes a different direction, may be observed. The fibres composing the external layer are disposed perpendicularly to the axis of the shell. In the middle stratum the fibres are placed obliquely and are slightly twisted, but so arranged that each meets at an obtuse angle the extremity of one of the fibres composing the outer layer, and in the internal stratum they again assume a perpendicular direction. Such a disposition of the fibres, which is met with in all Siphonibranchiate shells, is eminently calculated to resist external violence in whatever direction it may act, and greatly contributes to the solidity of the whole fabric.

Operculum.—Many of the spirivalve Gasteropoda, especially such as are aquatic, are provided with a calcareous plate, which is placed upon the posterior surface of the body, and closes accurately the mouth of the shell, when the animal is retracted within it. The texture of the operculum is sometimes horny, but it is more frequently calcareous and of a stony hardness, its contour being accurately adapted to the orifice. It is composed of parallel fibres disposed perpendicularly to the base of the shell, and deposited in successive layers around an axis, so as to give to the whole structure the appearance of a solid spirivalve, as may readily be seen on removing it from the animal and examining its inner surface. This has been looked upon by some zoologists as analogous to the second valve of bivalve Mollusca, to which, but for its want of a ligamentous attachment, it certainly bears a distant resemblance.

The deciduous operculum of terrestrial Gasteropoda, or *epiphragma*, as it is usually called, is a widely different structure, being merely an inspissated secretion, with which, during the period of hybernation, the entrance to the shell is closed; and on removing the outer plate, not unfrequently a second or even a third similar membrane will be found within, forming additional safeguards against intrusion or the vicissitudes of temperature.

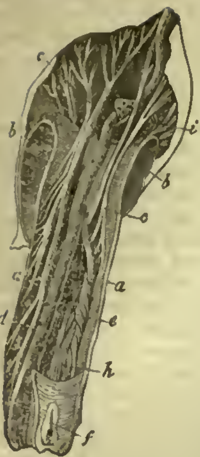
During the progressive growth of the shell the animal contained within it necessarily changes its original position, advancing gradually as the body enlarges from the earliest formed spires towards the aperture, as may easily be proved by sawing off the apex of a spirivalve shell containing the living animal. This circumstance is remarkably conspicuous in some of the Bulimi (*Bulimus decollatus*), enabling the occupant, as it grows, to break off the turns of its spire which first contained it, so that at the latter period of its life it does not retain any part of its original shell. The mode in which this advancement is effected is a subject of much curiosity, as it involves a power of detaching the muscles connecting the creature with its abode, from the place where they were originally fixed, and forming a new connexion with the shell; but whether this is effected by the removal of the original fibres and the production of others more anteriorly, as is believed by some, or whether, as is more probably the case, the creature has a power of changing the attachment of its retractor muscle at pleasure, is still a matter of uncertainty.

Organs of digestion.—We shall not be surprised to find that in a class so extensive, and composed of individuals living in such diversified circumstances, the alimentary organs are much modified in form in different species, according to the nature of the food with which they are nourished.

Mouth.—In most instances the mouth presents the appearance of a retractile proboscis, which can be protruded or shortened at the will of the animal, but unprovided with jaws or any apparatus for mastication; it is in such cases a muscular tube, formed of longitudinal fibres prolonged from the common parietes of the body, and of circular muscles, the former serving for the retraction of the organ, the latter causing its elongation by their successive action; by means of this simple structure every movement requisite for the prehension of food is effected. At the bottom of the tube is a narrow vertical aperture, the edges of which are slightly cartilaginous, and behind this is the tongue armed with spines variously disposed; the aliment therefore, having been forced by the contractions of the proboscis through the aperture at its termination, is received by the tongue, and by the aid of the latter organ is propelled into the œsophagus without mastication or any preparatory change.

In *Buccinum* and other syphoniferous genera, the structure of the proboscis is much more complicated and curious, (*fig.* 182.) " The proboscis, which carries with it the œsophagus in its different states of protrusion, is organised with wonderful artifice, being not only capable of flexion in every direction combined with limited power of retraction or elongation, but it can be entirely lodged in the interior of the body, folded within itself, so that that half which is nearest the base encloses the other portion: from this position it is protruded by unfolding itself like the finger of a glove or the tentacle of a snail, only it is never completely inverted. We may represent it as composed of two flexible cylinders (*fig.* 182, *a*, *b*,) one inclosed within the other, the upper borders of which join, so that by drawing outwards the inner cylinder, it is elongated at the expense of the other, and on the contrary, by pushing it back, the internal cylinder becomes lengthened by its shortening. These cylinders are acted upon by a number of longitudinal muscles (*c*, *c*), all very much divided at each extremity, the internal or superior divisions being fixed to the parietes of the body, whilst at the other end they are attached to the inner wall of the internal tube (*a*) of the proboscis, along its whole length, extending even to its extremity; their action is obviously to draw the inner cylinder, and con-

Fig. 182.



sequently the entire proboscis inward. This being done, a great part of the inner surface of the inner cylinder becomes a part of the external surface of the outer cylinder, whilst the contrary occurs when the proboscis is elongated and protruded.

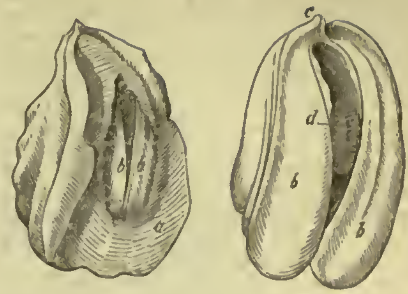
The elongation of the inner cylinder by the unfolding of the outer, or what is the same thing, the protrusion of the proboscis, is effected by the intrinsic annular muscles which assist in forming the organ; they surround it throughout its whole length, and by their successive contractions force it outwards; one especially, seen at *b*, placed near the junction of the extremity of the outer cylinder with the integuments of the head, which is stronger than the rest. When the proboscis is protruded, its retractor muscles acting separately, bend it in every direction, being in this case antagonists to each other. The internal cylinder incloses the tongue *(f)*, the salivary canals (*e*), and the greater part of the œsophagus (*d*), but its principal use is to apply the extremity of the tongue to such objects as the animal would suck or erode by its armed surface.

In Aplysia, Akera, and others, the mouth consists of a fleshy mass of considerable strength, to which are attached muscular bands proceeding from the sides of the body, serving for its movements, some drawing it forwards whilst others retract it, but there are no jaws nor anything equivalent to them, except the cartilaginous hardness of the lips.

But in such of the Gasteropoda as devour vegetable matter, the mouth, instead of being a proboscis, consists of a strong muscular cavity, inclosing a dental apparatus adapted to the division of the food. In the Snail, Slug, Limnæus, Planorbis, &c., this is a single crescent-shaped horny tooth, attached to the upper surface, and furnished along its opposite edge with sharp points, separated by semicircular cutting spaces, admirably adapted for the division of vegetable food.

The dental organs of Tritonia and Scyllœa are, however, still more perfectly contrived for such a purpose. The muscular mass of the mouth is strong and powerful, but instead of the single tooth of the Snail, it is armed with two cutting blades (*fig.* 183, *b*, *b*), horny in their texture and exceedingly sharp, resembling in every respect a pair of strong curved shears, from which in fact they only differ in the mode of their union, the spring of the one being replaced by an articulation (*c*) inclosed in a synovial capsule. These blades are approximated by strong muscular fibres, and few

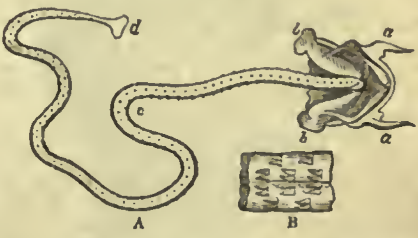
Fig. 183.



animal structures can resist their edge. The lips (*h*), which are placed in front of these teeth, are strong and very flexible, forming a muscular tube, by means of which the food is seized and brought within the power of its formidable jaws, and then the divided morsels, being seized by the horny teeth which invest the tongue (*d*), are conveyed into the œsophagus.

Tongue.—The tongue in these Mollusca is generally a very important organ, serving not only as a necessary auxiliary in deglutition, but often as a means of eroding the food: in fact, in one tribe only, *Thethys*, is it found to be deficient. In most of the proboscidean species the tongue is short, and covered with sharp, horny, and recurved spines, which, seizing the morsels of food taken into the mouth by a sort of peristaltic motion, push it backwards into the œsophagus. In some genera which have no proboscis, the tongue is of extraordinary length; thus in Haliotis it is half as long as the body, and in Patella, Turbo, Pica, and others, it much exceeds in length the entire animal. The tongue of Patella, which is three times the length of the body, is represented at *fig.* 184; it is supported by two cartilaginous pieces (*b*, *b*) placed on each

Fig. 184.



side of its root; from these arise strong and short muscular bands, which wield the organ. The surface of this singular tongue, a magnified view of which is given at B, is armed with minute though strong teeth, placed in transverse rows and arranged in three series; each central group consists of four spines, while those on the sides contain but two a-piece. It is only at its anterior extremity, however, that the tongue so armed presents that horny hardness needful for the performance of its functions, the posterior part being comparatively soft; it would seem, therefore, that in proportion as the anterior part is worn away, the parts behind it assume gradually the necessary firmness and advance to supply its place. The action of this curious instrument is as follows:—in the upper part of the circumference of the mouth we find a semicircular horny plate, resembling an upper jaw, and the tongue, by triturating the food against this, gradually reduces substances however hard. On opening the Patella, the tongue is found doubled upon itself, and folded in a spiral manner beneath the viscera.

The tongue of *Oscabrio* resembles that of the Patella, except in its armature, being furnished on each side with a series of hooked and three-pointed scales, and another set of long, sharp, and recurved spines, whilst its centre is simply studded with tubercles. In Turbo pica the scales, which are cutting and denticulated, are arranged transversely along its surface.

The tongue of Buccinum (*fig.* 182, *f*), is placed at the extremity of the proboscis, forming a most extraordinary apparatus, capable of destroying by its constant action the hardest shells; externally it resembles rather a mouth than a tongue, being divided into two lips, each of which is studded with sharp horny teeth. These lips are supported upon two cartilages which occupy the anterior half of the proboscis, and are moved upon each other by strong muscular fasciculi (*h*) in such a manner that the spines which arm the surface of the organ are alternately erected and depressed by their action, a movement the constant repetition of which soon wears away the substances upon which it is made to act. This spiny tongue is situated just within the entrance to the œsophagus (*d*), and besides acting upon foreign bodies will materially assist in propelling the food into that tube.

In other Gasteropods the tongue is short and merely an organ of deglutition: thus, in *Aplysia* it is broad, heart-shaped, and studded with sharp points. In Onchidium and Doris, the surface is marked with transverse grooves, which are crossed at right angles by others of great fineness. And in the Snail and Slug, in which the surface of the tongue is similarly marked, the striæ are so delicate that they can only be seen with a microscope.

Alimentary canal.—We shall commence our description of the intestinal canal of the Gasteropod Mollusca by the examination of the simpler forms which it presents. In the Snail (*fig.* 190), the whole alimentary tube (*e, f, g, k*) is thin and membranous. The stomach, which is merely a dilatation of the œsophagus, is semitransparent, but studded with opaque points and internally folded into delicate longitudinal plicæ. From this arises an intestine, of considerable length, without cœca, valves, or remarkable appearance internally, except near its termination, where the orifices of minute follicles may be detected; the intestine having performed several convolutions enveloped in the masses of the liver, with which it is connected by cellulosity and numerous vessels, at last runs along the margin of the pulmonary cavity, close to the orifice of which it terminates. In Vaginulus the arrangement is nearly similar (*fig.* 189, *g, h, i.*) In *Tritonia* and *Doris* the structure of the digestive tube is equally simple, and in these as well as in the majority of the Gasteropoda the only remarkable differences are found in the proportional size of the stomach and the length of the intestinal convolutions. In *Doris* we find near the orifices by which the bile is poured into the stomach, an aperture communicating with a round vesicle or cœcum, the inner surface of which is evidently glandular, and from its large supply of blood derived from one of the hepatic arteries, probably furnishing an abundant secretion analogous to that of the pancreas. In *Phasianella* the stomach is very voluminous and sacculated internally. In *Buccinum* the digestive apparatus is more complicated in its structure. The œsophagus commences, as we have already seen, at the extremity of the proboscis, and of course follows all the motions of that organ; when the proboscis is protruded in search of prey, the gullet is straight and adapted to the reception of food; but when the proboscis is retracted within the body, the œsophagus is bent upon itself, so as to be partially contained within the proboscis, whilst the greater portion is folded beneath that organ in its retroverted state. After making another fold it dilates into a small crop, the lining of which is plicated in the direction of its axis, and to this succeeds the stomach, which is a moderately sized round cavity, irregularly rugose internally. The intestine is very short, and has a small cœcum appended to its side; it terminates in a capacious rectum, placed, as is invariably the case, in the vicinity of the respiratory cavity, and having its lining membrane gathered into prominent longitudinal rugæ. Many of the Gasteropoda are provided with several digestive cavities, resembling in some degree the stomachs of ruminating Mammalia. In *Janthina*, which is furnished with a proboscis like that of the *Buccinum*, the œsophagus arising from this terminates by a narrow slit in a membranous cavity or first stomach, to which succeeds a second, having thicker walls and plicated internally. The intestine is extremely short, terminating as usual in the neighbourhood of the respiratory cavity. In *Pleurobranchus* the resemblance of the stomachs to those of a ruminating quadruped is very striking. The first stomach (*fig.* 185, *a*), which is membranous, receives the bile by a large orifice (*b*) placed near its communication with the second digestive cavity (*c*), which is smaller and more muscular; to this succeeds a third (*d*), the sides of which are gathered into broad longitudinal lamellæ, precisely similar to those of a ruminant; and to render the analogy still more perfect, a groove is found running along the walls of the second cavity from one orifice to the other, apparently subservient to rumination. The fourth stomach (*e*) is thin, and its walls smooth. This animal lives on Alcyonia and small Zoophytes.

Fig. 185.

Many Gasteropoda which devour shell-fish and other hard materials have a true gizzard adapted to break in pieces such food; this is the case with *Thethys*, an animal whose mouth is totally destitute of dental organs, but their want is supplied by a fleshy gizzard resembling that of a bird, having its interior lined with a dense cartilaginous membrane, like that which lines the gizzard of graminivorous fowls, and in its cavity shells of Mollusca and Crustaceans are found comminuted by its action. In *Limnæus* we find a gizzard strictly analogous in structure to that of a granivorous bird: it presents two dilatations, one at the cardiac, the other at the pyloric extremity, whilst the middle portion is occupied by two strong muscles, united at the sides by tendinous bands. The gizzard of *Planorbis* is precisely similar to that of Limnæus. In Onchidium the muscular gizzard is followed by two other stomachs, the lining membrane of that which immediately succeeds it being gathered into large folds, which must greatly retard the passage of the aliment; while the third cavity, which is short and cylindrical, is likewise lined with a membrane folded into more delicate plicæ, affecting a longitudinal direction.

There are some families in this class which are provided with a still more elaborate apparatus for the preparation of their food, their stomachs being armed internally with teeth variously disposed, and on many accounts extremely curious. In all the Bullæ (Akera) the gizzard contains three plates of stony hardness attached to its walls, and so disposed that they are evidently powerful agents in the trituration of the food. In *Bulla lignaria (fig.* 186)

Fig. 186.

two of these teeth are placed on either side of the gizzard, into the cavity of which they project, and are united to each other by strong muscular bands; the third piece is smaller than the other two, but similarly imbedded in radiating muscles, whose action must powerfully grind down the substances which come under the influence of this singular mill. In the other *Bullæ* the structure of the gizzard is the same, but the bony plates differ slightly in form and arrangement. In all, however, the fragments of shells and other hard substances found in it attest the efficacy of the apparatus.

The gizzard of *Scyllæa (fig.* 187, *e)* is, externally, a strong fleshy cylinder, and when this is opened there are found, firmly imbedded in its muscular walls, twelve horny plates, which are extremely hard and as sharp as the blades of a knife; their edges are dis-

Fig. 187.

posed in the direction of the axis of the organ, and as they project considerably into its cavity, their action upon the contents of the gizzard must be sufficiently evident.

Aplysia, however, furnishes us with the most curious form of these stomachal teeth. The œsophagus, which is comparatively narrow at its commencement, soon dilates into a capacious crop, which is generally found filled with pieces of fucus and the fragments of shells. To this crop succeeds a short cylindrical gizzard with strong and muscular walls, and after the gizzard we find a third stomach which leads to the intestine. On opening the gizzard and third stomach *(fig.* 188) they are found to have their

Fig. 188.

interior armed in a manner which is probably unique. The sides of the gizzard (*b*) are covered with pyramidal plates of a rhomboidal figure, the apices of which resemble the tubercles found upon the grinding surfaces of the human molar teeth. Of these there are twelve larger plates arranged in quincunx, besides several smaller ones placed near the entrance of the organ. These teeth are of a horny nature and formed of laminæ parallel to their bases: their adhesion to the surface of the lining membrane is so slight that they are detached by the slightest effort, without leaving any trace of membrane or other bond of union, the place of their attachment being only indicated by a smooth and prominent surface, corresponding in shape to the base of each tooth. The apices of all these teeth meet in the centre of the gizzard, and whatever passes through that cavity must be bruised by their action.

The third stomach (*d*) is armed with teeth of a totally different nature. These are little conical hooks (*c*) attached to one side of the organ only, and as little adherent in the dead animal as are the pyramids of the gizzard towards which their points are directed. In the figure many have fallen off, leaving slightly elevated spots indicative of the place of their attachment. Near the pylorus is a large aperture communicating with a cœcum of considerable size (*f*), evidently identical with the spiral cœcum of the Cephalopoda both in its position and relation to the insertion of the biliary canals (*e*), forming, as in Fishes, the rudiment of a pancreas. From the orifice of the cœcum a ridge is prolonged into the commencement of the intestine (*g*).

Accessory glands.—The auxiliary chylopoietic secretions found in the Gasteropoda are generally only two, the salivary and the hepatic. In some rare instances already adverted to, as in Doris and Aplysia, we may likewise add the pancreatic furnished by the cœca, which in those genera terminate in close vicinity with the ducts issuing from the liver, and which, from every analogy, represent the pancreas of vertebrate animals.

The salivary glands are constantly present and seem to present a size and importance corresponding with the mode in which the mastication of the food is accomplished. In those genera which are provided with a cutting apparatus placed in the mouth, they are very largely developed, as also in most of the proboscidean species, and it is only in the Cyclobranchiate order, where the long spiral tongue is used rather for the abrasion than the mastication of the food, that they become small, and, in a very few instances, undistinguishable. In *fig.* 190, which represents the viscera of the Snail, these glands are marked with the letters *á á*, and this engraving will give a good idea of the general structure which they present, and of the ordinary termination of the ducts which pour the saliva into the oral cavity. The glands are placed along the sides of the stomach, which they partially invest, and sometimes those of the opposite sides are intimately united with each other; their colour is whitish and semi-transparent, and they are formed of small lobes, which, in many species where their texture is less compact, may be distinctly seen to be formed of the ramifications of their arborescent ducts, each ultimate division of which is terminated by a secreting granule. In Vaginulus (*fig.* 189) the salivary glands are small, but in addition to the ordinary structure (*f*) we find an additional tube or slender cœcum (**f*), which, lying at first upon the stomach, passes through the nervous collar to join the duct by which the saliva is discharged. The secondary divisions of the ducts gradually unite to form an excretory canal for each of the two glands, which invariably pour the salivary secretion into the mouth in the vicinity of the tongue. When very small, as in Testacella, Onchidium, and Haliotis, they are found to be merely arborescent tufts placed on each side of the oral mass. In all the Pectinibranchiate order, where the mouth is converted into a protrusible proboscis, the glands themselves (*fig.* 182, *i*) are found within the visceral cavity, and their ducts (*e, e*) are very long and tortuous so as to follow the movements of the proboscis in which they are lodged, running in contact with the œsophagus to open at the extremity of that tube on each side of the spiny tongue; it is even probable that the secretion which they furnish at that point may assist, in some measure, in the destruction of the shells and other hard bodies, which are submitted to the continued action of this organ.

In *Doris* and *Pleurobranchus* a glandular structure of considerable size is found near the commencement of the œsophagus, which is of a brownish colour and plentifully furnished with bloodvessels. This has been looked upon as an auxiliary salivary organ, but as its duct has not been as yet satisfactorily traced, its real nature is unknown: but in *Janthina* there are distinctly four salivary glands, each furnishing a distinct duct; two of these run, as in Buccinum, to the extremity of the proboscis, whilst the other pair empties the secretion of the corresponding glands into the commencement of the œsophagus.

Biliary system.—The liver throughout the whole class is of great comparative size, enveloping the convolutions of the intestines and filling a large portion of the visceral cavity. That of the Snail consists of four large lobes (*fig.* 190, *h*), each divisible into lobules, and these again into secreting granules, from each of which issues an excretory duct. The ducts gradually unite into larger trunks, so that the whole organ, when unfolded, accurately represents a bunch of grapes, the stem of which would be the common biliary duct. In the same animal the excretory ducts from each of the divisions of the liver unite into one canal, which opens into the pyloric extremity of the stomach (*g*) in such a manner that as much bile must be poured into the stomach itself as into the commencement of the intestine. In the Slug the liver consists of five lobes, and from these are derived two distinct biliary canals, which open separately into the intestine, one on each side of the pylorus. A similar disposition occurs in *Vaginulus (fig.* 189, *l, h').*

Fig. 189.

In *Scyllæa* the liver *(fig.* 187, *d)* is divided into six small and detached round masses, the excretory ducts of which open above the point where the œsophagus joins the singularly armed gizzard (*c*). The liver of *Aplysia* is very large and forms three principal masses, among which are seen the convolutions of the intestine. The biliary canals are very wide and open into the third stomach near the aperture communicating with the rudimentary pancreas *(fig.* 188, *c).* In *Testacella Haliotoidea* there are two livers perfectly distinct from each other, and from each arises a proper duct, which opens separately into the commencement of the intestine near its origin. *Onchidium* furnishes us with a still more curious arrangement, being provided with three distinct livers, pouring their secretions by separate canals into different parts of the alimentary tube. Each portion perfectly resembles the others in external appearance, and in structure as well as in the nature of their respective secretions. The excretory canal which proceeds from the largest mass enters the œsophagus, discharging itself near to its cardiac termination; the duct of the second terminates near the same point, whilst the bile produced by the third is poured into the gizzard itself. The insertion of the two former above the gizzard would seem intended for the same purpose as the abundant secretion which is poured into the ventriculus succenturiatus of Birds, namely, to moisten the food before its introduction into the gizzard; it is, however, singular to find the biliary fluid employed for this purpose; nor is the insertion of the third duct into the first of the three stomachs of this animal less extraordinary, a similar arrangement occurring only in a few fishes, as in the *Diodon Mola.*

The liver of *Doris* is very large, and not only is the bile which it secretes discharged by large and numerous ducts into the stomach, so wide, indeed, that it is difficult to conceive how the food is prevented from entering them, but moreover the liver furnishes a second duct of large calibre, which opens externally in the vicinity of the anus. A part of the bile in this case is evidently excrementitious, as there is no doubt that the second canal takes its origin from the substance of the liver. "This," says Cuvier speaking upon this subject, "is the first instance of the kind which I have met with, and the fact was sufficiently singular to make me hesitate long and examine the matter with all possible precaution before admitting it. It is only by one supposition that it can be explained otherwise,—namely, that the lobes of two different glands are so interwoven that they are not to be distinguished from each other, one portion producing bile used in the process of digestion, and the other secreting a fluid which escapes by the canal in question." Before its termination externally, the secondary duct communicates by a short canal with a lateral receptacle, which forms a kind of gall-bladder, having its lining membrane much corrugated and its walls apparently muscular; this is probably a reservoir for the excrementitious fluid, in which it may be retained until the animal feels its discharge necessary. There is reason to suspect that the fluid thus furnished is a colouring matter, used as a means of defence, and expelled like the ink of the cuttle-fish on the approach of danger, but the matter is undecided.

The bile is in all cases produced from arterial blood, and the liver is provided with but one system of veins answering to the hepatic.

Organs of respiration.—The respiratory organs of the Gasteropoda are found to be constructed upon very various principles, adapted to the medium which they inhabit, or the peculiar exigencies of the individuals composing each order. Nevertheless in different groups allied by the generalities of their organization, the respiratory system is, in most instances, found to be constructed upon the same plan, and this circumstance more than any other has rendered the position and nature of the respiratory organs the most eligible basis of classification. On looking over the table which we have given at the commencement of this article, the reader will perceive at once that the names by which the different orders are designated indicate the general disposition of the pulmonary or branchial appendages, and we shall therefore follow the arrangement there adopted in considering more minutely the peculiarities belonging to each.

The first or *Nudibranchiate order* is distinguished by having the breathing apparatus perfectly exposed to the influence of the surrounding medium, which in all the genera belonging to this division is the water of the ocean; the branchiæ constantly assume the shape of arborescent tufts, placed in different situations upon the dorsal aspect of the animal. In Doris (see article Circulation, *fig*. 321, vol. i. p. 649,) they form a circle around the anus. In *Tritonia* they are disposed in two rows along the sides of the animal, extending from one extremity of the body to the other. In *Scyllæa* they consist of little tufts irregularly disseminated over the surface of the back and upon the fleshy alæ projecting therefrom. In *Glaucus* they form on each side three large and palmated fins, being used as agents of progression as well as instruments for the purification of the blood. In *Œolis* the branchiæ assume the shape of long riband-like lamellæ disposed in imbricated rows; but whatever their form their structure is essentially the same, each tuft or lamella containing the ramifications of the branchial vessels, and effecting the oxygenisation of the blood by the extent of surface which they expose to the action of the surrounding water.

In the *Infero-branchiata* the respiratory tufts or plates are arranged around the circumference of the body, lodged in a deep groove between the margin of the foot and the edge of the mantle which covers the back. The *Tectibranchiata* have the branchiæ covered by a little fold or operculum formed by a duplicature of the skin, and generally containing a horny or calcareous plate; beneath this are seen the respiratory leaflets arranged in rows upon the two sides of a semi-crescentic membrane: their structure in Aplysia is represented in *fig*. 191. Each branchial lamella (*a*, *a*) divides dichotomously into smaller plates until the divisions become extremely minute; the ramifications of the arteries and veins within them being distributed to each are spread over an extent of surface adequate to the efficient aeration of the circulating fluid which they contain. The principal trunk of the branchial artery (*c*) runs along the concave margin of the crescentic membrane, while the large venous trunk occupies the opposite or convex border; the veins from the branchiæ all terminate in this great vein, their orifices being disposed in circles, as seen at *d*.

The *Pectinibranchiate* order includes that large family of aquatic Gasteropods which are enclosed in shells, and the arrangement of the whole of their breathing apparatus is adapted to the respiration of water. The branchiæ resemble in structure those of fishes, and are pectinated or composed of parallel laminæ disposed like the beards of a feather, and attached in two or three rows to the roof of a large cavity placed under the integuments of the back; or else in some rare cases, as in the Valvata cristata, the branchia is single, resembling a pen, and floats externally.* A very material difference is observable between the truly aquatic species and the pulmonary Gasteropods which inhabit the water, but breathe air; in the latter, which are compelled to come to the surface to respire, the aperture leading into the pulmonary cavity is small and furnished with a powerful sphincter, so that the air taken in is retained at the pleasure of the animal; but in those which are provided with pectinated branchiæ, the entrance to the branchial chamber is a wide fissure, always allowing free ingress and egress to the circumambient fluid. Many genera of this order are provided with a special apparatus called the syphon, for conveying the water freely into the respiratory chamber; this is a semi-canal formed by a fold of the right side of the mantle, and lodged in a groove projecting from the mouth of the shell; through this channel the water at all times has free admission to the gills. The respiratory organs of the *Scutibranchiata* resemble those of the last order, and are contained in a similar cavity, to which the water is constantly admitted; but in the *Cyclobranchiata* the branchiæ consist of a series of lamellæ placed external to the body, around the border of the mantle, by the edge of which they are overlapped.

Respiration is effected in the *Pulmonary Gasteropoda*, whether they be terrestrial or aquatic, by an apparatus fitted for breathing the air of the atmosphere; the lung or pulmo-branchia, as we may call this singular organ, consists of a large cavity placed beneath the mantle, over the surface of which the vessels returning the blood from the system spread in beautiful ramifications, and from these the pulmonary veins take their origin, collecting the blood which has been exposed to the action of the air, and conveying it to the heart. A large orifice admits the air freely into this chamber, the walls of which alternately contracting, draw in and expel it at regular intervals by an action precisely similar to that of the human diaphragm. In the Slugs (Limax) the cavity is small, but the network of the vessels spreads over its whole surface. In the Snail (Helix), on the contrary, the organ is much larger, but its floor only is covered with the respiratory ramifications. In *fig*. 322, of the article Circulation, vol. i. p. 649, a diagram is given of this structure, and in *fig*. 190, (*m*, *n*,) the details of its arrangement are more minutely shewn; yet even in the beautiful drawing of Cuvier, from which our plate is copied, the minute divisions of this superb plexus are but inadequately shewn. The order which has been established by Ferussac, under the name of *Pulmonalia operculata*, is composed of individuals classed by Cuvier among the *Pectinibranchiata*, to which in every circumstance, with the exception of the structure of the respiratory system, they are closely allied; these, however, breathe the air in a cavity analogous to that which we have just described, only differing in the position and nature of the aperture leading to it, which here, instead of being a rounded orifice in the margin of the collar, opened and closed at the will of the animal, is a large fissure placed above the head, exactly as in the Pectinibranchiate order.

Organs of circulation.—Having thus described the different arrangements of the branchiæ, we shall be enabled more readily to investigate those modifications in the disposition of the organs subservient to the circulation of the blood which are dependent thereupon. Throughout the whole class, with

* For a figure of the branchial chamber of the Buccinum undatum, and an account of the ciliary movements which have been observed in many orders of Gasteropoda to be connected with respiration, the reader is referred to the article Cilia.

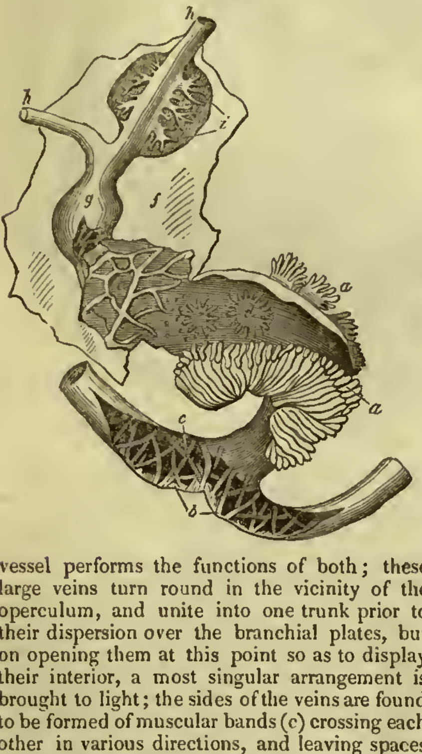
Fig. 190.

the exception of the Scutibranchiate and some of the Cyclobranchiate orders, the heart is single, consisting of an auricular and ventricular cavity, and is interposed between the branchial or pulmonary vessels and the system, receiving the aerated blood from the respiratory organs, and propelling it through the body. The heart of Aplysia (*fig.* 191, *e, g*) or of the Snail, (*fig.* 190, *o, p*) will exemplify its ordinary structure. The auricle varies slightly in shape in different genera, but is always extremely thin and pellucid, containing in its coats muscular bands of great delicacy. The ventricle is provided with stronger walls, and is generally separated from the auricle by a valve, formed of two pieces. The heart is enclosed in a pericardium, but its position is regulated by that of the branchiæ; and from the great diversity of arrangement which we have found the latter to present, a corresponding want of uniformity in the locality which the heart occupies may be readily expected. We shall select two forms of the respiratory organ as examples of the variable position of the heart, and as illustrations of the usual distribution of the bloodvessels, viz. the Snail, (vide Circulation, *fig.* 322, and the Doris, *fig.* 321,) and afterwards notice the principal aberrations from the ordinary disposition. In the Snail, the blood derived from the whole body is brought by great veins, performing the functions both of the vena cava and of a pulmonary artery, to the plexus of vessels lining the floor of the respiratory cavity; after here undergoing the needful aeration, it enters the heart, from whence it is driven into the aorta. The aorta immediately divides into two trunks, one distributed to the liver, the intestine, and the ovary; the other supplying the stomach, the oral apparatus, the organs of generation, and the foot. In the Slug the arteries are perfectly white and opaque, and their ramifications, which may be traced with great readiness, are extremely beautiful.

In *Doris* (*fig.* 321) the heart is, in consequence of the position of the branchiæ around the anus, removed quite to the posterior extremity of the body. The blood derived from all parts of the body is conducted by large veins to the respiratory organs; the pulmonary arteries which return it from thence unite into a circular vessel (*b, b*), surrounding the anus, and from this arise two vessels, emptying themselves into the auricle. The aorta, on issuing from the heart, divides into two large vessels, the first supplying the intestinal canal, stomach, and duodenum, the organs of generation, the foot, and the mouth; whilst the other large trunk is entirely distributed to the liver.

In *Tritonia* the heart is placed near the centre of the body, and the auricle itself resembles a cylindrical vessel placed transversely across the other viscera, and communicating with the ventricle near its middle. The blood arrives at the heart through four vessels from the long fringe of branchiæ, two coming from the anterior and two from the posterior parts. We have already described the disposition of the branchiæ in the Tectibranchiate order, but in following the course of the circulating fluid, we shall find in some of the individuals included in this division circumstances requiring special notice, as being of extreme interest to the physiologist. In Aplysia, the blood returned from the system is brought by two large venous trunks to the vena cava or pulmonary artery (*fig.* 191, *b*); for in this case the same

Fig. 191.



vessel performs the functions of both; these large veins turn round in the vicinity of the operculum, and unite into one trunk prior to their dispersion over the branchial plates, but on opening them at this point so as to display their interior, a most singular arrangement is brought to light; the sides of the veins are found to be formed of muscular bands (c) crossing each other in various directions, and leaving spaces between them; these intervals are seen even by the naked eye to be apertures establishing a free communication between the interior of the vein and the abdominal cavity, and allowing injection to pass with facility from the vein into the visceral cavity, or from the abdomen into the vein: the anterior portion of each of these vessels may indeed be said to be literally confounded with the general cavity of the the body, a few muscular bands, forming no obstacle to a perfect communication, being the only separation between the two. It is therefore evident that the fluids contained in the abdominal cavity may in this manner have free access to the mass of the blood as it approaches the respiratory organ, and that the veins can thus perform the office of the absorbent system; but in what manner the blood is prevented from escaping through the same channels is not at all obvious, although probably during life the contraction of the fasciculi which bound these apertures may in some measure obstruct the intercourse. It is from this circumstance, and the analogous communication which exists in the Cephalopoda by the intervention of the spongy appendages to the venæ cavæ found in those Mollusks, that Cuvier was led to the conclusion that in all the class the veins are the immediate agents of absorption, and that an absorbent system does not exist in any but the vertebrate division of the animal kingdom. We meet, moreover, in Aplysia with another peculiarity in the circulating vessels; the aorta, shortly after its commencement, divides into two large arteries (*h h'*), one of which presents nothing peculiar in its distribution; but to the larger of the two, whilst still enclosed in the pericardium, we find appended a remarkable structure, the use of which has been hitherto perfectly inexplicable: projecting from the opposite sides of the vessel are two vascular crests, represented in *i*, formed of a plexus of vessels issuing from the aorta itself, and ramifying in an exceedingly beautiful manner through the substance of these extraordinary organs; in other respects the arteries are distributed in the usual manner. The Cyclobranchiate and Scutibranchiate Gasteropods approximate the testaceous class in many points of their organization, but in none more so than in the position which the heart is found to occupy, and the arrangement of its cavities. In Patella, indeed, the heart is placed in the anterior part of the body, and still conforms in its general structure to the description which we have given above; but in Oscabrio the auricle is divided into two distinct portions, one receiving the blood from each range of branchial plates; and in *Haliotis, Fissurella, Emargenula*, and *Parmophorus*, not only is this division of the auricle met with, but the ventricle, as in many of the testaceous Mollusks, is perforated by the rectum, and the similarity of arrangement which is here presented with what is met with in the Conchifera will be readily appreciated by a reference to the article which treats of the anatomy of that division of the Mollusca.

Nervous system.—The nervous system of the Gasteropoda furnishes us with the most perfect form of the heterogangliate, or as it has been less happily denominated, cyclo-gangliated type. It consists of a variable number of ganglia or nervous centres disposed in different parts of the body, but connected with each other by cords of communication, and from these ganglia the nerves appropriated to different parts proceed. Each ganglion, therefore, is a distinct brain; and were the preponderance in size to be regarded as the criterion of relative importance, it would not unfrequently be hard to say to which the pre-eminence is due. There is, however, as we shall soon perceive, an uniformity in the arrangement of certain masses, and a regularity in the appropriation of the nerves proceeding from them to particular organs, which leave us little room for hesitation upon this point; before, however, entering upon a more detailed account, we will offer a few general observations upon this system, applicable to the whole class. The nervous centres are obviously of a different nature from the cords by means of which they are connected into one system, and from the nerves arising from them; the nervous mass of the ganglion itself is generally granular in its appearance, whilst the texture of the nerves is homogeneous and smooth; the distinction is, however, in a few instances, rendered still more remarkable by a striking difference in colour; thus in Aplysia, whilst the nerves are of a pure white, the ganglionic centres are of a beautiful red tint; the same circumstance is met with in the Bulimus Stagnalis, and has also been remarked in many of the conchiferous Mollusca. A second peculiarity may be noticed in the mode in which the nerves and ganglia are invested with a neurilema or sheath, so loosely connected with them that it may be inflated or injected with great facility, and for this reason the nerves have been mistaken for vessels by some authors.

As an example of the most perfectly dispersed arrangement of the nervous centres we shall select Aplysia, in which the ganglia are more numerous than in the generality of the Gasteropod Mollusks. In this animal we find a ganglion placed above the œsophagus to which the name of the brain is universally allowed, not so much on account of its size as because throughout the class it constantly occupies the same position, and as invariably supplies those nerves which are distributed to the most important organs of sense; in this case its branches run to the muscles of the head and to the male organ of generation; it likewise sends on either side a large branch to each of the great tentacles, which as they approach those organs give origin to the optic nerves.

On each side of the œsophagus is found another ganglion equalling the brain in size, and constituting two other nervous centres, which are united to each other and to the brain by cords so disposed as to form a collar around the œsophagus; each of these gives off a number of nervous filaments, which are lost in the muscular envelope of the body; a fourth ganglion joined to the brain by two cords is found under the fleshy mass of the mouth; this supplies the œsophagus, the muscles of the mouth, and the salivary glands. At a considerable distance from these, and placed near the posterior portion of the body in the vicinity of the female generative organs and the respiratory apparatus, is a fifth ganglion communicating with the second and third by means of two long nerves, and giving branches to the liver, the alimentary canal, the female generative system, as also to the branchiæ and the muscles of the operculum. From this account it will be seen that none of these ganglia can be said to preside exclusively over any particular apparatus, branches from each being distributed to very different structures; but yet, speaking generally, there appears to be some reason for classifying their functions. Thus the brain is exclusively the centre of the principal senses: the two great lateral ganglia supply the bulk of the muscular system; the sub-oral ganglion is particularly subservient to mastication and deglutition, and the fifth or posterior nucleus being almost entirely appropriated to the supply of the digestive, respiratory, circulatory, and generative viscera, might be regarded as analogous to the sympathetic. There are, however, but few of the Gasteropoda in which the ganglia are so distinct in position and function as in Aplysia. In the inoperculate pulmonary Gasteropods, as in the Snail and Slug, the nervous centres are only two in number, namely, the brain, placed in its usual position above the œsophagus, and a large sub-œsophageal ganglion connected with it by two cords embracing the œsophageal tube. The brain in this case supplies nerves to the muscles of the mouth and lips, as well as to the skin in their vicinity; it likewise furnishes the nerves of touch and of vision, besides those distributed to the generative organs, and from the sub-œsophageal ganglion, which fully equals the brain in size, arise those nerves which supply the muscles of the body and the viscera. There is, however, placed under the œsophagus a very minute nervous mass, which from the constancy of its occurrence is worthy of notice; it is formed by the union of two minute nerves arising from the brain, and the little filaments which it gives off are lost in the œsophagus itself.

One remarkable circumstance may be mentioned as being probably peculiar to the class under consideration, namely, the changes of position to which their nervous centres are subject; obeying the movements of the mass of the mouth, with which they are intimately connected, they are pulled backwards and forwards by the muscles serving for the protrusion and retraction of the oral apparatus, and are thus constantly changing their relations with the surrounding parts. In the Snail it would seem that the great size of the nervous collar which embraces the œsophagus will in some circumstances permit the mass of the mouth to pass entirely through it, so that sometimes the brain rests upon the œsophagus, and at others is placed upon the inverted lips.

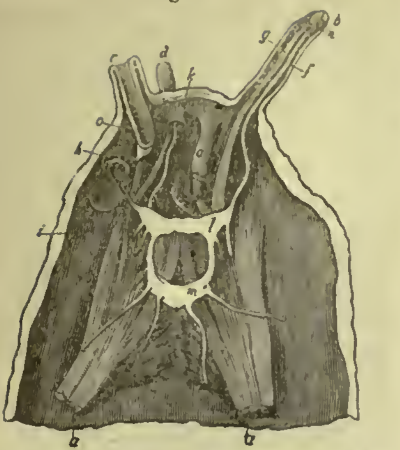
In most of the *Pectinibranchiata*, the brain consists of two ganglia united by a transverse cord; from these two centres arise the principal nerves, two of which unite to form a small ganglion beneath the œsophagus, from which that tube derives its peculiar supply.

It is in the Nudibranchiate division, however, that the nervous centres exist in their most concentrated form, and in these it is doubtful whether there are any ganglia, except the large supra-œsophageal brain. We may take Tritonia as an example of this form of the nervous system. In this beautiful Gasteropod the brain consists of four tubercles placed across the commencement of the œsophagus, the nervous collar being completed by a simple cord; all the nerves which supply the skin, the muscular integument, the tentacles, the eye, and the muscles of the mouth arise from the brain, and anatomists have not hitherto detected any other source of nervous supply, although Cuvier suspected two minute bodies, which he found beneath the œsophagus apparently connected with the brain, to be of a ganglionic nature.

The slow-moving and repent tribes of which we are now speaking have their powers of sense almost entirely limited to the perception of objects in actual contact with their bodies, and instruments adapted to touch and vision are the only organs of sense which the anatomist has been able to distinguish. The utter want of an internal skeleton or of an external articulated crust forbids us to expect that any of them are provided with an apparatus specially calculated to appreciate sonorous undulations. Their tongue, coated as it is with horny plates, studded with spines, or absolutely corneous in texture, is obviously rather an instrument of deglutition than an organ of taste. No researches have hitherto detected any part of the body which could be looked upon as devoted to smell; the eye is generally a mere point, rather inferred to be such by analogy than clearly adapted to vision; and the sense of touch in fact is the only one which anatomical evidence would intimate to be perfectly developed. Yet in spite of these apparent deficiencies, observation teaches us that many genera are not utterly deprived of the power of appreciating intimations from without connected with the perception of odours; it has been found by direct experiment that some of them are peculiarly sensible of the approach of scented bodies; thus the snail, although at rest within the shelly covering which forms its habitation, will with great quickness perceive the proximity of scented plants which are agreeable articles of food, and promptly issue from its concealment to devour them. Some anatomists have supposed that it is at the entrance of the respiratory cavity that we are to look for the special seat of smell, where, as the air alternately enters and is expelled by the movements of respiration, the odorous particles with which it may be impregnated are rendered sensible. Others with scarcely less probability conceive that the whole surface of the body which is exposed to the atmosphere may be endowed with a power of smelling, the quantity of nerves which are distributed to the integument, and the moisture with which it is constantly lubricated, seeming to adapt it perfectly to the performance of this function, giving it all the characters of a Schneiderian membrane. It is not impossible that sounds may be perceived in a somewhat analogous manner, although no proof has yet been adduced that any of the Gasteropoda are sensible to impressions of this nature. The sense of touch is exquisitely delicate over the whole surface of the animal, but more especially so in the foot, which is extremely vascular and abundantly supplied with nerves; yet in spite of this delicacy in the organisation of the skin which makes it so sensible of contact, it appears to have been beneficently ordered that animals so helpless and exposed to injury from every quarter, are but little sensible to pain, and that such is the case, M. Ferussac, a diligent observer of their economy, bears ample testimony. "I have seen," says he, "the terrestrial gasteropods allow their skin to be eaten by others, and in spite of large wounds thus produced, shew no sign of pain." But besides the sensation generally distributed over the skin, we may observe in most instances organs of variable form which seem peculiarly appropriated to touch. These are the tentacles, or horns as they are usually termed, which occupy a variable position upon the anterior part of the animal.

The tentacles vary in number in different genera: thus in *Planorbis* we find two, in the generality of cases four; in a few, as some species of *Œolis*, six; and in *Polycera* even eight of these appendages are met with. The structure of the tentacles is by no means the same in all the individuals belonging to this class. In the aquatic species they are to a greater or less extent retractile, but can in no case be entirely concealed within the body, as is usual in the terrestrial division; they are therefore not hollow, but composed of various strata of circular, oblique, and longitudinal muscular fibres, by means of which they are moved in every direction, and applied with facility to the objects submitted to their examination. In all instances they are plentifully supplied with nerves arising immediately from the brain. Their shape is subject to great variation; they are usually simple processes from the surface of the body more or less elongated, and in some cases even filiform, as in *Planorbis*. In *Murex* (*fig.* 193) each tentacle is a thick and fleshy stem, near the extremity of which a smaller one is appended. In *Tritonia* each tentacle is composed of five feathery leaflets, and is enclosed in a kind of sheath which surrounds its base. In *Doris* the two inferior are broad, flat, and fleshy, while the superior are thick and club-shaped. In *Scyllæa* they consist of broad fleshy expansions attached by thin pedicles to the anterior part of the body. In *Thethys* they are placed at the base of the veil which characterises the animal, but in all cases they are solid and incapable of entire retraction. In the terrestrial Gasteropoda, in which from many causes the tentacles are more exposed to injury, a much more complicated structure is needed, by which these important organs are not only moved with facility in different directions, but which allows them to be perfectly withdrawn into the interior of the body, from which position they may be made to emerge at the will of the animal: the mechanism by which this is effected will be understood by referring to *fig.* 192, representing a dissection of the common snail, and exhibiting the tentacles in different states of protrusion. Each tentacle (*c*, *d*,) is here seen to be a hollow tube, the walls of which are composed of circular bands of muscle, and capable of being inverted like the finger of a glove; it is in fact, when not in use, drawn within itself by an extremely simple arrangement.

Fig. 192.



Structure of the tentacles in the Garden-Snail (Helix Pomatia).

From the common retractor muscles of the foot four long muscular slips are detached, one for each horn; these run in company with the nerve to each tentacle, passing within its tube when protruded, quite to the extremity *(g)*. The contraction of this muscle dragging the apex of the organ inwards, as seen at *c*, of course causes its complete inversion, whilst its protrusion is effected by the alternate contractions of the circular bands of muscle of which the walls of each tentacle are composed. There is, however, another peculiarity rendered necessary by this singular mechanism, by which the nerves supplying the sense of touch may be enabled to accommodate themselves to such sudden and extensive changes of position; for this purpose the nerves supplying these organs are of great length, reaching with facility to the end of the tubes when protruded, and in their retracted state the nerves are seen folded up within the body in large convolutions. In the figure, *a a* indicates the origins of the retractor muscles of the foot from the columella; *b*, the right superior tentacle fully protruded; *c*, the left superior tentacle partially retracted; *d*, the left inferior tentacle extended, and *e*, the right inferior tentacle fully retracted and concealed within the body; *f*, the nerve supplying the superior tentacle elongated by its extension; *g*, the retractor muscle of the same tentacle arising from the common retractor muscle of the foot and inserted into the extremity of the tube; *h*, the nerve of the opposite side thrown into folds; *i*, the retractor muscle of the same tentacle contracted; *k*, the aperture through which the nerve and retractor muscle enter the tentacle *d*; *l*, the brain; *m*, the subœsophageal ganglion; *n*, the eye.

Vision.—The eyes of Gasteropoda are extremely small in comparison with the bulk of the animals, and seem more to represent the rudiments of an organ of sight than to be adapted to distinct vision. In many species indeed they appear to be absolutely wanting. When found, they resemble minute black points, by far too small to admit of any satisfactory examination of their internal structure; and even in the largest forms of the organ which are met with in the more bulky marine genera, it is with difficulty that their organisation can be explored. In *fig.* 193 we have delineated the position and structure of the eye in a large Murex.

Fig. 193.

Tentacles and eye of Murex.

The natural size of the organ is seen in the upper figure, in which on the right side the organ is represented untouched, while on the left a section has been made to exhibit its interior. This section when magnified, as in the lower figure, shews us that it consists of a spherical cavity lined posteriorly with a dark choroidal membrane, and containing a large spherical lens; the position and structure of the retina we have been unable satisfactorily to determine, although the visual nerve may be readily traced to the back of the choroid, where it seems to expand; but whether, as in the Cephalopods, its sentient portion is spread out behind the pigment which lines the eye-ball, or whether, as in the forms of the organ common to the vertebrate orders, the retina is placed anterior to the choroid, is a question which we are at present unable to solve. But however this may be, we see anteriorly a distinct pupil surrounded by a dark radiating zone, apparently an iris, to which it corresponds at least in position, although that it is really capable of contracting or enlarging the pupillary aperture is more than our observations warrant us in affirming. Finding, therefore, the eye of the Murex to offer a structure which indubitably entitles it to be regarded as an organ of sight, we are justified in considering the more minute specks of smaller Gasteropoda as similarly formed and subservient to the same office. In the aquatic species the eyes are generally placed at the base of the superior or larger tentacles, although not unfrequently they are supported upon short pedicles appropriated to them, as is the case in *Haliotis* and others. In *Murex* we have seen that the tentacles which support them are large and fleshy, and by the position of the eyes at the extremity of so long a stem these can be readily directed to different objects. In no case, however, can they be retracted within the body so as to be quite enclosed in the visceral cavity. In the terrestrial Gasteropods the eyes are generally placed at the extremity of the superior horns, a position which manifestly extends the range of vision, and moreover, in consequence of the structure which we have described when speaking of the organs of touch, may be completely drawn within the body. In *fig.* 189, *b*, the eye of Vaginulus is seen at the extremity of the upper tentacle, and the origin of the optic nerve *(c)* from the brain *(d)*, as well as the convolutions which it makes to allow of its adaptation to the varying length of the tentacle, and the bulb in which it terminates behind the eyeball *(b*)*, are sufficiently displayed. In *fig.* 192, *b*, the eye of the snail exhibiting the same circumstances has been represented, and the apparatus by which the movements of the whole organ are effected is so clearly shewn as to render further description superfluous.

Generative system.—The description of the generative apparatus of the Gasteropoda forms one of the most remarkable parts of their history, and the complication which it presents in some orders is probably unique in the animal kingdom. The class may be divided, as far as relates to this function, into three great divisions: — 1st. Hermaphrodite and self-impregnating; 2d. Hermaphrodite, but reciprocally impregnating each other by mutual copulation; 3d. Sexes distinct, the female being impregnated by copulation with the male. We shall consider each of these divisions in the order in which they have been enumerated. The lowest orders approximate the Conchifera in most parts of their organisation, and in the arrangement of their generative system we need not be surprised to see a manifest resemblance. The *Scutibranchiate* and *Cyclobranchiate* orders, therefore, present this great distinguishing character, which more than any other detaches them from the others, namely, that every individual being furnished both with ovigerous and impregnating organs is sufficient to the impregnation of its own ova. Nothing, in truth, can be more simple than such an arrangement. The ovary is found, when empty, embedded in the substance of the liver, but at certain epochs it becomes so much distended with ova as to cover in great part the rest of the viscera; from this ovary arises a simple canal or oviduct, which terminates after a short course in the neighbourhood of the anus. No trace of accessory apparatus has been found, and the only part to which the office of a testis is assignable is the tube through which the ova are discharged, which probably furnishes a secretion subservient to the impregnation of the eggs. Such is the structure of the generative system in *Haliotis*, *Patella*, and others of the orders to which these respectively belong, exhibiting a simplicity of parts widely different from what is found in the division which next presents itself to our notice. The second type of the generative apparatus is common to the *Nudibranchiate*, *Inferobranchiate*, *Tectibranchiate*, and *Inoperculated pulmonary* orders; in all of which every individual is provided with both male and female organs of copulation, and, accordingly, mutual impregnation is effected by the congress of two individuals, or in a few instances by the combination of several. We shall select the common snail *(Helix pomatia)* as the most familiar illustration of the general arrangement of the parts composing this double apparatus, leaving the varieties which it presents to subsequent notice. The admirable plate of Cuvier, of which *fig.* 190 is a copy, represents the whole system with that clearness and fidelity so characteristic of all the laborious contributions to science which we owe to his indefatigable industry. The female portion consists of the ovary, the oviduct, and an enlarged portion of the oviduct which forms a receptacle for the ova, and is called by Cuvier the womb *(la matrice)*. The ovary *(q)* is a racemose mass embedded in that portion of the liver which is enclosed in the last spire of the body, i. e. that part which is placed nearest to the apex of the shell; from this proceeds a slender oviduct (*r*), folded in zigzag curves, and variously convoluted: it commences by many small branches derived from the ovary, and terminates in a mass (*s*), regarded by Cuvier as the testis, in which it becomes so attenuated that it is difficult to trace it; emerging, however, from this mass, it expands into the womb (*t*), which is a long, capacious, and sacculated canal, and capable of much distension, in which the eggs are retained until they have acquired their full development: this viscus opens into the common generative cavity at *c*, *fig.* 194.

The male organs consist of a testicle, vas deferens, and penis. The testicle *(s, fig.* 190) appears to be composed of two distinct portions, the larger of which is soft and homogeneous in texture, but the smaller has a granulated appearance; the latter (*u*) runs along the womb like a mesentery, connecting its folds as far as the termination of that viscus. The testicle varies much in size at different periods, being generally very small, but during the season of love it dilates so as to fill nearly half of the visceral cavity, at which time the womb likewise is much enlarged. From the testicle arises its vas deferens or excretory duct, which terminates in the penis near the base of that organ. The penis (*fig.* 194, *n*) is a most singular instrument, resembling a long hollow whip-lash, formed of circular fibres, and, like the tentacles, capable of complete inversion, which in fact occurs whenever it is protruded from the body; it is also furnished with a retractor muscle *(fig.* 190, *w)*, serving to draw it back again after copulation is accomplished. The penis is not perforated at its extremity, but the vas deferens terminates within it by a small aperture, which of course during the inversion of the organ opens externally at about one-third of the length of the penis from its root; the aperture by which the vas deferens thus opens upon the exterior of the penis, when that organ is protruded, is sufficiently distinct, admitting with facility an ordinary bristle (*fig.* 194, *l*). On slitting up the penis as it usually lies retracted into the visceral cavity, its inner membrane is found gathered into longitudinal folds, and this provision is needful to allow of that distension which must occur during its erection, at which time this lining membrane becomes the external integument of the protruded organ.

These parts would seem sufficient in themselves to fulfil the functions belonging to the organs of both sexes, nevertheless we find others superadded, the uses of which are not so readily assignable; these are the *bladder*, as it is called by Cuvier, the *multifid vesicles*, and the *sac of the dart*.

The sac which has been called the bladder (*fig.* 190, *z*, *fig.* 194, *o*) is invariably present; it consists of a round vesicle, variable in size, communicating by means of a canal, generally of considerable length and diameter, with the termination of the matrix: it is usually found filled with a thick and viscid brownish matter, and is generally supposed to furnish an envelope to the eggs as they escape from the convoluted oviduct, an opinion, however, as we shall afterwards see, which is not without opponents.

The *multifid vesicles* (*fig.* 190, *x*, *fig.* 194, *c*) are much less constantly met with, and are in fact almost peculiar to the snail; they are two groups of cœca, each composed of about thirty blind tubes, which after uniting into larger canals ultimately form a principal duct on each side, through which the secretion which they furnish is poured at a little distance below the orifice leading to the bladder into the passage by which the ova are expelled. The fluid furnished by these curious glandular appendages is white and milky, but as this secretion is almost peculiar to the genus *Helix*, its use is extremely problematic.

The *sac of the dart* (*fig.* 190, *y*, *fig.* 194, *b*) is another part of the generative apparatus only found in the snail, and from the extraordinary instrument which it conceals is perhaps the most singular appendage to the generative system met with in any class of animals. It is an oblong sac with strong muscular walls opening by a special aperture into the common generative cavity, like which it is capable of complete inversion. On opening it, its cavity is seen to be quadrangular, and at its bottom projects a four-sided fleshy tubercle, which secretes the curious weapon that this sac is destined to conceal. This (*fig.* 194, *b*) consists of a four-sided calcareous and apparently crystalline spike, about five lines in length, which grows by successive layers deposited at its base from the surface of the fleshy tubercle to which it is attached: it will be evident that when the sac is everted, the dart contained within it will be protruded externally. This dart, if broken off from its place of attachment, is speedily renewed.

To complete our description of the parts composing this complex organisation, it remains only to mention the common generative cavity

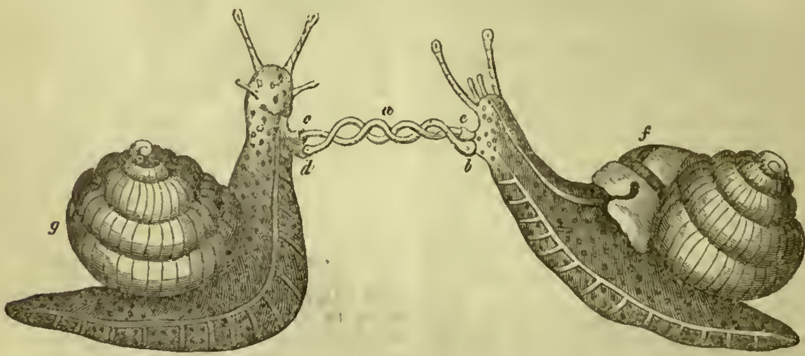
Fig. 194.

Generative organs of Helix Pomatia.

(*fig.* 194, *a*), into which the others open; this, when in its ordinary position, is a muscular bag, opening externally by a large aperture near the upper tentacle on the right side of the neck, whilst at its bottom are seen the orifices of three distinct passages, one leading to the penis, one to the female organs, and a third to the sac of the dart. This cavity, like that of the dart, is capable of inversion, which is effected partly by the action of its muscular walls, aided in all probability by a kind of temporary erection, and when thus turned inside out, the orifices leading to the penis, the womb, and the sac of the dart of course become external.

In order to understand the functions of these various parts it will be necessary to describe at length the singular mode in which copulation is effected. When two snails, amorously disposed, approach each other, they begin their blandishments by rubbing the surfaces of their bodies together, touching successively every part. This preliminary testimony of affection lasts for several hours, gradually exciting the animals to more effective demonstrations. At the end of this time the generative orifice, placed on the right side of the neck, is seen to dilate, and the common generative cavity becoming gradually inverted displays externally the three apertures which open into it. This being effected, an encounter of a truly unique character commences; the opening leading to the sac of the dart next expands, and that organ undergoing a similar inversion displays the dart affixed to its bottom. A series of manœuvres may then be witnessed of an unaccountable description; each snail, in turn, inspired with an alacrity perfectly foreign to its ordinary sluggish movements, striving with his dart to prick the body of his associate, which with equal promptitude endeavours to avoid the wound, retreating into his shell, and performing a variety of evolutions to get out of reach. At length, however, the assailant succeeds, and strikes the point of his weapon into the skin of his paramour at any vulnerable point which may be found. The dart is generally broken off by this encounter, sometimes sticking in the skin, but more frequently dropping to the ground. The reptile Cupid having thus exhausted his quiver, becomes in turn the object of a similar attack, exhibiting apparently an equal anxiety to avoid the threatening point of the weapon bared against him. At last he receives the love-inspiring wound, and the preliminaries thus completed, each prepares for the completion of their embraces. The other two apertures next dilate, and from one of them issues the long and whip-like penis, unrolling itself like the finger of a glove; this being fully developed is introduced into the vaginal orifice of the other snail, which in the same manner inserting its penis into the female aperture of the former, both mutually impregnate and are impregnated. See *fig.* 195.

Fig. 195.



It is difficult to conceive what can be the use of the dart so singularly employed; it would seem to be an instrument for stimulating the sleeping energies of the creatures to a needful pitch of excitement; yet why it should be peculiar to the snail is not obvious, for in the slug and other Mollusca certainly not less apathetic, no such structure has been detected.

In *Vaginulus (fig.* 189) a similar arrangement of the principal organs is observable, although some modifications are met with which deserve our notice. No *sac of the dart* is found in this animal, but a fasciculus of cœca, analogous to the multifid vesicles as far as their structure is concerned, is connected, not with the female apparatus, as in the snail, but with the male organs. The orifices of the two sexual systems are here separated by a considerable interval, the penis emerging at the side of the neck, near the right superior tentacle at *z*, while the orifice of the female parts is placed between the cuirass and the mantle, considerably further back. The ovary (*m*) is similar in structure to that of the snail; and its duct, in like manner, forms many convolutions in the substance of the testicle (*p*), from which it issues, much increased in size, to expand into a large membranous receptacle (*q*), corresponding in function with the tortuous matrix of the *Helices;* this part of the oviduct is filled with an albuminous fluid, and from it runs the narrower canal (*r*), which may be regarded as the vagina, and which before its termination communicates with a lateral pouch, identical with what has been called the bladder. The testicle (*p*) appears to consist of two portions, from which arises the vas deferens (*o*). On tracing this tube it is seen to divide into two branches, one opening into the bladder (*s*), an arrangement to which we shall again have occasion to revert, whilst the other runs forward to the root of the penis (*w*). The latter organ presents two portions, a long tubular cœcum (*v*), resembling the corresponding part in the snail, and a thick muscular cavity, from which the former arises as a kind of appendage; on opening the thicker portion its interior is seen to be rugose, and to enclose a small body, something like the *caput gallinaginis* in the human urethra. The *multifid vesicles* (*y*) open near the exterior orifice, through which the whole apparatus, by a process of inversion already described, is protruded so as to form the male organ of excitement.

In many of the Tectibranchiata a remarkable arrangement of the generative organs is found, as the male viscera are divided into two distinct portions, the exciting organ being at one extremity of the body, while the testis is found connected with the female apparatus in a distant part of the system. This will be seen in *Doridium Meckelii (fig.* 196); the penis (*l*), seen retracted in the figure, issues from the side of the neck, and has appended to its root a zig-zag tube, inclosed in a membranous canal, the nature of which is unknown. Quite detached from these, and placed near the anus, we have the matrix *(f)*, the testis (*g*), and the bladder (*i*), occupying their usual relative position as regards each other, and terminating in the *vulva* or sac of generation (*h*).

In Aplysia the organ of excitement is found

Fig. 196.

near the right tentacle, where it protrudes, as in the Snail, for the purpose of copulation, by the inversion of its walls; it is, however, absolutely imperforate, and receives no duct by which it can communicate with the testis so as to become instrumental in immission; but externally a deep groove is seen upon its surface when in a state of protrusion, which is continuous with a long furrow seen upon the surface of the body, continued from the base of the penis to the orifice of the female apparatus. *Fig.* 197 represents the secreting

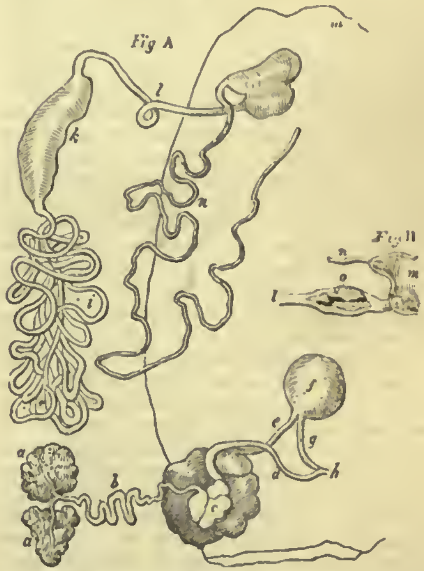
Fig. 197.

Generative organs of Aplysia.

portions of this system removed from the body, and displayed so as to expose the internal structure of the parts composing it. The ovary (*h*) is a large oval, whitish, and granular mass, from which the oviduct arises by several distinct tubes which emerge from different parts of its substance: this oviduct opens into the common tube (*e*), which may be called the vagina. The mass (*f*, *g*), called by Cuvier the testis, and supposed by him to be solid and homogeneous in its texture, is found, when opened, to be divided by spiral septa, resembling the scala cochleæ in the ears of Mammalia (*g*), and thus forms a long spiral cavity communicating with the commencement of the vagina, in which latter tube we also find apertures by which the vesicle (*p*) and the larger sacculus (*o*) communicate with the common passage.

In *Onchidium*, an aquatic species belonging to the inoperculate pulmonary order, the male and female parts are in a similar manner placed at opposite extremities of the body, but the former assume a more complicated structure than in the Tectibranchiata, which we have described. The ovary (*fig.* 198, A, *a*, *a*)

Fig. 198.



Generative organs of Onchidium.

consists of two masses replete with ova, each of which furnishes a short duct; the two thus formed unite into a convoluted tube (*b*), which is the common oviduct: arriving at the mass always regarded by Cuvier as the testis, it enlarges and forms within the substance of that organ many convolutions, on emerging from which it runs directly in the shape of a narrow canal (*d*), to the external orifice (*h*). The bladder (*f*) receives a large duct (*e*) from the mass here assumed to be the testis, and gives off another of equal size, which joins the oviduct (*d*) prior to its termination. This would seem to form a complete system in itself; yet, on examining the male organ of excitement, we find it connected with considerable appendages, the nature of which it is difficult to conjecture. The sac (*m*) is muscular, and resembles the muscular root of the penis in the genera already described, being, as in them, capable of inversion: at its base are seen two cul-de-sacs, into each of which opens a long and flexuous canal (*l*, *n*). The canal marked *n* is very slender, and when unfolded is four times the length of the body of the animal; its termination at the point most remote from the muscular sac into which it opens is apparently closed. The other tube marked *l* is much wider and of extraordinary length; its commencement (*i*) is extremely convoluted and fully eight times as long as the body; its walls are thin, but it is supplied plentifully with blood by means of a large artery interlaced with its convolutions; at *k* it becomes enveloped in a fleshy mass of considerable thickness, after which, assuming its original appearance, it proceeds to the cul-de-sac, at the bottom of which it terminates. In *fig.* B, 198, the muscular cavity (*m*) has been laid open, and the mode in which the above tubes enter it has been displayed; the smaller one (*n*) ends in a little horny papilla (*q*) seen in the engraving; the larger tube (*l*) terminates by a kind of glans penis, perforated by a large aperture and surrounded by a kind of prepuce (*p*): on opening the vessel a little before its entrance into the muscular sac, it is found to conceal a sharp horny dart (*o*), supported upon a fleshy pedicle, and readily protrusible through the aperture *p;* the analogy between this singular instrument and the dart of the Snail is obvious, for when the muscular sac (*m*) is everted, the papillæ (*p*, *q*) become external, and the horny point being pushed out of the former will probably form a stimulus of the same description.

We have hitherto abstained entirely from mixing up with our description of these principal forms which the generative system of the mutually impregnating Gasteropoda presents, the discussions which have arisen concerning the real nature of the different organs which have been described, and have designated them by the terms usually applied to the respective parts, without reference to their individual functions. It now, however, becomes necessary to lay before our readers the principal opinions which are recorded upon this subject. The chief points of debate have been the bladder, and the organ which we have described under the appellation of testicle. The bladder is, from its constant occurrence, evidently an organ of some essential use: it was regarded by Swammerdam as the secreting structure from which the colouring fluid peculiar to some species is produced, especially in the Murices and others of the marine genera; it was therefore named by him sac of the purple; but we shall afterwards find that this fluid is derived from another source. Blainville, on the other hand, considers this vesicle as analogous to the urinary bladder of Vertebrata; in reference to this hypothesis, however, we should be inclined to ask, with Cuvier, where are the kidneys? and even upon the supposition that the secretion of the bladder itself was analogous to the urinary fluid, we are not aware of any chemical proofs of its nature which are sufficient to establish the identity. Delle Chiaje again sustains that the sac of the purple is, in fact, the testis, and that its secretion, poured as it constantly is into the termination of the oviduct, is in reality the fecundating fluid; yet against this we must urge the distribution of the vas deferens met with in the *Helices*, which from its entire arrangement converts the organ of excitement in these animals into an apparatus of immission, whose nature cannot be mistaken. The opinion which we consider most consonant with all the circumstances of its position, is that it is a reservoir for the seminal fluid analogous to the spermotheca of certain insects. Cuvier expressly notices the constant relation which exists between the length of the penis and that of the canal which leads to this sacculus, and when we remark the long chains of ova which are slowly extruded in most of the Gasteropoda, we are readily disposed to admit of the necessity of such a reservoir, which, treasuring up the semen until the eggs are about to be expelled, applies it efficiently to the ova as they successively pass the orifice of its duct. This supposition derives additional weight from what we have found to be the arrangement of the seminal ducts in *Vaginulus* and *Onchidium*. In the former we observed that, besides the canal, which, as in the Snail, perforates the root of the penis and thus becomes subservient to copulation, the vas deferens actually pours a part of its contents by a separate canal into the bladder itself, which, as in all cases, communicates with the egg-passage. In *Onchidium* the connexion between the testis and this receptacle is equally striking, as will be obvious on reference to the drawing given above. In *Aplysia*, Delle Chiaje considers the testicle as described by Cuvier to be in reality the matrix or receptacle for the ova, in which they attain their full development prior to expulsion, basing his opinion upon the disposition of the spiral cavity which it contains.

We are entirely left to conjecture as to the uses of the other appendages found in particular species, and the multifid vesicles of the Snail, which are wanting even in the Slug, the tortuous canal connected with the penis of *Doridium*, and the still more singular organs belonging to the male apparatus of *Onchidium*, must still remain the subjects of observation and experiment.

The third form of the generative system in which the sexes are distinct, is met with in all the Pectinibranchiate order, and in the operculated Pulmonalia of Ferussac. In Buccinum, which we shall select as an example of the general arrangement of the sexual organs in the former, the male is at once distinguish-

Fig. 199.

Male organs of Buccinum.

able by the enormous penis attached to the right side of the neck (*fig.* 199), which is not, as in the last division, capable of retraction within the body, but remains permanently external, being, when not in use, folded back and lodged within the branchial cavity, from which however it is frequently protruded without any apparent object.

In the female there is no rudiment of such a structure, but the generative aperture is seen to be situated a little within the edge of the pulmonary cavity, being a simple hole leading to the oviduct. The internal organs of the male, represented in the annexed figure, consist simply of a testicle and its excretory canal. The testis is of considerable size, sharing with the liver the smaller convolutions of the shell; from this arises the vas deferens, which forms by its convolutions a kind of epididymis (*fig.* 199, *b*), and then increasing in diameter enters the root of the penis, through which it passes by a tortuous course (*d*) to the tubercle at the extremity of this organ, where it opens externally. The penis when opened, as represented in the engraving, is seen to contain strong transverse fasciculi of muscle, which probably cause the erection of this organ; they will at the same time lengthen it, so as to destroy in a great measure the zig-zag turns into which the vas deferens is thrown in its usual relaxed state.

In the female the position of the testicle is occupied by the ovary, while the vas deferens is represented by a thick and glandular oviduct.

In *Murex* the penis of the male is proportionally smaller; and, instead of a complete vas deferens, penetrating to its extremity, there is merely a groove along its surface, along which the semen flows. In *Voluta* the exterior groove only runs to the base of the penis, and in *Strombus* the male organ is a mere tubercle.

In the *Pulmonalia operculata* the organs of both sexes are in every respect similar to those of the Pectinibranchiate order. In *Paludina* alone (*Helix vivipara*, Lin.) the penis is retractile, issuing from a hole found in the right tentacle, and from the disparity in size between the tentacles, arising from this cause, the male is readily distinguished. The females of this genus are not unfrequently ovo-viviparous, the ova remaining in their capacious oviduct until they are hatched.

Spallanzani asserts that, if the young of Paludina are taken at the moment of their birth, and kept entirely separate from others of their species, they can reproduce without impregnation, like the Aphides and Monoculi, in which the same connexion with the male is found to fecundate not only the female herself, but her offspring for several generations. Nevertheless, whether Spallanzani's observations be correct or not, the males are fully as numerous as the females, so that it would be difficult to imagine the object of such a deviation from the ordinary proceedings of nature.

Ova.—The spawn of the Gasteropod Mollusca is found under diverse forms; it is usually in the marine species attached to the surface of stones, shells, or sea-weed, the ova being connected with each other in long ribands or delicate festoons, which are sometimes extremely beautiful and curious. The Doris and Tritonia deposit their ova in this manner, and the mass of eggs deposited by them resembles a frill of lace of extreme beauty. In Aplysia the spawn is found to resemble long gelatinous threads, in the centre of which the ova are seen, varying in tint, so as to give different colours to different parts of the thread; the whole strikingly resembles strings of vermicelli, and the Italians in fact have applied to them the name of *vermicelli marini.* In Helix and Bulimus the eggs are naked and protected by a hard shell, whilst in Buccinum, Voluta, Murex, and other marine species, the ova are enveloped in membranous sacs agglomerated together in large bunches; these sacs have been erroneously regarded as the eggs themselves; they are, however, merely coriaceous envelopes, answering the purpose of the gelatinous coating enclosing the eggs of other species, several eggs being contained in each bag, in which, when mature, the young are easily seen. It would seem that extraordinary provisions have been made by nature for the multiplication of these creatures, in spite of the numerous enemies which devour them, or the vicissitudes of temperature to which, especially in the terrestrial species, their eggs are necessarily subject. We are indebted to M. Leuchs for several interesting observations concerning the ova of slugs, which explain in a great degree the quantities of them which in some seasons infest gardens and vineyards, becoming, from the devastation which they cause, serious plagues to the agriculturist. The number of eggs varies with the healthiness of the animal, the supply of food, or the temperature of the season; yet it is probable that a single slug will lay five hundred, under ordinary circumstances: thus, supposing a thousand of these creatures to be collected in a given space, they will give birth in a few weeks to five hundred thousand young slugs, which multiplying in their turn would produce at the second laying two hundred and fifty millions of eggs. This fact is well worth the notice of the farmer, who, instead of driving away with so much assiduity crows and other birds which live upon these destructive, though apparently insignificant, animals, would do well occasionally to cherish them as fellow-labourers in his grounds. The Terrestrial Mollusca, helpless and incapable of defence, afford food to numberless indefatigable assailants, and their preservation is provided for, not only by the number of their eggs, but by a peculiar tenacity of vitality which these exhibit under circumstances which would be thought sufficient to destroy the young before they were hatched. The skin of the eggs of the slug is coriaceous and very elastic, so that when compressed they soon resume their shape: exposure to intense cold does not destroy their fertility, and they have been known to resist a temperature of 40° without apparent injury. When dried by artificial heat, they shrivel up to minute points only distinguishable by the microscope, yet in this state, if they be put into water, they readily absorb it and are restored to their former plumpness. The same thing happens to those which are dried by the action of the sun and apparently destroyed; a shower of rain is sufficient to supply them with the fluid which they had lost and to restore their fertility. This drying appears not to injure them. M. Leuchs found that after being eight times treated in this manner, they were hatched on being placed in favourable circumstances, and even eggs in which the embryo was distinctly formed, survived such treatment without damage.

Reproduction of lost parts.—Not less wonderful is the power which snails possess of reproducing lost parts, after mutilation by accident or design. The results of the experiments of Spallanzani upon this subject are very curious; he found that if the large tentacle of a snail were amputated, the extremity of the stump heals, forming a small swelling of a lighter colour than the rest of the horn; in this swelling a black point soon becomes visible, which is a new eye, and the mutilated member, increasing in length, shortly equals its original size, although it is for some time of a lighter colour than its uninjured fellow, which in other respects it perfectly resembles. The process sometimes varies a little; it frequently happens that the end of the stump, instead of becoming round, is elongated and tapers to a point, from the apex of which the new eye is seen to "squeeze out;" the end of the tentacle then assumes a globular shape, and the most accurate dissection cannot distinguish the newly formed eye from the original. If, instead of the horn, the head is cut quite off, a new one will succeed: the new head, however, does not at first contain all the parts of the old one, but they are gradually developed, piece by piece, at different intervals, until at length a head differing little, if at all, from the original pattern is completed. In some cases the object is effected by a different proceeding, the new part appearing like a round tubercle, containing the rudiments of the lips and of the smaller horns, which is united to the mouth and the new-formed tooth, the other parts, as the larger horns and the anterior part of the foot, being totally deficient. In another snail the larger tentacle on the right side first appeared, not more than one-tenth of an inch in length, but already provided with its eye, and at a short distance beneath this the lineaments of the lips separately developed themselves. In a third snail a group of three horns is seen, two of which will acquire their full developement, while the third is just above the level of the skin. These and many other varieties have been observed; but in most instances there is no perceptible difference between the new head and the one cut off, the exact line of separation being indicated by an ash-coloured mark distinguishable two years after the experiment. The same effects follow, whether the head be removed above or below the brain, and in the latter case a new brain, with all its nerves, is speedily constructed. The collar and foot are also perfectly restored after their removal.

Slugs reproduce their horns as well as snails, but their power of manufacturing a new head is much inferior.

Muscular integument.—None of the Gasteropoda have any thing analogous to an endoskeleton, a circumstance which sufficiently accounts for the varied forms which the same individual assumes under different circumstances, for the body being unsupported by any resisting framework, readily yields to the contractions of the muscular integument with which it is covered. It is from this circumstance that the zoologist finds the preservation of the natural forms of the recent animals a task of such extreme difficulty, owing to the corrugation and distortion produced by the ordinary modes of preservation; it is scarcely possible indeed, in many cases, to recognise with tolerable accuracy the natural appearance of these creatures in the shrunken specimens generally preserved in our cabinets, and the collector of these objects would do well never to omit, when circumstances allow him the opportunity, to preserve some sketch of the living forms of such exotic species as may come into his possession.

Body.—In the naked Gasteropods the whole body is found to be inclosed in a muscular integument, the basis of which is a cellular web of extraordinarily extensible character, in which the muscular fibres may be seen to cross each other in various directions, some passing longitudinally from one extremity of the animal towards the opposite end, while others, assuming different degrees of obliquity, are interwoven with the rest, so as to occasion the elongation or contraction of the body in every assignable direction. Within this muscular bag the viscera are contained, as well as the organs subservient to mastication, the apparatus of the external senses, and of the organs employed in copulation, which are, when unemployed, retracted within its cavity by special muscular fasciculi spoken of elsewhere.

Retractile muscles.—In the spirivalve genera the muscular walls which inclose the body only exist in such parts as, during the extended state of the animal, are protruded from the shell; that part of the body which is concealed within its cavity being provided with a much more delicate and membranous envelope; in such, however, a necessity exists for an additional muscular apparatus, serving to retract the body and foot within the cavity of its calcareous abode, and of course exhibiting various modifications of arrangement in conformity with the shape of the shell itself. In the turbinated shells, the retracting muscles consist of strong fasciculi of fibres arising from the columella or axis of the shell, and diverging from this point, spread in several slips, which become interlaced with the fibres composing the foot and muscular investment. In the flattened forms of Patella and Chiton, the muscular fibres arise all around the margin of the shell, excepting at its anterior part; these penetrating the mantle are intimately interwoven with the muscles forming the circumference of the foot. The animal of the Haliotis is fixed to its expanded and semi-turbinated shell by a single large and ovoid muscle, which takes its origin from near the middle of the last spire; whatever the disposition of these muscles, however, their action is obviously of two kinds; and not only are they the agents by which the creature retires within its covering, but by raising the central portion of the disc of the foot, whilst its margins are in apposition with the plane of progression, they will, by producing a vacuum beneath, convert the whole apparatus into a sucker, the adhesive power of which will be proportioned to the extent of its surface.

Foot.—The foot of the Gasteropoda is their principal agent of progression. It is generally a fleshy disc, of variable size and shape, attached to the ventral surface, and forming when expanded an organ by means of which the animal can adhere to surrounding objects. In the naked genera it is small, but in the conchiferous species, especially in such as are provided with dense and weighty shells, its dimensions and force are proportionally increased. In its internal structure it resembles the muscular investment of the body, of which in fact it is merely an expansion, consisting of muscular fibres interlacing each other in every possible direction, as may be developed by continued maceration. In the Slug, when opened from the back, the superior layer of fibres is found to run transversely, arising apparently from two tendinous lines which run longitudinally near the centre of the organ, and terminating near the margins of the disc; beneath these, longitudinal fasciculi may be detected, but so interlaced with other fibres assuming every degree of obliquity, that it is impossible to unravel the complicated structure which they form. In the Limpet (Patella) the lower fibres of the foot are transverse, but near the circumference they become distinctly interwoven with circular fasciculi; the superior stratum viewed from above consists of two series of oblique fibres, which meet at an acute angle on the middle line, whilst the substance of the organ is composed of muscular bands variously disposed: from such a structure the movements of the foot are readily understood; the transverse fibres by their contraction will elongate the ellipsis of the foot by diminishing its breadth, whilst the longitudinal, having a contrary action, will, by the combination of their effects, produce every movement needful for the progression of the creature. On minutely inspecting the foot of a terrestrial Gasteropod, as it crawls upon a transparent surface, it will be found to be divided into a certain number of transverse segments of variable size by a particular arrangement of the longitudinal muscular fibres, which seem to form, when the creature advances, undulations limited by the points of contact. These sections appear alternately to form a vacuum upon the surface where the animal is placed, that which follows advancing to take the place of that which precedes it, the transmission of movement occurring from behind forwards, a mechanism which causes the animal to advance by a slow and uniform progression.

The above structure of the foot, and consequent mode of locomotion, although the most usual, is susceptible of considerable modification. Thus in *Scyllæa*, we find it only adapted for grasping the thin stems of fuci and other submarine plants, being for that purpose compressed and grooved inferiorly into a deep sulcus. In the *Tornatella fasciata*, Lam. the structure of the foot is remarkable: beaten incessantly by the waves, in the cavities of rocks which it frequents, nearly on a level with the surface of the sea, to the violence of which it is always exposed, it has need of additional powers of retaining its hold; its foot is therefore divided into two adhering portions, placed at each extremity, and separated by a wide interval; when it crawls it fixes the posterior disc and advances the other, which it attaches firmly to the plane of progression, and this being effected, the hinder sucker is detached and drawn forwards, locomotion being accomplished by the alternate adhesion of these two prehensile discs. In *Cyclostoma* the foot is likewise furnished with two longitudinal adhering lobes, which are advanced alternately. But the foot is not merely an instrument of progression on a solid surface, in many species being convertible, at the will of the animal, into a boat, by means of which the creature can suspend itself in an inverted position at the surface of the water, where by the aid of its mantle and tentacles, it can row itself from place to place. The Bulimus stagnalis, so common in our pools of fresh water, is a good example of this mode of sailing; and in the marine species, Aplysia and Gastropteron may be enumerated as exhibiting a similar structure.

Some of the naked Gasteropods, as Aplysia and Thethys, are able to move through the water in the same manner as the leech by an undulatory movement of the whole body, a mode of progression which in Thethys is materially assisted by the membranous expansion of the mantle placed around the anterior part of the body, which forms a broad veil, and from the muscular fibres contained within it, must necessarily be an important agent in swimming.

Particular secretions.—Many of the Gasteropoda, in addition to the secretions which have been mentioned, furnish others adapted to peculiar circumstances, and produced from special organs.

In the Snail and the Slug tribes a slimy mucus is furnished in great abundance from an organ which has been denominated the "sac of the viscosity;" this is a membranous bag surrounding the pericardium, which when opened is found to be divided internally by delicate septa arising from its walls; from this proceeds a capacious duct, which follows the course of the rectum, to which it is intimately united, to open externally in the neighbourhood of the respiratory aperture. The viscid secretion of this gland spreading over the surface of the foot is most probably an assistant in progression, causing it to adhere more intimately to the surfaces over which the animal crawls.

Aplysia furnishes three distinct fluids issuing from different parts of the body. The first is a glairy mucus, which exudes in considerable quantities from the surface of the mantle, especially when the creature is irritated. The second is a whitish liquor, which is thick and acrid, and has been reputed venomous; it is emitted in very small quantities, but its smell is strong and highly nauseous: the gland which produces it is a little reniform mass placed near the vulva, close to which is the orifice of its excretory canal. Blainville looks upon this as the representative of a urinary apparatus, but it does not appear to exist in all the species, and is never emitted except when the animal is tormented.

The third secretion is much more abundant than the other two, and is generally of a beautiful lake colour, except in *Aplysia citrina*, in which it is yellow. It is contained in a spongy substance, which occupies all those portions of the little mantle or operculum to which the shell does not extend. All the areolæ of this tissue are filled with a purple matter, the colour of which is so intense, that when it is expressed it has a black violet hue, but when mixed with a large quantity of water, imparts to it the colour of port wine. This colouring fluid seems to exude through the skin of the mantle, no excretory duct having been found specially appropriated to its escape: it is apparently produced from a triangular glandular mass situated in the base of the mantle.

Several species of Murex secrete a similar fluid, which, like the ink of the cuttle-fish, serves as a defence from attack; in all cases it is expelled with force, and in such abundance as to colour the water around to a considerable distance.

There is a species of Limax, (*Limax noctilucus,*) described by M. Orbigny, which produces a phosphorescent secretion capable of emitting a light of considerable brilliancy. The luminous organ is a small disc of a greenish colour by day-light, soft in texture, and slightly contractile. The light is only visible when the creature is expanded and in motion. The disc is always covered with a greenish mucus, which, if wiped off, is speedily renewed. It is found to be connected with the generative organs, and appears to be principally useful during the season of love.

GELATIN (Fr. *gelatine*; Germ. *Leim. Gallerte*). This term is applied to an important principle obtained by boiling certain animal substances in water, and filtering or straining the solution, which, if sufficiently concentrated, gelatinises, or concretes into a translucent tremulous mass on cooling, which may be again liquefied and gelatinised by heat and cold. Many varieties of gelatin occur in commerce, of which *glue* is perhaps the most important: it is obtained by boiling the refuse pieces of skin and hide, and the scrapings and clippings from the tan-yard, in a sufficient quantity of water, till a sample taken out of the boiler forms, on cooling, a stiff jelly; the solution is then strained whilst hot, and run into coolers, where it concretes, and is afterwards cut by a wire into slices, which are dried upon nets. Membranes, tendons, cartilage, horn-shavings, and other similar substances also yield a jelly, which, however, is less stiff and binding than the former, especially when obtained from young animals: *size* is a jelly of this description. *Isinglass*, which consists of several parts of the entrails of fish, and especially the sound, &c. of the sturgeon, yields a very pure and tasteless jelly, which is chiefly used for the table; the jelly of calves' feet and hartshorn-shavings is somewhat similar.

As jelly cannot be extracted by cold water, and as we have no direct evidence of its existence in the various substances from which it is obtained previous to the action of boiling water, and, moreover, as it does not occur in any of the animal fluids or secretions, it has been regarded by some chemists, and especially by Berzelius, as a product of the action of water and heat, and not as a mere educt. He compares its formation to the conversion of starch into gum and sugar, and remarks that in both cases the change is accelerated by the presence of dilute acids.

Pure gelatin is colourless, transparent, inodorous, insipid, and neither acid nor alkaline; heat softens it and exhales a peculiar odour, and it burns with smoke and flame, leaving a bulky coal, difficult of incineration and containing phosphate of lime: it yields much ammonia, and the other ordinary products of analogous animal compounds, when subjected to destructive distillation.

In cold water dry gelatin swells and becomes opaque, and when gently heated it dissolves and forms a clear colourless solution, which gelatinises when cold. According to Dr. Bostock, one part of isinglass to 100 parts of water yields a perfect jelly, but with 180 of water it does not concrete.* Those modifications of gelatin which are the least soluble in hot water yield the strongest jelly. When the same portion of jelly is repeatedly liquefied and cooled, it gradually loses the property of gelatinising, and becomes so far modified as to leave a brownish gummy residue when evaporated, which readily dissolves in cold water. L. Gmelin kept a solution of isinglass in a sealed tube for several weeks at the temperature of 212°: it was thus changed to the consistency of turpentine, was deliquescent, soluble in cold water, and partially so in alcohol.

An aqueous solution of gelatin exposed for some time to the air at the temperature of 60° to 70° becomes at first thinner and sour, and afterwards ammoniacal and fetid: the addition of acetic acid prevents the putrefaction without impairing the adhesive power of the gelatin.

Gelatin is insoluble in alcohol and ether, and in the fixed and volatile oils. When a strong aqueous solution of gelatin is dropped into alcohol, it forms a white adhesive and elastic mass, which adheres strongly to the glass, and which, like dry gelatin, softens, but does not dissolve in cold water.

When chlorine is passed through a warm and somewhat concentrated solution of gelatin, each bubble becomes covered with an elastic film, and deposits, on bursting, a white, tough viscid matter; the whole of the gelatin is thus precipitated, and free muriatic acid is formed. This chloride of gelatin is insoluble in water and alcohol, and remains acid, and smells of chlorine, even after it has been kneaded in warm water Dissolved in caustic ammonia in a tube over mercury, it evolves nitrogen and becomes mucilaginous. It is soluble in acetic acid; but the solution, though rendered turbid by dilution, gives no precipitate by ferro-cyanuret of potassium, so that the gelatin is not thus converted into albumen, No analogous compound is produced either by iodine or bromine.

The action of sulphuric acid on gelatin has been studied by Braconnot.* When one part of glue and two of sulphuric acid are mixed, they form in twenty-four hours a clear fluid, which, when diluted with eight parts of water, boiled for eight hours, (the loss by evaporation being replaced by fresh portions of water,) and then neutralised by chalk, filtered, evaporated to the consistency of syrup, and set aside for a month, yields a crystalline crust of a peculiar saccharine substance, which is insoluble in alcohol and ether, unsusceptible of vinous fermentation, and gives ammonia by destructive distillation. It combines and forms a peculiar crystallisable compound with nitric acid, which he calls the *nitro-saccharic acid*, and which combines with the salifiable bases and forms distinct salts, the properties of which closely resemble the *carbazotates*.

Dilute nitric acid dissolves gelatin without the evolution of nitrous gas, and forms a yellow solution, which, by evaporation, (or the addition of an alkali,) becomes darker, and at last evolves nitrous gas, and passes (often with ignition) into a spongy coal.† By concentrated nitric acid gelatin is converted into malic and oxalic acids, a fatty substance, and artificial tan.‡

Acetic acid dissolves gelatin and the solution does not gelatinise, but upon drying, the adhesive power of the gelatin is unimpaired: the dilute acids do not generally prevent gelatinisation.

Neither the dilute caustic alkalis nor ammonia prevent the concretion of a solution of gelatin, but they render it turbid by precipitating its phosphate of lime. Gelatin is soluble in strong caustic potash, with the exception of a residue of phosphate of lime. The solution, when neutralised by acetic acid, does not gelatinise, and yields on evaporation a compound of gelatine with acetate of potash, which is soluble in alcohol. Sulphuric acid precipitates sulphate of potash from this acetic solution, in combination with gelatin; and this compound precipitate, dissolved in water, crystallizes by spontaneous evaporation to the last drop.§

Hydrate of lime does not affect a solution of gelatin, but much lime is dissolved by it: it also takes up a considerable quantity of recently precipitated phosphate of lime.

Gelatin is not precipitated by solution of alum, but when an alkali is added the alumine falls in combination with gelatin. The aluminous solution of gelatin is used for sizing paper, and for communicating to woollen cloth a certain degree of impenetrability to water.

The acetates of lead do not precipitate pure gelatin; by corrosive sublimate its solution is

§ Berzelius.

rendered at first turbid, and when excess is added a white adhesive compound falls: nitrate and per-nitrate of mercury and chloride of tin occasion nearly similar changes. But the metallic salt which is the most decided precipitant of gelatin, and which does not affect albumen, is sulphate of platinum; it throws it down even from very dilute solutions, in the form of brown flocculi, which, when collected and dried, become black and brittle, and which, according to Mr. Edmund Davy, to whom we owe this effective test, consist of about 76 per cent. of sulphate of platinum and 24 per cent. of gelatin and water.

We now come to the most important and characteristic property of gelatin, which is, that of combining with tannin, and upon which the art of tanning, or the conversion of skin into leather, essentially depends, for the true skin *(cutis)* of animals consists of a condensed and fibrous form of organised gelatin, and, when properly prepared and immersed in a solution of vegetable astringent matter or tannin, it becomes gradually penetrated by and combined with it, and when dried is rendered insoluble and durable. The tannin of the gall-nut is perhaps that which forms the most insoluble precipitate in gelatinous solutions, and is therefore the most delicate test of the presence of gelatin; but, as albumen is also thrown down by it, the absence of the latter must have been previously ascertained. (See ALBUMEN.) A strong infusion of galls occasions a precipitate in water holding less than a five-thousandth part of gelatin in solution, and, if added to a strong solution of gelatin, it throws it down in the form of a curdy precipitate, more or less dense and coloured according to the greater or less excess of the precipitant. The precipitated compound is insoluble in water, dilute acids, and alcohol, and when dried becomes hard and brittle, but again softens and acquires its former appearance when soaked in water: it may be termed tanno-gelatin. When tannin is added to a solution of gelatin, the latter being in excess, and especially if it be warm, no precipitate is immediately formed, for tanno-gelatin, when recently precipitated, is to a certain extent soluble in liquid gelatin. Tanno-gelatin does not appear to be a definite compound; at least it is difficult to obtain it as such: the precipitate by infusion of galls consists, when carefully dried, of about 40 per cent. of tan and 60 of gelatin. When obtained by other astringents, such as oak-bark, catechu, and kino, it differs in the relative proportion of its components and in its other characters, and often contains extractive matter. According to Sir H. Davy,* 100 parts of calf-skin thoroughly tanned by infusion of galls increase in weight 64 parts; by strong infusion of oak-bark 34, and by weak 17; by concentrated infusion of willow-bark 34, and by dilute 15; and by infusion of catechu 19.

Mr. Hatchett's researches have shewn that gelatin is also precipitated by the varieties of artificial tan, and that the compound thrown down resembles in its leading characters the tanno-gelatin of natural tan. The ultimate composition of gelatin (pure isinglass) has been quantitatively determined by Gay Lussac and Thenard, with the following results:—

	Atoms.	Equiv.	Theory.	Experiment.
Nitrogen	1	14	16.09	16.998
Carbon	7	42	48.28	47.881
Hydrogen	7	7	8.04	7.914
Oxygen	3	24	27.59	27.207
	1	87	100.00	100.000

As the combining proportion of gelatin has not been accurately ascertained, its equivalent number, as above given, is open to doubt, but it is probably correct, and the theoretical and experimental results closely correspond.

(W. T. Brande.)

GENERATION, ORGANS OF, (Comparative Anatomy).—Few subjects connected with physiology have been investigated more assiduously than that of the generation of animals; and in none, perhaps, has the poverty of our knowledge of the operations of nature been more conspicuously exemplified. In studying many functions of the animal economy, the laws of chemistry and mechanics have been successfully appealed to by the philosopher, and their application to the operations of the animal frame satisfactorily substantiated; but in attempting to explain the wonderful process by which organized bodies are perpetuated, all the resources of modern science have been found totally inadequate to the task, and we are still left to record facts and observations concerning the structure of the organs appropriated to the propagation of animals, without being in any degree able to connect them with the results so continually offered to our contemplation. In taking a general survey of the animal kingdom, we are at once struck with the infinite variety of forms which it presents, adapted to an endless diversity of circumstances, and might expect to meet with a corresponding dissimilarity in the organization of the generative apparatus peculiar to each: no such dissimilarity, however, exists in nature, the modes of reproduction conform to a few grand types, and the increasing complexity of parts, apparent as we ascend to higher classes, which it will be our business to trace in this article, will be seen to depend rather upon modifications in the arrangement of secondary structures than upon any deviation from the fundamental organization of the more immediate agents.

Without entering upon any discussion concerning the theories which have from time to time been advocated relative to spontaneous generation, we shall divide all animals as relates to the generative function into three great classes, grouping together such as are

1st. *Fissiparous*, in which the propagation of the species is effected by the spontaneous division of one individual into two or more, precisely resembling the original being.

* Philos. Trans.

2nd. *Gemmiparous*, in which the young sprout as it were from the substance of the parent.

3rd. *Oviparous*, producing their offspring from ova or germs developed in special organs adapted to their formation.

Of these modes of reproduction the two first are confined to the lowest or acrite division of the animal kingdom, whilst the third or oviparous type is common to all other classes.

Fissiparous generation is the simplest possible, and presupposes a corresponding simplicity of structure in the animals which propagate in this manner. It is principally confined to the Polygastric animalcules, most of which are multiplied by the spontaneous separation of an individual into two portions precisely resembling each other, and capable of performing all the functions which originally belonged to the undivided creature. Some of the larger species of Trichoda are well calculated to exhibit to the microscopic observer the steps by which this process is accomplished: the animalcule, prior to its division, is seen to become slightly elongated, and a transparent line is gradually distinguishable, indicating the course of the intended fissure; at each extremity of this line a contraction of the body is speedily observable, and the lateral indentations become deeper and deeper, till at length a perfect separation is effected. The direction in which this division occurs is not always the same even in the same species; thus, instead of traversing the shorter axis of the body it not unfrequently assumes a longitudinal or oblique direction, and from this cause it is not unusual to find the newly divided creatures differing materially in appearance from their adult or rather conjoined form; for in this process the old animalcules literally become converted into young ones.

In some of the more complex forms of Polygastrica the fissiparous mode of generation exhibits modifications which are extremely curious. In the beautiful *Vorticellæ*, whose bell-shaped bodies are supported on long and exquisitely irritable stems, the division commences at the large ciliated extremity of the animalcule, from which point it gradually extends in a longitudinal direction towards the insertion of the stem, dividing the body into two equal portions, one or both of which becoming speedily detached from the pedicle, might easily in this state be mistaken for creatures of a different genus, and have in fact been described as such by many authors. The new animalcule, when thus deprived of its pedicle, is seen to be furnished with cilia at the opposite extremity to that on which they were previously found, while from the other end, originally the mouth, a new foot-stalk becomes gradually developed, and the creature assumes the shape proper to its species. If one of the bells remain attached to the pedicle, it continues to perform the same movements as before the separation of the new animalcule; but if both become detached, the foot-stalk perishes.

In the strangely compound symmetrical bodies of *Gonium* a provision for separation appears to be made in the detached portions of which each perfect animal is apparently composed. The body of *Gonium pectorale* consists of sixteen minute transparent globes of unequal size, arranged in the same plane. This beautiful animalcule is propagated by a separation of its integrant spherules, the creature dividing into four portions precisely similar to each other, and composed individually of one of the central globules united to three of the smaller marginal ones; and no sooner is the division accomplished than the component globes of each portion increasing in number, the new animalcules assume the dimensions and appearance of that of which they originally formed parts.

In the *Gonium pulvinatum* the fissiparous mode of generation gives origin to a still more numerous progeny. The young animalcule is a minute, flat, diaphanous and quadrangular membrane, which swims through the fluid in which it is found by movements sufficiently indicative of its animal nature: as it enlarges, the surface is seen to become marked by two series of parallel lines which cross each other at right angles and divide the creature into smaller squares, which ultimately separate and become distinct representations of the original animalcule.

Some of the Nematoid worms, as the Nais, are likewise said to propagate by spontaneous division.

Gemmiparous generation.—This mode of reproduction, like the fissiparous, is confined to the lowest tribes of animal existence, and the creatures which propagate in this manner are unprovided with any apparatus specially appropriated to generation. The young appear as gemmæ or buds, which at certain periods sprout from the homogeneous parenchyma which composes the body of the parent, and these buds gradually assuming the form of the original by a kind of vegetative growth, become in a short time capable of an independent existence. The gemmiparous type of the generative function is met with through a wider range of the animal kingdom than the last, existing under modified forms in many species of Polygastric Infusoria, and of Polyps, as well as in Sponges, the Cystiform Entozoa, and probably in some Acalephæ.

It is in the Cystoid Entozoa that we find it in its simplest form. In the Cysticercus and likewise in the Cœnurus, the transparent membranous bag of which the animal consists is filled with a glairy fluid, in which occasionally young hydatids are seen floating about. These young Cysticerci in the earliest period of their formation are seen to pullulate from the parietes of the parent sac, and gradually enlarging they ultimately separate from their connexions, becoming detached and perfect animals.

Many of the Polygastrica are multiplied by a similar process, of which the *Volvox globator* may serve as an illustration. This beautiful animalcule is a minute diaphanous globe, which under the microscope is generally seen to contain a variable number of smaller globules, which are the young: these, when first discoverable, are attached to the inner surface of the parent, but speedily detaching themselves they are found rolling loosely within the body of the larger animalcule, effecting their rotatory movements by the agency of cilia of extreme minuteness, which under a good microscope are seen to cover their external surface. The contained globules having attained a sufficient maturity, the parent volvox bursts, and thus by its own destruction allows its progeny to escape from their imprisonment. The multiplication of these animalcules is effected with considerable rapidity, and it not unfrequently happens that even before the escape of the second generation the gemmules of a third may be observed within their bodies, which in like manner advancing through similar stages of development will terminate by their birth the existence of their parent.*

It would appear from the observations of Professor Grant, that in the sponges, notwithstanding their different form, the process of reproduction is entirely similar. In these curious animals the gemmules are developed in the substance of that living parenchyma which coats their porous skeletons, and when mature are expelled through the fœcal orifices to commence an independent existence. When separated from the parent sponge, these gemmules, like those of the volvox, are ciliated over a great portion of their surface, and being thus endowed with a power of locomotion, are enabled to swim to a considerable distance in search of a situation adapted to their future growth, until having at length selected a permanent support, they become attached, and developing within themselves the spicular or horny skeleton peculiar to their species, they gradually assume the porous texture and particular character of the sponge from which they were produced.

But it is in the gelatinous Polypes that we meet with the most perfect forms of gemmiferous propagation : of this the *Hydra viridis*, or fresh-water polype, affords an interesting illustration, and from the facility with which it may be procured and examined by glasses of very ordinary powers, it is well calculated to illustrate the mode of generation which we are at present considering. The body of this simple polype is transparent, and under the microscope appears to be entirely made up of translucent granules, without any trace of internal apparatus appropriated to reproduction. The gemmules by which it is propagated sprout from some part of the surface, appearing first as mere gelatinous excrescences, but gradually enlarging they assume the form of their parent, acquiring similar filamentary tentacles and a gastric cavity of the same simple structure. As long as the junction between the polype and its offspring continues, both seem to enjoy a community of being, the food caught by the original one being destined for the nourishment of both ; but at length, the newly-formed animal having attained a certain bulk, and become capable of employing its own tentacles for the prehension of food, detaches itself with an effort, and assumes an independent existence. This mode of multiplication is exceedingly rapid, a few hours sufficing for the perfect developement of the young creature ; and not unfrequently even before its separation, another gemmule may be observed emerging from the newly-formed polype, soon to exhibit the same form and exercise the same functions as the parent from which it sprouts.

The propagation of some of the lithophytous polypes resembles that of the *hydra*, the young being produced from buds or gemmules, which sprout from the living investment of their calcareous skeleton. Such are the *Fungiæ*, in which the young are at first pedunculated, and fixed to the laminæ upon the upper surface of the mass from which they spring ; in this state they might readily be mistaken for solitary Caryophyllia, but in time they separate from the parent stock, and loosing the pedicle which originally supported them, they assume the form of their species.

Oviferous generation.—In the third, and by far the most numerous division of the animal kingdom, the young are derived from ova or eggs, in which the germ of the future being is evolved, and from which the young animals escape in a more or less perfect state.

It will be seen that the ovum which gives birth to all the higher animals differs essentially from the gemma furnished by the gemmiferous classes ; in the gemmiferous type the bud or offshoot of the parent appears by a kind of vegetative evolution to assume the proportions and functions of the original from which it sprang. The ovum we would define as a nidus, containing not only the germ of the future animal, but a sufficient quantity of nutritious matter, serving as a pabulum to the embryo during its earliest state of existence, and supplying the materials for its growth until sufficiently mature to derive them from other sources. We have already shewn that in the fissiparous and gemmiferous animals there is no necessity for any special generative apparatus, but in the oviferous classes we find, for the most part, a distinct system, more or less complicated in structure, in which the reproductive ova are developed and matured. It must be confessed, however, that in the present state of our knowledge upon this subject we are not prepared to state how far the existence of a generative system is exclusively confined to the ovigerous type. We are well aware that many authors describe generative canals to exist in several of the polypiferous tribes, although the reproductive germs produced from them resemble in their ciliated organs of progression and mode of development the gemmules of less elaborately organized polypes ; yet, on the other hand, as we have abundant evidence to prove that such polypes as have the ovigerous canals most distinctly formed, as the Actiniæ for instance, produce their young perfectly organized and evidently developed from true ova, we are content, in the present state of our knowledge upon this subject, to regard the presence of generative canals as co-existent with ovigerous generation, and shall leave

* [Some physiologists, however, refer the generation of this creature to the fissiparous mode. See the succeeding article.—Ed.]

future observations to determine more accurately the mode of reproduction in the corticiferous polypes, which is a subject at present involved in much contradiction and obscurity.

Taking this view of the subject, we find, upon cursorily glancing over the ovigerous classes of animals, that important modifications of structure in the generative system render further classification necessary. In the lower forms, ovigerous organs only have been discovered, in which the ova are secreted, and when matured, escape from the body, fit in every respect for the production of a new animal. In other instances, in addition to the apparatus immediately appropriated to the developement of the ova, we find a superadded portion destined to furnish a secretion which is essential to their fertility, forming an *apparatus of impregnation*. Sometimes the impregnating organs are found in every individual, appended to the ovigerous parts, rendering each creature sufficient for the impregnation of its own ova: in other instances, although each animal possesses both ovigerous and impregnating organs, the cooperation of two individuals or more is necessary to fertility; and in other cases again, the apparatus which furnishes the ova, and that destined to the production of the impregnating fluid, are found in distinct individuals, distinguished by the appellations of male and female: we shall accordingly divide all oviparous animals into the following groups:—

1. Such as are provided with ovigerous organs only.

2. Animals having, in addition to the ovigerous apparatus, a glandular structure, the secretion of which is probably subservient to the fertility of the ova.

3. Ovigerous and impregnating organs, coexistent in each individual, but the cooperation of two or more needful for mutual impregnation.

4. The ovigerous and impregnating apparatus existing in distinct individuals.

First Division.—*Animals in which ovigerous organs only have been distinctly recognized.*

It would seem from the observations of Ehrenberg that some of the Polygastrica belong to this division, although the exact nature of the generative system in such species remains still a matter of uncertainty. In the Kolpoda Cucullus the spawn consists of a loose mass of ova, connected by delicate filaments, from which the young are gradually evolved after their extrusion from the parent animalcule, and some of the parenchymatous Entozoa appear to be similarly circumstanced.

In the Acalephæ, at least in such as have been most attentively examined, the generative system conforms to the type at present under consideration. From the researches of Gaede and Eysenhardt it appears that the ovaria are four in number, disposed in a cruciform manner upon the dorsal aspect of the body or that which is opposite to the mouth. These ovaria, which at certain seasons of the year are remarkably distended and often beautifully coloured, open into the interior of the stomach. The young Medusæ are hatched in the ovaria, and afterwards escaping into the alimentary canals excavated in the substance of the body, acquire in that situation a very perfect state of development, and are ultimately excluded through the oral aperture, or in the Rhizostomatous species through the ramified canals of the pedicle.

In the fleshy polypes (Actiniæ) the ovigerous system consists of long, convoluted filiform tubes, contained between the stomach and the parietes of the body, and separated by partitions which divide that space into compartments. These tubes are attached by a delicate mesentery, and according to Spix open in an irregular manner into the digestive cavity, into which the ova escape. The period or mode in which the eggs are hatched is unknown, but that the young escape fully formed and in every point resembling their parent through the stomachal orifice is attested both by Dicquemare and Blainville.*

The different forms of Echinodermata present a similar simple arrangement of the generative apparatus. In the Asteriadæ each ray is furnished with two clusters of short ovigerous tubes, which are closed at one extremity, but open at the other into a cavity common to each group. These organs open by a series of apertures placed around the circumference of the mouth at the base of each ray. In the spring these ovaria are distended with eggs of a reddish-brown colour, which are expelled in clusters and left upon the beach exposed to the influence of the sun, where they are ultimately hatched.†

The radiated type of structure is likewise manifest in the disposition of the generative organs of the Echinidæ: in these the ovaria are never single or simply bilobed, but are at least four in number, or, as is generally the case, five. Each ovigerous organ consists of a simple dilated sacculus, which at certain seasons is distended with ova, and at such times in some species, as in the edible Echinus, the eggs are sought after as an article of food. The ovaria open externally by a corresponding number of simple apertures, which are placed around the anal orifice when it is central, but otherwise are considerably removed from this point. Nothing analogous to a male apparatus has been detected in the Echinida. The eggs are deposited in spring in the recesses of rocks or among the fucus which covers them; and before they are hatched the young may be discovered in the interior partially covered with a calcareous shell, the rest of the integument still remaining membranous.

* Spix and Dello Chiaje assert that there are other filiform tubes mixed up with the ovarian ducts, which they regard as the testes, but neither the observations of other authors nor our own examinations confirm this view of the subject.

† Tischer and Spix describe a singular flexuous intestiniform organ which is found upon the dorsal aspect of the stomach as a male apparatus, and Blainville considers this part as in some degree connected with generation.

The Holothuridæ present in the elongated form of their bodies an evident approximation to the annulose type of structure, and a proportionate concentration of the generative system; in these we find but one ovary floating loosely in the visceral cavity, and composed of numerous very long cœca, which terminate by a single orifice placed on the median line, near the oral extremity of the animal.* The eggs when discharged are connected into masses composed of long strings of ova, but the mode of their development is but little known.

Although from the relations of the Molluscous division of the animal kingdom we might infer that a more elevated type of structure would characterize their organs of reproduction, the present state of our knowledge of the anatomy of these creatures compels us to arrange the lowest orders of that extensive class with those tribes which only possess an ovigerous system; for although an androgynous conformation is presumed by many to exist in all Bivalves, the presence of any superadded impregnating portion has not yet been pointed out, and even the course of the ova in their passage from the ovarian cavity remains a matter of speculation. In the Conchiferous order, from causes sufficiently obvious when we consider the peculiar structure of the animals which compose it, the full development of their numerous ova could not be accomplished in the ovary itself, which occupies a large portion of the body, as any material increase of bulk produced from this cause would materially interfere with the closing of the shell; at an early period, therefore, the ova are transferred from the nidus in which they were formed to the branchial fringes, between the laminæ of which they perfect their growth, and are fully exposed to the influence of the element around them. Oken traced a canal through which he supposed the ova to be conveyed directly from the ovaria to the gills;† but notwithstanding his observations Carus contends‡ that the eggs pass into the stomach through one of the openings hitherto considered as belonging exclusively to the biliary ducts, whence they are evacuated through the mouth and conveyed into the openings of the gills by the water which flows between the pallial laminæ from before backwards, and ultimately escape by two canals which open below the anal tubes.

In the Tunicata, and also in those forms of the Gasteropodous Mollusca which most nearly approximate the Conchifera in the details of their organization, the ovary is imbedded in the substance of the liver, and the ova are discharged through a simple duct, unprovided with any appendage which can be looked upon as a male apparatus. It is true, indeed, that in all these cases the walls of the oviduct may themselves furnish a fertilizing fluid, and by many physiologists they are supposed thus to supply the want of male parts; such an hypothesis, however, is, to say the least of it, entirely gratuitous; but as it is more our business to trace the development of organs than the modes in which their deficiency may be supplied, we are content to leave the question without further discussion in this place.

Second Division.—*Animals provided with ovigerous organs combined with an additional secreting structure, probably subservient to the fertilization of the ova.*

In this type of the generative system it must be obvious that the function attributed to the superadded portion is by no means indubitably substantiated, the opinions of physiologists relating to its office being rather based upon analogical reasoning than supported by direct evidence; and, in fact, some authors deny entirely that a necessity for the impregnation of the ova is more evident in this division than in the last. Nevertheless, although it is impossible distinctly to prove the identity in function between the appended portion and the testis of higher forms of organization, the evidence afforded from the position which it invariably occupies, and from the consideration of the parts connected with generation in diœeious animals to which we are insensibly conducted by this species of Hermaphrodism, is sufficiently cogent to warrant our application of the term ovarium to the nidus wherein the ova are produced, and to justify us in designating the accessory organ as a testis or apparatus for impregnation.

The Tænioid Sterelmintha furnish us with one of the simplest examples of this arrangement of the generative organs. In the long and tape-like bodies of these Entozoa each segment, with the exception of the smaller ones near the head, possesses distinct ovigerous and impregnating structures. The female part of the apparatus occupies the centre of the joint, and consists of lateral tubes ramifying from a central canal, which at times may be seen to be full of minute granular ova. From these ovigerous canals a duct issues, which communicates with the lateral pore and receives before its termination two delicate tubes, recognizable under the microscope as dark lines imbedded in the pulpy segment, and which may be presumed to furnish an impregnating secretion.

In the *Rotifera*, or wheel-animalcules, the female apparatus consists of two long and comparatively wide sacculi, in which the ova are developed; these open at the anal orifice, and receive near this point two narrow cœca, which, as in the last case, may secrete a fertilizing fluid, serving to impregnate the eggs prior to their expulsion. The ova of these minute creatures, before the escape of the young, are exceedingly beautiful subjects for the microscope, the wheels of the embryo

* Here, also, Blainville conjectures that there is a supplementary impregnating portion, but it is evident that in a treatise like the present it would be worse than useless to recapitulate the surmises of authors upon subjects only capable of solution by positive demonstration, and we shall therefore endeavour rather to adhere strictly to the narration of what is clearly established by observation, than to indicate what theory or analogy would lead us to suspect.

† Goetting, gel. Anzeigen, 1806.

‡ Introduct. to Comp. Anat.

being easily distinguished in rapid action through the pellucid coverings of the egg.

In the Cirrhopoda we have most probably an example of this mode of generation, presuming, that is, that the opinions of Cuvier upon this subject are correct. These opinions, it is true, have been disputed by various authorities, as will be evident on reference to the article CIRRHOPODA; but their correctness has been so fully supported by the dissections of John Hunter, recently given to the world,* that it seems best at least to pause before repudiating the conclusions to which these great anatomists, unacquainted with the labours of each other, were individually conducted. In the Cirripeds the ovaria are two in number, placed on each side of the stomach; the two oviducts which proceed from these unite to form a single elongated tube, the parietes of which are thick and apparently glandular. It is evident that in this case the walls of the common canal, or ovipositor as it is usually termed, may serve to secrete a seminal fluid, impregnating the eggs at the period of their extrusion; and such, in the opinion of the authors above mentioned, is a part of its office.

THIRD DIVISION.—*Ovigerous and impregnating organs co-existent, but the co-operation of two individuals necessary for mutual impregnation.*

This arrangement of the generative system occurs in some of the Parenchymatous Entozoa, in the Annelida, and also in the Pteropod and some Gasteropod Mollusca. Some of the Entozoa, as *Fasciola* and *Planaria*, furnish the simplest examples of this hermaphrodite condition. In these creatures the male organs consist of spermatic cœca, communicating with a minute extensible penis, which is placed behind the oral sucker. Near the penis a small orifice is seen, leading to the ovigerous canals, which have no communication with the impregnating apparatus; and the copulation of two individuals is thus indispensable to a reciprocal fertilization of the ova.

Those of the Annelida in which the generative system is best understood are androgynous, and mutually impregnate each other, although it is probable that in the tubicolous genera, which are immoveably fixed to the same spot, and almost deprived of locomotion, each individual may in itself be sufficient for reproduction.

In the Abranchiate and Dorsibranchiate Annelida the male apparatus is composed of several pairs of secreting bodies, arranged on each side of the mesial plane, those of the same side communicating with each other by a common vas deferens. In the Leech the vasa deferentia, which convey the secretion of the numerous testicular masses, terminate in a long protractile tubular penis, and at a short distance behind this the opening which leads to the female parts may be discovered. These latter consist of a simple uterine sacculus, or receptacle for the ova, to which two minute ovaries are appended. The congress of two individuals is effected by the reciprocal introduction of the organs of intromission into the vulvæ. In the Earthworm and Nais the intromittent apparatus is deficient, so that some authors have even doubted that the process of copulation, which is undeniably essential to fecundity, does more than stimulate each individual to self-impregnation. In the Earth-worm, as well as in Arenicola and Aphrodita, the ova, after escaping from the ovaria, are retained in the cellular meshes which surround the alimentary canal, in which they are not unfrequently hatched, the young being most probably expelled through a tubular aperture at the posterior extremity of the body.

As regards the generative system, the Pteropod Mollusca approximate the more complex type seen in the Gasteropoda. In *Clio borealis*, the ovary, which is partially enveloped by the liver, gives off a slender duct, which, after a short course, plunges into a glandular tube; this, becoming gradually narrower, terminates in a round sac placed on the left side of the head, where it opens externally: near this point is the penis, or organ of intromission, communicating with a small sacculus, by which the male secretion is probably furnished.

Fig. 200.

Testis of Helix.

The most complicated forms of this species of hermaphrodism are met with in the Gasteropod division of Mollusca, existing throughout the Nudibranchiate, Tectibranchiate, Inferobranchiate, and Heteropod orders, as well as in those pulmonary genera which are unprovided with a calcareous operculum. In all these cases the testis is single and divided into lobuli, connected together by the divisions of the vas deferens so as to exhibit a racemose arrangement, and each lobule, on minute inspection, is found to consist of little pedunculated vesicles (*fig.* 200). A slender vas deferens conducts the secretion of this testicle to the base of an intromittent organ of a most singular description; this is a muscular tube of great length, which, when not in use, is inverted and concealed within the body, but capable of protrusion at the will of the animal. The female portion of this system is composed of one ovary, provided with an ample and tortuous oviduct, which serves, indeed, as a kind of uterus or egg receptacle, wherein the

* Catalogue of the Physiological Series of Comparative Anatomy contained in the Hunterian Collection, vol. i.

ova are retained until ripe for extrusion. Near the termination of this oviduct are placed several additional appendages, some of which are apparently destined to furnish an investment for the ova, whilst one, which is constantly present, is probably a reservoir for the seminal fluid required to fertilize the eggs as they are expelled. (See GASTEROPODA.)

The external parts are so disposed that during the copulation of two individuals the male organ of each is introduced into the orifice leading to the female apparatus of the other, both thus impregnating and being impregnated at the same time.

In *Lymnæus stagnalis* we have a curious exception to this mode of copulation, for in this animal the sexual organs are so placed that mutual impregnation is impossible, and accordingly fecundation is accomplished by a combination of individuals, each of which performs the office of a male to another, while to a third it acts the part of a female, and long strings of them are often seen thus united.

FOURTH DIVISION.—*Sexes distinct, that is, the ovigerous and impregnating organs placed in separate individuals.*

This type of the reproductive apparatus extends through a wide range of animals, and is found in a great number of classes utterly dissimilar in outward form and internal structure; so that, in order to give a connected view of the comparative organization of the parts of generation, we shall be unavoidably compelled to group together animals widely separated by the laws of zoological arrangement. Feeling, however, that by so doing we shall lay before our readers a much more easily intelligible comparison of the organs belonging to our subject, we shall not scruple to bring together, in one view, analogous forms of the generative apparatus, in whatever classes they may be found. Animals in which the sexes are distinct may be divided into three classes; the first including such as are oviparous, the second embracing the ovo-viviparous orders, while the third will comprehend the strictly viviparous animals. It will be seen that the terms here employed have been used from time immemorial, but nevertheless in a widely different sense to that in which the present state of our knowledge sanctions their application. To us it appears that we ought to regard all creatures as oviparous whose offspring, at the period of their escape from the ovum, are sufficiently mature to admit of their independent existence. In the ovo-viviparous division, on the contrary, the ova are hatched and the embryo expelled at an early period of its formation; the embryo is thus born in an extremely imperfect state, the materials for its future developement being supplied by the mammary secretion of the parent; such is the case with all the marsupial orders. In the vivipara the earliest stages of growth are precisely similar to those which mark the progress of evolution in the oviparous type, and the provisions made for the nourishment of the rudimentary being in every respect analogous; the great distinction consists in the subsequent maturation of the embryo within a uterine cavity, and the formation of a placenta, which characterizes the highest form of mammiferous animals.

The oviparous classes, which form by far the most numerous division, produce their young from ova, in which the germs of the future beings are developed for the most part subsequent to the expulsion of the egg from the body of the parent. In this case the ovum necessarily contains a sufficient store of nourishment for the support of the embryo during the whole period of fœtal life, at the termination of which it is produced in a sufficiently advanced stage of its growth to render it capable of independent existence. It will readily be perceived that under this division we include many animals which, according to the old meaning of the terms, were looked upon as ovo-viviparous or viviparous in their mode of reproduction; a distinction which, as the words have been hitherto applied, appears to the writer by no means sufficiently grounded upon physiological views to admit of its continuance. It is certainly very true that some animals included in this division are found to produce their young in a living state; but the mere hatching of the egg within the oviductus of the mother, instead of subsequent to its expulsion, is not a circumstance of sufficient importance to be regarded as constituting another type of the generative process, more especially as such an occurrence is entirely fortuitous, observation having proved that the same animal at one time produces its young alive and at another in the egg state, in obedience to circumstances connected with food, temperature, or confinement. With this extension of the term, oviparous animals in which the sexes are distinct will be found in many classes belonging to the diploneurose, cyclogangliate, and vertebrate divisions of the animal kingdom, combined with modifications in the structure and arrangement of the generative apparatus, which it will be our business to trace.

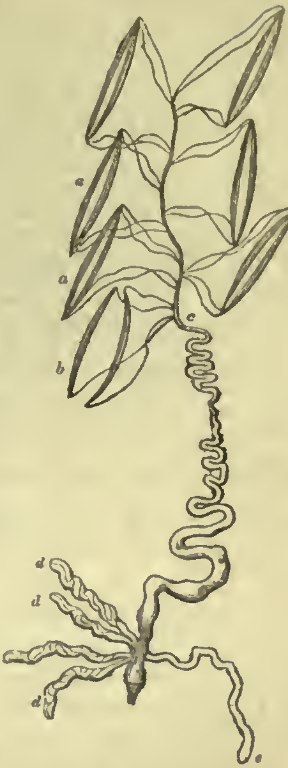
The earliest appearance of this type is found in the cavitary Entozoa (Cœlelmintha), and the sexual organs, both in the male and female of these creatures, may be regarded as exhibiting the greatest possible simplicity of structure, consisting merely of secreting tubes, which in one sex produce the seminal fluid, in the other develope the ova. The seminal organ, or testis of the male, is generally a single tube of extreme length and tenuity, winding in large folds around the alimentary canal, and occupying a large portion of the abdominal cavity; when unravelled, its length is found to be many times that of the animal; at one extremity it dwindles down to a filament of the utmost tenuity, which floats loosely in the juices of the body, whilst at the opposite end it terminates in a prolonged tubular penis, or organ of intromission, placed near the anal orifice. In the females of some species, as in *Ascaris*, the ovigerous system is composed of two tubes, each exceeding in length and tortuosity the seminal vessel of the male, and measuring in some cases upwards of six feet. These tubes, after becoming considerably increased in size so as to form a kind of receptacle for the ova which they generate, unite prior to their termination in the vulva, the aperture of which is found upon the ventral surface of the body at about one third of its length from the anterior extremity. In Strongylus the ovarian tube is single, and its orifice nearer to the mouth. In many species, as Filaria, the young are produced alive, the ova being hatched in the oviduct, a sufficient proof of internal impregnation having been accomplished.

The *Myriapoda*, in every part of their structure, form the transition from the *Annelida* to the articulated classes properly so called. They are divided by entomologists into two classes, the *Iulidæ* or *Chilognatha*, and the *Scolopendridæ* or *Chilopoda*, a division strictly in conformity with their internal structure; the former in fact represent the Annelida; like the Abranchiate division of that class, they breathe by air-sacs, communicating with spiracles seen upon the exterior of their bodies. The Scolopendræ, on the contrary, respire by tracheæ, which permeate their viscera, as in the insect classes. In the generative system of these creatures a similar relationship is evident. In *Iulus*, the generative system occupies the anterior segments of the body, the sexual apertures being found upon the rings near the cephalic extremity, whilst in Scolopendra they are placed, as in insects, near the anal orifice. As regards the internal sexual organs of Iulus, but little is known conclusively, and our own researches upon this point have not been sufficiently satisfactory to enable us to speak positively concerning them, although the result leads us to suspect that in these creatures not only are the sexual parts analogous to those of the Annelida, but that, as in many of that class, the ova are retained in cellular interstices surrounding the intestinal canal for some time prior to their expulsion.

In the Scolopendra the generative organs are more easily distinguishable, and much resemble those of insects; they are, however, exceedingly curious. In *fig.* 201 we have represented the male apparatus of the *Scolopendra morsitans*. The testes (*a, a, a*) are seven in number, and closely packed in parallel lines; each testis is composed of two parts, precisely similar to each other, which are seen separate at *b*; from each extremity of the fusiform testis arises a narrow duct, so that there are fourteen pairs of ducts arising from the fourteen secreting organs. Each of the testicular bodies is hollow internally. The ducts ultimately end in a common tube (*c*), which soon becomes enlarged and tortuous, terminating by a simple aperture near the anus. Just prior to its termination, the enlarged canal receives five accessory glands, four of which (*d, d, d, d*) are intimately united, until unravelled, as seen in the figure, while the fifth (*e*) is a simple cæcum of considerable length.

The ovarian system of the female Scolopendra is a single tube, apparently without secondary ramifications.

Fig. 201.



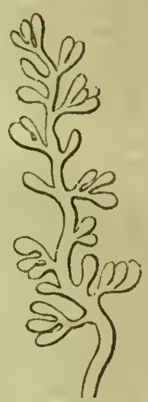
Male generative organs of the Scolopendra morsitans.

Insects.—In the numerous and diversified tribes of the insect world a great uniformity is observable in the general arrangement of the generative apparatus. The sexes are invariably separate, but while the internal organs are constantly double and symmetrically disposed on both sides of the mesial plane, the external parts which are subservient to copulation are removed to the posterior extremity of the body, and are single. Throughout the whole class the sexual system only arrives at that state of perfection which is compatible with reproduction in the perfect or imago state of the animal, although it may be detected in a rudimentary form even in the larva, being gradually more and more perfected during the developement of the pupa. The business of procreation in insects thus exclusively belonging to the perfectly formed creature, is accomplished only at the termination of their existence, and the whole tribe is remarkable from this circumstance.

The internal generative organs in male insects are described as consisting of three portions, the testes with their vasa deferentia, the vesiculæ seminales, and the canalis excretorius. The testes, or, in other words, those portions of the apparatus which are supposed to furnish the essential part of the fecundating fluid, like the rest of the glandular system, consist of cæca or utricles floating loosely in the abdominal cavity, immersed in the juices of the body, from which they derive their secretion. Nevertheless, although essentially constructed upon similar principles, the testicular cœca present a singular diversity of form in different genera, and some of the modifications are sufficiently curious, although in the present state of our knowledge it would be hopeless to attempt to explain the reason of their existence. Müller, from a comparison of the researches of various authors upon this subject, has given the following summary of the principal forms of the sperm-secreting organs, and although the catalogue of varieties might doubtless be considerably extended, those given will abundantly answer our present purpose. Beginning from the tubular vessel, which is the simplest form of the testis, he traces it through the various complications here enumerated.

1. Simple tubes not branched, but more or less convoluted and closed at one extremity.
2. Spiral tubes similarly closed, as in *Sphodrus terricola.*
3. Spiral tubes rolled up into little balls, as in *Carabus auratus, Aptinus displosor, Dytiscus,* &c.
4. Simple tubes irregularly branched, each branch vesicular near its extremity, as in *Prionus coriarius.*
5. Simple tubes, divided in a verticillate manner, each division being terminated by a capsule; *Scarabæus nasicornis,* (Swammerdam.)
6. Simple tubes, divided as the last, but each division ending in a vesicle, as in *Trichius fasciatus.*
7. Simple tubes ending in stellated capsules, the apices of which are produced into slender tubes; *Nepa cinerea,* (Swammerdam.)
8. Simple tubes giving off a series of canals, each of which is terminated by a disc-shaped capsule; *Cetonia aurata.*
9. Simple tubes, ending in flower-shaped capsules, i. e. each capsule consisting of a central vesicle, with other smaller ones placed around it, as in *Asida gigas, Œdemera calcarata, Diaperis violacea, Tenebrio obscurus, Œdemera cærulea,* &c.
10. Simple tubes, each terminated by a transverse capsule, resembling the anther of a flower, as in *Apis, Bombyx, Scaris, Calvinia,* &c.
11. Simple tubes, dividing into minute radiating utricles; *Bostrichus capucinus.*
12. Simple tubes, each terminated by a capsule, which is covered externally with innumerable little vesicles or utricles, as in *Musca asilus, Elater murinus, Blaps gigas, Telephorus fuscus.*
13. Simple tubes, ending in an elongated sacculus, to the sides of which are appended small vesicles arranged in longitudinal rows, as in *Scmblis bicaudata.*
14. Simple tubes terminating in verticillate utricles, as in *Clerus alveolarius.*
15. Simple tubes, from which arise utricles arranged like the teeth of a comb, as in *Hydrophilus piceus.*
16. Simple tubes, terminated by a simple sacculus; *Gyrinus natator.*
17. Simple tubes, terminated by a bunch of vesicles.
18. Simple tubes, dividing into minute canals, forming a kind of cauda equina; *Trichodes apiarius.*
19. Branched tubes, each branch being terminated by a vesicle, as in *Staphilinus maxillosus.* (*Fig.* 202.)
20. Tubes very much branched, some of the ramusculi ending in bunches of leaf-like utricles, others dilating into pedunculated vesicles; *Sylpha obscura.* (*Fig.* 203.)
21. Simple loculated utricles, as in *Ephemera.*

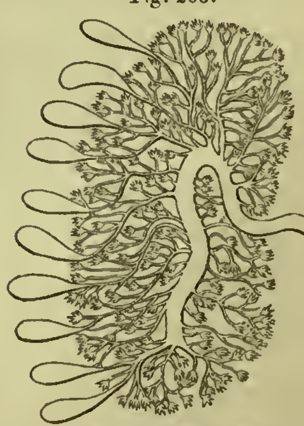
Fig. 202.



Testicle of Staphylinus maxillosus.

It is manifest from this survey that, although the secerning organs differ so much in form, the canals composing them invariably terminate in blind extremities; nor is it less obvious that the nature of the testis does not depend upon any peculiar arrangement of the seminal tubes, but upon the increase of surface obtained by the various arrangement of the vessels. Secretion, therefore, here, as in every other case, is effected by the internal surface of tubes, utricles, sacculi, &c. the same end being accomplished in some cases by means of very long simple canals, which in others is effected by smaller branches, tubes, or agglomerated vesicles.

Fig. 203.



Testicle of Silpha obscura.

Appended to the excretory ducts of the testicular organs, near their termination, is found a group of cœcal tubes, evidently destined to provide an accessory secretion; these have been named from analogy *vesiculæ seminales.* They vary much in their form, being sometimes elongated, tortuous, convoluted, or ventricose, or at others short and straight. The seminal vesicles are generally two in number, even in those Lepidoptera in which the testis is single. In some insects, as *Tenebrio molitor* and *Hydrophilus piceus,* there are four; in others, as *Dytiscus marginalis,* six; and in *Locusta* and *Blatta,* they are very numerous. In some insects these tubes are found to be of surprising length; thus in *Oryctes nasicornis* they are twenty times as long as the body, and in *Cetonia aurata* even sixty times the length of the animal. The vasa deferentia and vesiculæ seminales ultimately terminate in one common tube, the canalis excretorius, which communicates with the root of the penis; this canal is composed of muscular walls largely supplied with tracheal vessels, serving as a receptacle for the genital secretions, and no doubt is the agent by which, during coition, their expulsion is effected. The penis of insects is a hollow tube, capable of being protruded from the anal extremity of the body: its texture is generally membranous, but sometimes horny, and its shape exhibits considerable variety; it is usually cylindrical or nearly so, becoming more slender towards its termination. In *Chermis pyrus,* however, the end is enlarged; in the common *wasp* it is spoon-shaped; in *Crabro* bilobed, and in some *Vespæ* curved and bifid at its extremity. In *Musca vivipara* its apex is covered with spines; in *Tyrophaga putris* and some other Muscidæ it is spiral. The penis of Coleoptera is furnished with a bivalve sheath, destined to open the vulva of the female prior to its insertion. In some Diptera (Muscidæ) a remarkable inversion of the usual arrangement of the organs of copulation is observable; in these the females are provided with a retractile penis, whilst in the males the generative apparatus terminates by a simple aperture. During coition in this case, it is the penis of the female which is introduced into the genital opening of the male, and thus becomes the recipient of the fecundating fluid. The Dragon-flies (Libellula) are remarkable from the position which the male organ is found to occupy, being placed under the anterior part of the elongated abdomen, but in the female the sexual aperture occupies the usual situation near the anus. This arrangement accounts for the singular position which these insects assume during copulation.

In addition to the organs above enumerated as composing the male system in insects, we may notice appendages which are found in some tribes which materially assist in effecting the intercourse of the sexes: these are named *prehensores,* and serve to seize and secure the female during coitus. These holders assume a great variety of shapes, and likewise are differently disposed according to circumstances. They generally surround the aperture through which the penis is extruded, but in Libellula the mode in which the sexes embrace each other renders additional security indispensable; in this tribe, therefore, besides the anal *prehensores,* an additional pair of forceps is placed under the second abdominal segment. The prehensores are generally two in number; but in many Lepidoptera, Conopis and Libellula, three are placed around the anus. In Culex there are two pairs. In *Locusta morbillosæ* there are five, and in Formica six holders. In some tribes, as Megachilis, Agrionidas, and Locusta, they are retracted within the abdomen when not employed.

In insects the ovigerous or female generative apparatus consists likewise essentially of tubes or cœca, the arrangement of which is tolerably uniform. They may be divided into the ovaria, the oviducts, the spermotheca, or receptacle for the seminal fluid of the male, the accessory glands, and the ovipositor, which latter is, in many insects, an instrument adapted to introduce the eggs at the period of their extrusion into situations suited to their developement.

The ovaria are double throughout the whole class, each being composed of a variable number of membranous tubes arising from the oviduct. Rifferschweils considers the ovaries to be formed upon two primary types, being either *flagelliform,* that is, composed of conical tubes of equal length, which are inserted at the same place at the extremity of the oviduct, as in the *Lepidoptera,* the *Bee,* &c.; or racemose, consisting of short conical tubes, so proceeding from the primary branches as to render the ovary racemose or pinnated, such as they are in many *Neuroptera, Coleoptera,* and *Diptera.*

The number of tubes composing each ovary varies in different genera and species; sometimes there are but two, at others four, five, six, eight, or twelve, and in the more prolific insects this number is much increased; thus, in *Acrida viridissima* there are thirty, and in the hive-bee not fewer than a hundred and fifty cœca in each ovarian packet. The number of eggs will of course depend upon the number and divisions of these ovarian tubes, and thus while some insects only lay two, four, or six eggs, others will produce sixty or seventy, and some gregarious insects a much greater number: thus the hive-bee will probably give birth to many thousand young, and in the Termite ant (*Termes bellicosus*) the fecundity of the female is absolutely incalculable. This extraordinary fertility renders indispensable certain restrictions which we find imposed upon this numerous class, tending materially to limit their excessive multiplication. Thus, throughout the whole race one generation only is produced from the same insect, the business of reproduction being usually the termination of its existence; and in the most prolific tribes, namely, those which live in society, as the *Bee* and the *Termite,* one female only in each community is found to be fertile, the sexual organs of all the rest remaining in a rudimentary or undeveloped state, although capable of developement, should the destruction of the queen render such a provision for the preservation of the race indispensably necessary. (See Insecta.)

The *oviductus* or excretory canal common to the ovarian tubes of the corresponding side of the body, sometimes opens into the cloaca, the eggs escaping by the anal passage; but in other cases, having joined that of the opposite side, it terminates externally by a distinct aperture; near its extremity, however, it receives the auxiliary tubes or cœca, namely, the spermotheca and the accessory glands.

The *spermotheca* is a membranous sacculus of varying size and shape, regarded by Herold and Malpighi as a receptacle in which the seminal fluid of the male is deposited and retained,—an opinion which has been sanctioned by subsequent anatomists; it is found only in such insects as deposit their eggs in slow succession, and is presumed to be a provision for the gradual fertilization of the ova during their transit through the oviduct. It is only upon this supposition that it is possible to account for the impregnation of some insects which are employed for a long period in the business of oviposition, as is the case, for instance, with the hive-bee, in which a single coitus fertilizes all the eggs that are laid for a space of two years, amounting sometimes to twenty or thirty thousand in number; and yet, in this case, it is difficult to conceive how so small a reservoir, scarcely larger indeed than the head of a pin, can retain a sufficiency of this fluid for such a purpose, a difficulty which is scarcely lessened by admitting the hypothesis of Dr. Haighton, who refers the act of impregnation rather to some penetrating effluvium or *aura seminalis*, which the seminal liquor may emit during a long period, than to actual contact between the semen and the ova.

The auxiliary glands *(glandulæ succenturiatæ)*, which are appended to the oviduct of insects, perform an office which is by no means satisfactorily determined; the most usual supposition is that they furnish some secretion connected with the investment of the ova, either for the completion of the shell, or, as is more probably the case, for the purpose of uniting them together by a tenacious mucus into the long strings or masses in which they are not unfrequently extruded. The structure of these secerning cœca differs in different insects, but will be found to conform in most cases to one or other of the following types:—

1. Most frequently they are merely elongated tubes closed at one extremity while the other opens into the oviduct.

2. In some cases the primary cœca give off secondary branches.

3. In others, as in *Hippobosca*, they are ramified tubes terminated by blind canals.

4. In *Elater Murinus* they present a very remarkable structure, being composed of a number of triangular capsules united by canals arising from each angle until the terminal vessels are reduced to simple cœca.

The *ovipositor* is the last part of the female generative apparatus of insects which we have to notice. This singular appendage to the oviduct presents many varieties in its structure, being adapted to the introduction of the ova into certain localities either fitted for their maturation, or, as is more frequently the case, suited to the necessities of the larva after its escape from the egg; but a detailed account of the forms which this organ assumes in different tribes would necessarily be incompatible with the limits of this article, and the reader is therefore referred for further information to the article INSECTA.

Some insects are ovo-viviparous in a modified sense, and their offspring are produced in the larva or even in the pupa state, the eggs being hatched in the body of the parent, and the young matured to a certain extent before they are expelled. In such cases the oviducts unite to form a capacious matrix, in which at certain seasons the larvæ are contained either agglomerated in masses, or arranged parallel with each other in flat bands. In his state each larva is invested in a delicate membranous bag. It is remarkable that all these larvæ are carnivorous, their office being to remove putrifying flesh; hence the necessity of their being produced in such a state as immediately to commence the woik to which they are destined.

Some *Aphides*, or plant-lice, are ovo-viviparous in the early part of the year, but oviparous as winter approaches,—a provision evidently intended to secure the preservation of the embryo during the inclement season, the eggs remaining unhatched until the return of spring.

The Aphides likewise in their mode of generation furnish the physiologist with one of the most extraordinary anomalies met with in the animal kingdom. From an accurate series of observations, first instituted by Bonnet, and subsequently confirmed by the indefatigable Lyonnet, it is now received as an established fact that the females of these insects have the faculty of giving birth to young ones without having had any intercourse with the other sex. From the experiments of these naturalists it appears to have been incontestably proved that if a female Aphis at the moment of its birth be rigorously kept from communication with others of its species, it will, if supplied with proper food, give birth to a brood of young ones, and not only so, but if one of the offspring so produced be similarly treated, it likewise will prove fruitful, and so on to the fifth generation, according to Bonnet, or even still further, as Lyonnet afterwards ascertained. Bonnet supposed, in explanation of this circumstance, that the Aphides are truly androgynous, each being possessed both of ovigerous and impregnating organs; yet this supposition is incompatible with the fact, that the male insect is almost as common as the female, and that the sexes copulate in the usual manner during the termination of the summer season. The only solution of this phenomenon appears to be that one intercourse with the male suffices for the impregnation of all the females which in one season spring from the same union. But the *Aphides* are not the only examples of this curious fact, as some of the Branchiopod Crustaceans, as *Daphnia pennata*, Müll. *(Monoculus pulex, L.)* are equally capable of producing fertile females through several successive generations; nevertheless both Bonnet and Jurine observed that the female Aphides and Branchiopods that were fertile without the usual intercourse of the sexes were less fruitful than their mother, and those of the last generation less so than the first.

Arachnida.—In the Arachnida the generative system, both in the male and female, is even more simple than that of insects. The testes of the male are two in number, each being an elongated membranous bag, closed at one extremity, whilst the opposite is continuous with a slender and tortuous vas deferens, the terminations of which are indicated externally by two very small orifices distinguishable on the under surface of the abdomen near its junction with the thorax. The apertures through which the seminal fluid is discharged are totally unprovided with any apparatus of intromission or excitement; in lieu of which many genera are provided with a singular substitute, or at least with an organ supposed by some authors to be an exciting organ. This is found at the extremity of the maxillary palpus, but for a detailed account of its structure and presumed functions the reader is referred to the article Arachnida.

The female organs of the Araneidæ are equally devoid of complication. The ovaries are simple membranous bags, which occupy when distended a considerable portion of the abdomen, and are found to contain ova aggregated together in considerable numbers. From each of these ovigerous sacs a short canal leads to an aperture situated near the base of the abdomen, through which, when mature, the ova are discharged. The most remarkable circumstance observable in this form of the generative system is the complete separation which exists between the sexual organs of the two sides of the body, which, both in the male and female, not only do not communicate internally, but open upon the exterior by distinct apertures; the insulation is, in fact, so perfect that in some cases the eggs generated in the two ovaria are laid at distinct and distant periods. According to Audebert some spiders are rendered fertile for several years by one intercourse with the male.

In the Scorpions the male generative apparatus consists of a testis composed of numerous tubes united together, so as to form a series of loops, the secretion of which is discharged externally by a double penis resembling that of some reptiles, which is protruded through a valvular aperture seen upon the ventral surface of the thorax.

The female organs of the Scorpion, like those of the male, are composed of loops of tubes, uniting together at different points, and when distended with ova resembling a necklace of beads: they open by two canals, (vol. i. *fig.* 84, *c*, p. 205), at the same point which the sexual aperture of the male has been seen to occupy, each having a small cæcum or succenturiate gland appended near its termination. The eggs of Scorpions are hatched in the oviducts, and the progress of the developement of the embryo may be easily distinguished through the transparent coats of the ovum, resembling most accurately that observed by Herold in the evolution of the young spiders, figures of which are given elsewhere.*

Crustacea.—As in the Arachnida, the generative system of Crustaceans is for the most part double, the parts belonging to the two sides of the body being generally completely distinct from each other, not only internally but at their termination. In the higher orders the testes of the male and the ovaries of the other sex are found to be situated in the dorsal region of the thorax; in both cases these organs appear at first sight to be of a dense glandular structure, but, on examination, are found to be essentially composed of tubular convolutions. In both the male and the female, the excretory canals are simple tubes, which, after some convolutions, terminate in the male by prominent apertures, found upon the coxal portion of the fifth or posterior pair of true legs, and in the female by similar openings at the base of the third pair.

As in Insects, the female organs have in many genera a sacculated appendage, or copulatory pouch as it is termed, which is, in fact, analogous in function to the spermotheca of insects, serving as a reservoir in which the male semen is detained for the purpose of impregnating the eggs as they successively escape from the body. After their exclusion from the oviduct the eggs of Crustaceans are generally carried about by the female. In the *Decapoda* they are appended by a glutinous material to the false feet situated under the tail. In the *Isopoda* and others they are retained in receptacles formed by scales placed under the abdomen, whilst in the Entomostracous forms, as well as in many Epizoa approximating the Crustacea in structure, a remarkable provision is made for perfecting the eggs external to the bodies of these minute creatures, the females being provided with one or two membranous sacs appended to the posterior part of the abdomen, into which the oviducts open, and in which the ova are retained until they arrive at maturity.

Mollusca.—Several of the more perfectly organised Mollusca come likewise under this division of our subject. Such are the *Pectinibranchiate Gasteropoda*, in which the structure of the generative apparatus is sufficiently simple. In the male a large testis, composed of racemose follicles, shares with the liver the convolutions of the shell: from this the seminal secretion passes by a long and tortuous vas deferens to the extremity of the penis, which is in these creatures an extensile and very muscular organ, situated on the right side of the neck, and not unfrequently of enormous size when compared with the bulk of the animal.

The ovarium in the female *Pectinibranchiate* Gasteropods corresponds in position with the male testis; the oviduct arising from it is capacious, glandular, and convoluted, serving in some genera, as in *Turbo*, as a receptacle

* Vide Article Arachnida.

in which the eggs are frequently hatched. Near its termination the oviduct communicates with a glandular apparatus supposed to furnish the viscid envelope by means of which the eggs are generally agglutinated together.

In the *Cephalopoda* likewise, as in the Mollusca generally, the generative system is single. In this class the testis is an azygos viscus, composed of elongated branched cœca, inclosed in a membranous capsule, into which apparently the seminal fluid escapes. The vas deferens is narrow, and convoluted at first, but afterwards it enlarges and becomes muscular in its structure, serving doubtless as an instrument for the expulsion of the semen. This seminal canal receives the duct of a large glandular mass, and dilating into a pouch, ultimately terminates at the root of a rudimentary penis, apparently adapted to intromission, although it has not yet been ascertained whether actual copulation takes place, or whether the ova are fecundated after their extrusion, as is the case with fishes.

In the female *Cephalopoda* the ovarium, like the testis of the male, is azygos, and placed in the same situation. Its structure is remarkable, being a strong capsule, to the interior of which adheres a cluster of vesicular bodies denominated ovisacs, from which, at certain seasons, the ova escape. From the ovarian capsule arises the oviduct; this is in some instances a single tube, but in others divides into two canals; in either case, before its termination behind the base of the syphon, it passes through a thick laminated glandular structure, which secretes the dense coriaceous investment enclosing the ova, and the material which unites them into the racemose clusters in which they are usually found.

Vertebrata Ovipara.—In the vertebrate division of the animal kingdom the generative system presents great varieties, although from the lower to the higher orders we may distinctly trace a series of gradations which, in a physiological point of view, are of the highest interest.

In Fishes the ovaria are formed upon two distinct types. In the osseous fishes they are for the most part two large membranous sacs, which, when distended, occupy a considerable share of the abdominal cavity; these open by a short canal in the vicinity of the anus. In these capacious sacs the ova are developed: they are found united together by a delicate membrane, and attached in numerous festoons to the walls of the ovary until sufficiently mature for expulsion, when, breaking loose from their connexions, they escape into the ovarian cavity and are discharged through its excretory duct. In this case the Fallopian tubes found in other vertebrata do not exist, the oviduct being prolonged from the ovary itself in the same manner as the duct of a secreting gland, and the whole apparatus, in fact, strongly resembles what we have found in the Conchifera and other Mollusks, the great distinction consisting in the necessity which here exists for the impregnation of the ova by the agency of the male. The fecundation of the eggs is effected externally, after their expulsion, and, in fact, it is the spawn rather than the female, which forms the object of the pursuit of the male, as in most instances both sexes appear as careless concerning each other as they are of the offspring which they produce. The ova, which are incalculably numerous, are deposited in shallow water, where they may receive the influence of the solar beams, and in this situation are eagerly sought after by the males destined to make them fertile; these, urged apparently by the necessity of ridding themselves of an inconvenient load, discharge the secretion of their voluminous testes into the water, which, becoming diffused in the vicinity of the ova, is sufficient for their impregnation. In the males of this class of fishes the testes are of enormous size, equalling in bulk the ovaria of the other sex, and occupying a corresponding situation in the abdomen. Each testis is made up of a congeries of seminal canals, which, when inflated through the excretory duct, distend the whole organ. The seminal tubes are in most instances arranged parallel to each other, and are closed at one extremity while the other terminates in the common canal or vas deferens, which in every respect resembles the oviduct of the female.

This is the most usual structure of the male apparatus of fishes, but in some, as in the Shad (*Clupea Alosa*), the seminiferous tubes form innumerable ramifications and anastomoses in the substance of the testicle, easily discernible by the naked eye; and from the plexus thus produced cœcal tubes are prolonged to the surface of the organ, where they terminate by rounded extremities, giving the whole viscus, externally, a granulated appearance. (*Fig.* 204.)

A few of the osseous fishes form remarkable exceptions to the usual mode of impregnation, the ova of the female being in such fecundated prior to their expulsion by actual copulation with the male; and in some rare instances, as in the *Blennius* viviparus, the young are even produced alive, the ova being retained within the oviduct until they are hatched. In such cases the termination of the vas deferens swells into an external projection resembling a rudimentary penis, and, indeed, actually performing the office of an organ of intromission.

In the more highly organized cartilaginous fishes, and even in some osseous genera, the structure of the generative system is entirely different, commencing that type which characterizes the reproductive organs of all the other vertebrate classes. In these the ovaria are not hollow sacs which have their cavity prolonged to the exterior of the body, but the ova are developed between layers of membrane suspended in the abdomen, which are unprovided with any canal immediately communicating with them. Such are the ovaria of the Eel and the Lamprey, which are formed of numerous festoons of delicate and vascular membrane suspended in front of the spine. The ova produced between these membranous layers when mature break loose into the cavity of the abdomen, and are discharged through a simple orifice in the neighbourhood of the anus. In

Fig. 204.

Structure of the Testes in Clupea Alosa.

this arrangement we have, therefore, the simplest form of the isolated ovaria of Reptiles, Birds, and Mammalia, *in all of which the ova escape from the surface of the ovary, not from its interior;* and in the orifice through which the eggs are ultimately expelled from the abdomen we see the first rudiment of a Fallopian tube. In the Lamprey this orifice is prolonged into a short canal, and in Rays and Sharks assumes the form of an oviduct with which we shall afterwards see the Fallopian tubes of Mammals are identical; for whatever the complication which it afterwards assumes, the oviduct or Fallopian tube (for the two are the same in function) only receives the ova after their escape into the cavity of the abdomen to facilitate their ultimate expulsion. In Rays and Sharks the oviduct is double, commencing, however, by a fimbriated aperture common to both, which receives the eggs from the ovaria; each oviduct is at first narrow and membranous, having its lining membrane longitudinally plicated, but before its termination the walls suddenly increase in thickness, developing in their interior a large gland destined to furnish the horny covering which invests the eggs of these creatures. Beyond the gland the oviduct expands into a capacious bag, which communicates with the cloaca.

In this class of fishes the testis, like the ovary, is not hollow. In the Eel and Lamprey the secretion of the testis escapes from the external surface of the organ into the abdominal cavity, whence, like the eggs in the females of the same tribes, it is expelled through a simple orifice provided for its egress. In these creatures the testis and ovarium are so entirely similar that they have been confounded by authors, the secreting granules in the one sex and the ova in the other being both disposed in regular laminæ, and only differing inasmuch as the testicular granules are smaller than the mature ova.

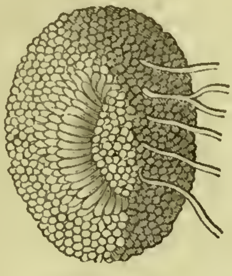
The structure of the testis in Rays and Sharks is peculiar, these animals being apparently provided with both the kinds of testis above described. Each testicle consists of two portions quite detached from each other; the one is formed of an aggregation of globular masses as large as peas, from which no excretory duct has been found to issue; the other is made up of convoluted canals, which, gradually uniting together, terminate in a capacious tube. The tuberculated mass has been described as the testis, while the convoluted tubes of the other portion were regarded as an epididymus, whence the vas deferens took its origin. There is, however, no communication between the granular part and that whence the vas deferens issues; it is, therefore, probable that the former is analogous to the solid testis of the Eel and Lamprey, pouring its secretion into the abdominal cavity, whence it is emitted through the apertures well known to communicate in these creatures between the peritoneal bag and the exterior, while the latter is identical with the usual form of the testis in osseous fishes.

The Batrachian Reptiles in their mode of generation, as well in so many other points of their economy, form the transition from the branchiferous to the pulmonary forms of the Vertebrata, and hence the study of their sexual organs is exceedingly interesting. The ovaria of these animals in their entire organization resemble those of the Lamprey. Their size, however, is much inferior, and the whole organ exhibits a more concentrated arrangement. The vascular membrane which forms each ovary is arranged in large folds on the sides of the spine, and the ova are deposited in great numbers between the lamellæ of which it consists. The oviducts are long and tortuous, each commencing by a fimbriated aperture which is found to be situated at the side of the pericardium, and so bound down in that position by its peritoneal attachments that when the interval which separates this point from the ovaria is considered, it is difficult to conceive how the ova, when dislodged from the nidus in which they were formed, can be brought into the oviduct; the only supposition, in fact, which will account for it is, that the eggs break loose into the abdominal cavity and thus make their way to the extremities of the oviducts. Before terminating in the cloaca the oviducts expand into capacious receptacles, in which the ova are collected prior to their expulsion, and glued together by a glairy secretion into masses which distend the whole of the abdomen.

The ovaria of the Salamanders resemble those of the frog, as do the oviducts, but the membranous sacs which retain the ova are less considerable than in the Anourous Batrachia: the same observations apply to the perennibranchiate orders.

The structure of the testis in frogs is almost the same as that of the same organ in the cuttle-fish. If the investing tunic be removed, the whole substance of the organ appears composed of globules; but if these are gently separated, they are found to be merely the blind terminations of as many seminal tubes which run from the centre to the circumference of the testicle. The seminiferous ducts arising from

Fig. 205.

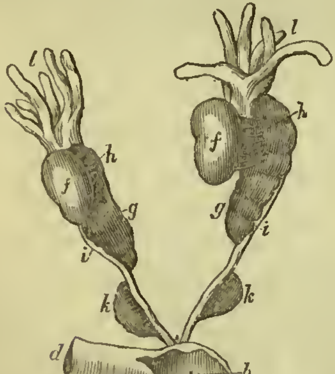


Testis of Frog.

these perforate the investing tunic of the kidney, upon which the testis is placed, and, according to Swammerdam, terminate in the ureters, which thus perform likewise the office of the vas deferens.

We have carefully repeated Swammerdam's dissection of these parts, which are represented at *fig*. 206.

Fig. 206.



Generative organs of Male Frog.

a, Cloaca; *b*, opening of genito-urinary canal; *c*, opening of bladder into cloaca; *d*, rectum; *e*, bladder; *f*, testes, that of the right side in situ; *g*, kidneys; *h*, seminiferous tubes; *i*, tube serving both as ureter and vas deferens; *k*, vesiculæ seminales; *l*, fatty appendages to the kidney.

In other Amphibia the organization of the testis is essentially the same, but the seminal cœca, owing to their greater length, are tortuous and convoluted.

The ova are impregnated in exitu by the aspersion of the seminal secretion of the male, who, firmly fixed upon the back of his mate, assists by his embraces the expulsion of the gelatinous masses in which the eggs are imbedded. No organ of intromission, therefore, is required, and the generative ducts, both in the male and female, open by simple apertures into the cloaca. Nevertheless, in a few instances internal impregnation is effected; such is the case with *Triton*, Laurent. in which, although no copulation takes place, the male fluid diffused through the surrounding water finds its way into the genitals of the female in sufficient quantities to secure fecundation. Moreover, in the Salamander *(Lacerta Salamandra)* an intromission is accomplished, the male possessing a rudimentary organ for that purpose; in this latter case the eggs are even hatched in the oviduct and the young produced in the tadpole state.

In the other reptiles the structure and arrangement of the generative organs is very similar; the same organization, in fact, exists through the whole class with slight modifications adapted to the different forms or habits of different orders.

Fig. 207.

The testes are invariably double, placed symmetrically on the two sides of the body, and attached by membranous connexions to the vertebral column. On unravelling their internal structure they are found to consist entirely of blind tubes enclosed in a membranous capsule; these seminiferous canals are much longer than in the amphibious tribes, and, consequently, present a tortuous arrangement, readily seen through the transparent covering of the testes. *(Fig.* 207.) From these tubes a variable number of efferent canals proceed, which, after remaining for a short distance enclosed in a prolongation of the tunics of the testicle, unite into a vas deferens, which is prolonged on each side to the cloaca, and there terminates at the root of the rudimentary penis.

In the higher Reptilia impregnation is always effected internally, and the males are consequently provided with an organ of excitement, differing much in form, but invariably imperforate, being merely grooved upon its surface by a channel, along which the semen flows into the cloaca of the female, but without any provision for its forcible expulsion.

This kind of penis consists entirely of the corpora cavernosa, arising by two crura, which unite intimately along the upper aspect of the organ, but leave inferiorly a deep fissure which is continued to the extremity. In the *Chelonia* this organ of excitement is very large, and terminates in a single point, but in many *Saurian* and *Ophidian* species its extremity is bifid, each division being covered with sharp and recurved spines, an arrangement which, in creatures so deficient in organs of prehension, is evidently adapted to ensure efficient copulation.

In the females of these reptiles the structure of the ovaria is interesting, gradually leading us from the folds of vascular membrane, between which the numerous eggs of the Batrachia are generated, to the form which they present in Birds. Each ovary assumes a racemose appearance, and consists of a number of ova in various states of perfection, which are loosely attached to the sides of the vertebral column by folds of peritoneum. Their structure, however, is essentially that which has been already described, and the ova, when matured between the vascular laminæ of the ovarian investments, escape, as in frogs, from the surface of these viscera by a laceration of the investing membrane, and would break loose into the abdominal cavity did not the more perfect developement of the oviducts, which here have their patulous extremities so disposed that they can grasp the ovaria during excitement, prevent such an occurrence, by receiving the germs immediately from the ruptured ovary. The oviducts are two in number, membranous at first, but glandular as they approach their termination in the cloaca. In these the eggs receive an albuminous investment which they absorb in the first portion of the canal, and prior to their expulsion are furnished with a coriaceous or calcareous covering produced from the thicker portion of the oviferous tube.

The females of the *Chelonia* have a clitoris, or rudiment of the male penis, which is in a similar manner provided with muscles for its retraction into the cloaca after extrusion. In other Reptiles the clitoris is deficient.

Birds form a remarkable exception to the usual arrangement of the internal sexual organs in oviparous vertebrata, the ovarium and oviduct being single throughout the class, an organization which is evidently in relation with that lightness and activity essential to their habits. This deviation from the usual type, however, is only apparent, arising from the non-development of the ovary and its duct on one side of the body, although both exist in a rudimentary state.

The ovarium, as in Reptiles, is racemose, consisting of ova in different stages of growth, each enclosed in a vascular membrane, which forms a pedicle attaching it to the general cluster, and is ruptured by the escape of the germ enclosed within it. The oviduct is short in comparison with that of many reptiles, and the structure of its lining membrane indicates the offices performed by different portions of the canal, being smooth and vascular in its upper portion, where the yolk receives its albuminous covering, but becoming villous and plicated where it secretes the shell.

Male birds, like reptiles, are furnished with two testes, which, from their comparatively insignificant size, do not materially interfere with the bulk of the viscera; yet even these only assume their full proportions at stated times, namely, at that period of the year when their office is required.

The testes are constantly situated in the abdominal cavity immediately behind the lungs and under the anterior extremity of the kidney: as in all cases, they consist of sperm-secreting tubes, but of such extreme tenuity that their diameter was estimated by Müller as not greater than the 0·00528 of a Parisian inch. These canals are enclosed in a proper capsule, which sends septa into the interior of the organ; they unite to form a slightly flexuous vas deferens, which accompanies the ureter of the corresponding side. The vasa deferentia terminate by separate orifices in the cloacal cavity near the root of the rudimentary penis when such exists, but even in its most perfect forms the male organ is merely an instrument serving for the conveyance of the seminal liquor along a groove seen upon its surface, there being as yet no corpus spongiosum or inclosed urethra as in the Mammiferous classes, adapted to an efficient injection of the semen into the female parts, nor any auxiliary secretions subservient to the same purpose. In the females of those genera in which the penis is most developed, a clitoris is found to occupy a similar position.

The Mammalia differ remarkably from the other vertebrate classes in the elaborate developement of the sexual organs in both sexes. The increased complication of these parts is attributable in the male to the necessity for a much more efficient intromission of the spermatic secretions during coitus, and in the female to the superadded function of gestation which characterizes the class.

On comparing the male organs of Mammifera with those of the oviparous vertebrata, several circumstances demand our notice, the most striking of which is the separation of the canals provided for excretion into two distinct systems, each terminating externally by an appropriate orifice, thus detaching entirely the digestive emunctory from the genito-urinary apparatus, which hitherto we have found to discharge themselves by one common orifice communicating with a cloacal cavity. With one interesting exception furnished by the Monotremata, such a separation exists throughout all the Mammiferous orders. Internally a still further isolation is evident in the separation of the urinary and generative organs by the provision of a urinary bladder, in which the secretion of the kidneys is stored up until its expulsion becomes necessary; the same excretory canal, however, is still common to both these systems. In the ovipara the penis was merely furrowed with a sulcus, along which the semen trickled during the union of the sexes without being impelled by any expulsive apparatus; but in the class of which we are now speaking the urethral canal becomes surrounded by vascular erectile tissue, forming a complete tube through which the seminal liquor is powerfully ejaculated during copulation by a muscular arrangement provided for that purpose; and in the last place the emission of the fecundating fluid is further provided for by the addition of secondary secretions, which from augmenting its quantity facilitates its ejection.

We shall proceed to speak of these circumstances seriatim, examining first, the structure and position of the testis and its duct; secondly, auxiliary glands which add their secretions to the seminal liquor; thirdly, the structure of the penis, and arrangement of the organs of intromission.

We have found in all the classes of vertebrata of which we have hitherto treated, that the testes consisted essentially of blind tubes. In Frogs these sperm-secreting canals were exceedingly short; in other Amphibia they become elongated and flexuous. In Reptiles their length and convolution was still further increased, until at length in Birds and Mammalia their length is so great, and their delicacy so excessive, that they are with difficulty unravelled. In all animals the terminations of the seminal tubes are found to be closed, neither is any increase or diminution perceptible in the diameter of one of these vessels throughout its whole course. Another circumstance which, with one or two exceptions, is common to all Mammals, is that they never ramify or divide.*

Mammalia differ much amongst each other as regards the length, number, convolutions, and general arrangement of these secerning vessels of the testis. In the Ass they are very delicate; of greater diameter in the *Cynocephalus* and larger Carnivora, as well as in the Hog and Rhinoceros. They are very large in the *Glires*, and in *Sciurus* their diameter reaches ·0·01453 inch (Paris), whilst in the Hedgehog they are only 0·00970 inch.

The tenuity of the walls of these seminal vessels is extreme, and scarcely applicable by the micrometer; they are united together by a most delicate tissue of capillary bloodvessels, serving to imbue them with that blood from which the semen is separated, which when secreted accumulates in the cavities of these tubes in readiness for expulsion.

The testes are very variously situated in the adult state of different mammals. Sometimes they are contained within the abdominal cavity, attached on each side of the spinal column by folds of the peritoneum, as in the ovipara; at other times they descend into the skin of the groin through the inguinal canal, and not unfrequently are contained in a scrotal pouch formed by the integument behind the pubic arch; and in the Marsupial division, which, when describing the female sexual organs, we shall find to constitute a distinct type of the generative system, they are suspended in front of the pelvis.

The excretory duct of each testis or vas deferens is formed by the junction of the seminal canals of the testis; it is at first much convoluted, forming a mass appended to the testicle, denominated the epididymus; and whatever may be the position of the testicle, it runs to discharge itself into the canal of the urethra near the commencement of that tube.

The *prostate gland* is a secreting body of peculiar structure, which, in man, embraces the neck of the bladder, and opens by ten or twelve ducts into the urethra near its commencement. It is very constant in its existence, being found in all orders of Mammalia, excepting, perhaps, the greater number of the Rodentia, the Mole, and the Hedgehog, in which it is apparently replaced by secerning organs of a widely different structure; otherwise, the internal organization of this gland is nearly the same in all animals that possess it, consisting essentially of cells, each of which is subdivided into others of extreme minuteness. From these cells the excretory ducts take their rise, and the whole organ may be readily inflated by forcing air into the canals which issue from it: the whole is enclosed in a dense fibrous capsule. In some animals, as the Elephant and Solipeds, the prostate is double or even quadruple, and in this case the centre of each portion has within it a large cavity which communicates with the smaller cells, and gives origin to the excretory tube.

Cowper's glands.—These glands in the human subject are two very small bodies situated behind the bulb of the urethra, which furnish minute canals, opening obliquely into the urino-generative canal near its posterior portion; but minute as they are in man, they are found in other creatures to be much more voluminous, not unfrequently equalling the prostate in size, and in some cases, especially in the Marsupial division, they are increased in number; thus in the Opossums and Kangaroo-rat there are four, while in the Wombat (*Phascolomys*), the Kangaroo, and others, even six are found: nevertheless in most of the Carnivora, except the Felidæ and Hyenas, and in the greater number of Ruminants, Solipeds, Amphibia, and Cetacea, they are deficient.

The internal structure of *Cowper's glands* varies. In man and many others they are composed of simple follicles; in other cases, as in *Sciurus*, the Marmot and the Hog, they consist of conical sacculi, which exhibit internally a cellular appearance. In the Beaver (*Castor Fiber*) their texture is spongy, being formed of large cells, divided by septa into smaller ones of extreme minuteness; those of the Mole are similarly constructed. In *Viverra Zibetha*, the feline tribes and the Hyena, they are made up of separate lobules; and in the Ichneumon these glands are composed of vesicles united by a common duct. In the Hedgehog (*Erinaceus Europæus*) they are found in a very singular position, being partly situated beneath the rami of the pubis and ischium, and partly beneath the skin on the inner side of the thigh, being so remote from the other glands that their existence was overlooked by Cuvier. Each gland consists of pyramidal lobules, which, by their apices, give rise to the excretory canals.

In some of the Marsupiata their minute structure resembles what is found in the Hedgehog; and each of them is surrounded by a

* In *Sciurus* they have been observed to divide dichotomously.

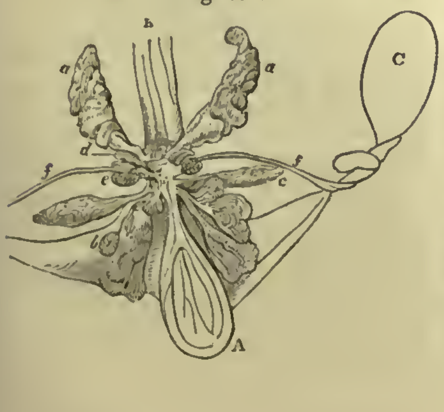
powerful muscular sheath, calculated to ensure the expulsion of the fluid which they elaborate.

The most remarkable arrangement of Cowper's glands is seen in the Ichneumon (*Herpestes Ichneumon*, Illiger): in this animal they are very large and occupy their usual position, being invested with a strong muscular coat; but their excretory ducts, instead of terminating as usual in the bulbous portion of the urethra, are prolonged beneath the penis nearly to the extremity of that organ, where they open into a cul-de-sac common to them and the canal of the urethra.

Accessory vesicles. — These are auxiliary glands, which pour their secretions into the canal of the urethra. They appear, when present, to take the place of the prostate, being only found where that organ is deficient, and accordingly, although of a totally different structure from that body, they have been called prostates by various authors. They are usually packets of membranous cœca, more or less ramified, and in the season of sexual excitement are filled with a fluid resembling that contained in the vesiculæ seminales. These organs exist in all Rodents except Squirrels, Marmots, and Hares, and also in the Hedgehog and the Mole, but have not been found in any other mammalia. They are invariably composed of intestinules or branched cœca, arranged in packets, the number of which varies much. Thus in the Mole there are five such bundles, forming a mass of ramified tubes larger than the bladder; in the Hedgehog there are four, and in *Cricetus vulgaris* and *Dasyprocta Aguti* two fasciculi.

But besides the secreting structures above enumerated as forming the ordinary appendages to the male generative system of Mammifers, additinnal ones are occasionally found, placed out of the positions in which the succenturiate glands usually exist. Thus in Solipeds a long cœcum containing a glairy fluid is placed between the insertions of the vasa deferentia, which communicates with the urethra by an appropriate orifice; and in *Cricetus* and many of the *Muridæ* the ends of the deferent canals before their termination are provided with bunches of small glandular follicles, which in the former resemble small bunches of grapes.

Fig. 208.



The annexed figure, (*fig.* 208,) representing the male generative viscera of the Rat (*Mus Rattus*) exhibits an example of the greatest complication of these parts, and will serve to illustrate the situation of the organs above described. A represents the bladder turned forwards, B the rectum, and C the testis of the left side. The succenturiate glands here found are *a*, *a*, the *vesiculæ seminales*; *b*, the anterior fasciculus of the *accessory vesicles* or anterior prostate of some authors, which on the opposite side is unravelled to display the cœca which compose it; *c*, the middle prostatic cœca; *d*, the anterior prostatic cœca. These all communicate with the urethra, and in addition to these we have on each side the racemose bunch of follicles (*e*) which is appended to the termination of the vas deferens (*f*).

Structure of the penis.—The great difference between the penis of Mammifers and that which has been described as existing in the oviparous vertebrata, consists in the inclosure of the canal of the urethra, which is no longer a simple groove formed by the junction of the *corpora cavernosa*, but becomes surrounded with a cylinder of erectile tissue usually denominated the *corpus spongiosum urethræ.* The *corpus cavernosum*, which generally forms the great bulk of the organ, arises by two crura, which are firmly attached to the rami of the ischium in the males of all placental Mammalia; and even in the *Cetacea*, where there is no pelvis, two bones placed on each side of the corpus cavernosum give a support to the penis, which is attached to them by fibrous ligaments; nevertheless, in the Marsupiata the crura of the corpus cavernosum are quite free, or only loosely attached to the ischiadic bones by the muscular sheaths in which they are enveloped. The crura of the corpora cavernosa unite to form the body of the penis, their union being generally marked by a strong septum, which more or less completely divides the organ into two lateral halves. In some animals, as in the Dog, this septum is very distinct; but in other cases, especially in many of the Plantigrade Carnivora and in most of the Pachydermatous and Cetaceous tribes such a partition is entirely wanting; in such cases the fibrous lamellæ, which arise from the dense capsule surrounding this portion of the penis, and traverse the vascular tissue which is contained in its interior, unite at a central part in a kind of cord formed by their union. In some animals the organ is supported by a bone developed in its interior: this arrangement exists in the *Quadrumana*, *Cheiroptera*, the *Plantigrade* and *Digitigrade Carnivora* (except the Hyæna), and in the *Rodentia*, also in Seals and Cetaceans. In a few instances it is so large as to form a large portion of the penis, as in Whales; in others, as in many Carnivora and Rodentia, it is extremely small, but whatever its form or size it is invariably found intimately connected with the corpus cavernosum.

The *urethra*, as in man, consists of a muscular and of a vascular portion, the former receiving the ducts of the succenturiate and seminal glands, the latter embedded in the erectile tissue of the corpus spongiosum. The muscular portion does not always join the vascular part in a straight line; but, on the contrary, in some animals, as in Ruminants generally and in the Boar, the former opens by an orifice perforated in the upper wall of the latter, at a little distance from its commencement, so that a cul-de-sac is left excavated in the bulb of the urethra or commencement of the spongy portion, in which the fluids poured into the muscular part are mixed with the secretion of Cowper's glands, which enters the sides of the excavation.

In Squirrels and Marmots a similar cul-de-sac exists, which only receives the secretion of Cowper's glands, and is continued forwards as a narrow tube surrounded by vascular tissue, beneath the urethra, as far as the middle of the penis, where the two canals unite.

The course of the urethra in the great Kangaroo *(Macropus major)* is peculiar; instead of passing, as is usually the case, beneath the corpus cavernosum, it is inclosed in a canal passing through the centre of the penis, from which it only emerges at the extremity of the glans; owing to this arrangement, the spongy investment of the canal is in this animal confounded with the vascular tissue of the *corpus cavernosum.*

In others of the Marsupiata the *corpus spongiosum*, like the cavernous body, arises by two crura, which are quite unattached, each being invested with a strong muscular sheath, and even in some placental Mammals, as the Water-rat and the Camel, rudiments of this division are distinguishable.

The *glans penis*, or extremity of the intromittent organ, presents many modifications in form and in the nature of its surface. It is frequently smooth and highly sensible, as in man, being only covered by a delicate skin; yet in other instances, as in the feline Carnivora, it is armed with stiff recurved bristles; sometimes the armature represents horny scales or strong spines, and in not a few genera we find horny serrated plates projecting from its surface; and, as though these formidable saws were insufficient, they are occasionally combined with horny prongs protruded from the extremity of the penis during its erection. These last appendages are found in various families of the Rodentia, as in Guinea-pigs and Agoutis. The limits of this article will not permit us to expatiate further on this part of our subject; we must therefore refer the reader for a description of the various forms of the penis and of the muscles belonging to that organ to the articles which treat of the Mammiferous orders individually.

The female Mammalia exhibit in their generative system a beautiful gradation of structure. They naturally divide themselves in conformity with their mode of gestation into two classes, viz. the *Ovo-vivipara* or Marsupiata, and the *Vivipara*, properly so called, comprising the placental orders.

The former division approximates in every particular to the oviparous type of structure: the ovaria are racemose, as in birds; the oviducts, which now assume the name of uteri, are still double, opening by distinct orifices into the vagina, which also is not unfrequently divided. But the great feature which distinguishes the ovo-viviparous mammals is the peculiar apparatus in which gestation is completed, the embryo being expelled from the uterus at a very early period, without ever contracting any vascular connexion with that organ, to be lodged in a marsupium or pouch connected with the abdomen of the mother, in which the nipples are contained. In this situation it becomes attached by its mouth to one of the teats, and thus derives from the mammary secretion the nourishment essential to its growth.—See Marsupiata.

In the Placental division gestation is completed within the uterine cavity by the development of a vascular mass of different construction in different classes, called the Placenta. The ovaria here gradually lose their racemose appearance, and are converted into small and solid masses, in which the ova or Graafian vesicles are evolved. The uterus, at first completely divided, as in some of the Rodentia, in which the two cornua open separately into a single vaginal canal, by degrees unites, and by a progressive coalescence attains that concentration most perfectly exhibited in the human female.

To enter more largely into details connected with the generative organs of the Mammiferous classes would needlessly swell the bulk of this article, in which our object has been to lay before the reader a connected view of the modifications met with in the reproductive system throughout the animal kingdom, and thus to connect with each other the numerous facts relating to this subject which are elsewhere more minutely recorded in this work.

For the anatomy of tho Organs of Generation in Man, see Penis, Prostate, Testis, Vesiculæ seminales.

(T. Rymer Jones.)

GENERATION (in Physiology) *generatio;* Fr. *génération;* Germ. *Zeugung;* Ital. *generazione;)* is the process by which the young of living bodies are produced, and their species continued. In common language the term is frequently confined to the mere act of union of the sexes of animals; but in general and animal physiology it is generally employed in the more extended signification given to it in the following article, viz. to denote the assemblage of all the functions of animals concerned in the formation of their young, and as synonymous, therefore, with the function of Reproduction.

In directing our attention to the mode in which the function of reproduction is effected in various classes of animals, so many striking differences present themselves, that we find it difficult if not impossible to point out any general circumstances in respect to which they all agree. Some animals, for example, are propagated by the division of their whole bodies into pieces, each of which by a peculiar change becomes an independent individual entering upon a new life. Others arise like the parts of a tree by buds which remain for a time attached to the parent stem, and being afterwards separated from it assume an independent existence. A third class of animals have the power of forming and throwing off from their bodies a small portion of organized matter, which, though at the time of its separation from the parent, not resembling it either in form or organization, is yet possessed of the power of living for itself, and, after passing through a variety of successive changes of growth and evolution, of at last acquiring the exact semblance of the parent by which it was produced. In a fourth and last class, comprehending much the greatest number of animals, the function of reproduction involves a greater complication of vital processes than in the three other classes above alluded to. The union of two individuals of different sex becomes necessary, and the young owe their origin to the evolution of a more complex organized structure termed the egg, which is formed in and separated from the body of the female parent, and is the product of the union of the male and female of all animals in which the distinction of sex exists. The ovum or egg is most familiarly known to us in the eggs of domestic birds, to which the product of sexual union in all animals belonging to this fourth class bears a strict analogy in every essential particular.

It may be stated as a general fact, that the reproductive function involves a greater number of vital processes in the higher and more complicated than in the lower and simpler kinds of animals. Yet there are exceptions to this rule, and we do not always trace a correspondence between the degree of complication of the generative process of any animal and the place which that animal holds in the scale of being; for there are some tribes of animals which are propagated in more than one of the ways above mentioned, and there are some, to which, from the simplicity of their other functions and organization, a low place in the zoological scale has been assigned, and which nevertheless resemble the higher animals in respect to their mode of reproduction.

A very superficial view, however, of the varieties of the form obvious in the reproductive process of different animals demonstrates the importance of the reproductive functions in the economy of life, as it points out the intimate relation which these functions bear to the habits, mode of life, and organization of each animal, and shews the infinite care and foresight with which nature, in every variety of circumstance, has provided for the regular and undisturbed performance of those acts by which the species of organized beings are continued from age to age, in an undeviating succession of generations. These facts also fully justify our regarding, along with Cuvier, the reproductive function as constituting one of the fundamental divisions in a classification of the processes of the animal economy.

While, therefore, the principal object of the present article is to describe the process of generation in Man and the higher Vertebrated animals, it will be necessary and proper for us to allude also to the reproductive function as it is performed in all the various members of the animal series; for in this, as in other departments of Physiology, the more complicated forms of the process derive much illustration from the study of the more simple, and we may hope thus more fully to point out the general importance of the functions now under consideration.

We purpose to follow an arrangement adapted chiefly to the consideration of Human Generation. In all the animals in which distinction of sex subsists, the male and female organs subservient to reproduction must co-operate for the completion of the generative process; and in the greater number of the more perfect animals, as also in Man, the two kinds of sexual organs being placed on separate individuals of the same species, the concurrence of both these individuals, or of both male and female parents, is necessary for the formation of the fruitful products from which the offspring proceeds. The circumstances, then, which give rise to the union of the sexes, and the phenomena which accompany that union, form some of the topics of the present article. The product of fruitful sexual union in all animals is one or more eggs, from each of which, under the influence of certain favourable circumstances, different in different tribes, the young animal is produced by an intricate process of vital growth. The greater part of the substance composing the egg is furnished by the female parent: but this egg of the female would be wholly barren, or would not undergo any of those changes by which the young animal is formed, unless it received in some way or other the influence of the product of the generative organs of the male; and the egg formed by the female may be regarded as imperfect until the change now alluded to has been effected in it. It is then said to be fecundated or rendered fruitful by the semen of the male. The mode of formation of the egg and seminal matter, the mode of their separation from the place of their formation, the structure and properties of each of these products, the manner in which they are brought together, the influence which they exert upon one another, and the consequent result in the production of the young, constitute the principal remaining topics which fall to be discussed by us at present. In this article our attention must chiefly be confined to such operations or functions of the male and female parents as are preliminary to or necessary for the formation of a ripe and fruitful ovum,—that is, an egg capable of giving birth to a new animal the same as either of its parents, when placed in those circumstances which are favourable to its evolution. It is not intended to speak in this place of the changes of the ovum itself in which the formation of the young animal consists: the consideration of these is reserved for the article Ovum.

Before treating in detail of Human Generation, we introduce some remarks on the nature of the reproductive function in general, and a sketch of the principal varieties of the forms it assumes in different classes of animals.

I. THE FUNCTION OF REPRODUCTION GENERALLY CONSIDERED.

1. *Introductory remarks.*—The process by which the young of animals are formed has, from the earliest periods of science, always been an object of peculiar interest and attention to inquirers into the functions of animated beings. Scientific men as well as the more ignorant have looked with a mixed feeling of wonder and admiration upon the intricate changes which precede and accompany the first appearance and gradual formation of all the different textures and organs belonging to animal bodies. The gradual construction or building up of the whole frame-work of the animal body, and its various important organs,—the formation of the nerves and brain that feel and think, the muscles that move, the blood with its containing organs that propel it and apply it to the purposes of nutrition,—the appearance step by step of all the remarkable structures out of which the different organs are formed,—the development of the appropriate vital powers of each of them,—the comparatively simple structure of the substance of the egg, and the impossibility of detecting in it by the most exact scrutiny, before the commencement of the formative process, any appearance of the parts afterwards arising there—have naturally led physiologists to inquire minutely into the properties of that egg, and the process by which so remarkable a production is generated. The ascertained fact that the egg possesses vital powers belonging to itself, and that its life is in a great measure independent of that of its parents,—that the vital powers of the egg are capable of being called into operation and influenced in many animals by determinate external physical agents, such as heat, air, light, and electricity,—the obscure nature of the influence exerted by the male upon the female product in the perfecting of the egg,—the preservation of the specific distinctions of animals from one generation to another in undeviating succession,—the transmission of occasional varieties or peculiarities of form and of hereditary resemblances from parent to offspring,—and, in fine, the important relation which the generative process bears to other functions of the animal economy, are among the more prominent circumstances which, while they throw a certain air of mystery over the functions of reproduction, have at the same time given them an interest in the eyes of the physiologist, which increases as his acquaintance with their details becomes more extended.

It is a common remark that generation is at once the most obscure and the most wonderful of the processes occurring in organized bodies. Hence, perhaps, it has happened that, while there are few subjects of physiological inquiry upon which so many authors have written, there is none upon which so many have freely indulged their fancies in framing unwarranted hypotheses and absurd speculations. This is an error which belongs to the early stage of investigation in most branches of natural knowledge, and which in the instance before us may be traced very directly to the comparative want of correct information which for a long time prevailed regarding the phenomena of the generative processes. For, if we except the remarkable investigations of Aristotle, Fabricius, Harvey, Malpighi, Wolff, and Haller, it may be said that it is only towards the conclusion of the last or the commencement of the present century that our subject has been studied with that accuracy of observation and freedom from hypothesis which are calculated to insure steady progress in the attainment of physical knowledge. When extended observation shall have rendered more familiar to the physiologist the different steps of the intricate processes by which an egg is formed and the young animal is developed from it, although he may not cease to admire the changes in which these processes consist, the feeling of wonder will be in a great measure lost to him; and he will not be inclined to look upon the gradual formation and growth of the child as more extraordinary than the constant and regular nutrition of the fully formed body. Are the inscrutable workings of the brain and nerves, the constant energy of the beating heart, the unwearied and powerful exertions of the voluntary muscles, the secretion of different fluids from the glands, and the regular supply of suitable organic materials to all parts of the body, so as to maintain the healthy structure of each and fit them for the performance of their respective offices, less remarkable and astonishing, or, in other words, less far removed from our accurate knowledge and comprehension, than the first origin and early growth of the same organs at a time when both their structure and functions are greatly more simple? Certainly not. These remarkable changes are all objects of wonder to the vulgar in proportion as they are unknown. The man of science regards the ultimate cause of all vital processes as equally inexplicable, and, aware of the bounds set to his knowledge of life, limits his inquiries concerning its various processes to the investigation of their phenomena.

At the same time it may be allowed that the fact that the mere contact of the male seminal fluid seems to awaken and call forth from the otherwise inanimate egg all those vital powers which are afterwards concerned in sustaining the life of the new being, is one of the most striking and simple examples of vital agency, and one less suited than most others to be observed or experimentally investigated. The theoretical physiologist, in contemplating this fact, is apt to conceive that here he has arrived at one of the primitive causes or foundations of animal life, and that he has here obtained the key to many of its hidden wonders: he passes the limits which ought to bound his inquiries, and in most instances invents fanciful and curious speculations rather than makes sound generalizations of ascertained facts.

2. *Theories of generation.*—The vast number of the theories of generation renders it impossible to mention even the more important in this place. Drelincourt, an author of the last century, brought together so many as two hundred and sixty-two "groundless hypotheses" concerning generation from the writings of his predecessors, "and nothing is more certain," quaintly remarks Blumenbach, "than that Drelincourt's own theory formed the two hundred and sixty-third."*

Of these theories two principal classes may be distinguished, according as they more directly relate, 1st, to the action of the parent organs, or 2d, to the changes in the egg belonging to the formation of the new animal. Of the first of these classes of theories Haller made three divisions, according as the offspring is supposed to proceed, 1st, exclusively from the organs of the male parent, 2d, entirely from those of the female, or 3d, from the union of the male and female products. The second class of these theories, that, viz. which relates more particularly to the formation of the new animal, may be arranged under two heads, according as the new animal is supposed, 1st, to be newly formed from amorphous materials at the time when it makes its appearance in the egg, or 2d, to have its parts rendered visible, by their being expanded, unfolded, or evolved from a previously existing though invisible condition in the germ.

The greater number of the older theories of generation may then be brought under one or other of the above-mentioned divisions, viz. the theory of the Ovists, of the Spermatists, that of Combination, Evolution or Epigenesis.

According to the first-mentioned of these hypotheses, or that of the Ovists, the female parent is held to afford all the materials necessary for the formation of the offspring, the male doing no more than awakening the formative powers possessed by, and lying dormant in, the female product. This was the theory of Pythagoras, adopted in a modified form by Aristotle; and we shall afterwards see that it resembles most closely the prevailing opinion of more modern times. The terms, however, in which some of the older authors expressed this theory are very vague, as, for example, in the notion that the embryo or new product "is formed from the menstrual blood of the female, assisted by a sort of moisture descending from the brain during sexual union."

According to the second theory, or that of the Spermatists, among the early supporters of which Galen may be reckoned, it was supposed that the male semen alone furnished all the vital parts of the new animal, the female organs merely affording the offspring a fit place and suitable materials for its nourishment.

* See Blumenbach über den Bildungstrieb, 12mo. Gotting. 1791. Anglice by A. Crichton: An Essay on Generation, 12mo. Lond. 1792.

Immediately upon the discovery of the seminal animalcules, these minute moving particles were regarded by some as the rudiments of the new animal. They were said to be miniature representations of men, and were styled homunculi, one author going so far as to delineate in the seminal animalcule the body, limbs, features, and all the parts of the grown human body. The microscopic animalcules were held by others to be of different sexes, to copulate, and thus to engender male and female offspring; and the celebrated Leeuwenhoek, who was among the first to observe these animalcules, described minutely the manner in which they gained the interior of the egg, and held that after their entrance they were retained there by a valvular apparatus.

The theory of Syngenesis or Combination seems to have been applied principally to the explanation of reproduction of quadrupeds and man, the existence and nature of the ova of which were involved in doubt. This hypothesis consists in the supposition that male and female parents both furnish simultaneously some semen or product; that these products, after sexual union, combine with one another in the uterus, and thus give rise to the egg or structure from which the fœtus is formed. In connexion with this theory we may also mention that of Metamorphosis, according to which a formative substance is held to exist, but is allowed to change its form in order to be converted into the new being; as also the notion of Buffon that organic molecules universally pervade plants and animals, that these are all endowed with productive powers, that a certain number are employed in the construction of the textures of organized bodies, and that in the process of generation the superabundant quantity of them proceeds to the sexual organs and there constitutes the rudiments of the offspring.

The theories of generation proposed before the commencement of the seventeenth century are either unsatisfactory or erroneous from the entire want of accurate knowledge prevailing before that time regarding the relation of the egg to reproduction. The conversion of one animal into another, constituting equivocal or spontaneous generations, was very generally believed in; and the process of the formation of the egg was equally ill understood in the lower and higher classes of animals. It was in the course of the seventeenth century that the labours, first of Harvey, and afterwards of Swammerdam, Redi, Malpighi, De Graaf, and Vallisneri, gave rise to greater precision of knowledge and opinions regarding this subject, and finally established the Harveyan dictum, "omne vivum ex ovo," which may be regarded as the starting-point or basis of modern researches.

The theories of generation seem after the period of Harvey to have changed somewhat their object, and to have been directed more exclusively to the explanation of the formative process, or the manner in which the parts of the fœtus are first formed in the egg and afterwards attain their ultimate structure and configuration.

It was then that the foundation was laid for the discussion between Epigenesis and Evolution, the two theories of generation which have more recently occupied the attention of men of science, and which, as has already been remarked, relate principally to the nature of the formative process. Harvey and Malpighi may be regarded as the first who endeavoured, from the observation of facts, to establish the general law of Epigenesis as opposed to the older views of Preformation entertained by the Ovists or Spermatists; but it was not till near the middle of the last century that these opinions were opposed to one another in a decidedly controversial manner.

At that time Caspar Frederick Wolff* supported the system of Epigenesis by a reference to observations on the minute changes of the egg of the fowl during the early stages of formation of the chick, while Haller and Bonnet advocated the opposite opinion of Evolution.

Wolff and those who followed his system held that no appearance of the new animal is to be found in the perfect impregnated egg before the commencement of incubation, but that when the formative process is established by the influence of heat, air, and other circumstances necessary to induce it, the parts of the fœtus are gradually put together or built up by the apposition of their constituent molecules. Haller† referred both to his own observations on the chick and to a variety of collateral arguments in support of the system of Evolution, holding that when the fœtus makes its appearance in the egg, it does so merely in consequence of the enlargement or evolution of its parts which pre-exist, though in an invisible condition, in the egg. Bonnet‡ carried this theory further than any one else, but trusting mainly to the observations of Haller on the formation of the fœtus, he supported his overdrawn views on highly hypothetical reasoning. Bonnet, in what is termed the theory of Emboitement, held not only that the whole of the parts of the fœtus pre-exist in the egg before the time of their appearance, but also that the germs of all the animals which have been or are to be born pre-exist from the beginning in the ovaries of the female; that the genital organs of the first parents of any species, therefore, contain the *germs* of all their posterity; that these germs lie dormant in their abode until one or more are aroused by the exciting influence of the male; and that consequently there is not in nature the new formation of any animal.

We shall have occasion to shew in the article Ovum that the most recent researches concerning the mode of formation of the fœtus in birds, quadrupeds, and other animals, and more particularly the microscopic observations of Meckel, Pander, Baer, and Rathké,* have shewn the theory of Epigenesis or superformation of parts to be much more consistent with what is known from observation than the theory of Evolution. In modern writings, however, the term Development is, without reference to theory, employed to denote the mode of growth of the fœtus more frequently than any other.

We would further remark in relation to our present subject that various names have at different times been given by authors generalizing the phenomena of development to the powers supposed to operate in the formation of the young; as, for example, the *Anima vegetativa*, *Nisus formativus*, *Vis plastica*, *Vis essentialis*, expansive, resisting, and vegetative forces. These terms can be considered as little else than general expressions of the fact that the fœtus is formed and grows in the egg, and are not more satisfactory explanations of the cause of its formation than the hypothesis of organic affinity is of the process of assimilation in the adult animal. As the knowledge of minute anatomy and physiology has increased, and the accurate observation of the process of developement has been more extended, the number of such hypotheses has gradually diminished.

Thus the somewhat vague discussion as to the relative probability of Epigenesis and Evolution has led to the laborious and accurate investigation of the various steps of the formative process or developement of the fœtus, and the conjectures as to the forces or causes which give rise to the growth of the new animal have fallen into comparative neglect; the erroneous notions respecting the source of the germs of male or female offsprings from one or other ovary or testicle have been replaced by a more satisfactory examination of the mode of developement of the sexual organs in the early stages of their advancement; and the inquiry as to the share taken by one or other parent in the process of generation has been pursued in more modern times by the attentive investigation of the functions of the male and female organs of reproduction, upon the same principles that guide the physiologist in his attempts to explain any other class of functions of the economy.

Recent writings on our subject are not, however, altogether free from vague hypotheses of the same nature as the older theories of generation above mentioned. The mechanical explanation of fecundation by the entrance of the seminal animalcule into the egg has been revived by one author; a second considers all the changes of development as under the influence of electro-magnetic currents; and a third explains the same changes by attributing them to a spontaneous motive power and organic affinitive properties of the molecules of the ovum.

It has been well remarked by Professor

* After these observers may be mentioned Serres, Prevost and Dumas, Dutrochet, Rolando, Purkinje and Valentin, Coste, and others, as contributing materially to the knowledge of this subject.

Burdach that the generative function, comprising the production of a fruitful egg and the formation of the young animal from it, are natural phenomena not more secret in their essence than others occurring in organized bodies, and which, therefore, ought to be investigated by obtaining a knowledge of the conditions in which they take place, and of the operations and changes in which they consist.

The illustrious Harvey in his 51st Exercitation expresses himself thus decidedly a supporter of the theory of Epigenesis,—" it is plain that the chicken is built up by Epigenesis or the additament of parts budding one out of another;" but he does not admit that separate powers, such as the "alterative or immutative, formative, attractive, retentive, digestive, and expulsive faculties, or those of apposition, agglutination, and assimilative nutrition described by Fabricius," can be distinguished in the production of the chicken. He thus limits our knowledge of the subject in the 54th Exercitation: " But as in the greater world we say *Jovis omnia plena*, all things are full of the Deity, so also in the little edifice of a chicken, and all its actions and operations, *digitus Dei*, the finger of God or the God of nature doth reveale himself." " A more sublime and diviner artificer (than Man is) seems to make and preserve man; and a nobler agent than a cock doth produce a chicken out of the egge. For we acknowledge our omnipotent God and most high Creator to be every where present in the structure of all creatures living, and to point himself out by his workes; whose instruments the cock and hen are in the generation of the chicken. For it is most apparent, that in the generation of the chicken out of the egge, all things are set up and formed, with a most singular providence, divine wisdom, and an admirable and incomprehensible artifice." " Nor can these attributes appertain to any but to the Omnipotent Maker of all things, under what name soever we cloud him; whether it be the *mens divina*, the divine mind with Aristotle, or *anima mundi*, the soul of the universe with Plato; or with others *natura naturans*, Nature of nature herself; or else Saturnus or Jupiter with the heathen, or rather as befits us, the Creatour and Father of all things in heaven and earth; upon whom all animals and their births depend: and at whose beck or mandat, all things are created and begotten."*

3. *Spontaneous generation of animals.*—In this introductory view of the function of generation, it may be proper shortly to inquire whether a regular affiliation from parent to offspring be an indispensable condition for the continuation of the species of every kind of animal,—a question somewhat speculative in its nature, but of considerable interest in relation to some of the general doctrines of physiology, as well as closely connected with our present subject. It has already been stated in general terms that origin by generation and the power of reproduction are characteristics belonging to all organized bodies whether of the vegetable or animal kingdoms. The existence of life implies the sequence of decay and death, or in other words, those varied operations and changes which together constitute the living state continue to occur in each organized body for a limited period only: they sooner or later undergo a gradual alteration, are less regularly performed, and ultimately entirely cease in death. But although every individual belonging to the organized kingdom of nature is necessarily subject to death, the species of each plant and animal never becomes extinct, but is continued upon earth in an undeviating succession of generations. The origin of a mineral, on the other hand, is wholly independent of any pre-existing body of its own kind; and, in the mineral kingdom, all those bodies are held to belong to the same species which agree in external form, physical properties, and chemical constitution. The mineral owes its first origin, as its subsequent increase, to the simple union of its component particles; but the successive generations of every species of organized bodies constitute an uninterrupted chain extending from the time of their first creation, and in which the formation of every new link that is added depends on its temporary attachment to that which preceded it. So fixed, indeed, is the law of continued reproduction of organized bodies, that many naturalists have, in the absence of more definite distinctive characters, adopted the circumstance of reproduction as the only certain means of determining what individuals ought to be regarded as belonging to one species.

While most naturalists readily admit the correctness of the above-mentioned general law, some are inclined to hold that it is not universally applicable, and that there are exceptions to it both in the vegetable and animal kingdoms of organized nature. It is among the simplest kinds of plants and animals that these exceptions are conceived to exist, and more particularly among cryptogamic plants of the nature of mould, small microscopic animalcules formed in infusions of decaying organic matters, and the Entozoa which live in the bodies of other animals. These living productions are supposed by some to arise independently of others of the same kind, nearly in the manner of minerals, by the aggregation of their component molecules, with this difference, that these molecules are of an organic kind. This sort of production without parents has been termed Spontaneous Generation. It has also received at different times various other appellations, such as equivocal, doubtful, primitive, original, and heterogeneous generation.

At one time it was a common belief among scientific men as well as the vulgar that many animals might be produced by spontaneous generation, as for example, the numerous insects or their larvæ infesting putrid substances, various kinds of worms (Annelida), and Molluscous animals, as well as even

* Anatomical Exercitations concerning the Generation of Living Creatures. London, 1653, p. 310 et seq.

some fishes and reptiles; but the increased knowledge of the structure and habits of these animals, and in particular the observations of Redi* and others, demonstrated the error of this opinion, and shewed it to have arisen merely from the circumstance of their real mode of generation not having been observed. After this many felt inclined to reject entirely the occurrence of spontaneous generation in any class of organized beings, and at the present day the question cannot be regarded as by any means entirely set at rest. From the nature of the observations and experiments required in an investigation of this nature, there is almost an impossibility of arriving at a perfectly satisfactory conclusion; but so far as the facts at present entitle us to form an opinion, it may be stated that spontaneous generation, if it occurs, takes place in the simplest kinds of organized beings only; that in most of them it is only occasional; and that therefore this form of generation is to be looked upon as a rare exception to the usual and almost universal mode of reproduction by the separation of a living portion from a parent body.

Minute animalcules, the greater number of which are so small as to be visible only with the microscope, are formed in the infusions of almost all kinds of organic matter, such as starch, sugar, gum, seeds, and different animal substances, when these infusions enter into putrefaction. The kinds of these animalcules are very numerous, and the circumstances which seem to determine the formation of one or other sort are infinitely varied. Thus the nature of the substance suspended in the infusion; and, in the same infusions, the degree of heat, the extent of the decomposition, the quantity and nature of the air admitted, the rapidity with which it is renewed, and the strength of the infusion or the relative proportion of water and organic matter in it, all appear to exert a certain influence in determining the formation of one or other of the kinds of animalcule.

Two suppositions may be entertained regarding the first origin of Infusoria; the one, that of their spontaneous generation; the other, that of their developement or evolution from some pre-existing egg or germ. Those who disbelieve in the first and adopt the second hypothesis hold that the ova of the animalcules exist in the substances of the infusions, or are floating every where in the atmospheric air; that these ova become developed in that species of infusion only which is suited to serve as their proper nidus or matrix; and that all the varieties of animalculæ in different infusions depend upon the infusions being suited, from their composition or the external agencies to which they are subjected, to cause the development of different sorts of ova. The supporters of the hypothesis of Spontaneous Generation hold, on the other hand, that certain changes of composition of the organic molecules in the infusions, in whatever way induced, are the sole cause of the formation of one or other kind of animalcule.

Spallanzani,* one of the most strenuous opponents of the hypothesis of spontaneous generation, shewed by very accurate experiments that no animalcules are formed when the access of air to the infusion is completely prevented, as for example, when it is covered with a little oil, or the vessel containing it is closely sealed; and he thence concluded that the germs of the animalcules must exist in the atmosphere; but the supporters of the hypothesis consider themselves as entitled to hold that no production of animalcules takes place in these circumstances, merely because the exclusion of the air has the effect of preventing that species of decomposition which they regard as necessary for the formation of the Infusoria.

It is stated by some experimenters that animalcules are produced when the infusions are exposed to hydrogen and nitrogen gases, or to atmospheric air artificially prepared; in which it is held that there can be no living ova of animalcules. Again, it appears from numerous experiments, that when the infusions have been exposed to a boiling temperature, which is generally believed to have the effect of destroying the life of all organized productions, the quantity of animalcules formed is not diminished. Some air, it has already been stated, must always be present; but so far as we are aware, the experiments on this point have not been performed in such a manner as to ascertain, whether or not, when an infusion is allowed to come in contact with a considerable portion of confined air, and the whole apparatus is exposed to a temperature above that of boiling water, the production of Infusoria may still take place; and we are consequently obliged, in the absence of more direct experiment, to have recourse to analogical reasoning.

The following considerations appear to us to throw the balance of evidence in favour of the spontaneous production of Infusoria, mould, and the like.

Firstly, those organic matters which are most soluble in water, and at the same time most prone to decomposition, give rise to the greatest quantity of animalcules or cryptogamic plants.

Secondly, the nature of the animalcule or vegetable production bears a constant relation to the state of the infusion, so that, in similar circumstances, the same are always produced without this being influenced by the atmosphere. There seems also to be a certain progressive advance in the productive powers of the infusion, for at the first the animalcules are only of the smallest kinds or Monades, and afterwards they become gradually larger and more complicated in their structure; after a time the production ceases, although the materials are by no means exhausted. When the quantity of water is very small and the organic matter abundant, the production is usually of a vegetable nature; when there is much water, animalcules are more frequently produced.

Thirdly, on the supposition that infusory animalcules are developed from ova, it is neces-

* De Generatione Insectorum. Amst. 1686.

* Tracts on the Nature of Animals and Vegetables. Edin. 1799, (transl.)

sary to conclude, from the experiments already referred to, that these ova are in some instances derived from the atmosphere, but yet the number of Infusoria is by no means in direct proportion with the quantity of air. We are also reduced to the necessity of holding that every portion of the atmospheric air is equally impregnated with infusorial germs or ova, and that these bodies may remain for years dissolved, as it were, or invisibly suspended in the atmosphere, and in a perfectly dry state—a supposition contrary to analogy, and not fully warranted by the fact that Vibriones may be resuscitated by means of moisture after they have been kept in a dry state for long periods.

Fourthly, it may be remarked that the existence of ova, as belonging to many of the Infusoria, is entirely hypothetical, since most of these animals are known, when once formed, to propagate by other means, as by the division of their whole bodies or by budding.

The production of infusorial animalcules from solutions of granite, silex, &c. recently described by Mr. Crosse, we have no hesitation in pronouncing to be either a mistake, or the result of changes occurring in admixed particles of organic matter.

The Entozoa, or that class of animals which live only in the bodies of others, afford proofs of spontaneous generation still more convincing than those already mentioned. These remarkable animal productions are capable of existing no where but in the bodies of those animals which they naturally inhabit: they live either loose or attached, within cavities or imbedded in the substance of the textures; sometimes in places, such as the alimentary canal or respiratory passages, to which the external air has access, and at other times in close cavities of the body, into which there is no opening from without, such as the chambers of the eye, the serous sacs, cysts, and other cavities, in the parenchyma of organs, the bloodvessels, &c. Entozoa do not live for any length of time after being discharged from the natural places of their abode; and they survive a very short time only after the death of the animals in which they live.

If Entozoa are not admitted to be the product of spontaneous generation, in order to account for their origin, it becomes necessary to suppose either that these creatures themselves or their ova pass directly from one animal to another, or that they are introduced through the medium of air or water. Upon the first supposition, carnivorous animals ought to be affected with entozoa, at least in greatest quantity, if not in some instances exclusively; and the entozoa infesting any particular animal ought to be of the same kind as those which exist in the animal serving it for food. But such is by no means the case. Herbivorous as well as carnivorous animals have entozoa, and in no less quantity, and each animal is the abode of its own peculiar kind. The same entozoa infest the same animals in all localities and climates; thus all the human entozoa, with the exception of the Dracunculus or Guinea-worm, which is an external parasite rather than a true entozoon, are the same in all races of men. Neither do we recognise any similarity between the entozoa infesting animals of a particular district and allied tribes of animals living in the neighbouring waters.

In adopting the second supposition that the eggs or germs of Entozoa may gain the bodies of animals by circuitous routes, we are met by many difficulties in addition to those already stated in reference to a similar explanation of the origin of Infusoria. Many Entozoa reside only in particular organs of the body, and in the very interior of these organs, as the human Cysticercus cellulosus in the choroid plexus of the brain, in the substance of the brain itself, in the chambers of the eye, &c. so that it is necessary to suppose the ova of Entozoa to have been introduced into the circulation, carried through the smallest bloodvessels, and deposited in the places in which they are developed. Animals living in the same situations and feeding on the same substances have different kinds of Entozoa. The ova of some of the Entozoa, as for example, those of the common round worm, (Ascaris lumbricoides,) are so large that they could not pass through the largest even of the capillary bloodvessels: the ova are so heavy that they could not be transmitted through the atmosphere; and the supposition of the passage of the ova from parent to offspring is opposed by the mechanical difficulty of the transmission, as well as by the facts that parent and child are not always affected with the same kinds of worms, and that though the complaint of worms may be said to run in families, yet many escape, and one or more generations in the hereditary succession are frequently exempt from it. Entozoa have been observed in the fœtus of animals, and supposing them to be introduced from without, it would be necessary to hold that the entozoa themselves or their ova have passed directly from the mother to the child in the uterus, or to have traversed a route through which the globules of the blood are not transmitted.

Some of the Entozoa, we may further remark, when once formed, are viviparous or bear their young alive; and with regard to these kinds it would be necessary to suppose that they may arise by invisible ova or germs as well as propagate in the viviparous mode.

These facts appear to us to speak strongly in favour of the occasional occurrence of spontaneous generation,—"a doctrine which, had it not been applied in many instances where it was manifestly untrue, would have met with less ridicule and a more just appreciation than it has usually obtained." The epithet "spontaneous," which we have retained as the most common, is equally inappropriate as applied to this or to any other of the processes of nature; and the analogy of by far the greater number of plants and animals militates against the probability of the hypothesis; but it must at the same time be held in mind that the organized bodies in which spontaneous production has been said to occur differ widely in their general structure and functions from those which are reproduced by means of ova; and we are scarcely entitled to reject the hypothesis of their spontaneous generation, merely on the ground that, in this respect, they do not agree with the rest of the animal kingdom. Harvey even, who established the proposition *omne vivum ex ovo*, seems yet to have acknowledged the necessity of admitting some difference between the more ordinary form of generation by means of an egg and that which he called of the spontaneous kind.*

In conclusion, we may remark, that while we feel inclined to admit the existence of spontaneous generation among some species of cryptogamic plants, infusorial animalcules, and entozoa, it must be held in recollection that many of these productions, after their first origin, propagate their species as parents,—that the so-called spontaneous kind of generation is to be looked upon as no more than an exception to the general law of reproduction,—and that therefore extreme caution is necessary in admitting any organized body to be the product of spontaneous generation upon the mere negative evidence of the absence of its seeds or ova.

II. Sketch of the principal forms of the reproductive function in different animals.

Before proceeding to detail the different steps of Human Generation, which forms the more immediate subject of consideration in this article, we shall endeavour to present a short preliminary sketch of the various forms which the reproductive function assumes in different classes of animals.

Reproduction may be divided into non-sexual and sexual, according as the whole process is accomplished by one class of organs in a single individual, or by the concurrence of two different kinds of organs placed either upon one or upon two separate individuals of the same species; the first form occurring among the simplest kinds of animals only, the second belonging to all the vertebrated and the higher classes of invertebrated animals.

1. *Non-sexual reproduction.*—Of the non-sexual mode of reproduction three principal kinds may be distinguished, viz. first, by division; second, by attached buds; and third, by separated gemmæ.

Fissiparous generation.—The most common form of the fissiparous generation, as the first of these varieties has been called, is met with in some of the simpler Infusoria; but it also occurs occasionally in animals higher in the scale. It consists essentially in the division of the parent animal body into a certain number of subordinate masses, each of which, being endowed with independent life, becomes a new individual similar to that of which it originally formed a part. In some of the Infusoria in which the process of subdivision has been minutely observed, fissures are seen to form in the sides of the animal which is about to be reproduced; these fissures gradually enlarge, and meeting with one another, completely separate the parts. In one kind of fissiparous generation the parent body is split into irregularly shaped masses, in some two in number, in different others, four, six, eight, or twelve, and in one, the Gonium pectorale, into as many as sixteen. Each of the subordinate masses, when first separated from its fellow, has an irregular shape, from which it gradually passes into the form and size of its parent.

In a second form of the fissiparous generation, the infusorial animal is divided into two equal and symmetrical halves; in some instances in a longitudinal direction, as in Bacillaria and some Vorticellæ; in others in a transverse direction, as in Paramœcium, Cyclidium, and Trichoda.

The propagation of the Volvox globator, a remarkable infusorial animalcule, may perhaps be considered as belonging to the first of the above-mentioned varieties of fissiparous generation.* This animal consists of an external vesicle of a lenticular shape, moving rapidly through the water by means of cilia in a whirling manner. Within this outer vesicle there are smaller ones of the same kind, in the interior of each of which still smaller ones may be distinguished by the aid of a high magnifying lens. The outer vesicle may be regarded as the parent, and the inclosed vesicles as its young, for in propagation the outer vesicle bursts and is torn into shreds, while the inclosed ones are set free, each of them to execute its independent motions in the water, and in its turn to burst, and thus propagate its like in discharging those which it contains.

A fissiparous kind of generation is not, however, confined to the Infusoria, but occurs also in some of the Cestoidea and Annelida. The most remarkable example is met with in the Nais and Nereis. In the first of these genera, a small portion separated from the tail becomes the new animal. Before the actual separation of this caudal portion, it is marked off from the rest by a notch, and there are gradually formed on its sides the joints, hairs, and other indications of the organs of the complete animal in miniature. The notch enlarges, and the part at last drops off capable of independent existence. In the Nais, that part of the offspring by which it is attached to the parent becomes the head, and in this way, according to the singular notion of Gruithuisen, who observed this sort of reproduction with attention,† the tail of a Nais may be considered as gifted with perpetual life, since this part is extended into each of the new descendants.‡

We may regard as somewhat analogous to this kind of propagation the multiplication of individuals by division, which happens occasionally only or from accident in several of the lower animals which are usually reproduced

* See his Exercitations, as before quoted, pp. 327 and 343.

* Another view taken of the reproduction of the Volvox globator is, that the young are formed in the manner of internal buds.

† Nov. Act. Nat. Curios. tom. xi.

‡ The segments of the infusorial animalcule that is propagating in the fissiparous mode are united by the parts which afterwards become the tails of the new individuals.

in another manner. The most remarkable examples of this are met with in Polypi, Entozoa, and Annelida. When the Hydra viridis is cut through either longitudinally or transversely, each segment continues to live and grow, and is gradually furnished with those parts of the body of which it was deprived by the division. Thus, when the polype is divided across the body, the part with the head and tentacula is gradually furnished with a body, while tentacula grow on the elongated extremity of the other part. When, again, the animal has been divided in a longitudinal direction, and four tentacula are left on each part, the opposite edges of each segment turn round and unite so as to complete the tube of the stomach, and four additional tentacula are formed upon each.

Segments of the Tape-worm, Filaria, and also of some other Entozoa, are capable of living after separation and being converted into independent animals. In the Leech and Earth-worm, as well as some other Annelida, the division of the body into two or more segments is not invariably followed by death, but some or all of the portions continue alive, and, acquiring the deficient organs, become converted into more or less perfect animals.

Gemmiparous generation.—The second form of non-sexual propagation that deserves our attention is that in which the new individual grows upon the parent as a bud or sprout, at first exhibiting little appearance of the form or structure of the perfect animal; gradually assuming its form while still attached to the parent stem; and being afterwards separated to enjoy independent existence.

The best known examples of this kind of generation occur in the polypine and coralline animals, and the process has been observed with great attention by Trembley in the Hydra viridis.* In this animal the young polype makes its first appearance as a small conical eminence on the body of the parent: this gradually enlarges and becomes cylindrical; a cavity is formed in its interior, which at first is separate, but afterwards comes to communicate with the stomach of the parent, so that aliments taken by the parent penetrate into the stomach of the offspring. As the new polype enlarges, the internal cavity opens at the free extremity, where a mouth, provided with tentacula, is formed. The young animal then catches and swallows food for itself: this food at first finds its way into the stomach of the parent, but after some time all communication between the two stomachs is prevented by the closure of the root of the stem of the small polype; and afterwards the offspring is detached from the parent, becomes a separate individual, and in its turn propagates new ones from its sides. The time at which the separation takes place seems to depend in some measure on the quantity of food within the reach of the parent; this occurring at an early period when the supply is small, and when there may be supposed to be a necessity for the young to move about from place to place in search of sustenance. Sometimes indeed the separation is much retarded, and the young ones also propagate while remaining on the parent stem; so that the polype assumes a branched form, the parent stem bearing families of several generations.

The Sertularia, Vorticella, Zoantha Ellisii, and Cornularia Cornucopiæ, also propagate by shoots somewhat in the same manner as the Hydra.*

Reproduction by separated buds or sporules.—The last form of the non-sexual reproduction is that in which the young are formed from small detached masses after they are separated from the body of the parent. These bodies, generally of a rounded form, may be regarded as buds formed in the parent body, as those of polypes are, but detached from it before the evolution of the new animal begins. They bear the same relation to the offspring as the egg of higher animals to their fœtus or embryo, and might be regarded as ova but for an important difference of structure to which we shall afterwards advert. They are called sporæ, germina granulosa, and gemmæ, or germs: they are homogeneous in their structure, and the whole of the substance of which they are composed is converted in the process of their development into the new animal.

In some animals these sporules are formed in all parts of the body indiscriminately, and are therefore found dispersed through it; in others there is present a peculiar organ in which they are formed, constituting the simplest form of a reproductive organ. The Actinia, Medusæ, and some of the lower tribes of Mollusca belong to the first of these sets. In the Aphrodita the sporules lie in the interstices between the different organs of the animal. In those animals in which a particular organ is provided for the formation of the sporules, the name of ovary is given to that organ,—an application of the term not strictly correct, as it belongs more properly to the organ in which complete ova are produced. The production of sporules from a particular generative organ is much the most frequent mode of their formation, and it obtains in the greater number of the lower tribes of Mollusca.

It is a fact worthy of notice that the sporules of some Zoophytes, as those of the Sponge observed by Dr. Grant, are endowed with a faculty of moving, sometimes darting with rapidity in various directions through the fluids in which they are produced. These motions seem to depend on Cilia: the sporules are also provided with a hook, by which they become attached to other objects when they settle,

* Mém. pour servir à l'Hist. des Polypes d'eau douce. Leyden, 1744.

* According to Burdach the propagation of the Volvox globator, already mentioned, and of the Vibrio, Cercaria, and Cysticercus, is effected by the formation of buds, and differs from that of the polype merely in the buds being formed and discharged inwardly. We might, perhaps, consider the regeneration of lost parts which takes place in some animals higher in the scale than those propagating by buds as a manifestation in them of a similar power.

preparatory to their growth and conversion into the fixed and immoveable Zoophyte.

We may here recal to the recollection of the reader that the different forms of non-sexual reproduction which we have now attempted to sketch are not confined respectively to particular classes of animals, for several of these animals are reproduced in more than one manner.

The alleged instances of non-sexual propagation occurring in animals higher in the scale than those already mentioned are very doubtful, and ought to be regarded either as founded in imperfect knowledge of their reproductive organs, or as rare exceptions to the general law of their propagation by the sexual mode.*

2. *Sexual reproduction.*—The existence in animals of generative organs of two kinds, and the necessity of the co-operation of both these organs in reproduction constitute the distinction of sex, or of male and female. In sexual reproduction both kinds of organs produce a substance essentially concerned in the process. The product of the female organ, or ovarium, as it is called, is the ovum or egg, a consistent organised body of a regular and determinate shape, in which the new animal is first formed and resides during its early growth. A whitish fluid is almost always the product of the male organ or testicle,—termed semen, or the seminal fluid, from a belief formerly prevailing that it constituted, like the seed, the greater part of the new being.

Nature of the ovum.—The egg is naturally produced by the female without the concurrence of the male, that is, the whole substance is apparently formed by the female organ, but the egg so formed is incapable of giving birth to a new animal unless it receive a certain portion of, or influence from, the seminal substance of the male. This addition of seminal fluid to the egg makes no immediate perceptible alteration in its structure or appearance, but awakens in it the power of reproduction, fructifies or fecundates it by causing a physical or vital change, the essential nature of which is not fully understood.

In the egg immediately after its fecundation, none of the parts of the new animal are visible. A certain time must elapse during which the egg is exposed to certain favourable influences of heat, air, &c. before the commencement of those changes of development and growth in which the formative process of the new animal consists. The great mass of the substance composing the egg consists of a fluid, holding in suspension granules of animal, albuminous, and oily matter. The form of the egg is given by the external coverings, and there is in every egg a determinate part or region, corresponding in all animals, at which the small rudimentary parts of the embryo first make their appearance. To this part of the egg, which might be called its germ, the power of independent life and reproduction appears more immediately to belong; the granular fluid serves but to afford nourishment to the young being for a certain period. A gemma or sporule, on the other hand, is generally held to differ from the ovum in being homogeneous in its structure, having no investing membranes, and being entirely converted into the substance of the new animal produced from it. In the present state of our knowledge, however, the distinction between an ovum and a sporule must be admitted to be somewhat arbitrary.

The position of the male and female generative organs upon the same or upon different individuals, and the place or manner of the development of the young animal from an egg, are the two most prominent circumstances in regard to which the forms of sexual reproduction differ from one another in various animals. The principal processes in which sexual reproduction essentially consists, are, 1st, the formation of an egg by the female organs; 2nd, the secretion of the seminal fluid by the male organ; and 3rd, the union of the sexes, and means by which the seminal fluid is applied to the egg so as to confer fecundity upon it.

Hermaphrodite generation.—In some of the lower tribes of animals belonging chiefly to the Annelida, Acephala, and Gasteropoda, the male and female sexual organs are placed on one individual, an arrangement of the sexual organs termed Hermaphrodite, and all the individuals belonging to one species are consequently similarly formed In Insects, Crustacea, some of the Mollusca, and all the Vertebrata, the different sexual organs are placed on two distinct individuals, which are thus constituted respectively male and female. In the greater number of those animals in which the last-mentioned arrangement exists, besides the sexual peculiarities, there are in each certain general differ-

* In many of those instances in which female animals have been supposed to give rise to productive ova, the males have at first escaped notice from the smallness of their number or other causes; and with regard to others of the lower animals, it may very reasonably be doubted whether the products called ova have not been rather of the nature of gemmæ or sporules, such as those formed in the Actinia and other animals naturally propagating in the non-sexual manner. As in this predicament may be mentioned, according to Burdach, Oxyuris, Filaria, Ligula, Tricuspidaria, and others of the Entozoa; Serpula, Sabella, and other Tubicola; Cirrhopoda, and Mussels, and Scutibranchiata and Cyclobranchiata. The Syngnathus was erroneously regarded by Pallas, and the Perca Marina by Cavolini, as propagating without sex. It is, however, probable that some animals provided with both sexual organs, and which usually propagate in the sexual mode, are occasionally reproduced without the immediate concurrence of the male. Thus the female Aphis, after being once impregnated by the male, bears, for a certain portion of the year, female young only, which are capable of being reproduced for nine generations without any of these female animals receiving any new influence from the male. In the last of these generations occurring in autumn, males also are produced which impregnate the females destined to carry on the same succession of generations during the next season. According to some this extension of the fecundating influence of the male through more than one generation is not confined to the animals just mentioned; but without doubt the instances in which this has been supposed to be the case have been greatly over-reckoned.

ences in the structure of the other parts of the body.

In Hermaphrodite animals there are two modes in which fecundation takes place. In some of the Acephala, and in the Holothuriæ, the union of the sexual organs necessary for fecundation takes place in a single individual; while in others, as Helix and Lymneus among the Gasteropoda, copulation, or the union of two individuals, is required, and there is mutual impregnation, the female organ of each animal being fecundated by the male of the other,—a mode of impregnation which also exists in the common Earth-worm, Leech, and some other animals. Occasionally we find that three or more individuals engage in this sort of mutual fecundation, being arranged in a chain or circle.* (See HERMAPHRODITE.)

Diœcious reproduction, or with distinct individuals of different sexes. Oviparous and viviparous generation.—In those animals again in which the position of the sexual organs on separate individuals renders copulation necessary, the mode of production of the new animal from the egg seems to be the most prominent circumstance according to which the reproductive process is modified. Thus, while in a certain number of them the young are born alive, in others they are hatched from eggs laid by the female parent. This constitutes the difference between Viviparous and Oviparous animals; to the first of which classes Mammalia belong, to the second Birds, and most Reptiles and Fishes. A short comparison of the more important steps of the generative process in the Mammiferous animal and the Bird will most readily explain the difference between viviparous and oviparous generation.†

In both these classes of animals ova are formed from the ovary, and in both the ova are fecundated within the body of the female parent. The process by which the egg is separated from the place of its formation, and the changes it undergoes in being perfected after this separation, are the same in both: but after the fecundation and completion of the egg, it is differently placed in the two classes of animals; for in birds the egg passes through the oviduct and leaves the body of the female parent, to be hatched into life under the influence of favourable external agents; while in the mammiferous quadruped, the egg remains within the uterus of the female generative organs, becomes attached to it, and has there formed from it the young animal, which does not quit the body of the parent until it is capable of independent life. The egg of the bird leaves the body of the mother provided with a considerable quantity of organic matter, by which alone, under the influence of heat and air, the embryo is nourished during incubation. The egg of the mammiferous animal is extremely small compared to the size of the young animal at birth, and the fœtus consequently draws a continual supply of the materials of its nourishment from the uterus of the mother, with which it is more or less intimately connected. The residence of the child or young animal in the body of the mother during its formation and growth is termed pregnancy, or utero-gestation.*

Ovo-viviparous generation.—There are other animals, however, besides Mammalia, which bear their young alive, as is the case in many cartilaginous and a few osseous fishes, in several Batrachia, Sauria, and Ophidia, and also in some Gasteropodous Mollusca, Insects, Annelida, and Entozoa. But there is an important difference to be pointed out between the viviparous form of generation occurring in these animals and that which belongs to the Mammalia. For the female generative organs of the above-mentioned animals, as well as the eggs they produce, resemble much more closely in their structure those of oviparous than those of strictly viviparous animals. As, in the animals now under consideration, the

* In the Cyclostoma viviparum the sexes are distinct.

† Harvey in the Sixty-third Exercitation thus enforces the analogy between the oviparous and viviparous modes of reproduction. "I have already given you the reason why I have drawn out documents concerning all other egges from the egges of Hens; namely, because they are cheap and every man's purchase."—"But there is more difficulty in the search into the generation of viviparous animals; for we are almost quite debarred of dissecting the humane uterus: and to make any inquiry concerning this matter in Horses, Oxen, Goats, and other Cattel, cannot be without a great deal of pains and expense. But those who are desirous to make tryal whether we deliver the truth or not, may essay the business in Doggs, Conies, Cats, and the like."—"But we in the entrance of these our observations have concluded that all animals are in some sort produced out of an egg: For the fœtus of viviparous creatures is produced after the same manner and order out of a pre-existent conception, as the chicken is formed and constituted out of an egge. There being one and the same species of generation in them all, and the exordium or first principle of them all is either called an egge, or at lest something answerable and proportionable to it. For an Egge is an exposed conception from which a Chicken is produced; but a conception is an egge retained within, untill the fœtus have attained its just bulk and magnitude: in other matters it squares with an egge," &c. "Besides, as a Chicken is hatched out of an Egg, by the fostering heat of the sitting Hen, or some other ascititious hospitable patronage, so also the fœtus is produced out of the conception in the egge, by the soft and most natural warmth of the parent.—"And then, concerning that which relates to procreation, the fœtus is produced out of the conception in the selfe same manner and order as the chicken out of the Egg; with this only difference, that in an egge, whatever relates to the constitution and nutrition of the Chicken, is at once contained in it; but the conception (after the fœtus is now formed out of it) doth attract more nourishment out of his parent's womb; whereupon the nourishment increases with the fœtus."—"The first Conception, or Rudiment, therefore, of all Animals is in the uterus," (this applies to Quadrupeds,) "which, according to Aristotle, is like an egg covered over with a membrane when the shell is pilled off." And Harvey finally concludes with Aristotle: "All animals, whether they be swimming, walking, or flying animals; and whether they be born in the form of an Animal or of an Egge; are all generated after the same manner."

* The nature of the egg of viviparous animals, which has only recently been fully understood, will be described in a subsequent part of this paper, and more in detail in the article OVUM.

egg is proportionally large, the fœtus grows principally by the assimilation of materials procured from it, and there is not that intimate connection of structure nor interchange of substance between the mother and fœtus which occurs in Mammalia. The term ovo-viviparous is applied to the variety of reproduction now under consideration; as expressing that in it, although the fœtus is produced fully formed and alive, the ovum is merely hatched within the parent body. We find, accordingly, that this form of generation is liable to vary, and occasionally to run into the truly oviparous kind. Thus, some animals which bear live young at one season lay eggs at another season of the year, as occurs in some Insects; and in others, as Lacerta agilis, the ova remain within the mother's body for a part only of the time employed in the development of the young; the process of hatching beginning and going on for a longer or shorter time within the female parent, and being completed as in the bird without.

In all truly viviparous, in most ovo-viviparous, and also in many oviparous animals, the ova are fecundated within the parent's body; and we find provided for the purpose of introducing the seminal fluid into the female genital organs, a more or less complicated apparatus in both male and female, by which the union of the sexes is brought about. In the greater number of strictly oviparous animals, and particularly those that are aquatic, as osseous fishes and Batrachian Reptiles, fecundation is operated externally to the parent body; that is, there is no union of the sexual organs of the male and female, but the ova laid by the female are covered with a certain quantity of seminal fluid shed by the male.*

Utero-gestation in the Mammalia is terminated by parturition or the birth of the young; while in the bird or oviparous animal birth consists in the exclusion of the young from the egg. At this period in Mammalia, the organic connection between mother and offspring is dissolved, and in both viviparous and oviparous animals the birth is accompanied by important structural changes, which fit the offspring for independent life and aerial or aquatic respiration. The young of Mammalia after birth, though they cease to be organically connected with the mother, continue to derive a certain quantity of support from her, feeding on the milk secreted by the mammæ. But in all other classes of animals, the young are at birth capable of feeding on external aliment.

Varieties in respect to utero-gestation and the developement of the young.—There is considerable variety among different animals in the degree of perfection at which the young have arrived at the period of birth. Thus, Insects, Batrachian Reptiles, and some other animals leave the egg at a very early period; differing widely from their parents in structure and functions, they live for a time in a masked or larva condition, and undergo afterwards various changes or so-called metamorphoses before attaining the mature condition. Fishes leave the egg while their structure is yet very incomplete; and even in the higher animals we observe varieties in this respect: thus, some birds, more especially those building on trees, are unfledged, blind, and helpless when the shell is broken; and some quadrupeds, among which may be mentioned the Rodentia, Feline, and Canine species, are at birth blind and weak, and with little power of supporting their natural high temperature.* The most remarkable instance of variety of the kind now alluded to, however, occurs in the Kangaroo and other Marsupial animals, the generation of which deserves more particular mention in this place as it exhibits a considerable deviation from the more ordinary reproductive process in Mammalia, and is attended with some important modifications in the structure of the generative organs.

In the Mammalia generally, it has already been stated that there is an intimate organic connection between the fœtus and mother, by means of which the former is supplied with the materials of its growth. The intimacy of this union (as we shall explain more fully elsewhere) varies much in different tribes of animals. It is greatest in the placenta of the human female, and from this there may be traced a series of animals in which it becomes more and more loose. According to recent researches in Comparative Anatomy, there is also observable in the descending series of these animals a nearer and nearer approach in the general structure of the body, and in the conformation of the generative organs to the oviparous type. This approach to the oviparous structure is most strongly marked in the Marsupiata, as the Opossum, Kangaroo, &c. and in the Monotremata, as the Ornithorynchus and Echidna.†

Marsupiate generation.—The fœtus of the marsupiate animal leaves the uterine system of the mother or is born at an early period of its formation, while it is yet of a very small size, and its organs are comparatively imperfectly formed. On being born it is introduced by the mother into the pouch or marsupium formed by a reduplication of the integuments of the lower part of the belly, and a short time after it gets there, the fœtus is found attached by its mouth to one of the nipples of the mammæ, which are concealed within the marsupium. The young of the marsupiate animal

* In the land Salamander, which is ovo-viviparous and breeds in the water, although there is no sexual union of the male and female, there is yet internal fecundation, the seminal fluid being carried into the oviduct of the female along with the water in which it is effused.

* Under the head of OVUM we shall shew that all animals undergo changes which constitute metamorphoses of one kind or other during their formation or development.

† See the interesting papers by Mr. Owen on the Generation of the Kangaroo and Ornithorynchus in the Philosophical Transactions, part ii. for 1834, p. 333, and in the Transactions of the Zoological Society, vol. i. p. 221.

there receives its food by the mouth and is nourished by digestion at an early period of its advancement; and, although its external form and organization very much resemble that of the fœtus of other mammiferous animals at a similar stage of their advancement when they are still confined to the uterus of the mother, their internal organization undergoes at the time of their exclusion the same remarkable changes which occur at birth, and which are connected with aerial respiration and the independence of the vital functions.*

Monotrematous generation.—The generation of the Ornithorynchus and other monotrematous animals deserves also to be noticed here as differing in some respects from that of other Mammalia; but, unfortunately, this subject, which has been involved in obscurity ever since the first discovery of these remarkable animals, notwithstanding that several important facts have been recently ascertained, cannot be considered as completely understood. The Ornithorynchus and Echidna were long regarded as holding an intermediate place in respect to their organization between Mammalia and Birds. The existence of mammary glands was denied by the first dissectors of these animals; and from this circumstance principally, together with the analogy in general structure already alluded to, the Ornithorynchus was believed by many to be oviparous. The recent investigations of Owen have proved the existence of mammary glands as well as the suckling of the young, while they at the same time shew that the generative organs and the ova within the ovaries partake in a great degree of the oviparous structure.† In this approach to the oviparous type, however, it has been satisfactorily shewn that the Ornithorynchus resembles the class of Reptiles rather than that of Birds. The ova of this animal have not, however, been found in any of its haunts; and, although no one has yet had an opportunity of dissecting the gravid uterus, naturalists are now inclined to hold the opinion that it bears its young alive. Should this be fully proved to be the case, the Ornithorynchus may with justice be considered as an example among mammiferous animals of the ovo-viviparous form of generation, most analogous to that occurring in the Slow-worm or Adder; the ovum being, at the time of its descent into the oviduct, of proportionally large size, and there being no proper placenta or intimate organic union between the mother and fœtus.

Comparison of animal and vegetable reproduction.—In concluding this rapid sketch, it may not be out of place to introduce here a few remarks upon the analogies existing between animal and vegetable reproduction.

The seed of plants is generally regarded as corresponding to the egg of animals. The seed and egg correspond in being both the residence of the germ or living part from which the new organized body springs, and also in both containing a certain quantity of matter destined for the temporary nourishment of the growing embryo; but the germ is in a different state in the seed and egg; for while in the egg none of the parts of the new being are visible at the time of its separation from the parent, the rudiments of the embryo are frequently to be found, small but simulating in some degree the plant, in the germ of the seed when it is perfected, and before the commencement of germination. The circumstances favourable to evolution give rise to the development of the embryo in both, but in the animal the influence of the male conferring fecundity on the egg makes no perceptible alteration in the germ, while in the plant no part of the seed, neither cotyledon nor germ, is formed unless fecundation by the pollen of the male takes place; and the seed is not separated from the ovary or place of its production until the rudimentary parts of the embryo are already sketched out.

We have examples of non-sexual reproduction of plants among the Cryptogamia, in which the new plant springs from sporules or granules endowed with the independent vital properties of the seed.

The greater number of monocotyledonous and dicotyledonous plants may be regarded as hermaphrodite, as both the seeds and pollen are formed on the same individual, while in others the position of the sexual organs on distinct individuals corresponds with the more common arrangement in the animal kingdom.*

In different tribes of plants we also observe examples of occasional propagation in a manner different from the more common one by seeds or sporules. Thus the buds and branches, which are the means of their ordinary growth and increase, may, when removed, be capable of independent existence and give rise to distinct plants, or even when still on the parent stock may take root and grow anew. Some buds separate naturally and are evolved in the manner of seeds when placed in favourable circumstances; and in a third class of instances separated buds are preserved in the collections of nutrient matter constituting the tuberous and bulbous roots by which many plants are propagated.

To complete the enumeration of the points of analogy between animal and vegetable reproduction, it may be stated that there is the same reason for believing in the spontaneous generation of some of the Cryptogamic plants as in that of Infusorial animals.

* For the details respecting the structure and functions of the generative organs of the Marsupiata, the mode of passage of the embryo from the uterus to the pouch, see the article upon the Comparative Anatomy of these animals, MARSUPIATA. It is curious to note that until the discovery of the uterus of these animals by Tyson, the vaguest conjectures prevailed respecting their mode of reproduction, it being even supposed by some that the fœtus grew from the first attached to the nipple, and consequently originated as a bud.

† The name of Monotremata applied to these animals, it may be remarked, means *with one vent*, they having a cloaca.

* As in strictly Hermaphrodite, Monœcious, and Diœcious plants.

The following table is intended to exhibit a synoptical view of the various forms of the reproductive process occurring in different classes of animals.

Reproduction.	Non-sexual	Fissiparous	Parent splits, each part a new animal. 1. Transverse. 2. Longitudinal. 3. Irregular. Parent splits and discharges the young.
		Gemmiparous ..	Budding upon the parent stock. Separated buds. Gemmæ or sporules. 1. On all parts of the body. 2. On one part or organ only.
	Sexual	Hermaphrodite.	Both sexual organs on one individual. 1. Self-impregnation. 2. Mutual impregnation.
		Diœcious......	Oviparous, laying eggs which are hatched. 1. External fecundation. 2. Internal fecundation. Ovo-viviparous. Eggs hatched within the maternal body. Mammiferous, suckling the young. 1. Monotrematous. 2. Marsupial. 3. Placental or strictly viviparous.

III. Reproductive function in man and the higher animals.

1. *Sketch of this function in man.*—In now proceeding to a more detailed account of the function of generation, our description must be confined to the process of reproduction in the human species and in those animals which are most nearly allied to man.

The following may be mentioned as the principal steps of the reproductive process in the female of the human species.

The human offspring is derived from an egg like that of all the more perfect animals. The egg is gradually formed in the Graafian vesicle of the ovary at the period of maturity. In productive sexual union the vagina and uterus receive a certain quantity of the male seminal fluid, and a series of changes are induced in the female generative system which have the effect of dislodging one or more ova from their residence in the ovary, and of bringing these ova into contact with the seminal fluid, in order that they may be fecundated or rendered fruitful. The mechanism of the discharge of the ova is the following. The Graafian vesicle swells, and bursts at its most prominent part. The ovum escaping from its interior is received by the fimbriated cavity at the commencement of the Fallopian tube, along which tube it gradually passes until it reaches the interior of the uterus, where it arrives probably in ten or twelve days after sexual union. There is every reason to believe that before the ovum reaches the uterus it has already been exposed in some part of the genital organs to the influence of the male semen, and that it is consequently fecundated. We shall have occasion afterwards to inquire more minutely into the place and manner of this fecundation. The female is now said to have *conceived* or to be impregnated, and the ovum to be *fecundated*. We shall endeavour, for the sake of clearness, to bring the history of the steps of this process under the three distinct heads of, first, the changes of *conception* as regards the female, secondly, the process of *fecundation* as relating to the male, and thirdly, the effects of the union of the male and female product.

Before the ovum reaches the uterus a change has already commenced in the interior of that organ, which in its farther progress has for its object to bring about an organic union between the uterus and the fœtus with its coverings. The minute embryo soon becomes visible in the ovum, has envelopes formed over it which become connected with the lining membrane of the uterus, and as it advances in growth continually receives a supply of nourishment from the bloodvessels of the uterus. It is nourished in this way during the whole of its intra-uterine life, at the termination of which the child is brought into the world or born, being expelled from the uterus by those painful efforts and contractions of the uterus constituting parturition or labour. The child is now capable of being nourished by digestion of food in the stomach, independently of any organic connexion with the mother, and breathes air by its lungs. Although all organic connexion, however, between the mother and child is now dissolved, yet the infant is for a time dependent on the mother for nourishment, receiving by sucking from the mammæ the milk, which it assimilates by its own independent powers. In the present article our object is to describe only the processes of conception and fecundation, referring to the article Ovum for an account of the growth of the fœtus, and to the articles Uterus, Ovary, &c. for the more minute anatomical and functional relations of these organs in the unimpregnated and impregnated states.

Organs of reproduction.—The organs of reproduction in both sexes are frequently divided by anatomists into external and internal, according as they are situated more or less near the surface of the body; but a more suitable arrangement of these organs in a functional point of view is that which is founded on the part which each of them is destined to perform in the generative act. The male organs consist of the penis and urethra, testicles, seminal vesicles, seminal ducts, prostatic body, and Cowper's glands: the female organs, of the vulva, clitoris and nymphæ, vagina, uterus, Fallopian tubes, and ovaries. The testicles in the male and the ovaries in the female are the productive organs, secreting or forming by an organic process the product of each respective sex; the vasa deferentia and vesiculæ seminales conduct and retain for a time the seminal fluid; the Fallopian tubes conduct downwards the ovum from the ovary to the uterus; the uterus receives and retains the ovum during pregnancy or the formation of the child. These constitute the internal organs; the remaining parts are the external organs, and are chiefly connected with sexual union or the expulsion of the products from the body. The glans penis, the clitoris, and the neighbouring parts are the seat of that feeling which accompanies the venereal act: the penis, with its urethra, serves to conduct the seminal fluid into the vagina and uterus of the female: the vagina, besides receiving the seminal fluid, is the issue for the child when it is expelled from the uterus in parturition.

Puberty.—It is only during a stated period of life that animals are capable of reproduction. In infancy, youth, and old age the functions of the sexual organs are in abeyance. The name of puberty is given to that period of life at which either sex first becomes capable of reproduction, at which time various important structural and functional changes occur both in the sexual organs and in the whole economy.

These changes are upon the whole more marked in the female than in the male, a circumstance which may be attributed to the longer and more intimate connexion of the female with the product; the maternal parent affording a supply of nourishment to the child during the whole of its intra-uterine life, while the male does no more than furnish momentarily a small quantity of the seminal fluid necessary for fecundation.

Structural differences of the sexes.—In infancy and youth the two sexes do not differ materially in the general shape of the body, nor in physical powers; but as the age of puberty approaches, and the sexual organs undergo those changes which fit them for the performance of their appropriate functions, the male and female bodies become altered in form, and acquire a more marked difference, while the mental and physical powers also partake of this discrepancy.

We shall do no more than mention here the most striking of these peculiarities, as a more detailed account of them belongs to another place.

Besides these differences which belong immediately to the sexual conformation, the comparatively broader shoulders and wider chest of the male, and the larger pelvis and abdomen of the female, are universally known as constituting the chief peculiarities in the general contour of the body. The smaller size of the whole body in the female, amounting in general to a tenth of the whole height, the greater slenderness of the female frame, the less prominence of the muscles, the more tapering and rounded shape of the limbs, the greater quantity of fat under the skin and elsewhere, the smaller, smoother, and finer bones, and the more delicate texture of some other parts of the body, are all peculiarities of female conformation contrasting with the opposite qualities in the male body. As belonging to the male may be mentioned the low and rough voice from the larger size of the larynx and longer vocal cords,* the occurrence of hair on the chin, upper lip, and cheeks, as well as over the body and limbs, in which situations it is rarely met with in the female, the greater physical power and activity, capability of enduring fatigue and daring, &c.

As these changes in either sex are gradually developed, hair grows on the skin covering the symphysis pubis, in the neighbourhood of the genital organs,† and later under the axillæ.

The local changes attendant upon puberty in the male are the enlargement of the penis, its more frequent erection, and accompaniment of this by the sexual feeling; the enlargement of the testicles, vesiculæ seminales, prostatic gland, and other accessory parts; the more depending condition of the testicles in the scrotum; the secretion of a certain quantity of the seminal and prostatic fluids; and, after the attainment of the full sexual powers, the occasional spontaneous emission of some of the seminal fluid, occurring in general at night during sleep, and being accompanied by some sexual feeling in dreams.

In the female at this period, both external and internal organs undergo a considerable and rapid enlargement; the mons veneris and external labia become more full; the clitoris and nymphæ in many, but not in all, become susceptible of a certain degree of swelling or erection; the breasts enlarge, the vesicles in the ovaries become dilated, and some of them more prominent, and there is established a periodical discharge of a certain quantity of a sanguineous fluid from the internal genital organs.

Menstruation.—This periodical loss of blood demands the attention of the physiologist as one of the most remarkable of the sexual peculiarities of the human female, and as bearing an intimate relation not only to the generative process, but to most of the other functions of the economy.

The periodical recurrence of the discharge of blood every lunar month or twenty-eight days

* Comparative measurements have been made of the length of the vocal cords in boys immediately before and after puberty, and those of the young men have been found to be nearly double the length of those of the boy.

† Hence the name of this bone and of the period of life of which we are now speaking—pubes and puberty.

has given to it the name of menses or menstruation: the Greek word catamenia is also employed to denote it by medical men, and the English expressions of "the illness" or "the courses" are those in most common use among the vulgar.

The menstrual flow of blood lasts usually for about five days, beginning and leaving off gradually, and being in greatest quantity towards the middle of the period. The interval is thus generally about twenty-three days. The discharge in general takes place slowly, or drop by drop.

The menstrual flow of blood is preceded in most women by some symptoms of fever, a quicker and fuller pulse than usual, languor, headach, pains in the back, and frequently in the hypogastria or region of the ovaries, and by many other symptoms of general derangement of the functions, particularly in weak or unhealthy women. In young women upon the occasion of the first appearance of the menses all these symptoms are frequently more strongly marked.

Menstruation may be regarded as the most certain sign of the arrival of puberty, and of the fitness of the human female for marriage, as there are very few instances on record in which conception has taken place before the occurrence of the menstrual discharge. It continues for the whole of that period of life during which women are capable of bearing children; and after this, when it ceases, a considerable change in the female constitution ensues: the "change of life" or "critical period" is said to have arrived, from the liability there then is to the conversion of the plethoric state, previously relieved by menstruation, into some morbid affection either of the sexual or other organs of the body.

During menstruation, the uterus, vagina, ovaries, and other parts of the genital organs are usually more vascular and turgid with blood than in the interval; the mammæ, which exhibit at all times a remarkable sympathy with the condition of the uterus, frequently participate in this increased activity at the menstrual period, as they then swell and become hard.

Menstruation consists essentially in the exudation of a fluid resembling blood from the female genital organs, and principally from the uterus. Haller states that the blood has actually been observed to proceed from the uterus in women labouring under prolapsus of that organ, and John Hunter as well as others have found the cavity of the uterus filled with the fluid in women who have died during menstruation.

Menstruation usually ceases during pregnancy, and in the majority of women during lactation also. In those instances in which the monthly flow has continued to take place during pregnancy, there is reason to believe, according to Haller, that it may have proceeded from the upper part of the vagina, as the first changes attendant upon utero-gestation usually close firmly the neck of the uterus.

The quantity of fluid which exudes during one menstrual period amounts in general to five or six ounces; but this is subject to great variation from the mode of life of the individual, state of her health, diet, and other circumstances. The quantity is usually greatest, cæteris paribus, in healthy women living well, but the increase of the quantity above a certain point or its diminution below another are equally to be regarded as unnatural or diseased states of the action. In tropical countries the quantity is greater than in more temperate regions, amounting occasionally to twelve or even twenty ounces. In Lapland and some other northern countries the quantity is, on the other hand, much below the mean, being occasionally as low as three ounces; and yet in both these situations the women are to be regarded as within the bounds of health.

The quantity of fluid lost in menstruation is increased by all those circumstances which cause a determination of blood to the pelvis or its contained viscera; hence the effect of posture, irritating diuretics, drastic purgatives, and those medicines termed emmenagogues.

The nature of the fluid discharged in menstruation has not yet, we believe, been investigated with sufficient accuracy. It bears a close resemblance to blood, having generally the colour of the venous kind. It is generally fluid, but sometimes coagulates from exposure to air: it is generally believed to contain less fibrine than blood, and to be less prone to putrefaction.

Respecting the causes of the menstrual discharge and its uses in the economy, many very absurd hypotheses have been advanced in medical writings. It was a common belief among the ancients that the menstrual fluid exerted a baneful influence on every living object, plant, or animal, and many of the institutions and laws of antiquity shew that this natural process was looked upon with abhorrence. The correspondence in the length of time of the moon's changes with the recurrence of the menstrual period induced many to believe in an influence exerted by the moon on the female generative system; but the error of such a notion is sufficiently proved by the circumstances, first, that more women are not found to menstruate at one period of the moon's changes than at another. and, second, that the women of any place mentruate at all different times. Besides this, many women do not menstruate regularly every lunar month. In some this change takes place every three weeks, in others every fortnight, and there are many in whom there is a variation of one or two days on either side of the common period of twenty-eight days.

When we consider the circumstances previously mentioned respecting the intimate connexion subsisting between the menstrual flow and the processes of reproduction, we shall be led rather to the opinion that menstruation is to be regarded as a means of relieving the female system periodically from an overplus of blood which exists during the whole of the time in which it is capable of propagation. It occurs at this period of life only, it generally ceases during pregnancy, and it may therefore correctly be regarded as the indication of the presence in the system of that quantity of nutrient matter, which, during pregnancy, is destined to serve for the nourishment of the child. We say that this flow does no more than *indicate* the surplus quantity of blood in the female genital organs; for, as Burdach remarks, the loss of six ounces of blood for ten successive lunar periods amounts to only three pounds twelve ounces, whereas the fœtus and its appendages during that period attain the weight of from ten to fifteen pounds, to which we might add the enormously increased weight of the uterus in order to estimate the whole addition which is made to the uterine system during pregnancy. Again, during lactation or nursing the tendency to a superabundance of blood or plethora in the uterus is generally relieved by the flow of milk from the mammæ, which, as has already been remarked, sympathize very constantly with the uterus and other parts of the generative system.

Such a tendency to plethora as that we have just alluded to, it is scarcely necessary to remark, can have no connexion with lunar or planetary influences, and we are, perhaps, more justified in classing it along with those other changes of the economy which indicate a remarkable tendency in the human constitution to periodical recurrence of its actions.

The crises of fevers on days terminating periods which are most frequently of the duration of seven, fourteen, twenty-one, or twenty-eight days, are of this kind; and it is deserving of notice that menstruation recurs more frequently in periods, the number of days of which are multiplies of seven, than in any others.*

It has been attempted to be shewn that the male is subject to a periodical plethora in some respects similar to that which gives rise to menstruation in the female, but without any just reason, unless we choose to consider as such the gradual accumulation of seminal fluid, which frequently takes place in healthy men of sanguine temperament, and which gives rise to its periodical emission.

With regard to menstruation we shall only farther remark that, according to Haller, Burdach, and some others, women are more liable to become pregnant immediately or within a few days after the cessation of menstruation than at other parts of the interval; the probable reason of which will appear from details given in a subsequent part of this article.

Periodical heat in animals.—None of the lower animals in the natural state appear to be subject to anything like a menstrual change or periodical discharge of blood. In lascivious Apes and in some of the domestic animals fed highly, an exudation of bloody mucus from the vagina and external genital organs of the females sometimes occurs, but this is manifestly quite different from menstruation. There is, however, in most of the lower animals a very obvious periodicity in the functions of the reproductive organs; for while the human female is, during a certain period of life, nearly equally fit for propagation at all times, this is the case with very few animals, and, indeed, chiefly among those living in the unnatural state of domesticity.

At certain seasons of the year there occurs in most of the lower animals a determination of blood to the genital organs of the female, accompanied by sexual desire, which leads them to the propagation of their species. This state of excitement, generally named " the heat,"* lasts for a longer or shorter period; in the ewe for twenty-four hours only, in the cow and mare for a few days, in the bitch nine or ten days, and in the hen-pheasant for as long as two months. In most animals, after it has run its accustomed course, it disappears naturally, but it is more certainly and sooner dispelled by fruitful sexual union.

The heat belongs more properly to the female than to the male, as there are many species whose females receive the male only at particular seasons, while the male is at all times fit for propagation. In others, constituting the majority of instances, the male organs are subject to the same periodical increase of activity as the female. The male in these animals is usually in heat at an earlier period than the female.†

In some animals there is a more frequent periodical return of the heat than in others; thus the ewe which remains unimpregnated comes in heat every fourteen days; the cow and some apes, the mare, ass, and buffalo every four weeks; the sow every fifteen or eighteen days; but in these animals the high feeding attendant on domesticity may very probably occasion a more frequent and less natural return of the period of heat than would occur in the wild state.

It would appear that the season of the year at which animals most commonly breed is subject to very many and extensive variations, according to the temperature, latitude, and other circumstances connected with the country which they inhabit.

During the continuance of the heat a peculiar odour is exhaled from the genital organs, and there exudes chiefly from the external organs some bloody mucus, which, in some lascivious apes, resembles blood so much as to have given rise to the belief already alluded to that these animals menstruate.

Age at which puberty occurs.—The appear-

* According to the researches of Mr. Roberton of Manchester, detailed in an interesting paper, published in the Edinburgh Med. and Surg. Journal, vol. xxxviii. p. 237, out of 100 women, in sixty-eight the menstrual discharge returned every fourth week; in twenty-eight every third week; in one every second week; in ten at irregular intervals. These varieties usually exist as family and constitutional peculiarities.

* Termed the Rut in the deer, wild boar, &c.

† In some male animals the signs of heat are very apparent. The fine colour of the plumage of most male birds in the breeding season, the deep colour of the comb, &c. in gallinaceous fowls, the thickness and bushy hair of the deer's neck, the greatly enlarged size of the testicles in the cock-sparrow, may be mentioned as familiar examples.

ance of puberty is gradual in both sexes, but, upon the whole, more slow in the male than in the female. The age at which it takes place varies in the same and in different countries according to the mode of life, physical and moral education, and other circumstances. It takes place at an earlier age in woman than in man: in the former most frequently in this country at from the age of thirteen to sixteen years, in the latter from fifteen to eighteen years; but instances are not unfrequent of girls menstruating and of boys passing into manhood one or two or even more years sooner or later than the above-mentioned periods, as from ten or eleven to twenty or twenty-two years.*

These variations are to be considered as dependent on constitution in the greater number of instances; but in respect to their occasional causes, it may be stated that all those circumstances which produce a determination of blood to the sexual organs or pelvic viscera, which relax the body generally, or turn the attention of the young to the sexual function, tend to bring on sooner than natural the local changes of puberty. Warm rooms, a sedentary mode of life, particular kinds of reading, and some bad habits are all hurtful in this respect.

According to the observations of many travellers, puberty arrives sooner in warm than in temperate climates; and some have hence too hastily concluded that the warmth of the tropical country has been the cause of the more precocious appearance of menstruation in women and puberty in men, an opinion the error of which is shewn by the fact that instances of very early puberty are not unfrequently met with in high northern latitudes.† The occurrences of marriages, therefore, or sexual union at the early age of six or seven years in the South Sea Islands and elsewhere is to be looked upon rather as a proof of the barbarous and debased state of civilization of these people, than taken as an evidence of their being fitted by nature for the functions of propagation at the period of life now mentioned.

There do sometimes occur, however, in all nations unfortunate examples of precocity in the development of the sexual organs and activity of their functions. Thus in male or female children of four and even of only three years old all the changes of the sexual organs, and some of those of the body generally, which belong to puberty of a more advanced and natural age, take place. The attention of such children is soon called by their local feelings to the condition of the sexual organs, and vicious habits are induced, which, from the misery they carry along with them, it becomes the duty of the medical man to counteract by all the resources of his art.

Period of life during which the generative function is exercised.—The length of time during which the male and female of the human species retain the power of propagation is subject to the same variations which attend the arrival of the age of puberty. The most healthy women are in general capable of bearing children between the ages of fifteen and forty-five, or for a period of thirty years. Men retain the powers of their sex for a longer time, as from the age of seventeen to sixty or seventy, that is, for forty-five or fifty years. There are, however, on record instances of both sexes, but more especially the male sex, having retained their respective powers for a longer period than that just stated;—of women menstruating a second time (after the cessation of this function at the usual period) at the age of sixty or seventy,* and in one or two instances bearing a child at that advanced age;—of propagation in the male sex to the age of seventy, eighty, and ninety, and in the celebrated case of old Parr even to that of one hundred and thirty years.†

Among the lower animals the variations in this respect are so numerous as to preclude the possibility of our mentioning even the more im-

* According to Mr. Roberton's observations previously quoted, the following are the ages at which 450 women began to menstruate:

In their	11th year	10	women.
,,	12th ,,	19	,,
,,	13th ,,	53	,,
,,	14th ,,	85	,,
,,	15th ,,	97	,,
,,	16th ,,	76	,,
,,	17th ,,	57	,,
,,	18th ,,	26	,,
,,	19th ,,	23	,,
,,	20th ,,	4	,,

This table shews that the age of puberty of females in this country extends over a considerable number of years, and is more equally distributed than is commonly alleged.

† The opinion that menstruation happens at an earlier age in warmer climates is very generally entertained, as may be seen by a reference to the works of Haller, Boerhaave, Denman, Burns, Dewees, and others. Mr. Roberton has successfully shewn its inaccuracy by an appeal to the facts stated by modern travellers, as Hearne, Franklin, Richardson, and Back with regard to the Northern Canadian Indians; by Lyon and Parry with respect to the Esquimaux; by Clarke in reference to the Laplanders; and by Tooke in relation to the Northern Russians; all of which shew that puberty is attained in the arctic regions at least as early as in more temperate climates. On the other hand, from the evidence of Crawford and Raffles relative to the inhabitants of the Indian Archipelago, of Messrs. Ellis and Browne (missionaries) in regard to those of Polynesia; of Dr. Winterbottom on the native Africans round Sierra Leone; of the laws of the Koran in regard to the Arabs; and of the observations by Russel on the Egyptians, Mr. Roberton endeavours to prove that though early marriages are common in warm and equinoctial countries, yet the period of puberty and of the capability of procreating is nearly the same as in temperate and northern latitudes. Mr. Roberton is therefore induced to form the conclusion that the variations from the standard or more common period of puberty in different nations are not greater than the individual differences to be observed in our own country, and that the opinion above referred to ought to be looked upon as a vulgar error.

* These instances are very rare indeed. Mr. Roberton states that of 3000 women delivered in the Manchester Lying-in Hospital, only one was above fifty years of age.

† See Haller's Elementa for an enumeration of such examples.

portant in this place. The male of some insects, it is well known, die as soon as they have fecundated the female; many plants and animals propagate only once, while others give rise to many successive families; but we are not acquainted with any general law to which such differences can be referred.

Effects of castration.—Nothing illustrates in a more striking manner the intimate relation which the sexual function bears to the general organization and functions of the body than the effect of castration, or the removal of the formative and essential parts of the sexual organs in either sex. When both the ovaries or testicles have been removed or destroyed, the power of propagation is of course entirely lost. When this operation is performed at an early age, there is also caused a remarkable alteration of the constitution and general habit of body of the animal. The functional and structural peculiarities of the body become less marked, and there is a great tendency in general to the universal deposition of fat in different textures.

In the castrated male, the form and texture of the body approaches that of the female, and the mental faculties seem to partake in a certain degree of a similar modification. The voice remains high and clear; and hence the barbarous custom prevailing to the present day in Italy and elsewhere of making eunuchs for the sake of their high voices in singing.

In the spayed female, on the other hand, there is a certain approach to the characters of the male. In women in whom it has been necessary to extract the ovaries on account of disease, the bones and muscles have been observed to have a more masculine contour, the voice is harsh like a man's, the breasts are flat, and there is frequently a formidable beard, and hair on different parts of the body.

The same or similar circumstances have been remarked in those unfortunate malformed individuals who present an approach to hermaphrodite formation, or in whom there is imperfect development of either the male or female genital organs. So also it has been observed that the females of some animals, as the sow, pheasant, and pea-hen, and even the human species, when the period of life for propagation is passed, assume some of the male characteristics, such as the plumage in the birds mentioned, bristles in the sow, &c.

It is well known that the annual change of the horns in deer is intimately connected with the generative function. Mr. J. Hunter first shewed by experiment that when the deer are castrated while the horns are complete, they remain permanently and are not changed as in the natural condition; and that, if the operation be performed when the horns have fallen, they will not again be renewed.

The operation of castration, particularly when it is not performed till late in life, while it produces complete sterility in the female and impotence in the male, does not entirely destroy sexual desire, for eunuchs and the castrated males of many animals are known to be lascivious. Some writers would even have us believe that it is possible for the power of propagation to remain in the male after castration. These cases appear extremely doubtful, and, even admitting the truth of the statement that a castrated male has propagated, this by no means invalidates the statement that the removal of the testicles has destroyed all productive power, because it is possible that some seminal fluid may have been retained in the seminal vesicles and vasa deferentia. The operation does not prevent the erection of the penis or venereal orgasm from taking place; consequently the act of sexual union, and even some emission of fluid from the vesiculæ seminales and prostatic body, may occur in the castrated animal; and in some kinds of animals, it may further be remarked, that the union of such males with the females, though altogether unproductive, is attended with several of the more important changes which belong to fruitful sexual union, such as the excitement of the internal organs of the female, the discharge of vesicles from the ovary, and the formation of corpora lutea.

The removal of one testicle or ovary only does not appear to be attended with any change in the sexual or other functions; and it appears to be equally inconsistent with fact, that those originally provided with only one of these essential organs, are endowed with less procreative power than others, as that those who are said to have had more than the usual number are remarkably salacious or fertile.

3. *Sexual feeling.*—In all animals in which the distinction of sex exists, the first act of the generative process or the union of the sexes is insured by instinctive feelings experienced by both of them in a greater or less degree. These feelings generally depend upon the condition of the body, and in particular of the genital organs, which at the time of propagation are in a greater than ordinary state of excitement. From the increase of peculiar secretions, at the breeding season, the odour of the genital organs of animals becomes stronger than at other times, and seems to have a very direct effect in exciting the sexual appetite. These feelings are in the greater number of animals strongest in the male, and he consequently generally seeks the retiring female; but in other instances the reverse is the case.

In the human species also, similar feelings exist, but under the control of the intellectual and moral powers of the mind. Hence the immense variety we observe in the effects of the exercise of the sexual passions on different people, and hence the various modifications which they undergo from the state of civilization among different nations; on the one hand being productive of scenes and habits of disgusting obscenity among those barbarous people whose propensities are unrestrained by mental cultivation; and on the other, attended by social ties and higher intellectual ideas among those in whom, from education and the cultivation of the mind, the bodily appetites or passions, subject to the reason, assume a milder, less selfish, and more elevated character. Hence it comes that the various customs of different nations, legislative enactments of ancient and modern statesmen, and even some religious injunctions and ceremonies relating to marriage and concubinage, are to be regarded rather as a picture of the state of civilization among the different people to which they have belonged, and as the result of local situation and circumstances, than a consequence of their physical organization or natural endowments, as some would have us to believe. But the consideration of these modifications in the customs and habits of different nations belongs more appropriately to the province of the political economist than of the physiologist.

4. *Relation of reproduction to the brain.*—In how far the sexual feelings just spoken of, and the reproductive function as a whole, are connected with the brain or any of its parts, we leave to be discussed by others. We shall only remark in this place respecting this connection, that the mental feeling and local affection relating to sex are very intimately associated together; on the one hand, the local irritation of the genital organs exciting mental desire, and on the other, the erection and other signs of affection of the sexual organs being immediately caused by all those ideas and passions of the mind which bear a relation to sex. In the same manner as the action of the heart, the flow of the blood in some of the bloodvessels, the processes of digestion, respiration, and secretion are modified by mental emotions, the sexual function may be regarded as subject to their influence, and consequently subject to modification from the condition of the mind or brain.

In the phrenological system, as is well known, it is held that the cerebellum is that particular part of the encephalon which presides over the sexual function,—in other words, that sexual feeling belongs to the cerebellum as its sensorium commune, to which impressions of a sexual kind proceed, and from which emanates sexual desire, as well as the influence under which the reproductive organs execute their appropriate functions. The proofs alleged in favour of the phrenological hypothesis are principally of the following kind: 1st, that the back of the head and neck, and particularly the cerebellum, is largest in those of the human species who shew much sexual love, and among animals in those in which sexual feeling and productive power are greatest; 2d, that local affections of the genital organs, and variations in the degree of sexual desire, frequently coincide with congenital deviations from the natural form and structure of the cerebellum, and morbid organic changes of that organ, such as inflammation, suppuration, effusion, tumours, and softening, or violent injuries, such as wounds producing the destruction or removal of portions of the same part of the brain.* We leave to others the examination of the truth of this view, observing merely that we are not inclined to adopt the hypothesis as already established upon sufficiently accurate or extensive data; and we would remark that the comparative anatomy of the brain (in which, rather than in experiments on animals, we should feel disposed to place much reliance, from the acknowledged difficulty of making correct deductions as to function from the effects of morbid alteration or artificial injury of the encephalon) affords very few arguments in favour of the view now alluded to, and furnishes several facts which militate strongly against it.

5. *Distinction of species. Mules.*—The instinctive feelings which lead to the union of male and female animals of the same species may be looked upon as one of the means provided by nature for the distinct preservation of each specific race. So general indeed is the law that animals of one species propagate with one another only, that, as we already remarked, this circumstance alone has been adopted by some as the true specific character. We shall see reason, however, to doubt its sufficiency.

While the natural repugnance which the males and females of different species or genera have to propagate together may be regarded as one of the most powerful means by which the distinction of species is insured, we must not lose sight of other circumstances which contribute to the same effect. Among these may be mentioned, in the first place, the unfruitfulness which generally attends the union of different species when it has occurred; then the difference in the size of animals, the discordant properties of the semen of the one and ova of the other, the difference of season at which nearly allied animals come into heat, as well as many other circumstances which put a bar to the extension of races by promiscuous propagation of species or genera.

In the state of domesticity, however, this,

* The proofs of the connection of the cerebellum with the sexual function may be more fully stated as follows:

1st. The coincidence of barrenness or impotence with hydrocephalus, ramollissement, suppuration, or wounds of the head, and in particular of the back part and cerebellum.

2d. The coincidence of excited states of the reproductive organs, as priapism, nymphomania, and satyriasis, with inflammation of the same parts.

3d. Instances occurring in birds (mentioned by Serres) of cerebellar apoplexy from the persistence of unsatisfied sexual desire.

4th. Coincidence of cerebellar apoplexy, inflammation, &c. and diminution of the sensorial power, with over-exertion of the sexual powers, excess in venereal pleasures, &c.

5th. Large size of the cerebellum or upper and back part of the neck in those individuals among the human species or among animals in which the sexual desire and reproductive power are greatest.

6th. The reverse being the case in those in whom the function is inactive; as the small size of the back of the neck, &c. in castrated animals.

In endeavouring to ascertain the value of this kind of evidence adduced in favour of the phrenological view, we must consider well the nature of the alleged facts themselves, and weigh them candidly against facts of an opposite tendency adduced on the other side, such as those cases of small size or absence of the cerebellum, in which the sexual propensities have been highly developed, and the converse cases; and we must, at the same time, not lose sight of those other experiments and observations which would tend to shew either that the cerebellum is intimately connected with other functions than the reproductive, or that the sexual powers are influenced by the condition of other parts of the brain besides the cerebellum.

like other laws of the reproductive function, is subject to some modification, and we find accordingly several allied species of the domestic animals breeding freely together; and there are not wanting, even in the wild state, examples of the mixture of distinct species.

The animal produced by the union of the male and female of distinct species receives the name of Hybrid or Mule, which generally partakes of the qualities of both its parents in a greater or less degree. Here again we find another effectual impediment put by nature to the mixture of different species, in this circumstance, that the mule, whether male or female, is usually unfit for propagation. The offspring of male and female of distinct species is much more frequently fruitful than that of distinct genera.* The instances of the former are not few, as in the wild and tame cat, the wild boar and domestic hog, the pheasant and domestic fowl, the wild and tame duck. But the instances of the latter or mixture of distinct genera are very rare, and most of them require confirmation. We must at the same time always hold in mind that the distinction of species by naturalists is at all times artificial or made by man, how much soever he may conceive his classification to be founded in nature, and those animals which are regarded by one naturalist as different species of the same genus are made by others to constitute distinct genera.

It is well known that in gardens and elsewhere, although the pollen of very various plants is almost constantly flying about through the air, it is only among the most nearly allied races or varieties that mixture occurs, and the instances of the mixture of different species of plants are very rare indeed. Many of the mixed varieties so produced cannot be propagated by seeds; so that there is in the vegetable as well as in the animal kingdom a constant tendency to return to the original distinct species.

The milt and spawn of different fishes are at the same time floating in the same water, but even thus brought into close union with one another, no mixture happens. The ingenious experiments of the celebrated Spallanzani, who attempted to impregnate artificially the ova of one animal with the seminal fluid of another, and the unsuccessful attempts of many to cause different animals to breed together, afford still farther proofs, were they wanting, of the number and completeness of the impediments which nature has opposed to the promiscuous breeding of distinct species.

The horse and ass are caused, it is known, to unite by man, and do not naturally do so; and in the wild state it is probable that the exceptions to the general rule before-mentioned occur only when the male is deprived of his natural female. It seems scarcely necessary to state that the stories of fruitful union of either male or female of the human species with apes or other animals, considered as authentic by some authors, are entirely fabulous.

In a subsequent part of this article we shall have occasion to revert to the subject of the mixture of races in our remarks upon the transmission of the qualities of the parent to the offspring.

6. *Functions of the external organs of reproduction.*—In addition to sexual feelings, the state of turgescence or erection of the external organs by which copulation is effected, is a more or less constant antecedent and concomitant of the first act of the generative process. This condition belongs more properly to the external sexual organs of the male, and especially the penis; but it also frequently exists in some parts of the female organs.

The erection of the penis producing the rigidity of that organ necessary to ensure ejaculation or forcible emission of the seminal fluid, consists essentially in the increased quantity of fluid in its bloodvessels, and is with most reason to be attributed chiefly to the peculiar structure and inherent properties of the tissue, so called erectile, of which it is mainly formed. The manner in which the greater accumulation of blood in the erectile tissue is brought about is by no means sufficiently clearly explained. Two different opinions prevail as to the cause of this phenomenon; the one, that the flow of blood is retarded in the veins by the contraction and consequent pressure of certain muscles situated towards the root of the penis; the other, that the turgescence of erection is caused by an altered action or condition of the bloodvessels themselves, peculiar to the erectile tissue, in which they are capable of admitting and retaining a greater quantity of blood in the erected than in the collapsed state.

We must refer to the various anatomical articles for an account of the structure of the erectile tissue and the organs in which it occurs; we shall in this place advert to those points only which seem to bear upon the physiological view of their function.

The glans penis, corpus spongiosum urethræ, and corpora cavernosa penis, consist in great

part of largely convoluted veins of considerable size; but these veins are differently arranged in the last-mentioned of these parts from what they are in the two first: first in this respect, that in the glans and corpus spongiosum urethræ the tortuous veins are less dilated and more branched than in the corpora cavernosa; so that it is more easy to trace their continuity with one another; and, second, that in the corpora cavernosa the dilated veins are bound together and crossed in various directions by ligamentous fibres and bands,—an arrangement which, while it tends to obscure the connection of one vein with another, and causes their tortuosities to appear rather like cells than continuous tubes, at the same time serves to prevent their distension beyond a certain point during erection, and thus adds to the rigidity occasioned by the accumulation of blood in the venous convolutions or sinuses.

The mode of union of the arteries with the veins in the erectile tissue of the penis is not yet well known; for, although the arteries of the penis have been traced to very small ramifications, corresponding small branches of the veins have not been observed, and consequently anatomists are nearly in complete ignorance of the nature of the small vessels of communication or capillaries of the erectile tissue, and are left to conjecture only respecting the means of passage for the blood from the small arteries into the cells formed by the convoluted veins. Professor Müller, of Berlin,* has lately made an important step in the investigation of this point of structure, by the discovery of a remarkable set of little dilated and ramified branches appended to the terminal twigs of the arteries distributed on the sides and interspaces of the venous cavities in the penis of man and several animals; but so far as we are aware, the exact mode of passage of the blood from these helicine arteries, as they have been termed from their tortuosity, has not been detected, and the operation of these arterial branches in modifying the circulation, or their relation to the process of erection, has not been pointed out; it appears probable that so peculiar a piece of mechanism must have some connection with this process. (See Erectile Tissue and Penis; also *Figs.* 98 and 99, p. 146, vol. ii.)

The principal exciting causes of erection may be referred to the following heads:—

1. Mental emotions relating to sex: in animals, odour of the genital organs, more especially in the breeding season.

2. Nervous affections. Epilepsy, convulsions. Inflammations of the brain, and similar affections.

3. Warmth or other local irritation of the penis and sexual organs.

4. A full state of the testicles, their excretory ducts or vesiculæ seminales.

* See his Archiv. für Physiol. &c. 1835, pp. 27 and 220, and his paper, "Ueber die organischen Nerven der erectilen männlichen Geschlectsorgane," in the Abhand. d. k. Akad. d. Wissensch. v. Berlin für 1835.

5. Irritation of the parts in the vicinity of the penis, as of the urinary bladder by stone, riding, cantharides, savine, alcohol, &c.; of the rectum by strong purgatives; and, in short, every thing which irritates or determines a greater than usual flow of blood to the pelvic viscera or sexual organs.

6. Ligatures, and all other causes of obstruction to the return of blood from the penis.

Erection is an involuntary act; for we have neither the power directly to produce it, nor, when it occurs, to recall the state of collapse. When the penis is in the state of erection, however, the rigidity may be increased by the voluntary exertion of the ischio-cavernosi or erectores penis, and the acceleratores urinæ muscles; and no doubt also by the action of the muscles lately described by Dr. Houston* under the name of compressores venæ dorsalis penis, to the contraction of which, and the consequent impediment produced to the return of blood from the penis, that anatomist has attributed in a great measure the erection of the organ.

The turgescence of erection begins at the root of the penis in the corpora cavernosa, and at the glans in the corpus spongiosum. The glans and spongy body of the urethra may, in general, be made to collapse by pressure, but the corpora cavernosa cannot unless the erectile action itself ceases. The arteries of the penis appear to beat with more than usual force during erection.

The phenomenon of erection is not confined to the penis or such parts as are provided with muscles, but occurs in all situations where that arrangement of the bloodvessels constituting the erectile tissue is to be found. The nipple of the mamma, the cock's comb and wattles, and the turkey's neck are all affected in a similar way; and, although some circumstances seem to shew that erection may in some instances be promoted by muscular contraction, we are inclined to adopt the opinion that it is mainly due to an altered condition of the bloodvessels themselves, and that it may in some degree be analogous to the dilatation of the bloodvessels which occurs in blushing, and some other local determinations of blood.† The large size of the numerous nerves which accompany the bloodvessels of the penis is also in favour of this view.

In many animals the penis is furnished with a bone which adds to its rigidity. This is the case chiefly among Cheiroptera, Quadrumana, Solipeda, Digitigrada, Rodentia, Phoca, and Cetacea. We refer to the articles on Comparative Anatomy for a description of the many varieties in the form of the penis in different animals, and their uses in the act of propagation.

The texture of which the glans clitoridis and corpora cavernosa of that body as well as the nymphæ are formed, is of an erectile kind and strictly analogous to the corresponding

* Dublin Hospital Reports, vol. v.

† See the article Circulation, vol. i. p. 672.

parts* of the penis, to which the clitoris bears a great similarity; and it may be remarked that there is also a functional analogy, as these parts in the female sometimes undergo the change of erection under local irritation or venereal excitement.

The glans penis is endowed with a high degree of sensibility, and is regarded generally as the chief seat of venereal pleasure; but this also belongs to the urethra at the time of emission. The papillous structure of the mucous membrane covering the glans, and the large quantity of nerves distributed on its surface, relate to this high sensory endowment.

The lower part of the vagina and the clitoris in particular are possessed of a similar high degree of sensibility, and in some women, but not in all, are the seat of venereal feelings from excitement; but in many women such feelings are altogether absent; and it is most erroneous to suppose, as some have done, that these feelings are in either sex necessary to insure the fecundating power of the one, or the liability to conception of the other.

With regard to the uses of the hymen we have no conjecture to offer.

The vagina, besides serving to receive the penis in copulation and to conduct the seminal fluid to the uterus, is the passage by which the child issues in parturition.

IV. CHANGES CONSEQUENT ON FRUITFUL SEXUAL UNION.

1. *As regards the female chiefly. Conception.*—The consequence of fruitful sexual union in man and quadrupeds is the dislodgement of one of the ova contained in the ovarium, and the fecundation of this ovum in some part of its passage from the ovarium, where it is formed, to the uterus, in which the fœtus is developed from it.

In now proceeding to treat of the mode in which these further steps of the generative process are brought about, the following subjects present themselves for our consideration. 1st. What changes are operated in the internal female organs after fruitful sexual union, and by what means are the ova dislodged from the ovary? 2d. What changes do the ovaries or their vesicles undergo after the discharge of any of the ova? 3d. What happens to the ovum from the time of its discharge from the ovary until the commencement of the development of the fœtus? 4th. In what part of the female generative system is the change of fecundation effected by the agency of the seminal fluid upon the germinal part of the egg? and lastly, In what does the change of fecundation consist, or upon what properties of the seminal fluid may it be supposed to depend?

These topics comprehend the history of the functions of the male and female internal generative organs, in so far as they relate to the processes of conception and fecundation; under which two heads, as has been already mentioned, it is our intention to bring the remainder of the facts respecting generation which come within the limits of the present article. We shall begin with those facts relating chiefly to the female, or conception.

The immediate consequence of sexual union upon the female internal generative organs is their great excitement, and a turgescence produced by an accumulation of blood in their vessels. When sexual union proves productive, this turgescence lasts for some time after it has taken place, so that in animals opened at this time, the ovaries, Fallopian tubes, and uterus are found to be of a much deeper red colour, and more vascular than in their natural state. In the female Rabbit, for example, opened soon after coition, the internal organs are nearly black from sanguineous congestion.

There also occurs in some of these parts a change of position in regard to one another, which is connected with the discharge of ova from the ovarian vesicles. The fimbriated extremities of the Fallopian tubes are turned towards the ovaries on each side, and embrace these organs closely, so that the infundibular opening is applied against the ovary, and must of necessity receive the contents of the Graafian vesicle when it bursts. In some animals the ovary is inclosed in a sac along with the infundibulum by a reduplication of the peritoneum, so that the ovary is kept always to a certain extent within the infundibulum; but in other animals in which the connection between these parts is not of this permanent kind, there is an equally firm union of them after copulation. In regard to the means by which this approximation and union of the fimbriæ and ovaries are brought about, it may be stated, that in some animals the action seems to be somewhat of a muscular kind; for there are strong fibres, having all the appearance of muscular fibres, which pass from the ovary towards the fimbriated portion of the Fallopian tube; and in these animals, as well as in others even, in which the muscular fibres are less obvious, irritable contraction may be supposed to be a means of bringing the parts nearer to one another. The observations of Hartsœker and Haller, however, would appear to shew that the vascular turgescence which follows copulation, amounting to a state approaching to erection, may also contribute to give rise to the change of position now under consideration, for they found by repeated trials that the forcible injection of fluids into the bloodvessels of the generative organs in the human dead body caused the approximation of the fimbriæ and ovaries. But, although it may be admitted that vascular turgescence may cause this approximation of the parts, we would venture to suggest that some power of the nature of muscular contraction is necessary to give that degree of firmness to the union which it is found to possess some time after copulation.

We must remark, however, that when a

* The glans penis and glans clitoridis, the nymphæ and corpus spongiosum urethræ, and the corpora cavernosa penis and clitoridis are considered anatomically as the respective corresponding parts in the male and female body.

female quadruped is opened immediately after copulation, the fimbriæ are frequently not observed to be in contact with the ovary; and this is found to be the case only when some hours are allowed to elapse between the copulation and the death of the animal. Haighton never found it to have taken place in the rabbit previous to nine hours after union with the male, and De Graaf not even before twenty-seven hours; but observations of this nature upon animals opened soon after being killed, do not make it certain that the action had not taken place; for it may be supposed that the adhesion between the infundibula and ovaries had commenced, but was less firm than it becomes at a subsequent period, and that it was merely disturbed by the violence of the death or rough handling of the body. This is the more probable, seeing that the same change of position has been observed to take place before sexual union in animals in the state of heat, as by Cruikshank in the rabbit, and by Haller in the sheep. In some birds, particularly domestic fowls and ducks, it is well known that when they are well fed all the changes necessary for the formation of an ovum and its discharge from the ovary may take place without the concurrence of the male, and in quadrupeds there is reason to believe that the turgescence and change of position of the generative organs above alluded to may frequently occur independently of fruitful or unfruitful sexual union, as from excitement of the generative organs in the state of heat, or as in the cases observed by Haller, of ewes having connection with wedders or castrated males only.

There is every reason to suppose that the same changes which we have described as occurring in quadrupeds after sexual union, take place in the same circumstances in the human female; that is, that the fimbriated infundibula of the Fallopian tubes are brought near to the ovaries, and are made to embrace them firmly, so as to receive the contents of any vesicles which may burst; and that this change is produced by an action which begins usually during sexual union, but which may also occur without any venereal orgasm.

The ovaries, we have already stated, become unusually vascular during and after sexual union; but the changes in the ovary which most demand our attention, are those connected with the bursting of the Graafian vesicles, and the discharge of their contents. In the unimpregnated female arrived at the age of puberty, the Graafian vesicles of the ovary are of unequal size. Some time after sexual union, one or more of these vesicles, probably those which are at the time farthest advanced, undergoes a greater enlargement, and from its swelling projects beyond the rest of the surface of the ovary, and after various other changes, an aperture is formed in the most projecting part of the coats of the vesicle, through which its contents find an issue. But before proceeding further with this narrative, we must recall to the recollection of the reader the nature of the ovum, which, on the occasion of the rupture of one of the Graafian vesicles, is discharged from its interior.

The ovarian vesicles of man and quadrupeds are filled with fluid, which, viewed by the unassisted eye, appears to contain only a little granular and flaky matter. This fluid is coagulated by heat, alcohol, or acids, as albumen is, and also by exposure to air. The membrane forming the vesicle consists of two layers, an external and internal, and the whole vesicle is covered also by the general peritoneal and vascular envelope of the ovary.

From the earliest times anatomists and physiologists seem to have considered the ovarian vesicles as the source of the offspring; and many, from a sort of loose analogy with oviparous animals, regarded the vesicles themselves as the ova in which the viviparous fœtus is developed. The large size of these vesicles, however, as compared with the Fallopian tubes through which the ova have to pass, and the subsequent observations of De Graaf, Vallisneri, and Cruikshank, as later those of Prevost, Dumas, and others, who found in the first days after copulation ova in the Fallopian tubes of a size considerably less than the vesicles of the ovary from which they had proceeded, proved satisfactorily that the ovarian vesicles and ova are not identical. Various conjectures were in the meantime offered by different authors as to the source of the ovum; some holding it to be formed by a process of secretion, others by an organic union of the male semen with the contents of the Graafian vesicle, and so forth; but no one ever observed the ovum itself of mammiferous animals within the ovary, until Baer made this important discovery in 1827, by the examination with the microscope of the fluid contents of the Graafian vesicle.*

Baer found that, in the centre of a granular layer, placed generally towards the most prominent part of the vesicle, to which he gives the name of proligerous disc or layer, there is fixed a very minute spheroid body, seldom above $\frac{1}{200}$th part of an inch in diameter. The appearance of this body he found to be constant, and on examining it with attention in the vesicles of the ovaries, and after their rupture in the Fallopian tubes, he traced the changes it underwent in the first days after copulation, and established satisfactorily the identity of this body with the ova found by previous observers in the Fallopian tubes and cornua of the uterus; thus proving by actual observation what had before been held only from analogy, that in the mammiferous or truly viviparous, as well as in the oviparous animal, the fœtus derives its origin from an ovum already formed in the ovary before fecundation.†

* Epistola de Ovi Mammalium et Hominis Genesi. Lipsiæ, 1827.

† We have no hesitation in giving the sole and undivided merit of this discovery to the indefatigable and talented Baer, whose observations have contributed, perhaps more than any other single individual of the present time, to extend our knowledge of the early formation of the fœtus. We ought not, however, to omit to mention that Messrs. Prevost and Dumas conceived that in two instances they had perceived ova in the ovarian vesicles of quad-

Some time after sexual union the fluid contained in the vesicles which are about to burst, previously transparent and nearly colourless, now becomes more viscid and tenacious, somewhat turbid and of a reddish colour; and in some animals it is possible in such ripe vesicles to perceive, with the unassisted eye in a favourable light, a whitish opaque spot on the most prominent part, indicating the layer of granules or proligerous disc, in the centre of which the ovum is situated. After a certain time a small opening is formed at the most prominent part of the coverings of the vesicle, the vesicle bursts, and its contents escape through the opening; they are received in the infundibulum, which is now applied firmly against the ovary; and the ovum entering the Fallopian tube is conveyed along it, probably by its slow and gradual vermicular contractions, until it at last arrives in the uterus.

With regard to the time at which the opening of the ovarian vesicles takes place, there are considerable varieties in the same and in different animals. In the sheep, the vesicle has been found burst so early as at two hours after coition. In the dog, Haller found the vesicles burst before the sixth day; in one instance the day after coition; but Prevost and Dumas, not until the seventh or eighth. In the rabbit, Cruikshank observed vesicles burst two hours after coition, while Haighton considers forty-eight hours as the usual time at which the rupture happens in this animal. M. Coste has observed it most frequently between the second and third day in the rabbit.

After the bursting of the Graafian vesicles, there occur in them and in the neighbouring part of the ovary some important changes of structure, which claim our attention in this place as intimately connected with that part of the process of conception which is now under consideration.

If the Graafian vesicle which is enlarged from venereal excitement and is ready to burst, be examined with care, it will be seen that at the most prominent part of its coats the bloodvessels converge towards the point at which the rupture afterwards takes place, and this point is itself comparatively destitute of bloodvessels.*

At the time of the formation of the opening into the vesicle, from the division of some of the bloodvessels, a small quantity of blood is generally mixed with the fluid contents of the vesicle; and after the vesicle has been emptied of these fluid contents, their place is generally supplied by a greater or less quantity of coagulated blood, probably poured out by the same ruptured vessels.

The membranes of the vesicle at this time have become thicker than before: the inner one in particular appears more vascular and uneven, perhaps in part from its being puckered up on the vesicle becoming flaccid and comparatively empty. The wrinkled appearance on the inner surface of the vesicle increases, and there grows gradually out from it a new substance which comes to occupy the whole cavity of the vesicle; and in many instances, as this new substance is formed in greater quantity than can be contained within the limits of the vesicle, it protrudes some way out at the opening of the vesicle, forming a dark red prominence like a nipple, which rises above the neighbouring surface of the ovary. This substance, at the time of its first formation, is of a pink or reddish colour, but as it becomes gradually less filled with blood it acquires a yellowish hue, which is more or less apparent in different animals. In the human species it is of a bright yellow colour, whence the name of corpus luteum applied to this new production of the ovarian vesicles.

The substance of the corpus luteum has a lobular structure; the lobules radiating in a somewhat irregular manner from the centre to the circumference. The central part of the corpus luteum frequently remains hollow for some time after its production, opening exteriorly by a narrow passage from the place where the rupture of the vesicle originally took place; at other times this passage is closed more early, and there remains nothing but an indication of its place in a depression in the centre of the most projecting part of the corpus luteum. The lobules of the corpus luteum, examined with the microscope, exhibit merely a granular structure, and are not formed of acini, as some have described them, so that there is no reason to consider these bodies as of a glandular nature.

The size which corpora lutea attain when fully developed varies much in the same and in different animals. In the human female they become as large as a common hazel-nut; in the cow they are sometimes as large as a ches-

rupeds, (Annal. d. Scien. Nat. tom. iii. p. 135,) but without any certainty or exact knowledge as to their nature. M. Coste, with a spirit of appropriation too common, we regret to say, among his countrymen, has taken advantage of some speculative views and strained analogies brought forward by Baer concerning the bodies which he discovered, in which he compared them (erroneously as we think) to the germinal part only of the ovum, rather than to the whole ovum of the oviparous animal, to take from the merits of Baer in their discovery; but we feel assured that every unprejudiced inquirer who reads with attention Baer's admirable "Epistola de Ovi Mammalium et Hominis Genesi," in which his discovery was first announced in 1827, and compares it with other works on the subject, will be convinced that Baer has no sharer in the discovery, and fully understood the nature of the ovarian ovum of viviparous animals; although it may be the case that subsequent investigations have added considerably to the knowledge of the relations of these ova. We shall return to a more minute detail of this body in considering the process of formation of the ovum in the present article and under the article OVUM.

* The ovarian capsules of the bird, which are obviously the analogous parts of the ovarian vesicles of quadrupeds, present on their most prominent part a remarkable band, extending for nearly one-third of the periphery: towards the margins of this band the small bloodvessels all converge, but they do not pass upon the band itself, so that it is left free from bloodvessels. It is in this non-vascular or less vascular part of the capsule that the rupture takes place when the yolk escapes.

nut; and in the sow or ewe they are somewhat larger than full-grown peas.

The corpus luteum may, by dissection, be easily separated from the surrounding parts and turned out of the ovary; and when this is done, the external membrane of the original vesicle remains lining the cavity left in the ovary. From this it would appear that the corpus luteum is most intimately connected with the inner membrane of the vesicle; and, in fact, Baer* observed that, before the rupture of the vesicle in the dog, the inner membrane had become thickened, rugous, and of a villous structure, as if the corpus luteum grew from that internal membrane itself. This observation also makes it probable that the growth of the corpus luteum may contribute to cause the rupture of the vesicle.

The corpus luteum at first increases gradually in size, remains for a time stationary, and then decreases till it either wholly disappears or leaves only a small mark or cicatrix to indicate its place. The time at which it attains its full size seems to vary considerably. In the sheep two or three days are sufficient for the formation of the corpus luteum, and its cavity becomes obliterated within a fortnight after copulation. Haller found corpora lutea in the dog on the sixth day; Cruikshank observed the corpora lutea to go on progressively increasing till the ninth day in the rabbit; and it is probable that in the human species the corpus luteum is not fully developed till after the second month of pregnancy.

After the corpus luteum has attained its full magnitude, its colour becomes paler and of a clearer yellow; its size then gradually diminishes, its tissue becomes more compact, its cavity is obliterated, and it is converted into a body nearly solid. It generally retains, during utero-gestation, a considerable size, and this remark applies especially to the human species, in which it diminishes much more rapidly in size after than before the birth of the child. In some animals it at last wholly disappears; in others, among which is the human species, it always leaves some mark.

In what has now been said regarding the corpus luteum, that body has been described as it is formed in the place of a vesicle which has been burst after fruitful sexual union; but we may remark that the same series of changes always follows the rupture of an ovarian vesicle from whatever cause that may have proceeded. It is now well known that in some animals the rupture of ovarian vesicles and subsequent changes take place without sexual union merely from the state of heat or venereal excitement of any kind, while in others these phenomena are never observed but as accompaniments of conception. The sow and mare belong to the first of these classes of animals. The rabbit, bitch, ewe, and cow may be mentioned as examples of the second, as also is generally the case in the human female; but in woman, as in some other females, various circumstances induce us to believe that the rupture of ovarian vesicles and the formation of corpora lutea in their place occasionally happen without sexual union from all those causes which excite greatly the sexual organs; and we are not, therefore, inclined to admit the presence of a corpus luteum, taken alone, as a certain sign of sexual union having occurred; though conjoined with other signs, the presence of one or more corpora lutea or the appearance of ruptured vesicles must be regarded as good presumptive evidence.

In some of those animals in which vesicles frequently burst without sexual union, there are occasionally very many corpora lutea in the ovary, so as to alter completely its form, and disguise its natural structure, as may frequently be seen in the sow. In those animals again in which sexual union alone brings about the rupture, we at once distinguish the ovary of the unimpregnated animal from that of the one that has had connexion with the male, and we very generally observe an exact correspondence in the number of corpora lutea and the ova or fœtuses contained in the uterus;* and the same correspondence is very frequently found after conception, even in those animals in which corpora lutea are formed without sexual union.

While the corpus luteum, then, is always to be found in the ovary of a pregnant quadruped, the formation of this body is to be regarded as the uniform consequence of the rupture of the ovarian vesicles, whether that rupture shall have been occasioned merely by excitement of the organs, or by productive or unproductive sexual union; but it is only when conception and pregnancy occur that the corpus luteum attains its full size, and runs through the whole of that series of changes which we have described as peculiar to that body.

We ought not to omit here the mention of a totally different view which has been taken of the corpora lutea, that, viz. of Buffon and Vallisneri,† supported more recently by Sir E. Home,‡ according to which it is held that the corpora lutea exist before the rupture of the vesicles, and are the matrix in which the vesicles and ova are formed.

Two circumstances principally have been brought forward in favour of this hypothesis:—1st, that corpora lutea occur in the virgin state; and 2d, that they frequently contain vesicles. Now the existence of corpora lutea, we have already stated, in the sow (observed by Sir E. Home), and even, we are inclined to hold, in the human female, is not necessarily a proof of sexual union having previously occurred, since the rupture of the vesicles may have

* See Epistola, &c.

* It may be mentioned that more than one ovum have sometimes been found in the same Graafian vesicle, in which case it will readily be understood there might be only one corpus luteum in the ovary and two ova in the uterus, but this is rare. The author has verified the above correspondence in many hundred pregnant ewes, in a considerable number of cows, rabbits, some cats, and other animals.

† Vallisneri, Hist. of the Generation of Man and Animals (Ital.).

‡ Phil. Trans., vol. cviii. p. 256, and vol. cix. p. 59.

followed simple excitement of the sexual organs, and might therefore take place either with or without the male; and in the second place, the occurrence of cavities and vesicular membranes within the corpora lutea is by no means a proof that these cavities are new or forming ovarian vesicles; on the contrary, there is every reason to regard them as unnatural or the product of disease. But though lately revived upon the above-mentioned grounds, it is long since this hypothesis received the most satisfactory refutation, both from the observations of De Graaf and of Haller. Haller in particular traced in the most accurate manner all the steps of the development of the corpus luteum, from the first rupture of the vesicle till its completion: he employed the animals least liable to lead to fallacy in such observations; those, viz. in which rupture of the vesicles and formation of corpora lutea is usually produced only by sexual union; and he always remarked in them an exact correspondence in the number of fœtuses in the gravid uterus with the number of corpora lutea in the ovaries, while at the same time he found the first appearance of these bodies to take place at a fixed period after sexual union, and their size and structure always to bear an exact relation to the period of utero-gestation at which they were observed.*

The uses of the corpora lutea are entirely unknown. The fact that these bodies become larger and remain proportionately of a larger size during pregnancy than when produced in other circumstances (as without sexual union, or after unproductive copulation, or when the product is blighted at an early period of utero-gestation,) would seem to indicate some connexion between the corpora lutea and the development of the fœtus in utero. By those who have regarded the corpora lutea as of a glandular nature, they have been supposed to secrete fluids which assist in the nourishment of the fœtus. We have already stated the reasons for considering such hypotheses as groundless. (See OVARY.)

Descent of the ovum. Its structure and changes during its passage.—The attention of accoucheurs in all ages and countries has naturally been directed to the study of the structure of the human ovum and fœtus in the more advanced stages of utero-gestation, and a great body of facts has been collected from the examination of aborted products or the gravid uterus of women dying during pregnancy, from which scientific men have acquired an accurate knowledge of the structure of the human fœtus and its covering in the ovum during the greater part, and especially in the more advanced period of utero-gestation; but very little is known of the nature of the egg in the first stages or immediately after conception has occurred. We have, in fact, no direct observations which inform us of what happens to the human ovum immediately after its escape from the ovary, and, indeed, for some little time after its arrival in the uterus, when the parts of the fœtus have already begun to be formed in it. This subject has, however, been investigated with considerable success in several mammiferous animals; and although there remain several points which still require elucidation, yet, from the analogy which is known to exist in the structure of the ovum and fœtus of the human species and those of quadrupeds and birds, we are enabled to bring together the detached observations which chance has thrown in our way, and thus to give a connected account of the generative process in man, imperfectly as that process has as yet been observed.

Our design at present is to follow the ovum only as far as into the uterus, or until the commencement of the formation of the fœtus in it. We believe we shall place this part of our subject in the clearest point of view, by prefixing to our remarks regarding the ovum of man and quadrupeds a short sketch of what happens to the egg of the common fowl after its discharge from the ovary.

The substance of the yolk enclosed in its membrane, together with the germinal portion in which after incubation the rudiments of the new animal begin to be formed, constitutes the essential parts of the bird's egg as it exists in the ovary. The ovarian egg, when it has left the place of its formation and passed into the oviduct, receives the addition of various other parts, viz. the albumen, chalazæ, shell and its lining membrane, as it gradually descends through different portions of the oviduct, each of which is destined to secrete one of these newly added parts. These parts may, however, be considered as accessory to the more essential constituents of the egg, which we are inclined to regard as the germinal spot or cicatricula, the granular and oleaginous fluid of the yolk, and the dense transparent membrane with which they are enveloped. To the unimpregnated egg of the ovary we shall give the name of ovulum, and henceforward in this paper apply the name of ovum to the perfected egg, that is, the ovulum to which the accessory coverings have been added, and which has received the influence of the male. The ovarium of the common fowl in the breeding season, or when it is laying eggs, has the form of a bunch of clustering ovula, which are contained in capsules, the more advanced of which hang down from the rest of the ovary by the elongated pedicles of the containing capsules; while the smaller ovula of various sizes, composing the body of the ovary, cluster more closely together. The fully developed ovula only have the deep yellow colour peculiar to the yolk; as the smaller ones are less advanced their colour is paler, and the smallest are nearly colourless and transparent from the absence in them of the oleaginous and granular matter peculiar to the riper yolks.

The little white spot or granular layer which

* The corpus luteum is developed then and becomes perceptible after the bursting of one of the vesicles; but let us not here lose sight of the fact before announced that the first commencement of its formation dates from a short while before the rupture, as indicated by a thickening of the inner membrane of the vesicle.

constitutes the cicatricula or germinal disc is easily seen in the larger ovula, occupying almost always the same position on the surface of the yolk, somewhere near the pedicle of the ovarian capsule. When the cicatricula is examined carefully in the ovulum, a small dark round spot is perceived in its centre, the relations of which to the first production of the fœtus are very important. This little dark spot was discovered by Purkinje to contain implanted in the centre of the cicatricula a minute transparent vesicle filled with fluid. He farther shewed that during the passage of the ovulum from the capsule of the ovary into the infundibulum of the oviduct, this little vesicle disappears, being probably burst, and leaves in its place a thin and tender transparent membrane. The vesicle of Purkinje, as it is called from its discoverer, occupies then the centre of the germinal spot, and it is in the transparent membrane left in its place when the vesicle is dispelled that the first rudiments of the fœtus afterwards make their appearance. Hence the vesicle has also received the name of germinal vesicle, a most appropriate term, since it may be regarded as the more immediate seat of the germ or germinating faculty of the egg.

The Purkinjean or germinal vesicle exists in the smallest as well as in the more advanced ovula of the fowl's ovary, and it is proportionally much larger in small than in large ovula. In the very small ovula it is not, as in the riper ones, situated on the surface of the yolk, but towards the centre of that body; and as the ovulum advances to perfection, the germinal vesicle gradually approaches more near the surface, and becomes more prominent on the surface of the cicatricula. In ovula less than two lines in diameter the vesicle is usually unconnected with the germinal layer or cicatricula, but in those of four lines in diameter it is already placed in the middle of the germinal spot.

In all oviparous animals a vesicle, similar to that now described in the common fowl, occupies the central part of the germinal layer so long as the ovulum remains in the ovary, and undergoes the same rupture and other changes at the time of the discharge of the ovulum from the ovary.*

In turning now to mammiferous or viviparous animals, it may be remarked in the first place, that although the extremely minute size of the body discovered by Baer to be constantly present in the ovarian vesicle prevents us from observing it with ease, and establishing with certainty its analogy to the yolk and its accompanying parts in the egg of the fowl before development begins; yet after the commencement of fœtal formation, the early changes which this body undergoes prove its correspondence with the ovum of birds in a most satisfactory manner. We have already, however, stated the reasons for regarding the vesicle of Baer as the ovulum of mammalia, and need not now recapitulate them. We shall only remark that although the vesicle of Baer and ovulum of birds differ widely in size, that vesicle appears to contain the same essential parts of the egg belonging to birds and other oviparous animals, viz. a fluid granular mass or yolk enclosed by an investing membrane, and furnished also with a more compact granular layer situated on the surface of the yolk, but also enveloped by its membrane, in which the rudiments of the fœtus first appear, and which is, therefore, the germinal layer of the mammiferous ovum.

The membranes of the ovarian vesicle in mammalia and the capsules of the ovary in the fowl are corresponding parts, and the principal difference between the ovarian cavities containing ovula in oviparous animals, and those of viviparous animals, consists in this, that in the latter the ovulum (the vesicle of Baer) is placed in the granular proligerous disc, and has all the fluid of the vesicle interposed between it and the coats of this cavity.

At the time when Baer first discovered the ovulum of mammalia, there was still wanting, in order to complete the proof of its analogy with the ovulum of birds, the observation of the germinal vesicle (vesicle of Purkinje) within it. This additional proof has been supplied within the last few years by the researches of T. W. Jones, Coste, Purkinje, Valentin, and Wagner, which we have ourselves confirmed.

The germinal vesicle of the very small ovulum of quadrupeds is of course a most minute object, and in fact it can only be seen with a good microscope; but in favourable circumstances it is nevertheless quite distinct, and the investigations above referred to, conjoined with analogical evidence, make it highly probable that the little vesicle found within the ovulum of viviparous animals occupies the place in which the fœtus first makes its appearance, and that at the time of the passage of the ovulum from the ovary to the Fallopian tube this little vesicle is burst, and undergoes analogous changes to those which have been noticed in the fowl.*

In birds the shell with its lining membrane forms the external covering of the egg; and in all oviparous animals a similar external envelope (besides the membrane enclosing the yolk) is to be found, though varying greatly in thickness, consistence, and structure in different animals. The ovum of mammalia at the time

* Purkinje's description of this vesicle was first given in his excellent "Symbolæ ad ovi ovium historiam ante incubationem, Vratisl. 1825," and second edition at Leipzig, in 1830. Baer contributed in his "Epistola" many important facts concerning its existence and changes in other oviparous animals. Coste, Valentin, and Wagner have since added several observations. We may state here that the bursting of the vesicle does not occur in all oviparous animals exactly at the time of the escape of the ovulum from the ovary, but nearly about the same time.

* In his "Epistola," published in 1827, Baer compared the vesicle he had discovered within the Graafian vesicles of the ovary to the vesicle which Purkinje had in 1825 discovered in the cicatricula of the fowl's yolk: erroneously as we think; for the facts mentioned above are sufficient to disprove any such analogy. For the sake of clearness we here subjoin a tabular view of the parts which correspond with one another in the bird and quadruped.

when it arrives in the uterus has also a similar external envelope, which has received in man and most animals the general appellation of chorion. Baer is of opinion that the chorion exists ready formed in the ovulum of the ovary; but his observations appear to us as yet insufficient to prove this point, and we feel inclined rather to adopt the view of Valentin, who holds that it is probable that the chorion is added to the ovulum after it has left the Graafian vesicle, that is, during its passage from the ovary to the uterus, somewhat in the same manner as the albumen or shell is added to the egg of the common fowl in its passage through the oviduct. The analogy of all oviparous animals is at least strongly in favour of such a view of the mode of the production of the chorion or external envelope; while on the other hand we ought not to lose sight of the fact that though the external envelope or chorion occupies the same position as the external covering of the eggs of oviparous animals, its structure and functions are very different, for almost in every quadruped the chorion serves important purposes in establishing that more intimate union peculiar to viviparous animals, which is formed between the ovum and uterus in the placenta or analogous structure.

It is only in the dog and rabbit that the ova have hitherto been traced by actual observation in the whole course of their progress through the Fallopian tubes from the ovary to the uterus. These observations we owe chiefly to the careful researches of Cruikshank, Prevost and Dumas, Baer, and Coste. In regard to other animals we have only a few detached observations in some of them, and in the human species the ova have never been observed in the Fallopian tubes, nor indeed for some time after they must have entered the uterus. We do not therefore know, with any degree of certainty, at what distance of time after sexual union the ovum passes into the uterus of the human female. Great difficulties attend the elucidation of this point. In the first place, we are opposed by the impossibility, in the greater number of cases in which we may happen to obtain a pregnant uterus for investigation, of knowing accurately the age of the product or the time at which impregnation has occurred; and in the second place, we are here deprived of the assistance derived in many other parts of our subject from analogical evidence by the wide discrepancies we find among animals in respect to the period of the arrival of the ova in the uterus; for there does not appear to be any exact correspondence yet shewn between the time at which this happens and the length of duration of utero-gestation. It may be well, however, to endeavour to form an approximative opinion. In the rabbit, although ova are known frequently to be discharged from the Graafian vesicles on the second day after sexual union, they are in general not detected in the uterus before the third or fourth day, and frequently not before the fifth or sixth, at which time they appear as vesicles a little more than a line in diameter, lying unattached in the upper part of the cornua of the uterus.*

In the dog ova have been observed in the Fallopian tubes on the eighth day, but they have not been found in the uterus before the twelfth day. In the cat we have found ova of the size of peas beginning to be attached to the uterus at the twelfth day, and in both the cat and dog we think it probable from the size of the ova that they had already been in the uterus for at least one day, so that the tenth or eleventh day may be regarded as the time when ova generally appear in the uterus of these animals.

Haller and Kuhlemann† never found an ovum in the uterus of the sheep till the seventeenth day after copulation, and our own observations on both the sheep and sow agree precisely with theirs. Hausmann never found the ova in the uterus of the sow before the period of four weeks after conception, and those of the bitch before three weeks; but here we must caution the reader against the error of supposing that in the sheep and some other animals, because the ova have not been observed in the uterus, they do not actually exist there previous to a certain date; for the large size of the ovum and its membranes, as well as the state of the fœtus, which though small is already somewhat developed, entitle us to conclude that the ovum of the sheep must have been some time in the uterus. The recent interesting observations by M. Coste have thrown great light upon this subject, he having detected the ova of the sheep so early as five days after conception. In the cow also, in which the period of gestation is nearly twice the length of that in the sheep, the ovum seems to arrive almost as early in the uterus, if we may judge from the state of advancement of the fœtus at an early period.‡

In the Quadruped.	*In the Bird.*

* M. Coste has shewn that there is considerable variety in respect to the time at which the ova descend in the rabbit, and thus very reasonably accounts for the difference one generally finds in the state of advancement of the ova in the pregnant uterus.

† Vide Kuhlemann's Observ. quæd. circa negotium generationis in ovibus fact. Gott. 1753.

‡ Immediately after the arrival of the mammiferous ovum in the uterus it increases in bulk with amazing rapidity, and its membranes being thus suddenly dilated become in consequence very weak and thin; so tender indeed are they, that if they

With regard now to the time at which the ovum first enters the uterus in the human female, let us examine the facts which are before us. The greater number of observations of this kind are made on aborted products; many of these are malformed or diseased, in consequence of which very probably they have been thrown off by abortion; others are injured by the violence of the action which causes the uterus to be emptied of its contents. Our knowledge of the time of conception is generally founded upon the cessation of the menstrual flow on the first occasion when it ought to have recurred after conception has taken place, and conception may in the greater number of instances have taken place at any period of the interval. In a very few cases only have we any means of determining the time of conception, and in still fewer instances has there been an opportunity of examining the uterus in situ at an early period after conception when the period of sexual intercourse was known. In by far the greater number of instances, therefore, there may be an error in the calculation of ten days or a fortnight.

It is by no means rare to see specimens of the human ovum or fœtus in anatomical collections marked as being a fortnight or three or four weeks old; but it is now generally acknowledged that the greater number of these are incorrectly marked. We have seen, however, more than one such ovum, which, both from the history of the cases and from the structure and size of the parts of the ovum and fœtus, we should be inclined to consider as dating between three and four weeks after conception.*

There are some who describe the human fœtus at less than a fortnight old, and even as early as the eighth day, as in the well-known and often-quoted example described by Sir E. Home. But there is some reason to think that Sir E. Home was mistaken in the case alluded to. Either, supposing that conception had occurred eight days before death, the body in question was not the fœtus, or if it was the fœtus, it must have been considerably older than he supposed.

The earliest example of the human ovum with which we are acquainted is that mentioned by M. Velpeau in his work *sur l'Embryologie Humaine;* which, if he was not deceived by the person who gave it to him, he had the best reason to believe was discharged on the fourteenth day after sexual intercourse.

This ovum, the description and drawings of which are very meagre, is described as about the size of a pea; the fœtus was already somewhat formed, though very small; and all points of structure in the fœtus and ovum appear to us (so far as we can judge from the description) to correspond with one another, and to shew that the product was quite natural. This ovum from its size and from the state of advancement of the fœtus must have been in the uterus at least two or three days.

We possess also the recent record of two valuable observations made on the structure of the gravid uterus of females dying suddenly eight days after sexual intercourse; the one by Weber, the other by Professor Baer. No ovum was detected in either of these instances either in the uterus or tubes. We feel inclined to place much reliance on these two observations as being made by persons well acquainted with the various circumstances necessary to be attended to in such a delicate investigation, and with all the advantages of recent knowledge, and though they afford negative evidence only, yet we are disposed to found upon them as proofs that at the eighth day the ovum has not descended into the uterus.

On comparing the degree of advancement of the fœtus in the ovum described by Velpeau and in others with that of the fœtus in the dog, cat, and sheep, at known periods, we would hazard the opinion that the human ovum arrives in the uterus on the eleventh or twelfth day after conception. Valentin thinks the twelfth or fourteenth day, but we are inclined to believe that it cannot be much later than in the dog.

Change of the uterus after conception.—Before the arrival of the ovum in the uterus, a change has already taken place in the interior of that organ preparatory to the reception of the fœtus. An exudation of a substance having many of the characters of organizable lymph

once burst it is impossible to recognize any parts of the ovum, frequently in instances where we are certain it has existed. Baer in a second epistle (published in Breschet's Repertoire, vol. viii. p. 175) mentions these difficulties of manipulation in extracting the ova from the gravid uterus of the dog during the early periods, and advises that, on account of the violent contractions which are apt to ensue in the uterus from its exposure to the air, the animals should not be opened, but left perfectly quiet for eight or twelve hours or more after death. We have frequently pursued this plan advantageously in the rabbit and cat; and have even found it necessary to harden the ovum and uterus in alcohol before being able to extract the former. The same circumstances may account for our never finding the ovum of the sheep before the seventeenth day, for those we examined were all killed at the market, and consequently opened immediately after death while the contractility still remained in the uterus. At earlier periods we have in fact frequently found shreds of membrane, and some of the earliest ova which we found were partly destroyed; but in a very short time afterwards the membranes of the egg and parts of the fœtus acquire sufficient consistence to resist the pressure.

* So common in museums are the specimens of blighted ova which are considered as examples of very early date, that the author confines himself here to the mention of those which he has himself seen, making this general remark, that in all those specimens below the alleged age of six or seven weeks, in which the fœtus and membranes, particularly the amnion, are disproportionate in size, that is, the first very small and the latter large, then the product is unnatural, and we ought to judge of its age more by the extent of the membranes than by the size of the fœtus. We feel inclined to believe that some of the views adopted by Dr. Pockels of Brunswick, in his interesting paper on the early structure of the human ovum and fœtus (to the consideration of which we shall return in the article OVUM), are founded upon the examination of unnatural specimens.

furnishes a soft flaky lining to the cavity of the uterus, and serves to form a covering of the ovum when it afterwards descends into the uterus. This newly formed substance is reflected over the ovum so as to give it a double covering, the two layers of which constitute the two folds of the decidual membrane. The decidua is filled with bloodvessels formed by a process of organization similar to that which occurs in inflammatory adhesion by coagulable lymph. These bloodvessels are continuous with those of the uterus, and as the ovum advances in the progress of development, they are much dilated in some parts so as to form sinuses, which are ultimately intermingled, though by no means continuous with the bloodvessels which pass out of the umbilicus of the fœtus. The placenta or organic connection between the female parent and child, by means of which the respiration and partly also the nutrition of the latter is carried on, is in great part formed in the decidua with which the flocculent chorion is closely incorporated; but the description of these parts belongs to another place.

In a former part of this essay it was remarked that rupture of the Graafian vesicles and discharge of the ovula from them, as well as the formation of corpora lutea, may take place in some animals without the concurrence of the male: there is reason to believe that in some cases the decidua may in part be formed without conception having occurred, as in the cases of moles, &c. When these changes have occurred without conception in Mammalia, it is quite possible that the ova may have been carried down the Fallopian tubes; but as they are unfecundated, they undergo no enlargement, and consequently we do not know what becomes of them.

In many oviparous animals the same is the case, that is, ova are frequently discharged from the ovaries without the concurrence of the male, as happens in the common fowl and other birds, in some reptiles and fishes. But even in those animals in which barren ova are thus excreted by the female, union with the male renders the exclusion of the egg more easy and regular, and it is consequently not uncommon for female oviparous animals which are removed from the males to die at the season of breeding, when the ova are formed in their ovaries or descend from that organ into the oviduct. This is beautifully described by Harvey as befalling his lady's parrot, which he had always taken for a male bird, but which, after being much fondled, died of "a corrupted egg impacted in the oviduct;" and also in a cassowary kept in the royal gardens, which, after being some time there, was excited by being placed in the vicinity of a male and female ostrich, and having laid one egg, died of a second being retained in the oviduct.

In the common fowl indeed, when highly fed, so great is the productive energy both of the ovary and oviduct that they will continue to lay eggs during a whole season without the assistance of the male; but this is well known to be often very pernicious to the bird, as many of those kept without the cock die; and it not unfrequently happens that eggs, or bodies like eggs, are laid by them containing no yolk, but consisting only of the albumen, membrane, and shell, which are the product of secretion from the oviduct, and that in others large masses of imperfectly formed eggs accumulated together are lodged in the genital passages.

These facts exhibit in a strong point of view the powerful productive energies of the female generative organs independently of the concurrence of the male; for it is sufficiently obvious from them that the greater part of the substance of the egg is due to the female, and that ova, to all appearance perfect,* though unfit for reproduction, may be brought forth by the female wholly independent of the male. Some authors also adduce as examples of this independent productive energy of the female, the occurrence of bones, hair, teeth, &c., in close cysts of the ovaries of women and female quadrupeds, but this leads us too far into the regions of vague supposition.

Irregularities in the descent of the ovum.— This appears to be the proper place at which to make mention of a few irregularities that have been observed in the descent of the ovum, which are attended with important modifications of the generative process.

In the bird it not unfrequently happens that the yolk or ovulum which has been discharged from its burst capsule in the ovary, instead of descending through the oviduct, and having added to it the external accessory parts, escapes from the infundibulum or oviduct into the cavity of the peritoneum. This irregularity occurs most frequently among those fowls which are laying eggs without the male, and in which it may be supposed the usual and regular performance of the appropriate motions is not ensured by venereal excitement. These yolks sometimes remain for some time in the cavity of the abdomen, and are afterwards gradually removed by absorption: in other instances they cause death. Upon every occasion when the ovulum is discharged from an ovarian capsule, the oviduct is excited to the secretion of albumen, membrane, and shell, and hence the ova subventanea, which consist only of these accessory parts without the yolk.

In other instances, either from a mechanical obstruction to the passage of the egg, or from a deficiency in the muscular power of the oviduct, the product becomes impacted in the passage, and there are formed large masses of accumulated ova subventanea, with or without yolks in some part of the oviduct or in its vicinity.

In some instances, extremely rarely met with, it is stated by Geoffroy St. Hilaire (Annal. du Museum d'Hist. Naturelle) that ova detained in the oviduct have become slightly developed, and the author owes to the kindness of his friend, Mr. Daniel Ellis, the history of several examples of the same ano-

* We shall have occasion to consider elsewhere more minutely the difference between the fecundated and the unfecundated ovum.

maly; but it may be stated as a general rule that this does not occur in oviparous animals, and more especially in birds, in which a continued supply of fresh air around the shell is necessary to promote incubation, and we do not know of any examples of truly oviparous animals in which the fœtus has been formed in an egg accidentally retained within the body of the parent. In none of those which we have observed was there any appearance of fœtal formation.

It is possible that some irregularities in the position of the ovum of mammalia during gestation may receive an explanation from mechanical disturbances similar to those we have now mentioned in birds; for supposing that in a viviparous animal the ovum does not gain the uterus or usual place of its abode during gestation, development of the fœtus still takes place. In those instances in which a fœtus is formed in the region of the ovary, or in what are termed ovarian conceptions, for example, it is not probable that the ovum is ever developed in the ovary itself without the bursting of the Graafian vesicle: it may be fixed close to the ovary, but it is always independent of that body. After the Graafian vesicle has burst, the ovum may be supposed either not to have been received in the Fallopian tube, or, after having entered that passage, to have been expelled from it by an inverted action of its muscular fibres or other causes. Fecundated by the contact of some of the seminal fluid which has reached so far into the Fallopian tube, the ovum remains in the neighbourhood of the ovary, has a cyst formed round it, and becomes organically united to the ovary or parts in its vicinity by structures similar to those which unite the ovum to the inner surface of the gravid uterus; for the bloodvessels of the mother which run into the cyst enlarge and form a placenta by their union and intermixture with those of the fœtus, and thus for a considerable time (amounting sometimes to four or five months) this ovarian or extra-uterine gestation is carried on.

In other instances of misplaced gestation, the ovum seems to have been arrested in its course when more or less advanced in the Fallopian tube; but here also the parts are susceptible of all those remarkable changes and growth which favour the development of the fœtus in the ovum. We mention these instances of extra-uterine gestation with the view of directing the reader's attention to an inference which may be drawn from them, viz. that all those changes of growth upon which the development of the ovum in viviparous animals depends may be regarded rather as belonging to the ovum itself than as resident in the uterus alone. It is worthy of remark, however, that in ovarian and tubular conceptions the decidua is formed within the uterus, nearly in the same manner as if the ovum had descended in the natural way into its cavity; from which we may infer that the production of the decidua is to be regarded as one of a series of changes induced by conception in the internal genital organs, and occurring independently of one another, rather than as the effect of any stimulation from the ovum, as some have supposed. Such a decidua in fact may be compared to the subventaneous ovum of the bird.

Very little is as yet known as to the physical circumstances (independent of malformation of the organs) which may give rise to misplaced gestation; and this is not a subject which we can hope to have illustrated by observation or experiment. One or two cases are on record, however, from which it might appear possible that a violent disturbance of the body soon after sexual union may be a cause of misplacement of the ovum. Burdach mentions instances of this kind: one of a cow gored by the horns of another soon after copulation, and two instances of the human female in which sudden fright in the same circumstances was followed by ovarian conception.*

In endeavouring to apply such mechanical explanations, we ought not to forget that in by far the greater number of cases sudden motion does not appear to disturb the natural performance of all those actions by which the ovum is securely lodged in the uterus in the natural way.

Circumstances influencing the liability to conception.—The circumstances which influence the liability of the female to conception are so various and so little determined that our remarks on this subject must be very short.

The healthy condition of the female is of course an important circumstance in reference to conception, but we do not know in how far a robust constitution or high state of health is favourable or the reverse to the occurrence of conception. Some women, it would appear, (perhaps those of a spare habit of body and languid powers of constitution) are most liable to fall with child when in their strongest and best state of health, while weakness in others seems to induce conception. Among animals it is known that high feeding sometimes prevents pregnancy, and the same is the effect of the opposite extreme of starvation.

The regularity of the menstrual discharge is one of the most important circumstances which favours the liability of women to conception; perhaps more from its being an indication of the general healthy state of the generative organs than from any influence exerted by the menstrual change itself. Many circumstances, however, seem to render it probable that women are more liable to conception within a few days after the cessation of the menstrual flow than at any other period of the interval, and accordingly there are many accoucheurs who regulate their calculations of the time of birth from this circumstance, dating the commencement of utero-gestation from a period within a week after the cessation of the last menstrual discharge. We do not know with certainty upon what circumstances this influence of the menstrual function depends; but it seems reasonable to suppose that it is connected with that state of excitement and sanguineous congestion in the ovaries and

* See Lallemand's Observat. Patholog. 1818, and Dict. des Scien. Med. xix.; also Grasmeyer de conceptu et fecundatione humana, 1789.

rest of the generative organs which usually attend on menstruation. There seems to be very little reason to believe, as some do, that there is a greater than ordinary liability to conception immediately before the commencement of menstruation.

Lactation in the greater number of women prevents conception for a time, generally for from six months to a year, but in other women seems to have no effect.

It is very obvious that the state of mind of the female has very little to do with conception, as it is well known that conception * occurs where there is no love, no desire, in pain, in sleep, and in the state of insensibility; and it is equally well established that sexual feelings are not necessary for the occurrence of conception, although it is possible that they may in some instances indirectly assist. It is worthy of remark that there are examples of individuals of opposite sex whose marriage has been barren, both having had children with others.

Signs of recent conception in woman.—Before concluding the subject of the changes in the internal generative organs of the female which follow fruitful sexual union, let us recapitulate shortly the principal circumstances which may be considered as evidence of conception having recently occurred in the human female.

In the first place, there is no one point of evidence which is conclusive in the early period of gestation excepting the finding the ovum or fœtus; and here we must be on our guard against confounding the mole, or such productions which occur in the virgin, with the true ovum. The other signs of conception afford little satisfactory evidence singly, though they are important when several are conjoined.

The signs of conception may be distinguished into those which in some measure affect the whole system, which may be called constitutional or general, and those which are more strictly local, or affect principally the generative organs.

The more general signs are—

1. The interruption of the menstrual flow at the usual period when there is no other obvious cause for it.

2. Fulness and enlargement of the breasts, and vascularity of the areola surrounding the nipple.

3. Derangement of the functions of the stomach; frequent nausea and even vomiting, especially in the morning, with depraved appetite, headache, &c.

4. An accelerated pulse, and some febrile symptoms.

The local signs are—

1. A slight enlargement and increased vascularity of the uterus.

2. The closure of the mouth and cervix by a peculiar viscid secretion.

3. The existence of the commencing decidua or substance from which that membrane is formed.

4. A vascular condition of the ovary, with very much enlarged vesicles, a ruptured vesicle or corpus luteum, and an increased vascularity or enlargement of the Fallopian tubes.

Such local signs can only be obtained by the examination of the body after death. When the greater number of them co-exist and have been attended with the more general constitutional signs, there is strong presumptive evidence of conception having occurred. But nothing short of the appearance of the child either passed in abortion or found after death would entitle us to conclude with certainty that conception had taken place, until those more obvious signs, which are found after the period of quickening, make their appearance.

§ 2. *As regards the male organs.*

Fecundation.—In continuing the detail of the phenomena which accompany or succeed to fruitful sexual union, we come next to the consideration of the process of fecundation. We shall begin this subject by a sketch of the nature and properties of the product of the male generative organs, viz. the seminal or spermatic fluid, and afterwards state the more important facts which appear to throw light upon the mechanism of the remarkable influence exerted by that fluid on the ovulum produced by the female.

Properties of the seminal fluid.—The seminal product of most animals is a whitish fluid, which to the naked eye appears homogeneous or nearly so; but in the human species and some of the higher animals, the seminal fluid or substance, ejaculated from the male organs during sexual union, consists of two parts of different consistence and appearance; in the human species, the one being of a pale milky colour and more fluid, the other clearer, semi-transparent, and more of the consistence of thick mucilage.

The seminal product is derived from several sources. A part comes directly from the testicle, some is discharged from the vesiculæ seminales, and with the fluid from these sources is mixed at the time of emission a certain quantity of the product of the secretion of the prostate body and Cowper's glands: but it is by no means well ascertained from which of these organs the two kinds of substance above alluded to are respectively derived. The more fluid and milky portion is first ejected; the gluey or clear mucilaginous parts, frequently collected into small hard masses, are more abundant in the portion which is last emitted.

Several circumstances render it highly probable that a considerable quantity of the fluid emitted during sexual union is derived directly by secretion from the testicle. With a view to the illustration of this, De Graaf performed the experiment of tying the spermatic ducts of a dog immediately before coition, and found, on examining them afterwards, that they were much distended by the accumulation of seminal fluid in the part of the vasa deferentia in-

* See the amusing speculations of the phrenologists on this subject.

tervening between the ligature and the testicle. It may be remarked, however, there are no vesiculæ seminales or reservoirs of semen in the dog, and the result of such an experiment can hardly with justice be applied to the human species. On the other hand, it may be remarked that in man, while the testicle continually secretes a small quantity of semen, and probably a larger quantity during venereal excitement, it is obvious that the vesiculæ seminales serve as reservoirs in which the seminal fluid accumulates; for when in the dead body fluids are thrown into the vas deferens, they pass into the seminal vesicle of the same side and distend it before issuing by the orifice leading into the urethra. The seminal fluid after being secreted probably follows in the living body the same course; and from this circumstance as well as the suddenness of emission, it is reasonable to infer that the greater part of the ejaculated semen, though formed in the testicles, comes in man immediately from the seminal vesicles.

The seminal vesicles we may suppose then always to contain a certain quantity of seminal fluid in the state of health. The accumulation of semen in these vesicles relieves the pressure which otherwise would distend too much the secretory and excretory ducts of the testicle, and the seminal vesicles are themselves relieved either by the sudden evacuation of their contents from time to time, or by the gradual absorption of the seminal fluid by the absorbents or bloodvessels.*

There is also reason to believe that the mucous lining of the seminal vesicles secretes a mucous fluid which is mixed with the prolific product of the testicles. In some animals, indeed, the vesiculæ seminales open separately from the vasa deferentia and discharge by their excretory duct a fluid peculiar to themselves.

The impotence caused by castration or by the ligature of the spermatic vessels sufficiently proves, that the testicles are the only source of that part of the emitted fluid upon which the fecundating power depends.

The properties of the fluid supposed to be derived from the prostatic body and Cowper's glands have not been satisfactorily examined.

The quantity of the seminal fluid emitted during sexual union varies in man from one to two or three drachms. The seminal vesicles are not, however, emptied at one emission, and, according to Haller, when by repetition this comes to be the case, two or three days are required in man to fit them again for reproduction by a new supply of fluid.

Chemical properties of the spermatic fluid.— On cooling immediately after emission, the seminal fluid jellies slightly, but in twenty or twenty-five minutes it becomes more fluid than at first,—a change which does not appear to depend upon the absorption of moisture from the atmosphere, as its weight is diminished rather than increased.

The chemical properties of the seminal fluid have been examined in man and several animals. It is generally considerably heavier than water, has a peculiar odour, which increases on keeping, is alcaline from the first, and gives off ammonia when heated. Left at rest for some time, it deposits crystals of phosphate of lime.

According to the analysis of Vauquelin human seminal l uid consists of the following ingredients:—

Water	90
Animal mucus	6
Free soda	1
Phosphate of lime	3
Peculiar animal principle	—
	100

In the spermatic fluid of the horse, Lassaigne has detected, besides the above-mentioned ingredients, the following substances:—

Muriates of potassa and soda,
Phosphates of lime and magnesia,
Peculiar animal matter called spermatine.

The milt of fishes, particularly that of the carp, analysed by Fourcroy and Vauquelin, contains—

An oily and saponaceous matter,
Gelatine,
Albumen,
Muriate of ammonia,
Phosphate of lime,
——— of magnesia,
——— of potassa,
——— of soda.
Phosphorus in such quantity as to emit light in the dark.

The semen is fluid in almost all animals. In some of the lower animals it is not so, but granular and crumbling. In the greater number of animals the fluid is of a white milky appearance and thinner consistence than in man, presenting in fishes the appearance of an emulsion of yolk of egg in milk.

In respect to its mode of discharge there are also many varieties dependent on the structure of the generative organs. In the lowest animals the testicle alone exists of the genital organs, and the secretory apparatus of this organ possesses a remarkably simple structure, consisting in many of a number of cœca or elongated follicles which pour the product of their secretion into a common duct. In the cuttle-fish a very curious modification exists in the mode of discharge of the seminal fluid; it being inclosed in small parcels in long-shaped transparent firm cases, somewhat like small phials. These cases are about three quarters of an inch in length, and are formed in the course of the vasa deferentia by an apparatus specially provided for the purpose: they are stopped at one extremity, and at the other are closed by

* This absorption of semen into the general circulation is conceived, not perhaps on very sufficient grounds, to cause some of the peculiarities of the male animal at the time of breeding; to render the flesh rank and unfit for eating; more readily putrescent, &c.

a lid somewhat like the cork of a phial, between which and the main body of the case a spiral spring is interposed, so contrived that when the case is immersed in water the spring expands, forces off the top of the case, and allows the seminal fluid to issue from the interior.

We must refer to the anatomical articles for an account of the varieties of structure of the male generative organs in different animals. In some of those in which the vesiculæ seminales are wanting, as in the familiar example of the dog, copulation is necessarily longer than in others. Very little is known as to the uses of the prostatic body or Cowper's glands. See GENERATION, ORGANS OF.

Spermatic animalcules.—The most remarkable circumstance undoubtedly which is known respecting the spermatic fluid, is the almost constant existence in it of an immense number of minute moving bodies of the nature of Infusorial animalculæ,—the well-known and celebrated spermatic animalcules, which, since the time of their first discovery in 1677, have excited the curiosity and speculative fancy of many naturalists.*

The spermatic animalcules have been found, at one time or other, in the semen of almost all the animals in which they have been sought for,† but at that period of their life, and in that season of the year only, when the animals to which they belong are fit for propagation. They are diminished in number, or even entirely disappear, after very frequent emission of the seminal fluid. They almost always exist in the fluid secreted by the testicles, and very often in that of the seminal vesicles, into which they have doubtless been introduced along with the fluid of the testicles.

From these circumstances, as well as others to which we shall afterwards advert, there is good reason to believe, that the existence of seminal animalcules in the male product is in some way or other intimately connected with the integrity of its fecundating property; if not, as some are inclined to hold, the essential cause of it.

The form, appearance, and size of the seminal animalcule are different in almost every different animal, and in each species of the more perfect animals the kind of animalcule seems, like that of Entozoa, to be constant and determinate. While, therefore, these little creatures, by their minute size and their general structure and appearance (so far as these are known), are distinctly animals of the infusorial kind, their residence in other living animals entitles them to be classed among the Entozoa. Baer considers them as most nearly allied to the Cercaria among the Infusoria, and gives them the very appropriate name of Spermatozoa.

In what we have hitherto said of the seminal animalcules, we have drawn our description principally from what has been observed in quadrupeds and birds, but they differ considerably from these in some of the inferior animals. Czermak* holds that these various forms may be referred to three principal heads, viz.:—

1. Cephaloidea, merely rounded bodies without tails, existing in fishes and some Annelida.
2. Uroidea, thread-like, in Mollusca, Amphibia, and some birds.
3. Cephal-uroidea, consisting of a globular and a tail part, in Mammalia, Birds, and Insects.

The first of these kinds of Spermatozoa are like the Monades among Infusoria, the second resemble the Vibriones, and the third, as has been already remarked, the Cercaria.

It is important to remark that, in so far as has as yet been ascertained, the form and size of the spermatic animalcules do not bear any intimate relation to the animal in which they exist, nor to the ova of the female. In respect of form, Messrs. Prevost and Dumas state that the head is usually of a round lenticular shape in quadrupeds, while in most birds it is of a long oval shape; but in some birds the form is the same as in most quadrupeds. The seminal animalcules present nearly the same appearance in man and in the dog. Various markings are represented in the cephalic portion of the animalculæ of some quadrupeds by Messrs. Prevost and Dumas, but these, we are inclined to believe, are not constant, and are appearances which have arisen from accidental circumstances.

In respect to size, there appears to be still a greater want of correspondence. The seminal animalculæ are said not to be larger in the whale than in the mouse. They are very much larger in Insects, Mollusca, and others of the lower animals than in Man. In the snail they are fifty-four times longer than in the dog, and considerably larger in the mouse than in the horse

The following table exhibits approximatively the sizes of the spermatic animalculæ of some

* Haller states as his conviction, that Ludwig Hamm (then a student at Leyden) was the first discoverer of the seminal animalcules in August of 1677. Leeuwenhoek claimed the merit of having made the discovery, in November of the same year, and in 1678, Hartsœker published an account of them, professing to have seen them as early as in 1674. A great deal has since been written regarding them. Needham, Buffon, Der Gleichen, Spallanzani, Prevost and Dumas, and Wagner, may be mentioned as those who have devoted most attention to these curious little animals. Our remarks are taken chiefly from the investigations of the three last authors, as well as from original observations.

† The class of fishes are stated by Messrs. Prevost and Dumas to form an exception to this remark, these observers not having been able to discover any seminal animalcules in the seminal fluid of fishes; but they are stated to have been seen by older authors (see Haller's Elementa, vol. vii. p. 521); and from the latest investigations it appears that they exist, though of a form different from the spermatic animalculæ of most other animals. The author has seen them very clearly in the seminal fluid of the Perch, and one or two other fishes. See Fig. 51, p. 112, vol. ii.

Gruithuisen states that he has observed the seminal animalcules to propagate by division of their bodies, or fissiparous generation. But we are far from attaching implicit faith to all that has been stated even as matter of observation regarding these bodies.

We ought not to omit in this place to state another and a different view which has recently been taken of the nature of the moving particles of the semen; we mean that of G. Treviranus, who, founding chiefly upon observations made by himself in the lower animals, as Mollusca and Insects, adopted the opinion that these particles are not independent animals, but analogous in their structure and properties to the fibrils and particles occurring in the pollen of plants. Their motion he seems to regard as of the same kind with that discovered by R. Brown to exist in infusions of these and other minute floating particles, and not as of an animal or spontaneous kind. He deduces this conclusion principally from the alleged observation that the motion of the so-called animalcules is not the same as that of ordinary Infusoria, but differs from it in this respect, that it is simply vibratory and constant, and not interrupted by any of those stops or pauses and changes from place to place which are held to indicate spontaneity in the motions of Infusoria.†

Some of the facts already stated by us shew the fallacy of the opinion of Treviranus. Baer, who regards the Spermatozoa as distinct living animals, holds that Treviranus has observed only an imperfect condition of the animalcule, and states in the work of Burdach‡ some additional observations of his own made in the snail, which promise, when pursued further, to remove some of the difficulties respecting the nature of these bodies. Baer states that he has observed the head and tail parts to become separated from one another, and both these parts, but especially the tail, to move about after separation. Baer has observed also that there are various stages of formation and change of the seminal animalcule, during which not only their form but also their motions undergo remarkable alterations, and he supposes that Treviranus must have observed the spermatic animalcule of the snail and mussel in one of these stages only. Observations made* by the author of this article and by Dr. Sharpey in the frog, seem to bear upon this point, and to be in some degree confirmatory of the view given by Baer. We have almost invariably found, in observing the seminal fluid of the frog in the spring or summer, that the animalcules contained in it are not of the kind described by authors in this animal, viz. with both head and tail, but of the thread-like form only. These were collected in bundles in the thick part of the fluid, and generally moved with a continued vibration such as we have previously described. In the thin part of the fluid there were a few round-shaped or monad-like infusoria. Occasionally it happened that when water was added to the thick part of the fluid, and the bundles of the thread-like bodies were artificially broken down, some of them moved progressively through the fluid by the undulatory riggling of one of the extremities; and during their motion we were surprised to see some of those, which, when at rest, appeared to be destitute of any cephalic part, frequently assume the appearance of a head. This phenomenon we remarked to be owing to the circumstance that the end by which the animalcule moved forward was bent backwards on the middle of the body, so as at one time to give exactly the tadpole-like appearance which is represented as a head in their plates by Messrs. Prevost and Dumas. There could be no doubt that this was the case, for in some, in which at one time the end was so closely joined to the body that it could not be seen, at another it loosened from it, and the thread-like animalcule still continued to progress in the fluid with its curve forwards, and the two ends (of unequal length) floating separate and loose. The author has observed nearly the same phenomena in the spermatic fluid of the pigeon. Lastly, the observations of R. Wagner on the spermatic fluid of the Guinea-pig seem to prove more decidedly than any of the previously mentioned facts that the spermatic infusoria are subject to remarkable changes of form at different periods, and that they even go through a regular gradation of development.

The discrepancy of these observations makes

* This table is taken principally from the measurements of Prevost and Dumas given in their excellent account of the seminal animalcules published in the Annales des Sciences Naturelles.

† See a paper in Tiedemann's Zeitschrift, vol. v. part 2, 1835.

‡ Vol. i. second edition.

* These observations were made five years before the publication of this article. For further information respecting the Spermatozoa we refer the reader to the articles ENTOZOA and SEMEN; in the last of which Mr. Wagner, who has investigated their nature with great success, will fully explain his views.

it apparent that we ought in the present state of our knowledge to be very cautious in making any general conclusion regarding the nature of the spermatic animalcules. It appears to be fully proved that some such animalculæ always exist in the seminal fluid of animals when they are fit for propagation; but it is by no means certain that they belong exclusively to the fluids which are the product of secretion in the testicle, for animalculæ very similar to them in general appearance and in motions are to be found in various other fluids and organs of animals. In all those parts of the body in which mucous secretions are accumulated, animalculæ are formed, and in some of the lower animals the Cercariæ of intestinal mucus are hardly to be distinguished from the animalculæ of their seminal fluid.

Nor is it well ascertained that these animalcules belong exclusively to the fluid of the testicle, and do not sometimes occur in the secretions of other parts of the generative organs. They exist no doubt frequently in the seminal fluid of the testicle, but some recent observations seem to shew that they are frequently imperfect in the fluid of that organ, and that in some animals at least they are not fully formed and do not acquire their powers of active motion till some time after the seminal fluid is secreted, and when it has passed from the testicle into other parts of the generative organs. On this account some hold, and with good reason, that they are to be regarded as the product of reciprocal changes of the ingredients of the seminal fluid on one another, rather than as secreted along with that fluid directly from the bloodvessels of the testicle, as others have supposed.

In conclusion, we would remark that in regard to the seminal animalculæ having both the body and tail, such as those that may be seen in the dog, cat, rabbit, or other quadrupeds, and which were described by the discoverers and early observers of the seminal animalculæ, no one who has had an opportunity of observing them carefully with a good lens magnifying three or four hundred diameters can doubt for a moment that they bear a close resemblance to some of the Infusoria, and that both from their structure and motions they are with as much justice as the Infusoria to be regarded as distinct animal beings. With regard to the other kinds above mentioned, or the changes they may undergo in different stages of their existence, farther investigations appear necessary to enable us to form an opinion.

Although the spermatic animalcules, like other Entozoa, are formed only in living animals and may be regarded as dependent for life on those animals in which they occur, yet they retain their life for a time after they leave the body. Thus the spermatic animalcules of the Polecat, which Prevost and Dumas observed with much attention, continued to move for fifteen or twenty minutes on the object-stand of the microscope; and these experimenters state that when the seminal fluid is allowed to remain in the genital organs, the animalcules continue to live for fifteen or eighteen hours after the death of the animal. Their motions cease instantly when a strong electric spark is passed through the fluid containing them.

Immediately after the discovery of the seminal animalcules, they were made the subject of very fanciful hypotheses, and were conceived to throw quite a new light upon some of the obscure parts of the generative process. To the supporters of the theory of pre-existing germs, their discovery opened up the prospect of being able to trace backwards one link more than had previously been done in the chain of life which connects the parent and offspring. By some they were considered as the cause of sexual enjoyment or venereal propensities. By others, the animalculæ were held to be of different sexes, and, according as one or other gained the egg during fecundation, to give rise to a male or female offspring, and thus to determine its sex. They have been supposed by others to form the first rudiments of the fœtus or lay the foundation in the germ of the egg from which the offspring is afterwards developed, and fecundation has thus been resolved into the simple passage of a seminal animalcule into the germinal part of the egg; and finally, one or two of the most fanciful of such dreaming physiologists have (as we had occasion to remark at a former part of our article) not failed to perceive on a sufficiently minute inspection of the animalcule, that it already possessed all the organs belonging to the mature condition of the animal in the seminal fluid of which it existed; compressed no doubt into a very small space, but from which it was easy to suppose the offspring to be formed by evolution.*

Such notions require no refutation. Let us rather pass now to the inquiry of how far observation and experiment have tended to throw light upon the essential circumstances upon which the fecundating property of the seminal fluid depends.

The nature of the change which confers upon the egg the power of production is entirely unknown to us, and we already remarked towards the commencement of this article that this action is to be ranked among those vital operations of the animal economy which are placed beyond the reach of our means of investigation. We should with equal prospect of success proceed to inquire how life originates and is maintained in the parent, as to investigate the secret manner of the transmission of the vital spark from the parent to the offspring. The physiologist who would study this subject must therefore limit his inquiries in this as in other departments of his science to the search after those conditions or chain of circumstances which appear to be essential to the occurrence of the particular change or phenomenon which is the object of his investigation.

Our present object, then, is not to investigate the nature of the change by which the living

* Gaultier, Génération des Hommes et des Animaux. Paris, 1750.

productive power is given to the egg, but to endeavour to establish what are the essential conditions of fecundation.

Difference between the fecundated and unfecundated ovum.—In the first place, in reference to this subject, it would be interesting to know whether any material difference exists between the structure of the fecundated and unfecundated egg.

In the common fowl we have seen that the whole substance of the egg, the yolk and germinal portion, the albumen, shell, and membrane, may be formed in the ovaries and oviduct, and excreted from the body of the hen without any connection with the cock; but such an egg, though apparently the same in structure with that which is laid after connection with the cock, when subjected to the requisite heat, undergoes none of the changes of development which incubation induces in the fecundated egg, but only passes into chemical decomposition like any other dead animal substance.

Did any difference of structure exist between the fecundated and unfecundated egg, we should be disposed to look for it first in that part of the egg which is more immediately connected with the new being, viz. in its germinal portion; but we regret to say that the investigations of naturalists have not as yet pointed out any marked difference in a satisfactory manner. Malpighi, it is true, long ago pointed out a difference in the structure of the cicatricula of the egg of the common fowl which had had connection with the cock, and those of the hen living single, and the observations of this author were afterwards confirmed by Prevost and Dumas. In the impregnated egg the cicatricula is a well-defined whitish spot, with a regularly formed transparent area in its centre; while in the unimpregnated egg there is no regularly shaped transparent area, but rather a number of small irregular clear spaces scattered over the surface of the cicatricula. We fear, however, that this appearance of irregularity exists as well in some eggs that have been laid after connection with the cock, and that the shape or appearance of the cicatricula can scarcely be depended upon as informing us whether an egg has been fecundated or not, since that appearance is much influenced by the state of the nucleus or white matter of the yolk situated below it, as well as by the state of the cicatricula itself. This subject is worthy, however, of the most accurate investigation, as it appears to offer the prospect of affording some information on this very obscure part of the generative process.

In the ovarian ovulum, the vesicle of Purkinje, it will be recollected, occupies the centre of the cicatricula; and this vesicle exists in the ovulum so long as it remains within the ovarian capsule, whether the hen have connection with the cock or not. In the impregnated fowl the germinal vesicle of Purkinje bursts, and leaves the transparent area in the centre of the cicatricula at the time when the ovulum passes from the ovarian capsule into the oviduct; but it remains to be known if the same is the case, or what phenomena ensue upon the escape of the ovulum from the ovarium in the fowl which is entirely separated from the cock.*

We do not know with certainty what befalls the vesicle of Purkinje in the ovulum of Mammalia at the time of its escape from the ovarium. The analogy of all oviparous animals is strongly in favour of the supposition that it bursts in the same manner. M. Coste states that it does not burst, and Valentin supports an opposite view.

While, therefore, we feel disposed to adopt the opinion that the seminal fluid, in fecundating the egg, operates its peculiar change chiefly on the germinal part, and that the bursting of the germinal vesicle is very probably connected with the change of fecundation, it must be admitted that further observations are still wanting to afford a satisfactory proof of the correctness of these hypotheses.

Is material contact of the semen and ovum necessary for fecundation?—No one has ever discovered any of the seminal fluid within the egg: the most minute observation does not detect any appearance of this. A question then naturally presents itself in reference to the subject of our present inquiry, viz. whether it is necessary that a certain quantity of the *substance* of the seminal fluid should be brought into actual contact with the egg in order to cause its fecundation? and if so, in what manner and in what part of the female organs such contact is brought about?

Were we to look no further than to the manner in which fecundation is effected in many of the inferior animals, we might be induced at once to form the opinion that the mere contact of a certain quantity of the seminal fluid with their ova, in whatever way brought about, is all that is necessary for producing their fecundation. Thus, in the greater number of fishes the milt or seminal fluid of the male is shed over the spawn of the female after it is laid in water, without there being any nearer sexual intercourse; the fecundation is external to the body of the female, and we thus know with certainty that the ova and the seminal fluid are the only parts immediately concerned in the process. The same is the case in the common frog, in which there is copulation; for in that animal, although the male and female remain united firmly together during a longer period than any other kind of animal, yet this union is not a means of producing fecundation, but rather of promoting the discharge of unimpregnated ova from the generative system of the female. There is in fact no true sexual union: the spawn is laid by the female unfecundated, and the male (separating then in general from the female) sprinkles seminal fluid on the ova floating in water.

External and artificial fecundation.—The mode of fecundation just now mentioned sug-

* We have long had the intention of instituting a series of observations comparing the changes of the impregnated and unimpregnated ovum in the oviduct, but have not yet had an opportunity, and we recommend it to those who may be anxious to engage in the investigation of this subject.

gested to Spallanzani* the ingenious experiment of artificial fecundation, which he first performed, and which furnished the most convincing proof that could be obtained, that, in such animals as the frog, sexual union is not essential to fecundation, and that, when the ova are ripe and the seminal fluid of the suitable quality, the mere contact of the male and female products is sufficient to confer fertility upon the ova.

Spallanzani opened very many female frogs at the time of propagation, but before they had laid any spawn, and consequently before impregnation could have occurred, and he satisfied himself that the ripest ova extracted from the oviduct, and placed in water, gradually passed into putrefaction without undergoing any of the changes of development; while some of the same ova, upon which he had sprinkled some of the seminal fluid taken from the body of the male, and placed in similar vessels of water, had tadpoles formed from them in the same manner exactly as those which were fecundated by the male frog itself.†

The same experiments were performed by Spallanzani on toads and newts with exactly the same result.

Spallanzani, in order to avoid every fallacy, allowed the female to remain in union with the male, and to lay her spawn in the natural way, preventing only the access of any of the seminal fluid of the male to the ova, by tying up the hinder part of the male's body in oiled silk, and these ova were alike barren, unless he added to them some of the seminal fluid in the artificial mode.

Treviranus‡ mentions the performance of the experiment of artificial fecundation in Fishes, viz. on the spawn of the Salmon, Trout, and Carp, by Duhamel and by Jacobi. Jacobi's experiments were repeated by Dr. Walker of Edinburgh; and very recently it has again been performed on the spawn of the Tench and Bleak by Rusconi of Pavia. (Cyprinus Tinca and Alburnus.)

The very complete series of experiments of Messrs. Prevost and Dumas§ on the frog afford the most satisfactory confirmation of those of the Abbé Spallanzani.

The following appear to be the more important results deducible from these two sets of experiments.

1st. That a very small quantity indeed of the seminal matter is requisite for the fecundation of the ovum.

2d. That dilution of the seminal fluid with water within certain limits does not impede, but rather is favourable to its operation.

3d. That the absorbent power of the albuminous or gelatinous matter which surrounds the black yolk is highly useful in bringing the seminal substance in contact with the yolk, where it is obvious its effect must be produced. This albuminous covering, corresponding to the white of the bird's egg, possesses the remarkable property of absorbing water, somewhat like gum tragacanth, in a determinate quantity, and thus increases greatly in bulk after being laid in water. In the experiments referred to, the absorption of the water by the jelly was fully demonstrated by the immersion of the ova in coloured water, and it was found also that the experiment of artificial fecundation succeeded best when the ova had not been immersed in water for any considerable time previous to the addition of the seminal fluid. The fecundation was less certain the longer the ova were allowed to remain in water before the addition of the semen; and it was shewn that this did not depend simply on the length of time of the separation of the ova from the body of the parent, by the fact that ova taken from the oviduct and kept without moisture retained their susceptibility of being fecundated for a much longer period, as sixteen or twenty hours.

4th. That the seminal fluid of the frog retains its fecundating power for about thirty hours after it has left the body of the male.

5th. Attempts were made by both the experimenters above quoted to ascertain, by way of experiment, whether the seminal animalcules are indispensable to fecundation. Spallanzani came to the conclusion that the seminal fluid did not lose its peculiar powers although deprived of its animalcules, or although the animalcules were dead; but it must be admitted that the means employed by that observer to ascertain the presence or absence of the seminal animalcule were inferior to those we possess in more recent times. Messrs. Prevost and Dumas, who, it has already been remarked, consider the animalcules as the most important part of the seminal fluid in reference to its fecundating properties, state that they found in their experiments, that that part of the seminal fluid which had been subjected to a very careful filtration, and which had thus been wholly deprived of its animalcules, had lost all fecundating power, while the substance which remained in the filter, and which was rich in animalcules when diluted with water, possessed the same powers of fecundation as the pure seminal fluid. We think this experiment requires repetition and some modifications, for other ingredients, besides the animalcules of the seminal fluid, might be retained on the filter.

6th. Both Spallanzani and Prevost and Dumas have attempted to estimate the quantity of seminal fluid required for the fecundation of a certain number of ova, and the latter observers, pursuing their favourite idea to the utmost, have even endeavoured to calculate the number of animalcules which are necessary for the fructification of one or more ova. In Spallanzani's experiments two grains of the semen of the toad fecundated one hundred and thirteen ova. Five grains of semen were mixed with eighteen ounces of water; the point of a needle dipped in this was made to touch an egg for an instant and produced fecundation. The proportion here might be estimated as

* Dissertazioni di fisica animale, &c.

† This experiment the author has more than once performed with a similar result.

‡ Erscheinungen und Gesetze des Organischen Lebens.

§ Annal. des Sciences Nat. tom. i.

semen 1, to egg 1,064,000,000. The addition of a larger quantity of semen, or its remaining longer in contact with the egg, did not, according to Spallanzani, render the fecundation more complete than the instantaneous contact of the wetted needle's point. Prevost and Dumas state that they found the number of ova fecundated by a given quantity of seminal fluid is always below that of the animalculæ which they estimated that fluid to contain; and by a simple process of calculation it was easy to find how many animalculæ served each ovum. A certain quantity of seminal fluid, for example, containing 225 animalcules, served to fecundate 61 only out of 380 ova, to which it was added, so that each ovum required about 3⅔ animalculæ for its fecundation, or making allowance for a few of the animalculæ which went astray into other ova, it may be stated as three in round numbers. It will be long before the vital processes can be traced with the arithmetical precision displayed in this calculation. Unfortunately for the calculations and even the observations upon which they are founded, one of the authors at a subsequent period published the theory which appears to have prompted them to revive an old and fanciful notion that the animalcule forms the rudiment of the new being. The animalcule, according to this hypothesis, makes its way through the stiff jelly surrounding the yolk, gains the centre of the germinal membrane, and esconces itself there in the very centre of that germinal membrane, laying thus the foundation of the primitive streak or the brain and spinal marrow of the fœtus: its position (which is always the same) being no doubt determined by the laws of polarity depending upon the electro-magnetic properties with which, according to equally fanciful theorists, the rudiments of the new being in the egg are endowed.

Hitherto cold-blooded and oviparous animals only have been alluded to; but there are not wanting facts which render it highly probable that in viviparous animals also, contact of seminal fluid with the ovum is the essential part of the fecundating process. Thus, Spallanzani confined a bitch for fourteen days before the arrival of heat, and for twenty-six days after it, so that, during that time, it could have had no connexion with any dog, and at the time of the heat he injected by means of a syringe a quantity of the dog's seminal fluid into the vagina. The bitch brought forth three young exactly at the usual length of time from the period of heat; — an experiment on artificial fecundation, which may in some sort be said to have been performed in the human species is the well-known instance in which John Hunter recommended to a man affected with hypospadiac malformation of the urethra, which rendered intromission of the seminal fluid impossible, the injection, by means of a syringe, of the seminal fluid into the vagina,— an operation which, it is related, was attended with complete success.

While these facts on the one hand tend to shew that no parts of the genital organs and no other agents are concerned in fecundation excepting the seminal fluid and the ova, and on the other hand afford the only *positive* evidence that can be obtained, that actual contact of the one with the other is necessary to induce the change, they have appeared unsatisfactory to some physiologists, who cling to the opinion that, in quadrupeds and birds at least, contact is not necessary, and that fecundation may be effected either by some hidden sympathy (or concurrent action taking place in remote parts) between the external and internal organs of the female, or that this change may be operated by some imponderable influence which emanates from the seminal substance, to which the vague name of aura seminalis has been given.

Course of the seminal fluid within the female organs.—In pursuing our examination of the alleged evidence upon which these and similar hypotheses are founded, it will be necessary to consider in this place another question, respecting which it is difficult in the present state of the inquiry to form a decided opinion, viz. whether, on the supposition of the seminal fluid and ova coming into actual contact, the course of the seminal fluid within the female organs of generation can in any instances be traced, and in what part of these organs it may be supposed to meet with the ova and operate their fecundation.

In the first place the examples of ovarian conceptions, or rather gestations, have been adduced by some as a proof that fecundation necessarily takes place in the ovaries themselves. But from what was said in a former part of this paper, it will be seen that such a belief is founded on an erroneous view of the nature of these misplaced gestations, as well as of the phenomena which occur in the ovary after conception. There is no reason to believe, we may repeat, that ova found developed in the neighbourhood of the ovary have retained their situation within the Graafian vesicle. On the contrary, they must in all probability have been first discharged from the ovary upon the rupture of the vesicle, and their places occupied by corpora lutea; and they may have been fecundated either while loose in the cavity of the peritoneum, or when they have descended some way in the Fallopian tubes, and meeting with the seminal fluid in the course of that tube, have been returned to the vicinity of the ovary by some inverted or unnatural action of the parts.*

Although, therefore, no very decided opinion respecting the place at which fecundation occurs can be formed from the observation of what are termed ovarian and tubular gestations, we are inclined to think that they shew

* We need do no more than mention here a view taken by Sir Everard Home of the uses of the corpora lutea, which he holds to be a means of bringing the seminal fluid into contact with the ovum of the Graafian vesicle. This opinion requires no remark, as it will be at once perceived that it proceeds on the assumption, shewn to be erroneous in a former part of this paper, that the corpora lutea are formed before the rupture of the vesicles.

that this process may take place, in some instances at least, in the upper parts of the Fallopian tube, or even in the infundibulum.

In the second place physiologists have endeavoured to argue respecting the place of fecundation from the well-known fact that, in the common fowl, turkey, and probably some other birds, a single connexion with the male serves to fecundate more than one ovum, as, for example, in the common fowl twelve or twenty ova; and that, as there is usually only one ovum in the progress of descent through the oviduct at one time, we must conclude either that the yolks or ovula are fecundated by the rise of the seminal fluid to the ovary, or that the seminal fluid remains somewhere in the course of the oviduct, to be applied to the ovum as it descends. If we exclude the notions of an aura and sympathetic action, the former of the above-mentioned views appears to us the most consistent with the facts that have already come under our knowledge. The notion entertained by Fabricius and others that there is a receptacle for containing the seminal fluid in the oviduct appears to be incorrect; and we find it difficult to believe that the seminal fluid can remain dispersed through the oviduct, or confined in any particular part of it and retain its power of fecundation, when we consider the manner in which each yolk descends from the ovary and receives in its passage the various accessory parts constituting the albumen and external coverings. Of course, in supposing fecundation to take place in the ovary, there remain two suppositions which may be entertained regarding the mode in which the seminal fluid gains the ovula; for it might either pass directly up the tube of the oviduct, or be absorbed and take some circuitous course.

In the third place, we are inclined to think that in quadrupeds the ova must be already fecundated before their arrival in the uterus, that is, either in the neighbourhood of the ovary or in the tubes, for this reason, that at the time when the ovum first arrives in the uterus, it has already become considerably enlarged, and has undergone some of the changes of development;* and when we consider how very regular and progressive these changes have been observed to be from the time when the ovum first enters the tubes, we shall be disposed to conclude that fecundation very probably takes place before then, or in the upper part of the tubes.

In the fourth place, attempts have been made to trace the seminal fluid in animals opened shortly after sexual union. Most authors agree that much of the seminal fluid frequently flows out of the vagina soon after coition, and Harvey, De Graaf, and Haller were all unable to discover any traces of seminal fluid in the uterus even of various animals killed and opened soon after sexual union. Haller, however, while he states this as the result of his experiments, admits that the means which he possessed of ascertaining the presence or absence of the semen were imperfect, and he himself believed that fluid to have entered the uterus.

Various other physiologists, also, state that they have found seminal fluid in different parts of the female organs. Morgagni and Ruysch had two opportunities of examining the body of the human female very soon after coition, and found, on opening the uterus, a fluid which they regarded as semen. John Hunter states that he observed the same in a bitch, as also did Hausmann. But in all these instances some doubt may be entertained regarding the fluid which was considered as semen.

Prevost and Dumas, trusting to the occurrence of the seminal animalculæ as a certain sign of the presence of seminal fluid, state that they have observed these animalcules, at different periods after coition, both in the uterus and tubes of dogs and rabbits; and it appears to result from the careful series of experiments performed by these physiologists that the longer the time was which had elapsed after coition, the farther the seminal fluid had advanced upwards within the female genital passages. Thus, at twenty-four hours after coition a great quantity of animalcules were found in the cornua of the uterus, but none either in the vagina or farther up the tubes; at forty-eight hours nearly the same was the case: on the third and fourth days there were many animalculæ still in the cornua and some in the tubes, which continued in the dog till the fifth and sixth days; and upon one occasion only they observed a few animalcules near the infundibulum.

Burdach and others, again, are not inclined to place much reliance on these observations, because animalculæ of the nature of Cercariæ have been noticed in the genital passages of female animals which had had no connection with the male.

In the fifth place, experiments on the mechanical obstruction of the uterus, Fallopian tubes, and vagina, appear of considerable importance in reference to this part of our subject. Experiments of this kind were performed first by Haighton,* and afterwards by Blundell; the results of which, making allowance for the more accurate knowledge we now possess respecting the indications afforded by the condition of the vesicles and corpora lutea in the ovary, may be stated as follows:—

1st. That when one of the cornua of the uterus or Fallopian tube of the rabbit is divided within a few hours after coition, and obliteration of the tube has followed, although corpora lutea are formed in both the ovaries

* We do not mean here to state that the parts of the fœtus have appeared, but only that changes in the germinal membrane preparatory to the formation of the fœtus have taken place. Nothing of this kind has ever been found in the unimpregnated animal, no appearance of any ovum, which, considering how often vesicles are burst without sexual union, we think must have been the case had the ovum undergone the same changes in the unimpregnated as in the impregnated animal until its arrival in the uterus.

* Philos. Transact. vol. lxxxvi. p. 173.

(as a consequence of the rupture of vesicles), ova are not to be found on the injured side of the uterus, but pregnancy takes place on the other side.

2d. When the vagina was divided in a like manner at its upper part, although the usual number of corpora lutea were found in the ovaries, pregnancy did not occur. That the mere wound itself locally, or its hurtful effects on the constitution, did not prevent the development of the ova, was proved by the experiment purposely made of dividing the parts in the same way and allowing them to reunite by adhesion without obstruction of the tube, in which case uterine pregnancy occurred nearly as in the natural condition.

3d. In another set of experiments obliteration of the tubes was caused to take place at a later period, probably when the ova had descended and may be supposed to have met with the seminal fluid, and in these animals pregnancy occasionally but not always occurred.

It would appear to follow from these experiments, that the seminal fluid does not rise in the female genital passages immediately upon its introduction, and not for more than a day after coition, and that those circumstances which impede the rise of the seminal fluid prevent fecundation. But they do not warrant the conclusion that impregnation must occur in the ovaries, since the vesicles may have burst, their contents be discharged, and corpora lutea formed without the seminal fluid having had access to the ovary; a fact which is well shewn by the interesting experiment performed by Dr. Blundell, of producing an obliteration of the upper part of the vagina in the unimpregnated rabbit, then allowing coition to take place, and then finding, no pregnancy, but corpora lutea in the burst vesicles of the ovary.

These experiments appear also as of importance in shewing that neither absorption of the semen by the lymphatics or bloodvessels, nor the passage by any other circuitous route, nor indeed any sympathetic action established by sexual union between remote parts of the female generative organs, can be the means of producing fecundation.

There are, no doubt, great difficulties in the way of our understanding by what manner the seminal fluid accomplishes the passage upwards in the genital organs of the female. Thus, the small size of the Fallopian tubes at once strikes us as a powerful obstacle; but in many animals, as, for example, in the Ruminantia, there is an equally great difficulty in comprehending how the seminal fluid gains the uterus itself even; for in these animals the os uteri forms a long and uneven passage, interrupted by many hard cartilaginous projections, and closed in general by a very viscid and tenacious mucus. But yet the seminal fluid must in all probability enter the cavity of the uterus.*

In conclusion, we would remark that we must either suppose fecundation to be the effect of the actual contact of the seminal fluid with the ova in the upper part of the Fallopian tube or somewhere near the ovary, or we are reduced to form the opinion that the action of the seminal fluid on the lower part of the female genital organs may be twofold, viz. first, causing the commencement of the process of fecundation by a sympathetic influence on the upper part of the tubes, and, in the second place, perfecting the change in the uterus when it meets there with the ovum. We feel inclined, in the present state of our knowledge, to give a preference to the first of these opinions.

Nature of the fecundating process. Hypothesis of an aura, &c.—We return now to the consideration of the essential nature of the change of fecundation.

The opinion that fecundation is attributable to the agency of an aura or emanation from, and not to the material contact of the seminal fluid, is founded chiefly upon alleged instances of conception having occurred in individuals (of the human species) in whom, from unnatural formation or disease, no direct passage existed from the vagina or external aperture to the internal organs, as well as upon some of the circumstances above alluded to, as shewing the difficulty of such a passage both in man and animals, even in the natural condition.

No very definite idea, it may be remarked, can be attached to the term "aura," for it has been employed in varous acceptations by different authors; one considering it as of the nature of a gaseous or vaporific exhalation from the seminal fluid, another denying it the nature of a substance even of the most etherial kind, and considering it more as a spiritual or vital principle; and a third regarding it as of the nature of a nervous impression. These discrepancies only shew us that the term aura is to be taken rather as an expression for the unknown agency of the seminal fluid which causes fecundation, than as indicating its modus operandi or the part of its substance more immediately concerned in the action. Some authors have, however, even referred to direct experiment in favour of the agency of an aura. Mondat, for example, (De la Sterilité, 4to. edition, p. 17) states that he witnessed experiments performed by Morsaqui, of Turin, with this view, from which it was found that the bitch could be impregnated when it was impossible, as he states, that the substance of the seminal fluid could in substance pass into the uterus or other parts. Recurved tubes, containing in the closed end a quantity of the dog's seminal fluid, were introduced into the

* Burdach mentions, as supporting the view that the seminal fluid may be absorbed by the bloodvessels or lymphatics, and being carried into the general circulation occasion fecundation when it arrives at the ovary or other parts of the internal organs, Casp. Bartholin, Perrault, Sturm, and Grassmeyer. Dr. Harlan of Philadelphia, in a volume of Experimental Essays recently published, states that he found that the injection of semen into the bloodvessels of a bitch put a stop to the heat sooner than would otherwise have been the case.

vagina of the bitch in such a way that none of the fluid itself could escape, but only an emanation, vapour, or supposed aura rising from it, and in eighteen out of thirty animals on which the experiment was performed, with the subsequent occurrence of impregnation. But until these experiments shall have been confirmed by careful and frequent repetition, we must be allowed to doubt the possibility of performing such an experiment in a sufficiently accurate manner.

Spallanzani, with a view to investigate the powers of a vapour supposed to rise from the seminal fluid, exposed a quantity of the ripe unimpregnated spawn of the frog for some time in the same vessel with a quantity of seminal fluid, the latter being placed at the bottom of the vessel, the ova at the top, and never was any fecundation produced;—an experiment, it is true, from which no more than negative evidence can be derived, but upon the whole more worthy of trust as being subject to fewer fallacies than those of Mondat.

The instances in which it has been alleged that impregnation has taken place in the human female without there being any possibility of the seminal fluid itself passing inwards in the female genital passages, are of a very doubtful nature, and liable to so many sources of fallacy, that we feel little disposed to admit them as grounds of proof of the agency of an aura seminalis. In some of the cases in which it has been found, either in the course of pregnancy or at the time of child-birth, that the female passages are obstructed, there is reason to believe that the closure has been produced subsequent to the occurrence of conception; and the same may be said of those cases of ovarian gestations in which an obliteration of the Fallopian tubes has been observed. In the greater number of such cases, it may also be observed, the malformation of the parts has consisted in the much contracted state of the external orifice or some other part of the passage, rather than in their absolute closure, so that there was merely a difficulty and not an impossibility of the entrance of seminal fluid. But in opposition to such vague and ill-ascertained observations, a variety of circumstances, which it is not necessary to particularize, might be adduced, tending to show how very easily in the human female as well as in other animals all mechanical obstructions to the entrance of the seminal fluid into the uterus tend to prevent conception.

General conclusions respecting fecundation. In conclusion we would remark, 1st, that while we readily admit a very small quantity indeed of the seminal fluid to be sufficient to produce fecundation, we think that what has previously been stated warrants the conclusion, that material contact of a certain quantity, however small, of the seminal fluid with the ovum is necessary to give rise to its fecundation, and, consequently, that the hypothesis of an aura is untenable. And for the same reasons it follows that there are no just grounds for holding the opinion either that fecundation consists in a sympathetic action of a nervous kind, or that it is brought about by the absorption of the semen into the circulatory or lymphatic vessels of the generative system.

2d. It is sufficiently obvious that in quadrupeds there is no exact proportion between the quantity of seminal substance or fluid received by the female or emitted by the male, and its effect in producing fecundation,—a circumstance which points out a distinction which ought always to be borne in mind between that vital change on the female genital system and the whole economy and ovum, and the simple physical re-action which may take place between the semen and ovum themselves.

3d. We may regard venereal excitement of the genital organs and impregnation of an ovum as different phenomena, for though they usually occur together, there are instances in which they take place quite indepeudently.

4th. The action of impregnation is to be regarded as sui generis, or quite peculiar among the vital processes. It is not capable of being imitated by any other substance than the seminal fluid, and neither experiment nor observation enables us to form the most distant conjecture what the nature of that action may be, which, from the influence of the male product, confers upon the ovum a new and independent life, and enables to give birth to a new individual the mass of organic matter in the egg, which, without the change of fecundation, would prove altogether barren and undergo no other changes than those of similar dead matters. The action, however, is in some respects reciprocal, and we cannot determine what part either of the two agents concerned performs in the change of fecundation: we know only this, that unless the seminal fluid be of the suitable composition it is ineffectual, and that ova are susceptible of its influence only when in that period of their evolution when they are ripe. Nor can we with certainty fix on what part of the egg the influence of the male semen more immediately operates. Since the fœtus grows from the centre of the germinal layer, it has been commonly supposed that this is the part of the egg which is most immediately affected by fecundation, but we know nothing of this; and it might be held, on the other hand, that the effect of fecundation operates on the rest of the contents of the egg in enabling them to be assimilated round the germinal centre or rallying point of the development of the new being.

5th. It has not yet been shewn that one part of the seminal fluid is more necessary to impregnation than another. The seminal animalcules form a natural ingredient of the fluid secreted in the testicle at the time when it is excreted for the purposes of propagation; they appear to be invariably present, but additional experiments are still wanting to prove them to be the active or essential agents of fecundation, much more the rudiments of the new being within the ovum.

6th. Like others of the operations of the animal economy, the action of fecundation is known principally in its effects; but it seems to be a question worthy of investigation whether, in the phenomena exhibited during fecundation, or the laws by which this change is regulated, it be in any respect analogous in its nature to the operation of certain poisonous or contagious principles, as for example, the venereal virus, vaccine matter, the contagious principle of small-pox, measles, scarlatina, plague, fevers, &c. The inimitable Harvey thus expresses himself regarding the essential nature of fecundation in different parts of the forty-ninth Exercitation on the efficient cause of the chicken. "Although it be a known thing subscribed by all that the fœtus assumes its original and birth from the male and female, and consequently that the egge is produced by the cock and henne, and the chicken out of the egge, yet neither the schools of Physicians nor Aristotle's discerning brain have disclosed the manner how the cock and its seed doth mint and coine the chicken out of the egge." "This," he says, "is agreed upon by universal consent; that all animals whatsoever, which arise from male and female, are generated by the coition of both sexes, and so begotten as it were *per contagium aliquod*, by a kind of contagion." "Even also," he says, "by a breath or miasma," referring to the fecundation of the ova of fishes out of the body.

"The lac maris, male's milk, propagating or genital liquor, vitale virus, vital or quickening venom," are all names of the seminal fluid of the male. Again, "The efficient in an egge, by a plastical vertue (because the male did only touch, though he be now far from touching and have no extremity reached out to it) doth frame and set up a fœtus in its own species and resemblance." "What is there in generation, that by a momentary touch (nay not touching at all, unlesse through the sides of many mediums) can orderly constitute the parts of the chicken by an epigenesis, and produce an univocal creature and its own like? and for no other reason but because it touched heretofore."

"The qualities of both parents are observable in the offspring, or the paternal and maternal handy-work may be tracked and pointed out both in the body and soul." The first cause must therefore be of a mixed kind. "It is required of the primary efficient in the fabrick of the chicken, that he employ skill, providence, wisdom, goodness, and understanding far above the capacity of our rational souls."

7th. In respect to the part of the female generative system at which fecundation takes place, it appears most probable that in quadrupeds and the human species this change occurs before the ovum reaches the uterus, or some way in the course of the Fallopian tubes; perhaps most frequently in the upper part of them. There is, however, probably some variation among animals and in different circumstances regarding this point. But while we state this as the conclusion most consistent with facts in the present state of our knowledge, we ought not to omit the mention of the more prominent facts by which it is opposed.

In some of the lower animals, fecundation seems to extend beyond the sphere of the ova which are ripe. In the Aphis (as was already mentioned at an early part of the paper) the production of young by the female goes on for several generations (eleven) without any sexual intercourse after that which gave rise to the first. In the Daphnia Longispina this is said also to be the case for twelve generations, and in the Monoculus pulex for fifteen. The queen-bee lays fruitful eggs during the whole year after being once impregnated; and in the instance of the common fowl and some other birds, previously referred to more than once, if we reject the supposition of the seminal fluid remaining in action, it seems necessary to suppose that fecundation must occur in the ovary, since unripe ova are acted on by the fecundating medium at the same time with those which are arrived at maturity and are ready to descend into the oviduct.*

Many physiologists also believe that the influence of the first impregnation extends to the products of subsequent ones. Thus Haller remarks that a mare which has bred with an ass and has had a mule foal, when it breeds next time with a horse, bears a foal having still some analogy with the ass. So also in the often cited instance of the mare which bred with a male Quagga, not only the immediate product, but three foals in subsequent breedings with an Arabian stallion, and these three even more than the first, partook of the peculiarities of the Quagga species.

Instances of the same kind are mentioned by Burdach as occurring in the sow and bitch; and it is affirmed that the human female also, when twice married, bears occasionally to the second husband children resembling the first, both in bodily structure and mental powers.

According to Hausmann, when a bitch has connexion with several dogs (and this is generally the case during the continuance of the heat, sometimes to the amount of twenty,) she usually bears two kinds of puppies at least, and the greater number of these resemble the dog with which she first had connexion.

We feel at a loss to decide what weight ought to be attached to these observations; they appear to bear chiefly on the subjects which are discussed in the next part of this article.

V. MISCELLANEOUS TOPICS RELATING TO THE PRECEDING HISTORY OF GENERATION.

We have deferred until now the consideration of some topics which usually find a place in the history of the generative function, as we have thought it desirable to separate them from the preceding narrative on account of the vagueness of the facts and speculative nature of the opinions with which they are connected. The subject last discussed naturally leads to

* Burdach hazards the opinion that in some quadrupeds the ova may not even be developed at the time of impregnation, as in the Roe-deer, which pair in July and August, but do not bear their young till May, and the Fox, the period of gestation in which is much longer than we should suppose it ought to be, judging from the analogy of others of the Dog genus.

the first of these topics which we shall consider, viz.

§ 1. *Superfœtation.*—In the first section of Part IV. it has been mentioned that in the human female, as soon as the ovum has arrived in the uterus, and even a short while before that period, the passage through the mouth and neck of the uterus is closed by a viscid mucus, which opposes a firm barrier against the entrance of seminal fluid, and thus prevents the occurrence of subsequent or reiterated conception. In some of the lower animals, on the other hand, it would appear that several consecutive conceptions not unfrequently occur, and in some animals this may be considered as the natural mode of generation.

It becomes a point of some interest both in a physiological and in a medico-legal view to determine, whether, as has been supposed by some, the same ever takes place in the human species.

The quadrupeds in which superfœtation (as a second conception during pregnancy is called) is said to occur possess a uterus with two horns, and it may be that in them the product of the first conception has occupied only one of the cornua of the uterus, and that the second conception occurred upon the other or empty side. This may be the case in the hare, for example, which is said to be particularly liable to superfœtation. In woman also, it has been supposed that a double form of uterus, which is present in rare instances as a malformation of that organ, may admit of a second conception on one side in the course of uterogestation confined to the other. But though this may be regarded as possible, we are not aware that any example of the actual occurrence of pregnancy in both cornua of a double uterus affords a satisfactory proof of it.

Great caution is necessary in admitting the evidence of superfœtation, as many circumstances concur to render it very fallacious. Women occasionally bear twins, or two children differing greatly in size and apparent age; and many are apt at once to form the conclusion from thence that the two children must have commenced their existence or have been generated at different times; but it is much more likely in most of these instances, that the different appearance in the size and conformation of the children has arisen solely from a difference in the rapidity and vigour of their growth. In by far the greater number of such instances, the smaller of the children bears obvious marks of being stunted in its growth, and it is often deformed, blighted, or dead and shrunk; and even although this were not the case and the children were both alive, a mere difference of size of children born at the same time must be regarded as very slight evidence indeed of so great a deviation from the usual phenomena of pregnancy as superfœtation.

Those who believe in the possibility of the occurrence of superfœtation found their belief chiefly upon some rare instances of the birth of more than one perfectly developed child at successive periods so remote from one another that both cannot have been conceived at the same time, and it must be admitted that these cases, if correct, go far to prove the possibility of superfœtation.

In reviewing the cases of alleged superfœtation two questions at once present themselves for consideration, viz. 1st, whether a second conception may take place within a few hours or days after the first, or we may say at any period before the ovum is settled in the uterus; and, second, whether this may occur at a later period, as at two, three, four, or more months after the first conception.

The puppies of a bitch, we have already mentioned, generally bear a resemblance to more than one of the dogs with which she has had connexion during the period of heat, and this period may extend to eight or nine days. A mare, which had been covered by a stallion, was five days afterwards covered by an ass, and bore at the usual time twins, one of which was a common foal, the other a mule.*

Women have been known to bear two children of different colour; and in one of these instances the mother is said to have confessed to having admitted the embraces of a black servant a few hours after her husband, who was white.

Facts like these seem to shew that sexual intercourse limited to an interval of a few days (most probably before the uterus has been closed by the decidua) may produce superfœtation. But we would remark that, although it may be that the mechanical obstruction of the decidua opposes an obstacle to the passage of semen upwards, or the descent of a new ovum into the uterus, there is obviously another cause why superfœtation should not occur: we mean that fundamental change in the constitution which is induced by pregnancy, similar to that which continues in the majority of women during lactation. But for such a constitutional change, we conceive continual derangement of the function of utero-gestation would attend that process in consequence of the recurrence of some of the more general symptoms of conception, even although a lodgement of a new ovum in the cavity of the uterus were impossible.

The following cases serve to illustrate the nature of the more important facts on record which do not admit of an explanation, excepting on the supposition that superfœtation has taken place.

1. A woman bearing a full-grown male child had neither lochia nor milk after its birth, and a hundred and thirty-nine days afterwards bore a second child—a living girl, when the milk and lochia came naturally. Eisenmann, who had observed this case, explained the occurrence by supposing that a double uterus existed; but upon the woman's death some time afterwards, no unusual structure was found.†

* Archiv. Gén. tom. xii. p. 125. Another similar instance is related in tom. xvii. p. 89, of the same work.

† See Burdach's Physiol.

2. Desgranges observed another instance in which a woman bore two girls at the interval of a hundred and sixty-eight days in the same circumstances as in the above-mentioned case.*

3. A third case is related by Fournier in which two girls were born at the interval of five months, there being lochia for a few days after the birth of the first.†

4. A fourth instance is mentioned of two children born at the interval of a hundred and nine days.‡

5. Velpeau relates that a Mad. Bigaux had first a living child, and four and a half months, or a hundred and forty days afterwards, a second, also alive.§

We confess that we think these cases, if correctly reported, go far to prove the possible occasional occurrence of superfœtation in the human species. On the supposition that two children born alive at different periods remote from one another have been conceived at the same time, three months appears to be the greatest extent to which the interval between their births could reach, the first being born prematurely at six and a half or seven months, and the second being retained in the uterus till the period of nine and a half or ten months; but this is improbable in some of the instances before us, as both children appeared equally complete, and no mere difference in the rate of their growth could account for their birth at so remote periods.

We are reduced then to the necessity of admitting the possibility, in very rare instances, of superfœtation; but at the same time we may remark that the evidence regarding it is not sufficiently precise, and we are left entirely at a loss to explain what causes may give rise to this variation, and in what manner the seminal fluid may be supposed to pass through the uterus, or the new ovum to gain an entrance there.

§ 2. *Influence exerted by parents on the qualities of their offspring in generation.*— One of the most obvious and important laws of the reproductive function is that by which the specific distinction of animals is preserved. Like produces like; and for the most part an undeviating succession of generations of similar structure and qualities prevents both the extinction of any species and its being blended with or lost in any other. Numerous examples will recur to the mind of every one, of striking family resemblance, which point out in how many respects children frequently inherit their qualities from their parents; but it must be held in remembrance that family or hereditary resemblance is seldom if ever complete, but only of that more general kind which belongs to the species. Thus in one family we recognise numerous minute differences, and in fact it may be said that there are scarcely any two individuals of the same or of different family exactly alike. In respect to sex, the most obvious difference exists: the mother producing male and female; the son is not an exact copy of his father, nor the daughter of her mother, nor are they a mixture of both; but each of them bears certain resemblances to one or other or to both of the parents, into which it may be interesting to inquire,—an investigation which is to be regarded of some practical importance in reference to the breeding of cattle and other stock.

As the female parent furnishes the greater part of the substance of the egg in all animals, and in viviparous animals provides also the materials which serve for the nourishment of the young with which it is intimately connected during utero-gestation, it might, *a priori*, have been supposed that the offspring should be more subject to be influenced by the qualities of the mother than by those of the father; but no general fact of this kind is established, and instances need not here be adduced which shew that the offspring, whether male or female, bears nearly, if not quite, as many points of resemblance to the father as to the mother.

Such influence as the male parent exerts upon the qualities of the offspring must be transmitted and take effect at the period of conception only, and the impression being that of the contact of the seminal fluid with the ovum must be momentary only. A certain part of the female parent's influence is dependent on the original constitution of the ovum formed in her body, while another part of that influence may be supposed to extend through the whole period of utero-gestation.

We shall first consider those instances of the transmission of hereditary qualities which appear to belong to the original constitution of the male and female generative products, and subsequently make some remarks on the influence which the female has been held to exert during the whole of pregnancy.

The general structure of the body, the stature, form, size of the bones, disposition to the formation of muscle, deposition of fat, or the reverse, seem to depend as frequently on the female as on the male parent in the human species. In some animals the male parent more frequently determines the size and general form of the body, as among feline animals, dogs, horses, &c. The bantam cock is said to cause the common hen to lay a small egg, and the common cock causes the bantam hen to lay a larger egg than usual.

An enumeration of all the points of structure which constitute family resemblance would detain us too long, and is unnecessary as they are familiar to every one. It does not appear to be satisfactorily established that the family resemblance is derived more from one than from the other parent, though in one family the influence of the one parent, and in another

§ Traité d'Accouchements, tom. i. p. 345, where cases are referred to by Pignot in the Bull. de la Facult. 4e Année, p. 123, by Wendt, Journal des Progrès, tom. x. and Fahrenhorst, ibid. tom. viii. p. 161.

family the influence of the other parent, may predominate.*

Nor does it appear that any general law has been established regarding the transmission of the nature of the constitution, temperament, state of health, duration of life, &c.; for in the human species at least these qualities of the offspring seem to be inherited from either parent or from both indiscriminately.

The complexion and colour of the offspring has received much attention. In some animals the colour of both parents is sometimes preserved, as in the piebald horse; in others a mixture of the colours of the father and mother appears in the offspring as an intermediate tint. In other animals, and most frequently in the human species, the colour descends from one only of the parents. Thus among white races of the human species, it happens more frequently, when the parents are of different complexion, that the child takes after one or other of them than that its complexion is intermediate between those of the parents; but it does not appear as yet to be ascertained that one parent determines the colour more frequently than the other. The offspring from the union of people of dark and white races of the human species usually has a complexion which is a mixture of or is intermediate between the complexions of the two parents, as in the Mulatto and other degrees of colouring; but it is alleged that in these instances the colour of the father usually predominates over that of the mother. Thus a dark father produces with a white mother a darker child than a white father with a dark mother. Among animals there are infinite varieties in this respect. White colour is said to be more readily transmitted than others. In some animals, however, colour is transmitted with great regularity: thus it has been found that as many as two hundred and five of the product of two hundred and sixteen pairs of horses of similar colour inherited the colours of their parents.

The degree of fruitfulness in bearing offspring, or the opposite, sterility, the qualities of the voice, peculiarities in the degree of delicacy of the external senses, as long or short-sightedness, musical ear, &c., the physical powers of the body as illustrated in the speed or strength of horses, and peculiarities of the digestive functions of the nature of idiosyncrasies, are other familiar examples of bodily qualities usually transmitted in hereditary descent from one or other parent to the offspring.

Lastly, the qualities of the mind are, perhaps as much as the bodily configuration and powers, subject to influence from the hereditary influence of parents upon their offspring. The powers of observation, memory, judgment, imagination, the fancy, and all that belongs to what is usually called genius, the emotions, passions, desires, and appetites, as inborn mental qualities of the offspring, are all liable to be influenced in the act of generation by the parents.*

The hereditary predisposition of man and animals to particular diseases also illustrates in a striking manner the general law now under consideration, and from its importance in reference to life assurance has attracted considerable attention.

Almost all the forms of mental derangement are more or less directly hereditary, one of the parents or some near relation being affected. Of bodily diseases, pulmonary complaints, diseases of the heart, scrofula, rickets, worms, gout, rheumatism, hemorrhoids, hypochondriasis, scirrhus, apoplexy, cataract, amaurosis, hernia, urinary calculi, may be mentioned as examples of diseases more or less directly transmitted as predispositions from parent to offspring. The goitral and cretinous affections combined with deficient intellect are striking examples of the effect of hereditary influence combined with that of the situation in which the cretins live. The union of goitrous persons in particular districts leads to the production of cretins, while the union of a cretin with a healthy person tends to the improvement of the offspring, or its gradual return to the healthy state.

The predisposition to disease may be transmitted to the offspring from either parent, and from the one as often as from the other, but much more certainly when both the parents have been affected with the disease.

We may also mention, in connection with this subject, the transmission to the offspring of various marks and deformities in the structure of the parents or their relations. The cretinism already mentioned is one of these, and there are numerous other cerebral deformities which are so transmitted, as congenital malformations, such as the acephalous and anencephalous states, spina bifida, cyclopia, &c. which run remarkably in particular families. In many instances the hereditary cause of these deformities has been distinctly traced to one or other of the parents. Nævus, moles, growths of hair in unusual places, hare-lip, deficient or supernumerary toes or fingers, have all been traced to hereditary influence, and probably as often to the one parent or his family as to the other. Malformations of the heart, congenital hernia, and indeed most other malformations, are capable of being traced to a similar origin.

Were further illustration of this general law requisite, it would be found in the resemblance of mules or hybrids produced by the union of two distinct races, varieties, or species of animals, which productions also afford an excellent opportunity of observing

* Dr. Walker, in a short essay lately printed for private distribution, has attempted to shew that the upper and back part of the head usually resembles the mother, the face from the eyes downwards most frequently the father.

* In endeavouring to estimate the degree of original resemblance of offspring to parent mentally as well as bodily, but especially the former, great caution is necessary not to overlook that resemblance between them which depends on education, similar habits, pursuits, mode of life, and continual intercourse.

and comparing the amount of hereditary influence exerted by one or other of the parents. The hybrid usually combines to a certain extent the qualities of its father and mother, as in the familiar example of the common mule between the male ass and the mare, or in the product of the tiger and the lion, the dog and wolf, the pheasant and black grouse, the gold and common pheasant, and others. In some mules the qualities of the father predominate, in others those of the mother; but so far as we are aware, the isolated facts regarding this point have not yet been brought under any general law.

It has been asserted that acquired qualities, whether mental or bodily, of the parents are capable of being transmitted to their offspring. Thus the superiority of a civilized over a barbarous nation is said to depend, not solely on the influence of an advanced state of education upon each new comer, but also on the greater natural powers of the children, derived from their parents at the moment of their production, or, in other words, the greater capability of the children to receive the higher mental acquirements and more refined ideas belonging to the civilized condition of society.

Farther, it is asserted that dogs and cats which have accidentally lost their tails have brought forth young ones with a similar deformity. Blumenbach affirms that a man who had lost his little finger had children with the same defect. A wound of the iris and a deformity of the finger occasioned by whitlow are said to have been transmitted. The well-trained pointer of this country produces a puppy much more capable of being trained than the dogs of the original breed. The retriever spaniel and the shepherd's colly are said to do the same. Well-broken horses produce docile foals, and lastly, the young of foxes living in hunting countries are naturally much more circumspect than those living in countries where they are not exposed to the danger of pursuit.

We look upon all these alleged facts with distrust. Many of them are coincidences; others, we suspect, are false. It is obviously insufficient for our purpose to ascertain the qualities of the one generation which is born. We must also know to what circumstances the parent may have owed its peculiarity. We feel convinced that education more than any other circumstance has influenced the superior powers of the animals above alluded to, and there is no proof that the parent did not possess the same capabilities or natural powers as the offspring.

There are, on the other hand, innumerable instances which shew that acquired alterations of structure are not transmitted. How many men are there who have lost limbs and yet have produced children in no respect maimed. A quadruped without the fore-legs has borne entire young. A bitch in which the spleen had been extirpated had young possessing that organ. Men with only one testicle have sons with the usual number; and lastly, the people of nations, the males of which have been circumcised during hundreds of years, have children with foreskins not a bit shorter than those of nations in which no such practice exists.

The breeding of domestic animals of different kinds, suited respectively to the various useful purposes for which they are employed, is a subject connected with the present question of high practical importance; but unfortunately, though some practical men have well understood the proper method to be pursued, it is to be regretted that the facts have never been reduced to general rules, and that the theory has been almost entirely neglected.

It is generally admitted as a fact proven that in the ox, horse, and other domestic animals the purer or less mixed the breed is, there is the greater probability of its transmitting to the offspring the qualities which it possesses, whether these be good or bad. Economical purposes have made the male in general the most important, simply because he serves for a considerable number of females. The consequence of this has been that more attention has been paid to the blood or purity of race of the stallion, bull, ram, and boar than to that of their females; and hence it may be the case that these males more frequently transmit their qualities to the offspring than do the inferior females with which they are often made to breed. But this circumstance can scarcely be adduced as a proof that the male, cæteris paribus, influences the offspring more than the female.

Bad as well as good qualities may be transmitted, and, therefore, it is obvious that in endeavouring to improve any stock by engrafting a good quality, the breeder must choose a male which, besides the requisite good quality, is free from those defects of the female which it is desirable to sink. He must also select a male in the family of which the desired quality has been long resident. He cannot engraft the quality all at once, but must endeavour to introduce it by frequent crossing.

In the horse, for example, the strength of bone and weight of muscle suitable for slow draught, the light frame and prodigious swiftness of the race-horse, and the intermediate or rather combined qualities of the carriage-horse, hack, or hunter, are all capable of being produced by proper attention to purity or mixture of breeds. The pace, speed, action, temper, courage, colour or quality of hair, and almost all other qualities may be increased, diminished, or altered by a judicious admixture of different races. So also the immense weight of beef and fat of the large ox, the flavour of the flesh, the abundance or richness of the milk of the cow, are subject to modification in every different breeding.

The economical breeder, then, while he has settled in his mind the object which he wishes to accomplish in any of his stocks, must hold in recollection that it is only by the combination and continued succession of good qualities that he can ensure a permanent improvement. He must not expect to be able to effect this by crossing the breed of an impure blooded or worn-out female with a male of superior qualities. Bad qualities may become as fixed as good ones, and a judicious selection of the good ones (as adapted for his purpose) ought to be his first and principal object.*

A belief exists with some, founded, it is said, both on common observation and scientific research, that frequent breeding in the same family, or what is commonly called breeding in and in, has the effect of deteriorating a race. There appears, however, much reason to believe that the opinion just now stated is founded in error. In a state of nature it not unfrequently happens, among those animals especially which do not pair, that the strongest males take precedence of the weaker, and naturally select the finest females (as occurs in the deer); but in a state of domesticity this cannot always be the case, and inferior animals coming together give rise to inferior offspring; but, if in the farm-yard sufficient care be taken in the selection of the breeding males and females, it does not appear that near relationship has any effect in deteriorating the race, nor in impeding the transmission of good qualities which may be found in males and females of the same family.

The belief now alluded to has been held in relation to the human species also, and it is affirmed that both the bodily and mental qualities of the offspring suffer gradual and progressive injury from the continued mixture of successive generations of the same family or a small number of families. Hence we find that the marriage of cousins-german, which is according to law in this country, is reprobated as prejudicial by some; and various royal families and aristocratic families are referred to as examples of the bad effect of the restriction of conjugal union to a narrow circle.

It must be remembered, however, that the mutual selection of the parents is not quite the same in the human species as among the lower animals; and in the examples just referred to we feel even inclined to doubt whether, when due allowance is made for the nature of their education, it will be found that kings or princes have become worse or less talented in modern than in ancient times, or whether among that class there is, on an average, a greater proportion of stupid men than in other ranks of society.

The regularity of feature and beauty of the Persian race has been greatly improved by their choice of the most beautiful Circassian and Georgian wives; and there are many examples of particular families in this country in which regular and handsome features and a well-knit and fully developed form of body are hereditary. We shall not pursue the attempt, however, which some have made to apply the principles of cattle-breeding to the human species; for however desirable and necessary an improvement of the breed may appear to some Utopian philanthropists, we fear that the mind, with all its peculiar tastes, prejudices, and passions, has too much to do with the greater number of matrimonial alliances to allow physiological considerations much jurisdiction.

From the different facts now touched upon, it is obvious that the original type of the parents modifies that of their offspring; while, in general, varieties accidentally acquired do not pass in hereditary descent, unless they are of such a nature as to constitute a permanently distinct race or variety.

In the mixture of different races of the human species and of distinct species of animals we recognise a constant tendency in succeeding generations to return to the original type or pure breed; an effect which seems to proceed naturally from the general law already announced, that the purer the breed of either of the parents, or in other words, the more nearly it approaches the original type or unmixed race, the more readily will its qualities descend to the offspring. When the mixed offspring of the black and white races of men unites with either the black or the white, the offspring in successive generations becomes more and more nearly allied to the pure breed with which the cross is made, and at last wholly identified with it. We must look upon this general law of the tendency of all mixed varieties to return to the original type, together with the circumstance that hybrids rarely breed as means adopted by nature for the preservation of distinct species.

The transmission of hereditary resemblance, either as regards the general structure of the body or peculiarities, is not, however, invariable, nor always immediate from parents to offspring. Thus parents with certain deformities may produce all their children naturally formed and healthy; or some of them only (in one case the males, in a second the females, in a third some of both sexes) may inherit the abnormal peculiarity, while the rest of the children are healthy. But these healthy children, from some disposition of their constitution, may transmit to their descendants either in the first or in a subsequent generation the defect which existed in their parents. The varieties in this respect in the human species are almost infinite. Thus, in one family all the children resemble one parent in a striking manner; in another the male children take after the father chiefly, the females after the mother; and in a third the converse holds, the peculiarities of the father descending principally to daughters, those of the mother to sons,—an arrangement of family resemblance which is the most commonly prevalent according to M. Girou, who endeavours to shew that family resemblance frequently passes in an alternating manner from grandparent to grandchild. Thus, the grandchild resembles the grandparent of the same sex, so that a boy whose father is like his (the father's) mother resembles most the grandfather, as in the following plan.

1st Generation.	*Grandf.*	*Grandm.*	*Grandf.*	*Grandm.*
2d ditto	|	Father	Mother	|
3d ditto	Son	Daughter	Son	Daugh.

If it should be proved that a first or earlier

* We refer the reader to the Farmer's Series of the Library of Useful Knowledge. Vols. Horse and Cattle.

impregnation influences the product of a subsequent one, in breeding any particular stock of animals, it would appear of importance that the female should always breed with well qualified males; and farther, that the genealogy of both parents for one step, if not more, backwards, ought to enter as an item into the calculation of the probable qualifications of the offspring.

Much information is, however, still wanting on this subject, which, as it involves the most obscure parts of the generative process, we can hardly expect ever to be able to fathom. It cannot but be a matter of wonder and extreme interest to inquire how, in the unformed germinal spot of the egg of the female at the moment when it receives the vital fecundating influence of the male semen, the disposition to the formation of those minute modifications of structure and function which constitute hereditary resemblances is capable of being retained and transmitted to the future offspring.

The celebrated Darwin and some other fanciful speculators on physiological subjects held an opinion* that the transitory state of the minds of the father or mother at the instant of conception has a marked influence on the mental and physical qualities of the offspring. Thus it has been alleged that children begotten after debauchery or drunkenness are liable to idiocy or weakness both of mind and body; that when the amorous propensities are *too* much excited, the offspring runs the risk of erring in the same way; and in short, that according to the predominance of one or other sentiment, propensity, or frame of mind, the offspring may be a genius or a dolt, a sentimental swain or an unfeeling brute, a thief, a robber, a murderer, &c. Leaving to others the proof or disproof of the alleged facts upon which the above-mentioned belief is founded, we would take the liberty of expressing our doubts as to whether at the particular time alluded to by these theorists any idea but one is usually predominant. Nor shall we here dwell upon the obvious local treatment which is applicable upon the phrenological view of the subject; but as few may be aware of the real importance of that critical period in which life is conferred upon a new being, we have thought it right to put our married readers at least upon their guard against unrestrained yielding to any of the baser feelings or ideas, which do creep into the best-regulated establishments, requesting at the same time that they will communicate to their partners such information as may be considered necessary for the attainment of the grand object in view, viz. the improvement of the population of this kingdom.

The belief now stated as regards the human species has also been applied to animals, and that either parent may thus influence the offspring. Thus it is asserted that the male race-horse when excited by running, if not fatigued, is in the best condition for communicating speed to his offspring. Again, it is related that at the time when a stallion was about to cover a mare, the stallion's pale colour was objected to, whereupon the groom, knowing in the effect of colour upon horses' imaginations, presented before the stallion a mare of a pleasing colour, which had the desired effect of determining a dark colour in the offspring. This is said to have been repeated with success in the same horse more than once. As a similar case, the influence acting through the mother, it is related that a cow belonging to a farmer of Angus, in Scotland, had been grazing in company with an horned ox of a black and white colour for some time before it came into heat. The bull which impregnated the cow had no horns, and differed totally from the ox in colour, as did also the cow itself; and yet, wonderful to ralate, the next calf was black and white, and had horns.

These stories lead us to the consideration of a host of extraordinary relations, from which the general conclusion has been drawn, by no very logical process of induction, that the imagination of the female parent is capable of exerting a powerful influence on the structure and qualities of the offspring either at the moment of conception or during part of the period of utero-gestation.

The effects of the mother's imagination upon the child are so various that we cannot hope to be able to reduce them to any general or complete enumeration. Those which have attracted the greatest share of attention are of the nature of blemishes, spots, wounds, deficient and redundant parts, in short, all unnatural or so-called monstrous formations of the child. The alleged causes of these unnatural formations include all those circumstances which powerfully excite the moral faculties, the fancy, desires, or passions of the mother; sudden surprise, fear, anger, horror or disgust on her being a witness of any unusual or frightful event or object, or the opposite passions of joy, pleasure, admiration, &c. as well as strong longings, desires, and appetites, whether satisfied or not. The influence of the mother's imagination upon the child is not confined in its effects to bodily disfiguration or change, however, for those who carry their belief its whole length hold that the mind of the child may also be similarly modified. Thus it is stated that the ambition, courage, and military skill of Napoleon Bonaparte had their foundation in the circumstance that the emperor's mother followed her husband in his campaigns, and was subjected to all the dangers of a military life; while, on the other hand, the murder of David Rizzio in the presence of Queen Mary was the death-blow to the personal courage of King James, and occasioned that strong dislike of edged weapons for which that crafty and pedantic monarch was said to be remarkable.

We can readily believe that all sudden or violent changes in the functions of the mother, derangements of the general circulation, nervous affections, and other circumstances which tend to disturb the uterine function, must cause or be liable to occasion injury to

* More recently adopted by Mr. Combe, of Edinburgh, in his Work on the Constitution of Man.

the fœtus or its coverings during pregnancy. So also we can understand that any violent affection of the mind of a pregnant woman, in so far as it tends to derange the bodily functions, may produce some effect on the nutrition of the child.

Some contagious diseases pass from the mother to the child in utero. Syphilis and small-pox may be mentioned as those the effects of which have been most frequently observed.* Typhous fever, on the other hand, is said rarely to affect the child. We know also that severe affections of the mother may cause the death of the child, and its premature expulsion or abortion. According to Hausmann, the effect of variations of the external atmosphere is visible in the unusual number of blind colts and hydrocephalic pigs which are born after a wet summer. Malformations of the fœtus of birds have been artificially produced by external injuries and altered position of the eggs during incubation.† The transmission to the child of the effects of chemical poisons taken by the mother has also been observed; but in all the foregoing the effect of the injury has been more or less general; and there is no sufficient reason to conclude from them that a particular impression on the mind of the mother is capable of producing physical injury, or a particular deformity in one or other of the organs of the fœtus.

A vague notion is entertained by some that a certain influence is exerted by the hen or other bird on the eggs that they incubate, by which the qualities of the progeny are modified. But we must observe that hereditary resemblances are preserved in artificial incubation without the hen; and although we are disposed to admit that the female bird incubates its eggs with an instinctive care and perfection that art can rarely imitate, we are exceedingly sceptical as to the possibility of any other secret influence from the oviparous mother to its offspring once the eggs have left the body; and the attempt to support the theory of imagination by this opinion is an explanation of the obscurum per obscurius.

Were it possible to separate the better authenticated from the more fanciful relations of the effects of the mother's imagination, or to select those instances only in which the impression on the mind of the mother had been carefully noted before the birth of the child, we might expect in some degree to be able to free this question from the falsity and prejudice which obscures it. But such a separation we believe to be impossible, and we have therefore resolved to enumerate shortly some of the more remarkable cases taken at random,‡ from which we think the reader will best be able to judge what value or faith is to be attached to the facts now under consideration.

In a certain number of these cases we are told that an injury of an organ in the mother causes a similar injury in a corresponding part of the child's body; as in the following examples.

1. A cow killed by the blow of a hatchet is found pregnant of a fœtus with a bruise on the same place of the forehead.

2. The same was the case with the young one of a hind that had been shot.

3. A pregnant cat which had had its tail trodden on bore five young, in four of which the tail was similarly wounded.

4. A woman bitten on the pudenda by a dog bore a boy having a wound of the glans penis. This boy suffered from epilepsy, and when the fits came on during sleep was frequently heard to call aloud, "the dog bites me!" There are other similar cases on record.

5. A pregnant woman walking with a friend has her head knocked violently against her friend's, and shortly afterwards bears twins, which are joined together by the foreheads.

6. A gentlewoman who was cut for rupture in the groin during her pregnancy, bears a boy having a large scar in the same region, which he bore for thirty years afterwards.

The injuries of others operating on the imagination of the mother may affect the structure of the child: thus—

7. A woman who was suddenly alarmed by seeing her husband come home with one side of his face swollen and distorted by a blow, bears a child (a girl) with a purple swelling covering the forehead, nose, &c. of the same side.

8. A child is born with hare-lip, which was caused by the mother's frequently seeing a child with the same deformity during her pregnancy.

9. A mother seeing a criminal broke upon the wheel, bears an idiot child, of which the bones are similarly broken.

10. A woman seeing a person in an epileptic fit brings forth a child which is subject to epilepsy.

11. A lady in London, who is frightened by a beggar presenting the stump of an arm to her, bears a child wanting a hand.

12. A child is born with its head pierced, in consequence of its mother having seen a man run through the body with a sword.

13. A woman is forced to be present at the opening of a calf by the butcher. She afterwards bears a child with all the bowels hanging out of the abdomen. This woman was at the time of the accident aware that something was going wrong in the womb.

14. A similar misfortune happened to the child of another woman, who was imprudent enough to witness the disembowelling of a pig during her pregnancy.

* In reference to this, it is an interesting circumstance that the child is affected with small-pox some time after the mother, as if the contagion had taken the same time to operate as it does in passing between two persons.

† As in Geoffory St. Hilaire's experiments, which the author has more than once repeated with a similar result.

‡ From Burdach's Physiologie, B. ii. and from a talented Refutation of the Doctrine of the Imaginationists, by Dr. Blundell, of London. Professor Burdach, we may remark, is inclined to adopt the belief.

The mere description of an event may affect the child, as in the following curious case.

15. A woman who had listened with considerable interest to a description of the operation of circumcision bears a child with the foreskin split up and turned back!

16. A woman who sees another affected with prolapsus uteri bears a child affected with the same disease.

The examples of the effect of sudden fright, disgust, anger, joy, &c. are very numerous.

17. A lady absent from home is alarmed by seeing a great fire in the direction of and near her own house; and some months afterwards bears a female child having the distinct mark of a flame on her forehead.

18. A pregnant woman frighted by her husband pursuing her with a drawn sword, bears a child with a large wound in the forehead.

19. A man who had personated a devil (or satyr according to other authorities) goes to bed in his assumed dress, and his wife, being then pregnant, afterwards bears a child having horns, cloven feet, &c.

20. A mother frighted by the firing of a gun has a child wounded as by a gun-shot.

21. A pregnant woman falls into a violent passion at not being able to obtain a particular piece of meat at a butcher's shop; she bleeds at the nose, and wiping the blood from her lip, afterwards bears a child wanting the lip.

22. A woman two months before being brought to bed is alarmed by hearing a report that a neighbour had murdered his wife by a wound on the breast, and bears a child with a similar wound.

23. A child is born with the hair of one side black, that of the other white; competent judges declared at the time that both sides would have been white, but for the circumstance that the mother had carried a heavy sack of coals during her pregnancy.

24. A woman frighted by the sudden appearance of a negro brings forth a child with various black marks.

25. A mother is suddenly frighted by a lizard jumping into her breast, and afterwards gives birth to a child having a fleshy excrescence exactly like a lizard growing from the breast, to which it adhered by the head or neck.

26. A child has a face exactly like a frog's, from the mother having held a frog in her hand about the time of conception.

27. The remarkable resemblance of a woman to an ape was fully accounted for by her mother having been much pleased with one of these animals when with child of her.

The effect of the attentive contemplation of pictures, statues, &c. by pregnant women is worthy of notice.

28. A child is horn covered with hairs in consequence of the mother having been in the habit of beholding a picture of St. John the Baptist.

29. A woman gives birth to a child covered with hair and having the claws of a bear, from her constantly beholding the images and pictures of bears hung up every where in the dwelling of the Ursini family, to which she belonged. It is not stated by the Author of Waverley, whether any thing of the kind ever happened in the Bradwardine family.

30. A woman contemplating, *too* earnestly as it appears, a picture of St. Pius, has afterwards a child bearing a striking resemblance to an old man.

31. The tyrant Dionysius was aware of the effect of pictures; for he hung a beautiful picture in his wife's chamber, in order to improve his children's looks.

32. Two girls (twins) were born with their bodies joined together, their mother having during her pregnancy been in the habit of attentively contemplating two sacred images similarly placed.

33. A child is born with its skin all mottled in colour from the mother having made a visit to St. Winifred's Well, and seeing the red pebbles there.

34. Another child was marked on the face, in consequence of the mother having worn black patches.

The longings and depraved appetites to which pregnant women are liable are occasionally the causes of marks and deformities in their children.

35. There are a great many instances in which the longing of the mother after strawberries, grapes, cherries, peaches, and other fruits has caused the growth of tumours in the children exactly resembling in each the fruit that was wished for,

36. A woman who had *longed* for a lobster brings forth a child much resembling one of these animals.

37. Another woman had a female child, the head of which was like a shell-fish (a bivalve, which opened and shut as a mouth), which proceeded from the mother's having had a strong desire for mussels at one time of her pregnancy.

38. A pregnant woman *longs*, or has a great desire to bite the shoulder of a baker who happens to pass. The husband, wishing to humour this extraordinary fancy, hires the baker to submit to be bitten. The mother makes two bites, but of such a kind that the baker will not submit to more; and some time afterwards she is brought to bed of three children, one dead and two living.

39. A case of spina bifida near the sacrum is explained by the mother's having wished for fritters, and not obtaining them, having applied her hand (we know not with what object) to a corresponding place in her own body.

The impression on the fancy of the mother may be made before conception has taken place: thus—

40 A woman, whose children had previously been healthy, six weeks before conception is suddenly frighted by a beggar who presents a stumped arm and a wooden leg, and threatens to embrace her: the next child had only one stump leg and two stump arms.

The impression on the fancy may extend to the product of several successive conceptions.

41. A young woman frighted in her first

pregnancy by the sight of a child with hare-lip, bears a child with a complete deformity of the same kind: her second child had merely a deep slit, and her third no more than a mark in the same place.

We do not wish to argue against this hypothesis from its prima facie absurdity merely; but we think it will be generally admitted that the greater number of the foregoing cases are ridiculous and incredible; inasmuch as simple malformations of structure well known to anatomists have been regarded as the representations of animals and other objects to which they bear a very distant if any resemblance,—cases, in short, in which it is apparent that the imagination of the bye-standers has been more active than that of the mother.

We shall at once admit that we ought not to reject immediately an explanation of the mechanism of a vital function on account of its obscurity merely; but we assert that the general phenomena of the vital functions are capable of being observed and reduced to fixed and general laws, which is certainly by no means the case with the effects of imagination, which are as various and contradictory as they are absurd and ridiculous. The anatomical connection of the maternal uterus and child is so well known that we may with safety affirm that no such communication exists as would be necessary for the transmission of an impression from the body of the mother to any particular organ of the fœtus, and much less any means of conveying mental impressions only. The longings which are said to be so liable to cause injuries of the child seem to act in the same manner whether the appetite is satisfied or not, &c.

But moral reasons are much stronger against the belief. It is obvious that in much the larger proportion of the cases related, the coincidence of the mental impression on the mother with the injury done to the child is a post-partum observation and discovery. The mother and her friends, or the father, if such a deformity shall belong to his side of the house, are desirous of finding an explanation of the blemish which shall not be a stigma upon them; and in other instances it is to be feared that the idle and talkative women who attend upon child-beds, and even more scientific male accoucheurs, have encouraged the mother's belief in the effect of some alleged previous impression (selected from thousands) on her imagination, in order to hide undue violence employed during the delivery, or perhaps with a less culpable desire to quiet the fears of the mother while in the dangerous puerperal state.

There is no doubt that there are innumerable instances in which the imagination and all the moral and intellectual powers of women have been highly excited during pregnancy without their children having suffered in any respects; and there are not wanting instances of children being born with all kinds of deformity that have been attributed to the effect of imagination, without their being aware of any unusual impression having been made on their minds.

Again, it may be remarked that the stage of the period of pregnancy at which the injury of the child may take place is by no means defined, and that there is no correspondence between the time or advancement of the fœtus and the nature of the injury. Some injuries are said to have occurred or to have had their foundation laid at the very moment of conception, and even occasionally before that time, while others are inflicted only a few weeks before birth.

The monstrous appearances or malformations which constitute by far the greater part of the injuries attributed to the mother's imagination, are now no longer regarded as lusus naturæ merely, or "sports of nature's fancy," as they used to be called; but the times at which many of them must have occurred are known with some degree of certainty, and these times by no means correspond with the periods at which the imagination is said to have been affected. Besides this, nearly the whole of congenital malformations have been accurately anatomised, and their structure is reduced to general laws as regular and determinate in each individual form as the more usual or so-called natural structure. See Monstrosity.

In this question, as in others of a like kind, reference has been made to scriptural authority, in the history, viz. of Jacob's placing the peeled black and willow rods before the ewes which went to drink and afterwards conceived. But any one who pays the slightest attention to the whole of this relation will at once be convinced that the sacred writer, in describing the proceeding of Jacob, exhibits merely that patriarch's belief in the efficacy of such means; for in a subsequent part of the chapter Jacob is undeceived by the angel, who appears to him in a dream and informs him of the real cause of the multiplication of the speckled lambs, &c. viz. the circumstance that the ring-straked, speckled, and spotted males had leaped upon the females, and that the progeny therefore merely inherited their colour from their fathers.

We now leave this unsatisfactory subject, upon which we have perhaps dwelt longer than it deserves. We have introduced the foregoing remarks partly in accordance with custom, and also with a view to shew how little connection exists between the facts of our subject and the vague fancies to which allusion has been made. In doing so we are aware that we are liable to the accusation, on the one hand, of having treated with too much levity facts and observations upon which some are disposed implicitly to rely, and, on the other, of trifling with science in noticing even such vain fancies as belong to pregnant women and their attendant nurses.

We conclude by adopting and expressing the opinion of Dr. Blundell, "that it is contrary to experience, reason, and anatomy to believe that the strong attention of the mother's mind to a determinate object or event can cause a determinate or a specific impression upon the body of her child without any force or violence from without; and that it is equally improbable that, when the imagination is operating, the application of the mother's hand to any part of her own body will cause a disfiguration or specific impression on a corresponding part of the body of the child."

§ 3. *Number of children; and relative proportion of the male and female sexes.*

The simpler animals are, generally speaking, more fruitful than the complicated ones. As examples of great fecundity, may be mentioned some of the Entozoa and Mollusca, which produce hundreds of thousands of ova; among Crustacea and Insects some produce many thousand young. The Perch and Cyprinus genus among fishes produce some hundreds of thousands, and the common Cod, it is said, some millions of ova. Most of the Batrachia produce at least some hundreds. But in the warm-blooded Vertebrata, the necessity of incubation or utero-gestation puts a limit to the number of young; and there are also comparatively few in the Blenny, Skate, Shark, Land Salamander, or such animals as are ovo-viviparous.

In the human female, the number of children altogether produced is limited, first, by the number of Graafian vesicles in the ovaries, which usually amounts to from twelve to fifteen in each ovary; and second, by the length of the time during which a woman bears children, (the greatest extent of which is usually twenty-five years, that is, from the age of fifteen to forty, or twenty to forty-five,) the length of this period again depending upon the rapidity with which the births succeed one another, and the number of children produced at each.

Women most frequently bear every twenty months, but some have children at shorter intervals, as of fifteen or even twelve months. This often depends upon the circumstance that in some lactation prevents conception; in others it does not.

The number of the eggs of birds for one incubation varies from two to sixteen. The number of the young of Mammalia produced in one utero-gestation varies from one to fifteen, and occasionally more.

Woman usually bears a single child. The proportion of twin-births to those of single children is estimated by Burdach as one to seventy or eighty: the proportion of triplet births one to six or seven thousand; quadruplets, one to twenty or fifty thousand. Occasionally five children come at one birth, and there are instances on record of six or even seven children being born at once.

The causes of this greater or less fecundity are not known: they are in all probability various; being not of an accidental nature, but connected with the constitution of one or other of the parents, most frequently perhaps of the mother.

A healthy woman bearing during the whole time, and with the common duration of interval, may have in all from twelve to sixteen children; but some have as many as eighteen or twenty; and when there are twins, &c. considerably more, as in the following remarkable instances. First, eighteen children at six births. Second, forty-four children in all, thirty in the first marriage, and fourteen in the second; and in a still more extraordinary case, fifty-three children in all in one marriage, eighteen times single births, five times twins, four times triplets, once six, and once seven.*

Men have been known to beget seventy or eighty children in two or more marriages, but the tendency of polygamy is generally believed to be to diminish rather than to increase the number of the whole progeny.

According to Marc, not more than two or three children are born from two thousand prostitutes in the course of a year,—a circumstance depending in part on their want of liability to conception, and in part on frequent abortion.

The proportion of children born in each marriage varies much in different countries. The following statement of the average number is taken from Burdach: Germany, 6—8; England, 5—7; France, 4—5; Spain and Italy, 2—3.†

In reference to the average proportion of male and female births, it appears from very extensive data that in this and most other countries the number of males usually exceeds that of females; in this country in the proportion of four or five in a hundred.

The circumstances which influence the preponderance of male births are not known. The accompanying table shews how very constant it is in different countries.

Table of the proportional number of males and females born in different countries; the females being taken as 100.

Great Britain	104.75
France	106.55 103.38
Prussia	106.94 105.90
Sweden	104.72
Wurtemburg	105.69
Westphalia and Rhine	105.86
Bohemia	105.38
Netherlands	106.44
Saxony and Silesia	106.05
Austria	106.10
Sicily	106.18
Brandenburg	106.27
Mecklenburg	107 07

Russia	108.91
Jews in Prussia	112.
—— in Breslau	114.
—— in Leghorn	120.
Christians in Leghorn	104.

It has been found, on the other hand, that the first children of a marriage consist of a greater number of females and fewer males, in the proportion, according to Burdach, of fifty-three male births to a hundred females. A similar preponderance of females is said to exist among illegitimate children; but the difference is

* See Fournier, Dict. des Scien. Méd. tom iv.

† According to Burdach, one marriage out of fifty is unfruitful; there is one birth on an average for every twenty-five of the population of a place; and taking the whole population of the world at six hundred and thirty-three millions, about fifty-one children are born every second!

much less, not amounting to more than four or six in one hundred.*

Malformations are said to occur more frequently among illegitimate than legitimate children; and malformed children are more frequently of the female sex. This, together with the circumstance that illegitimate children are oftenest first born, may in some degree account for the greater number of females among them.

The data upon which it has been attempted to found an explanation of the cause of the formation of a male or female offspring are very slender indeed; nor are we likely ever to obtain knowledge which shall enable us to form a satisfactory theory regarding the cause of the determination of the sex. Some men beget always male children, others always females, in more than one marriage. The same seems sometimes to depend on the mother. In other marriages children of one sex are born for a time, and subsequently those of the other; or the male and female children may alternate, &c. &c. without our being able to point out any circumstance which has given rise to the production of one or other sex.

Accordingly many vague opinions have been entertained regarding this subject, as for example the following:

1. That the wishes or ideas of the parents at the time of conceptions may influence the sex of the offspring.

2. The nature of the food of the parents, particularly of the mother during pregnancy.

3. The use of various medicines: hence the numerous charms and recipes for begetting children of either sex.

4. The quantity of oxygen absorbed during development.

5. The manner in which the spermatic artery is given off from the aorta, and

6. The older and equally groundless notion that male children come from the right testicle or ovary, and females from the left; upon which hypothesis was founded the celebrated advice of Hippocrates: "Ubi femellam generare volet (pater) coeat, ac dextram testem obliget, quantum id tolerare poterit, sed si marem generare appetat, sinister testis obligandus erit."

A belief has long prevailed that the greater the strength of either of the parents in proportion to the other, the more of its own sex will be generated. M. Girou de Buzaraignes has paid considerable attention to the influence of age, strength, mode of life, &c. of the parents on the sex of the offspring, and has made a series of experiments on the domestic animals, from which, should they be confirmed, some important results may be expected.

According to M. Girou,† male fathers among the domestic animals which are either too old or too young, produce with mature and healthy females more female than male offspring; while female parents that are too old or too young in proportion to the males bear most males. This would appear to be the case in the human species also from the observations of Hofacker at Tubingen, and of Saddler on the English peerage: the children of a husband considerably younger than his wife being nearly in the proportion of ninety sons to a hundred daughters; while those of the husband considerably older than the mother are in the proportion of a hundred and fifty or a hundred and sixty sons to a hundred daughters; the intermediate ages being found to give a proportionate scale.

Burdach states that those women who are most fruitful bear many more boys than girls, as in the following examples:—

	Boys.	Girls.
1st woman bore	26	6
2nd ditto, in first marriage	27	3
in second ditto......	14	0
3rd ditto	38	15

According to Girou, female domestic animals bear more females when well nourished and left in repose than when much worked and on spare diet; and it has been alleged that the sexes of plants are influenced by their nourishment or soil in which they grow; diœcious plants having seeds which propagate more males in dry ground exposed to the sun, more females in moist, well manured, and shady ground; monœcious plants bearing more of the staminiferous or pistilliferous flowers in corresponding circumstances.

The explanation of the cause of this variation of the sex as well as of the original sexual difference, it has already been remarked, is beyond the reach of investigation. Very interesting observations have, however, brought to light the different steps of the process by which the generative organs of either sex are gradually formed during the development of the fœtus; and a series of facts has thus been established of great interest and importance as tending to elucidate the nature of those numerous remarkable malformations of the reproductive organs generally comprehended under the term Hermaphrodism. We refer the reader to the article upon this subject, and to that of OVUM, for a history of the process now alluded to, and shall not do more than merely mention in this place some of the more important results which have been obtained.

1st. It appears that in the earliest stages of fœtal life, the sexes (or what may become afterwards either male or female, that is, all the young) are perfectly alike in structure.

2nd. That there exists in all a common matrix or rudimentary organ or set of organs, which at a later period is converted by development into the male or female organs.

3rd. That the early type of the sexual organs is to be regarded as common and single, rather than double, as some have considered it.

In conclusion, we may remark that we must confess ourselves equally unable to fathom the nature of the original bias or determination given by the parents, in consequence of which a male or a female child is produced, and to ascertain the manner in which any other hereditary influence, quality, or conformation is transmitted from the parent to its offspring. At the same time it appears not improbable

that the nature of the sex may in some degree be modified by circumstances affecting the female at an early period of utero-gestation. In reference to this subject we ought not to omit the mention of a fact which is well established, viz. that when the cow bears two calves, one of which is a male, the other, exteriorly resembling the female, has its reproductive organs internally imperfectly formed, being of that kind of hermaphrodite formation usually called the Free Martin.*

GLAND,

Gr. ἀδὴν; Lat. *Glandula;* Fr. *Glande;* Germ. *Drüse.*

*An organ whose office is to separate from the blood a peculiar substance, almost invariably fluid; constantly provided with an excretory duct; formed of a process of the mucous membrane or of the skin, disposed either in the form of a sac or of a ramified canal; which sac or canal in all cases is closed by a blind extremity; and which, although amply supplied with blood, is never directly continuous with the bloodvessels.** It is absolutely necessary to give this definite explanation of the meaning which is attached to the word *gland* in the present article, inasmuch as there is no term in anatomy that has been more vaguely, and as it appears to me more incorrectly employed.

It is not necessary to point out the absurdity of applying this word to certain parts of the brain, or to the masses of fat contained in the joints, which were called by the older anatomists glands; in these instances the fallacy is immediately apparent; but there are other errors which, although less striking, are, I conceive, no less injurious in their effects. Thus in the glandular system many continental authorities include not only the liver, kidneys, salivary glands, and other organs, which are universally acknowledged to belong to this class; but likewise the lymphatic glands, the thyroid, the thymus, the spleen, the supra-renal capsules, and the ovaries.† It is con-

* The only real exception to this law is the testicle of fishes, in which no excretory duct seems to exist.

† Bichat, after condemning the application of the term to the thyroid, the pineal gland, the lymphatic glands, &c. states, "we ought only to call those glands, which pour out by one or several ducts, a fluid which these bodies separate from the blood they receive by their vessels." Anat. Gén. tom. ii. p. 598.

Meckel, on the contrary, objects to the opinion that an excretory duct is essential to a gland. According to his definition the glandular system comprises, 1. the mucous glands; 2. the sebaceous glands; 3. the liver, the salivary glands, the pancreas, the lachrymal glands, the tonsils, testes, the ovaries, the prostate, Cowper's glands, the kidneys; 4. the lymphatic glands, the thyroid, the mammary glands, thymus, spleen, supra-renal capsules. Man. d'Anat. tom. i. p. 511.

It is surprising that so admirable a physiologist as Meckel should adopt this opinion.

Professor Müller has also a classification, which seems to me objectionable; for he has admitted among the glands the spleen, thyroid, lymphatic glands, &c. It must not, however, be supposed from this arrangement that this profound anatomist considers these particular bodies as real glands. His classification is as follows. (Handbuch der Physiol. des Menschen, Coblenz, 1834, p. 418.)

I. Glands without a duct.	A. *Ganglia sanguineo-vasculosa,* the spleen in the digestive organs—the supra-renal capsules in the genital and uro-poïetic viscera — the thymus and thyroid in the respiratory apparatus—glandula choroidalis in the eye—the placenta in the fœtus. B. *G. lymphatico-vasculosa,* the lymphatic and mesenteric glands.
II. True glands with an excretory duct.	Liver, salivary glands, testis, &c.

tended by these writers that the last named bodies elaborate from the blood certain fluids, and that as far as the real function of a gland is concerned, it matters not whether the secreted fluid escapes by a proper excretory duct, or is taken up by the lymphatic vessels; it is, indeed, supposed by Haase that these bodies, like the true glands, possess excretory ducts, but this opinion has received little support.

This method of viewing the subject appears to be very injudicious; because it is based on the assumption that certain organs secrete fluids from the blood, but of which secretion we have no evidence; and further, because organs are classed together, between which there is no similarity either of structure or of function.

In establishing a well-founded distinction between parts which, in their general form and outward appearance, bear a resemblance to each other, it is proper to seek for some leading and obvious character, concerning which there can be no dispute. In applying this rule to the present case, we shall find that the special distinction of a true gland, as contrasted with those organs with which it has been assimilated, is the possession of an *excretory canal or duct;* and taking this as the essential characteristic, there is no difficulty in perceiving that the glandular system in the human body ought to be restricted to the following parts:—

Mucous glands, comprising, *a*, simple mucous glands or follicles, dispersed over the whole extent of the various mucous surfaces, either insulated or collected together, as the glandulæ Peyeri seu aggregatæ. *b*, *Compound mucous glands*, (g. agglutinatæ,) formed of the preceding, collected into masses, and slightly modified in their structure, comprising the molar, labial, palatine, and buccal glands, the lachrymal caruncle, tonsils, Cowper's glands, prostate, and seminal vesicles. *c*, *Sebaceous glands*, consisting of those of the skin, the ceruminous glands, the Meibomian glands. *d*, *Conglomerate glands*, (g. conglomeratæ;) these, which are the most complex of the glandular organs, consisting of the salivary glands and pancreas, the mammary glands, the testicle, the kidney, and the liver.

These glands may be classed according to their functions in the economy as follows:—

I. For lubrication and protection; *a.* mucous glands in all parts of the body; *b.* sebaceous glands; c. lachrymal gland; *d.* lachrymal caruncle.

II. Connected with digestion; *a.* salivary gland; *b.* pancreas; c. liver.

III. Connected with generation; *a.* testis; *b.* prostate; c. seminal vesicles; *d.* Cowper's glands; *e.* mammary gland.

IV. For excretion; *a.* kidney; *b.* liver.

By extending the principle that all glands are in reality nothing but processes of the mucous membrane ending in cul-de-sac, the lungs have, by some writers, been included amongst the glandular organs, the trachea, it is said, performing the office of an excretory duct. It is certain, as we shall subsequently show, that the lungs present, both in their formation and functions, a close approximation to the true glands.

The particular description of the above organs and the modifications of the general glandular structure they present, will be found in the articles KIDNEY, LACHRYMAL APPARATUS, MAMMA, &c.

Situation.—The principal glands are placed in the head and abdomen; in the extremities, with the exception of those of the skin, they are totally absent. In general they are protected from external injury by being lodged deeply in the cavities of the body; but to this rule there are several important exceptions, as the mammæ, testes, parotid glands, &c.

Organization.—In the whole range of Anatomy, whether Human or Comparative, there are probably no organs which, on account of the complexity of their structure, the number and variety of forms which they present, and the importance of their functions in the animal kingdom, are more interesting than the glands, or the structure of which, until within a very recent period, was more imperfectly understood. Even at the present time the prevailing ideas respecting the essential characters of the glandular organization are in general so vague and indefinite, and but too often positively erroneous, that I feel myself called upon to enter more fully into the investigation of this subject, than would otherwise be necessary. Much of this uncertainty has arisen from the fact that, whilst the views of the immortal Malpighi, founded as they are on truly philosophic grounds, have never attracted that investigation to which they are so justly entitled, the theoretical opinions of Ruysch, being received with all the eclat inspired by his unrivalled skill in vascular injections, have been generally adopted. It is true that, on many minor points, Malpighi was in error; and that the vagueness of his descriptions, and his infelicitous comparison of the ultimate divisions of the glands with clusters of grapes or *acini*,* greatly assisted in preventing his opinions being generally admitted or even comprehended. But those distinguished anatomists who have, by their recent inquiries, at length decided the long-disputed theories of Malpighi and Ruysch, have proved that in all essential points the conclusions of the former great authority are founded in truth.

Minute structure.—The investigation into the structure of the glands, when conducted in accordance with the enlightened principles of philosophical anatomy, shows that the laws which regulate their formation are simple and definite; and that, although Nature has displayed here, as in all her other works, immense fertility in modifying the forms and characters of the several glands, so as to render them efficient to the performance of their varied offices, yet in no single instance is there a departure from that structure, which constitutes the type of the whole glandular system. The unifor-

* This term, so much employed in descriptions of the glands, yet so indefinite in its acceptation, has caused such confusion and misconception, that it is most desirable to abolish it from the nomenclature of Anatomy. In the descriptive part of the present article, I shall therefore scrupulously avoid employing this expression.

mity which, with the aid of Comparative Anatomy, has been so satisfactorily demonstrated in the development of the nervous and osseous systems, is equally evinced in the glands; for whatever diversities may be presented in their form and appearances—whatever varieties may be remarked in the internal disposition of their component parts, as in contrasting a simple follicle with a conglomerate gland, or the tubular biliferous organs of insects with the apparently solid liver of the Mammalia; whether, in short, they appear solid, cellular, or tubular, every glandular organ is nothing else than a modification of a simple closed sac. This important truth is distinctly announced by Meckel in the following passage. "The most simple mucous glands, which are only simple sacs, present the type of the glandular formation. If we picture to ourselves this sac as being prolonged and ramified, and interlacing its branches between those of the bloodvessels, we shall at length arrive at the most compound gland, without there ever being a direct communication between the bloodvessels and the excretory ducts."* We have here briefly but clearly expressed the great principle, in obedience to which the various glands are developed; but that which Meckel only figuratively expressed, has since been realized in all its bearings and intricate details, by the extensive and laborious researches of several distinguished anatomists, and especially by Professor Müller of Berlin.

As it would be in vain to attempt to demonstrate the essential characters of the glandular formation, and to prove the uniformity which pervades the whole system, by selecting, as has been generally done, the most intricate organs; I propose, in the first place, to describe the most simple form of gland, and, seizing this as a clue, to trace its gradual development throughout the whole series of glandular organs, so as to convey a general, but, it is hoped, comprehensive account of this interesting branch of anatomy.

With this object in view, the simple follicles of the skin and mucous membrane may be advantageously selected; because by tracing the successive development of these bodies, the gradual transformation of a simple sac into a tube, a ramified canal, and even a conglomerate gland, may be very distinctly demonstrated. In fishes, whose aquatic mode of life renders an abundant defensive secretion necessary, the cutaneous follicles are more developed than in other animals, and constitute tubes or canals, which being carefully examined are found to end in cœcal extremities. A similar formation is seen in the bulbus glandulosus of most birds, where the mucous crypts are prolonged into short tubuli (*fig.* 209); whilst in the Ostrich (*Struthio camelus*) the follicles present an appearance of cells. (*Fig.* 209, *b*). In some Amphibia, *Salamandra maculata* for example, the glands of the external integument being very much developed, it is seen that each of

Fig. 209.

those bodies is composed of a small flask-shaped pouch of the skin, which at one extremity becoming enlarged into a base, there terminates in a blind sac; whilst at the other end being contracted, it opens by a short neck on the external surface. (See *fig.* 210.) A microscopical view of the cœcal canals in the simpler glands is appended. (See *fig.* 211.)

Fig. 210.

Flask-shaped cutaneous follicle or gland magnified=110.†

Fig. 211.

The simple sacs and tubes just described are very often collected together, giving rise to *aggregate* or *compound follicles*, the arrangement and degree of complexity of which are very various. In some instances these sacs unite so as to form a gland with a single orifice or excretory duct, of which the Meibomian glands of the eye-lids are an example; or again, the aggregate follicles may themselves be joined together with various degrees of complication, in the form of a cluster, from which several excretory ducts proceed, as in the caruncula lachrymalis, the labial, buccal, and other mucous glands of the mouth, the tonsils, &c. In all these instances there is nothing but an evolution of the original sac, so that in the same manner as this is formed from the mucous membrane or skin, are the tubes and canals prolonged from the third pouch, by which contrivance the surface subservient to secretion is, within a given space, greatly increased. The conversion of a sac or tube into a granular mass is also in this manner rendered very apparent; and thus it is easy to understand how a ramified canal may produce the apparently solid

* Man. d'An. i. p. 515. Béclard has a similar comparison: "it is true that a gland, like a follicle, consists of a canal closed at the extremity." Anat. Gén. p. 424.

* Home, Lect. on Comp. An. ii. tab. 46.
† Berres.

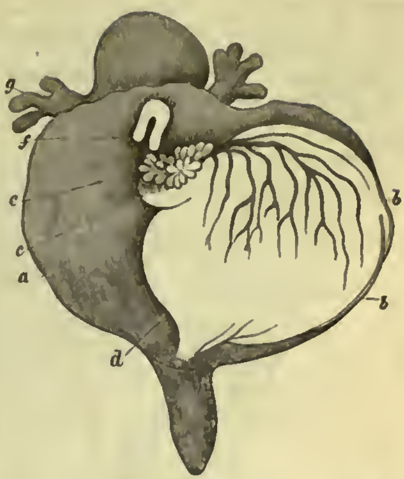
granules (the so much talked of *acini*) of the liver and other conglomerate glands.

Such, then, are the more simple forms of the glandular organs; and if we proceed to those which are more complex, no difficulty is experienced in proving, by the aid of comparative and developmental anatomy, that the structure, although it becomes more and more developed, is in character essentially the same. The inquiries of the anatomist in this respect are greatly facilitated by the existence of an universal law connected with the process of organization, in accordance with which it happens that, whenever any particular gland first appears in the animal series, it presents invariably the simplest form of the glandular structure, although this same gland may subsequently attain in the higher classes the most intricate formation. It is for this reason the salivary glands are so simple when they first appear in birds, the pancreas in fishes, and the liver in insects.

Ample confirmation of this gradual transition from simple to compound, which is in fact only another instance of the great laws which regulate the formation of the whole animal creation, is afforded by following any of the more intricate glands through the several stages of their development. Thus, if the pancreas be examined in its rudimentary state, it will be perceived that, like the mucous follicle, it is composed either of a fluid sac or of a tube more or less complicated. In the class *Cephalopoda*, the individuals of which are so remarkable by the complexity of their internal organization, the pancreas consists either of a simple sac opening into the intestine near the gizzard, (see *fig.* 219, *p*, *fig.* 220, *f*, vol. i. p. 533), or of a spiral canal, (*fig.* 221, *f*, p. 535,) the secerning surface being increased by a number of laminæ. In most fishes there are numerous fluid appendages placed near the pyloric extremity of the stomach, (*appendices pyloricæ*,) which are with propriety regarded as constituting a rudimentary pancreas, (*fig.* 212,) and which, in the in-

Fig. 212.

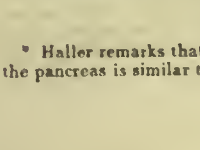
Fig. 213.



stance of the Sturgeon and Swordfish are aggregated into a glandular mass.* (See *fig.* 46, vol. i. p. 115.)

The liver is certainly the most intricate structure of all the glandular organs when examined in the higher animals; and yet, if we descend to the lower classes, which present, as it were, a natural analysis of the various parts of the animal machine, the texture becomes sufficiently simple. One of the most simple forms of this organ is probably furnished in the *lumbricus terrestris;* at least I have seen in that animal, in a few instances, a beautiful appearance of cœcal tubuli composing the yellowish substance which coats the intestine, and which is thought by some authorities to constitute the liver. In many insects, Crustacea and other Articulata, the biliferous organs consist of fluid sacs proceeding from the stomach or intestine, and often assuming the appearance of tubes, but always closed at their distal extremities. In some instances these tubuli are very simple, (see *fig.* 37, *d*, vol. i. p. 111,) but in other cases they are more complicated, and present a ramified arrangement; and in this manner the structure evidently approaches that of the most compound or conglomerate glands. The liver of the Lobster presents an excellent illustration of the cœcal tubuli which constitute the secreting structure of so many species of glands. By cutting out a portion of this organ, and slightly unravelling the tubes by moving the section in water, the canals ending in cul-de-sac are beautifully seen, and if slightly magnified, it is found that they closely resemble the pyloric appendages of fishes. The

Fig. 214.

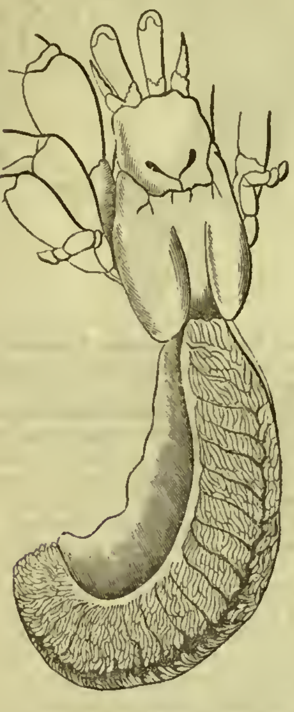


* Haller remarks that, in the Skate and Shark, the pancreas is similar to that of higher animals.

adjoining figure (*fig.* 214) conveys a very accurate representation of this structure as it exists in the biliary organs of the *astacus fluviatilis*, the digital tubuli (*c*) being depicted as they appear when partly unravelled.

In another of the Crustaceans, *pagurus striatus* (*fig.* 215), the same kind of structure is

Fig. 215.



observed, constituting a very complex liver. In the *squilla mantis* that organ is so remarkably intricate that Cuvier supposed it formed an exception when compared with the other genera of the Crustacea, which, as we have seen in the instances above, possess biliary organs composed of blind tubes, by being lobulated and solid like a conglomerate gland.* It has, however, been ascertained that the lobules are excavated in their whole extent, and communicate by openings with the intestine, which runs through their spongy mass, so that the secreting surface is wonderfully increased in extent.†

That the liver consists of a blind pouch, originating from the intestinal canal and becoming more and more complicated, is further shown in many of the Mollusca, in which the excretory ducts are so large that they appear like branches of the intestine, and thus present a structure which is somewhat analogous to those curious cœcal diverticula observed in certain of the Annelida, well seen in the *aphrodita aculeata*, and which are by some anatomists regarded as forming a rudimentary liver.

The evolution of the liver in the embryo affords an additional proof of the disposition of the secreting surface or membrane in the interior of the compound glands. In one of the Gasteropods (*Limnæus stagnalis*) the liver is first produced as a pellucid sac from the intestine. In an amphibious animal (*bufo campanisonus*) a prolongation in the form of a sac is seen in the intestinal membrane, which constitutes the first appearance of the liver; as the development proceeds, the hepatic duct is formed, and becoming ramified, produces at length a number of branching tubes, which present a granulated form. The evolution of the liver in the green lizard (*lacerta viridis*) is very similar, the organ first appearing under the form of a hollow sac proceeding from and communicating with the cavity of the intestine, and subsequently having branches of ramified tubes added.*

If from the investigation of these more simple forms, which might be multiplied almost *ad infinitum*, we proceed to the conglomerate glands of Mammalia, it will be observed that, although the component parts of these highly organized bodies are so closely packed together as to present a solid and granular appearance, yet by a careful inspection it may be satisfactorily determined that the true secreting structure consists of tubuli with cœcal ends. For this purpose the testicle may be advantageously selected: if this organ without any previous injection be divided, the section at first sight seems to consist of a great number of small roundish bodies or granules; but if, as occasionally happens, the tubes are distended with semen at the time of death, by a more cautious examination it is immediately apparent that these little bodies are composed of a very fine tube coiled up or convoluted. By injecting the tubuli seminiferi with mercury, the formation of the little grains is rendered more evident; but the most successful mode of displaying the whole internal formation of the testis is by filling the tubuli with a coloured size injection.†

It was remarked by Ferrein‡ that the kidney is a tubular organ, and the extensive researches of Müller as well as those of Huschke have proved that the secreting or cortical part is made up of an immense number of serpentine tubes of an equal diameter throughout, ending in blind sacs, and becoming continuous with the straight canals placed in the cones of the organ. This structure is seen in *fig.* 216, where a magnified view of the cortical ducts of Ferrein, the secerning apparatus, and the straight excretory tubes is given as the parts exist in the *sciurus*. This structure offers a close resemblance to the tubuliform liver of some insects.

* Leçons d'An. Comp. t. 4. p. 152. It is proper to observe that Cuvier, in thus alluding to a *solid* conglomerate gland, appears to have fallen into the common error respecting the nature of the minute granules, or acini as they are called.

† Müller de Gland. Secernent. Struct. p. 70, § 5.

* Müller l. c. tab. x. *fig.* 13.

† Sir A. Cooper on Testicle.

‡ Mém. de l'Acad. Roy. des Sc. 1749, p. 489.

(See the biliary organs of *Melolontha Vulgaris, fig.* 38, vol. i. p. 111.)

In the liver of Mammalia and Man, both in the embryo and after birth, it is much more difficult to demonstrate the ultimate tubes with their cœcal extremities; indeed the existence of such canals is rather deduced from the analogy of the liver in the lower animals than from actual observation. Müller states that the blind free extremities of the biliary ducts are visible on the surface of the liver with the microscope in the embryo of Mammalia; but that owing to their compact arrangement they are less distinct than in birds, so that their internal connexions cannot be perceived.* In a few Mammalia, however, as the squirrel, (*sciurus vulgaris,*) he observed with the microscope the blind cylindrical extremities of the biliary ducts on the surface of the liver, presenting a branching and foliaceous appearance. (*Fig.* 217.) The exact mode of termination of the biliary tubuli was still more distinctly seen in a portion of liver considerably magnified, taken from an embryo of the quail, (*Tetrao coturnix,*) about one inch long (*fig.* 218). From the published account of Mr. Kiernan's valuable observations on the minute structure of the liver, it does not appear that the actual terminations of the biliary tubes in blind extremities were perceived, although that such is their disposition is rendered very probable from what was seen with the microscope, and especially because it was found that much greater difficulty was experienced in injecting these tubes than the bloodvessels, on account, as it was surmised, of the bile contained within them having no exit.*

Fig. 216.

Fig. 217.

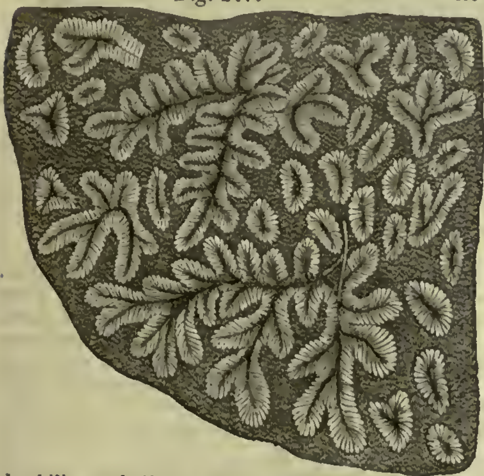


Fig. 218.

Lastly, in tracing the minute texture of these complex glands of the Mammalia, it is necessary to call the attention of the reader to a circumstance which of all others has been the most fertile source of error, so much so indeed as to have misled the great majority of anatomists. It is this: in many glands small rounded or berry-shaped corpuscles seem to be appended to the commencement of the secreting tubes, so that a deceptive appearance is produced, as if cells or little bags were placed between the terminal bloodvessels and the small excretory ducts. This appearance of cells or even of solid rounded corpuscles is dependent on two causes: in some glands the secreting canals are so coiled up that, as is seen in the human testis, when a section is made in the uninjected state an apparently granular texture is presented, (*fig.* 219;) but a second influential circumstance is that in many instances each of the secreting tubes swells out at its cœcal end into a slightly enlarged cul-de-sac (*pedunculated tubes*), so that when they are viewed in an aggregate form, the semblance of roundish-shaped granules is seen, (*fig.* 220.) As these and all other varieties which are presented in the glandular formation are

* Phil. Trans. 1833, p. 741.

Fig. 219.

considered in the several articles on the individual glands, it is only necessary to state in this place that what are called indifferently *lobules*, *glandular grains*, *vesicles*, *acini*, &c. are in every instance composed simply of the secreting canals variously disposed and arranged

It is, however, very remarkable that whilst those glands which arise from the alimentary canal present an immense variety in the arrangement of their secreting texture, the essential glands of the genito-urinary apparatus, the kidney and the testicle, have a most uniform structure, consisting of serpentine tubes of the same diameter throughout their whole extent.

The details into which I have thought it requisite to enter prove that the true secreting structure consists in every gland of nothing else than a vascular membrane, on the surface of which the glandular fluid is poured out; and consequently that in those complex organs, as the liver or kidney, in which the vascular se-

Fig. 220.

Peripheral ramification of the parotid duct, with some of the vesicular terminations, magnified = 110.*

creting membrane is, for the sake of convenience, disposed in the form of extensively ramified tubes, it is most important to recollect that the glandular fluid is poured not only into the cœcal extremity or commencement of each tube, as is the commonly received opinion, but along *the whole extent of the tube.* For the establishment of this fact, certainly the most important in the history of the glands, we are principally indebted to Professor Müller.

Excretory duct.—Although the essential seat of the glandular function is now ascertained, some difficulty exists in determining the actual extent of the secreting surface in the various organs; or in other words, at what precise point the mucous canals ceasing to secrete, become mere excretory passages.† An attempt to decide this point is, however, necessary, because until this time the majority of anatomists have signified by the term *excretory duct*, not only the canals which simply bear away the secreted fluid, but likewise those tubes which constitute the true secreting apparatus, and which, it is evident, are at the same time both secreting and excreting canals, as they not only secrete, but likewise carry to the larger and non-secreting ducts the fluids poured out by their parietes.

In the simple sacculi or follicles, it is evident that the secreting structure is co-equal with the extent of the bag itself, so that the little orifice becomes the excretory duct; in the tonsils, prostate, &c. there are several such orifices or ducts. But at what point does secretion cease in the compound glands? Mr. Kiernan states,* that in the liver the secreting portion of the organ is confined to what he calls the lobular biliary plexuses, or to those tubes which are placed within the lobules; so that here the excretory apparatus is very complex, consisting of the interlobular tubes, those

* Berres, l. c. pt. 5, tab. ix. *fig.* 2.

† I allude here of course to the peculiar secretions, as the bile, urine, milk, &c. and not to the secretion of mucus, which we know is poured out along the whole extent of the excretory ducts.

* Phil. Trans. 1833, p. 741.

of Glisson's capsules, and, lastly, of those which quit the organ. The limitation thus established, and which I have no doubt is strictly correct, may be applied to all those glands, such as the salivary, mammary organs, &c., which, like the liver, possess distinct lobules. In the kidney the true secreting structure is probably restricted to the serpentine tubes contained in the cortical texture, (*canales corticales*, or ducts of Ferrein,) the straight canals (*tub. Belliniani*) constituting the cones, which bodies, in a minute injection of the bloodvessels, are nearly colourless, being merely for excretion.* The testis, with its appendix the epididymis, presents an intricate arrangement; it is probable, however, that the principal secreting part consists of the seminal tubes which form the lobules, and that the vasa recta and efferentia are merely excretory in their office; in the upper part of the epididymis a second secreting structure is met with, constituting the coni vasculosi, whilst the lower part containing the convolutions of the vas deferens is of the excretory character.

It is proper to observe that the process of secretion is incessantly going on; but with the exceptions of the mucous, sebaceous, and a few other glands, the fluids produced are destined to be poured out only at stated intervals; it is, therefore, evident that some contrivance is required, by which the several secretions may be retained, till the moment arrives when it is necessary they should be discharged. The liver may be selected to illustrate this principle: one of the most essential functions of that organ being the decarbonization of venous blood, its constant action is no less indispensable, indeed considering the whole animal series, is even more indispensable than that of the lungs themselves; and yet the product of that action, the bile, is only designed to be poured into the duodenum during the process of digestion. In order to obviate the irritation of the bowels that would result from the incessant discharge of the bile, and at the same time to economise that fluid, the gall-bladder is provided, which, receiving the secreted fluid in the intervals of digestion, fulfils all the conditions required. The absence of the gall-bladder in several classes of animals can scarcely be admitted as being incompatible with this explanation; for the majority of these instances of deficiency occur in non-ruminant vegetable feeders, in several genera of the Pachydermata and Rodentia for example, in which it is evident that as the process of digestion must occupy a considerable period, a prolonged flow of bile is requisite, and a special reservoir is less necessary; in addition to which it is known that in some of these cases, as in the horse and elephant, the principal trunk of the biliary ducts is very large, and may in some degree supply the place of a gall-bladder.*

The urinary bladder is a provision rather of convenience than of necessity, enabling the animals that possess it to retain the urine as it flows from the ureters, until a considerable accumulation takes place. These are the only instances in the human body of a distinct reservoir being provided;† but every gland, by retaining its secretion in the excretory ducts, has a power of emitting the fluid, under certain circumstances, in larger quantities than usual, as in the case of the salivary and lachrymal glands; a similar accumulation must take place in the seminal tubes and prostatic ducts, and especially in the lactiferous tubes and their terminal sinuses. In animals the examples of distinct reservoirs are too numerous to be here enumerated.

Structure of the secreting canals and excretory ducts.—It is now certain that all these tubes are composed essentially of a prolongation of the mucous membrane. The former, according to Müller, consist only of a single coat, but it must be presumed that they possess in addition a tunic, having, independently of elasticity, a power of contraction by which their contents are propelled often in a direction opposed to gravity, and in obedience to the application of a mechanical stimulus to the surface on which the ducts terminate. In the excretory ducts the internal membrane is surrounded by a fibrous structure, which is very apparent in some of the larger canals, and probably exists in all. The fibres of this coat are of a greyish white or brownish colour, and are often so fine and compact that they are distinguished with great difficulty. The real character of this structure is not known; in appearance there is little or no resemblance to proper muscle; the action, however, of the excretory canal seems to require a contractile power; and Meckel states that he has distinctly perceived circular fibres in the vas deferens, which tube is said to be distinctly muscular in the bull.

Bloodvessels.—If it be recollected that the arteries carry to the glands the materials of their various secretions, and if the large quantity of fluid formed by those viscera be called to mind, we shall not be surprised to find that with a few exceptions, such as the lungs and the brain, there are no organs so abundantly supplied with arterial blood. This supply is in proportion to the activity of secretion, rather than to the size of the gland; thus the kidneys,

* It is stated by Müller that all his researches induce him to conclude that the serpentine tubuli of the cortical part constitute the true secreting texture; an opinion which is corroborated by a very curious preparation contained in the museum of the Webb-Street School of Anatomy, in which a sac has been formed on the outer surface of the kidney, containing a number of small calculi, and having no connexion whatever either with the straight tubes or with the infundibula.

* Carus, Traité Elem. d'An. Comp. ii. p. 269. It may be proper to state that the Otter, according to Daubenton, possesses the above dilatation of the duct in conjunction with a gall-bladder.

† Some anatomists conceive that the vesiculæ seminales are merely receptacles of the semen; but this opinion has been to a great extent abandoned in England since the observations of Hunter. See the works of Hunter, edit. by Palmer, vol. iv. p. 20. Note, p. 26.

furnishing about four pints of urine daily, receive, in proportion to their bulk, more blood than the pancreas, where the secerning process is less active. That this is the principle which regulates the supply of blood is also evidenced in the vessels of the mammæ, which receive a more ample supply of blood during lactation than at other periods.

The sanguiferous vessels, like the secreting canals, present many varieties in their disposition in the several glands, the varieties of form in each class being, however, definite in their character, and doubtless having a reference to the different kinds of fluids which are required to be separated from the circulating blood. Those organs which are provided with a distinct envelope, as the testicle, the kidney, and liver, usually possess but one artery, which enters at the same fissure as the excretory canal; other glands, presenting a more distinctly lobulated texture and having no proper capsule, the tonsil, pancreas, and mamma for instance, receive an indefinite number of arteries, which enter irregularly on all parts of the surface; lastly, in the most simple form, as the mucous crypts, the secreting vessels constitute a delicate plexus on the surface of the little bag.

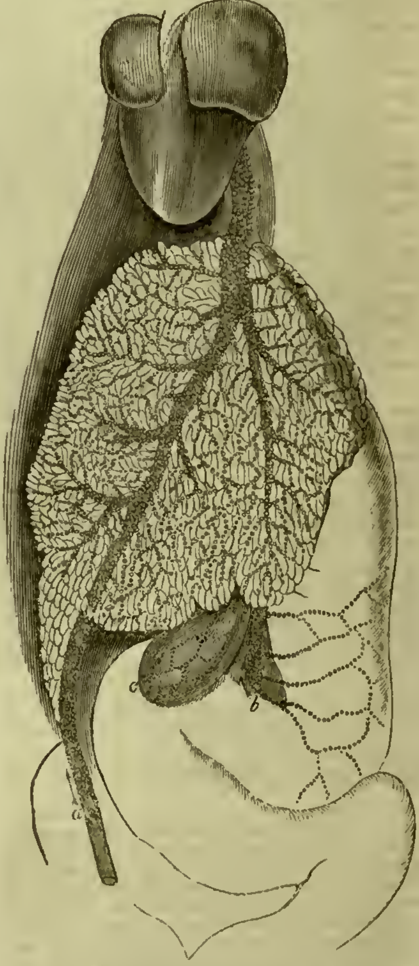
In all those instances where the gland is large enough to receive one or more arterial trunks, it is found that the vessel having entered begins to divide into smaller branches, which penetrate between the masses of the gland, and these becoming smaller and smaller at length furnish an intricate plexus, the branches of which, as in the case of the simple bag or follicle, ramify on the surface of the blind secreting canals.

It is only necessary to observe with respect to the veins, that when compared with their arteries, they are smaller than elsewhere; and also that in common with the veins of the splanchnic cavities, they are devoid of valves, so that in the kidney, liver, &c. they may be beautifully displayed by the aid of a successful injection, even to their ultimate ramifications.

Arrangement of the minute bloodvessels.— In considering the intimate texture of the glands, it is essential to state the manner in which the last divisions of the sanguiferous vessels are disposed. By the aid of minute injection these vessels may be demonstrated, though with difficulty, as far as their termination; and they may also be observed in a few instances during life and whilst carrying on the circulation.

An opinion to which we shall subsequently recur has been entertained by many anatomists, that the little arteries are either directly continuous with the excretory ducts, or, as we should rather call them, the *secreting canals*, or, at all events, that some kind of direct communication exists between the terminal arteries and the secreting canals. The most cautious and apparently successful researches, however, do not corroborate this opinion, but, on the contrary, show that no direct communication of any kind exists. In the lungs, which organs are formed and developed in exact accordance with the glandular structure, the ultimate divisions of the pulmonary artery, after freely ramifying over the surface of the air-cells, are known to terminate by direct continuity in the radicles of the pulmonary veins. Now, that which is demonstrated in the lungs equally applies in the case of the glands. In the simple lacunæ of the mucous membrane the arteries are disposed over the surface of the pouch, but they end in the returning veins without opening on the secreting surface. Müller states that on examining with a sufficient power the larva of the *triton palustris*, he observed streams of blood, traversed by single globules, running between the elongated secreting canals of the liver, and, further, that the last arteries pass immediately by a reticulate anastomosis into the small hepatic veins. This disposition is seen in the adjoining figure, which represents the circuit of the blood in the larva of the triton fifteen lines in length.

Fig. 221.



a, vena cava; *b*, vena portarum; *c*, minute currents of blood in the gall-bladder.

Müller expressly says, *that in no organ are the free extremities of the bloodvessels seen, but that the arteries always pass by a reticulate anastomosis into the veins;* that the blood circulates between the secreting canals of the liver, and at length on their surface, so as, as it were, to soak their coats with blood, but it does not pass into the canals themselves; or, in other words, that the sanguiferous vessels are not continuous with the biliary tubes.*

The important investigations of Kiernan respecting the minute anatomy of the liver, have shewn that the vena portæ having divided so as to constitute an intricate plexus in each lobule of the organ, and having ramified on the secreting canals, terminates in the hepatic vein.† In the section on the development further evidence is furnished in corroboration of these observations.

In all these instances, then, it is proved that there is no continuity between the arteries and the secreting tubes; and as the smallest secreting canals are always considerably larger than the smallest bloodvessels, the proportion varying in different glands, it may be assumed that in the whole glandular system, the arteries, having divided to a great degree of minuteness, and having ramified freely on the surface of the secreting canals, terminate directly in the returning veins.

Although in former times such a disposition of the bloodvessels as that now described would have been regarded as incompatible with the process of secretion, yet since the interesting researches of Dutrochet on Endosmose and Exosmose,‡ there is no difficulty in understanding that fluids may readily pass from the interior of the arteries into the secreting canals without there being any direct communication between these two orders of tubes. Not only may this passage take place, but even it is rendered probable by the experiments of Magendie§ that the bibulous matter constituting the glandular texture, and presenting, as we have found, so many varieties in its physical characters, may separate fluids, varying, according to the gland employed, from the diversified substances mechanically mixed together and suspended in the blood.

Lymphatic vessels.—Notwithstanding these are readily traced in the larger glands, their disposition, and especially their origin, are not known; a connexion, however, has been rather generally admitted in certain glands between their ducts and the lymphatics. In one instance Cruikshank filled the absorbents of the mamma from the lactiferous ducts; and both Walter and Kiernan contend that the absorbents of the liver may be injected from the biliary ducts. Müller, on the contrary, denies this communication, and states that the lymphatics are much larger than the smallest secreting canals. He also contends as to the results of injections, that the arguments drawn from them have no greater weight than all others derived from the fortuitous passage by rupture of fluids from one into a different order of vessels.

Nerves.—In proportion to their size the glands, like the other organs of the vegetative functions, receive very small nerves, which are, with some few exceptions, derived from the system of the great sympathetic. The nervous fibrils surround and accompany the branches of the arteries, till, in the interior of the gland, they become so minute that it appears impossible to detect their exact termination. Müller states that they never separate from the bloodvessels, and, consequently, that they do not supply the proper glandular substance. But in such a case as this the evidence afforded by microscopical inspection alone should be received with great reserve, especially when it is recollected that in opposition to the doubtful information thus acquired must be placed the unquestioned fact that the mind is capable of influencing the contraction of the secreting and excreting tubes, as is instanced in the flow of the saliva, of the tears, and of the semen under certain mental impulses. But perhaps a still more striking illustration of the control of the nervous system is afforded by the discharge of several glandular fluids resulting from impressions acting on comparatively remote but associated surfaces—the pouring forth of the saliva for example, in consequence of the contact of various substances with the tongue; of the bile and pancreatic juice from the application of food to the surface of the duodenum; of the semen from the stimulation of the glans penis. In all these and similar instances it must be presumed from analogy that the effect of the physical impression is conveyed through the only known media of conduction, the nerves.* The facts here adduced respecting the influence of the nerves merely relate to the contraction of the secreting and excreting canals; how far the nervous energy is essential to the process of glandular secretion itself belongs to another division of the subject. (See SECRETION.)

Interstitial cellular tissue.—A considerable portion of every gland is made up of the connecting cellular membrane, which, as in all other organs, enters the interior, where it fills up all the minute fissures and angles that intervene between the tubes and lobules, and at length, penetrating between the most minute of the secreting canals, it constitutes a nidus for the lodgement of the constituent parts.

The investing membrane is in many instances

* De Gland. Struct., p. 74, § 12. Phys. des Menschen, 1 Band, p. 441.

† Phil. Tran. 1833, p. 745. Mr. Kiernan infers that the hepatic artery terminates, not as is usually supposed in the vena hepatica, but in the vena portæ. Müller, however, thinks it is not probable that this is the true disposition, because the preparations of Leiberkuhn show that the capillary branches of the venæ hepaticæ can be as readily injected from the hepatic artery as from the hepatic vein. Notwithstanding these objections, analogy would induce us to suppose that Mr. Kiernan is correct in his supposition.

§ Lect. on the Physical Conditions of the Tissues, Lancet, 1834-35.

* I have in another place entered more fully upon this question: Obs. on the Struct. and Funct. of the Spinal Cord, p. 136, et seq.

simply formed by the condensation of the connecting cellular tissue, but in the larger glands a proper fibrous capsule is provided, which adheres more or less intimately to the proper glandular texture.

General conclusions respecting the minute structure of glands.

1. That throughout the whole range of the animal kingdom and in every species of gland there is one uniform type, from which the glandular formation in no instance deviates.

2. That every gland consists of a membrane derived either from the skin or mucous membrane.

3. That this membrane is disposed either in the form of a pouch or of a tube more or less ramified, and terminates in every instance, without an exception, in a blind extremity.

4. That the secreting canals are most diversified in form, being simply sacculated, branching, pennitifid, nail-shaped, or enlarged at the commencement, cellular, berry-shaped, serpentine.

5. That granules or acini in the hypothetical sense of writers do not in reality exist.

6. That whatever may be the variety of form it is always subordinate to the grand principle which the whole glandular system displays,—namely, that the largest possible extent of secreting surface is contained in the smallest possible space.

7. That there is no immediate connexion or continuity between the secreting canals and the sanguiferous vessels.

Hypotheses respecting the minute structure of glands.—I was desirous in the first part of this article to convey to the reader a comprehensive view of the glandular structure, unincumbered by any reference to the opinions of anatomists on this subject; but the hypotheses of Malpighi and Ruysch have so long divided the world of science, that it is necessary to ascertain how far the doctrines advocated by those celebrated men are in accordance with the above-stated conclusions. In doing this, however, much difficulty is experienced, especially in considering the opinions of Malpighi, inasmuch as his comparisons of the minute structure of the liver, of which organ he principally treated, are very vague and obscure, and being for the most part unaccompanied by illustrative plates, it is almost impossible in many of his descriptions to detect the meaning he wishes to convey. But, notwithstanding these obstacles, it is evident, on studying his account of the liver and kidney, that justice has not been done to his researches; for he not only corrected many of the then prevailing errors, but also ascertained several important points connected with this interesting branch of anatomy.

Malpighi compares the minute lobules of the liver and other conglomerate glands to a bunch of grapes, these lobules being joined to the neighbouring lobules by intermediate vessels. His words are, "for as an entire bunch of grapes is formed of small bunches by a communion and tying together of vessels, which small bunches are themselves formed into a mass by appended grapes *(acini)*; so the whole liver is formed by lobules many times folded, and which are themselves formed of glandular globules."* It is thus observed that Malpighi describes in the liver larger and smaller lobules; and it is to these latter that the celebrated but vague term of *acini* appears to be more particularly applied. He observes that the lobules are of various forms in different animals; in fishes having the shape of a trefoil, in the cat six-sided, &c. The interlobular spaces are noticed as being distinct in fishes, but as obscure in the more perfect animals.

With respect to the intimate structure of the small lobules, or acini, Malpighi conceived that each of them consisted of a hollow vesicle, receiving the secreted fluid from the small arteries and conveying it into one of the roots or branches of the hepatic duct; or, in other words, that the structure of the acinus was the same as that of the simple mucous follicle. Owing, however, to the imperfect means then possessed of prosecuting such inquiries, it is certain that Malpighi did not detect the ultimate structure; for more exact observations have proved that the last divisions of the secreting canals, although they constantly terminate in cœcal extremities, do not always end in follicles, but that they may consist of serpentine tubes, as in the kidney, or of pennatifid canals, &c. It also has been determined that what he regarded as the last divisions of the ducts, or acini, are themselves composed of smaller canals. But his observations on the developement of the liver in the chick shew that he was acquainted with the essential facts connected with the structure of that organ, and with the mode of its formation; for among other interesting remarks, he says that on the seventh day of incubation the liver of a yellowish or ashen colour presents granules of rather an oblong form, and "as it were blind pouches, appended to the hepatic duct."†

This hypothesis, founded as it is on so large a body of evidence, was generally received; but the discovery of the art of minute injection, which seemed to afford ocular demonstration of the fallacy of Malpighi's theory, induced the majority of anatomists to adopt the ideas rather pompously announced by Ruysch. This celebrated anatomist, rejecting the hypothesis of Malpighi, contended‡ that he had proved, by injection, that the arteries are directly continuous with the excretory ducts; or that the little ducts proceed from the minute arteries, like lesser from larger branches; and that each acinus consists principally of bloodvessels, but contains also an excretory duct.§

In considering the merits of these two hypotheses, it becomes apparent that Ruysch supported his opinion by evidence of a most insufficient character; for in investigating the

* De Viscer. Struct. cap. iii. p. 18.

† De Format. Pulli in Ovo, p. 20.

‡ Opuscul. Anat. de Fabric. Gland. Opera omnia, t. iii.

§ Loc. cit. p. 56, *fig.* 2.

most complicated glands he relied solely on his vascular injections, to the exclusion of the evidence afforded by the much more satisfactory researches of comparative and developmental anatomy. If, as Professor Müller has observed, Ruysch had carefully examined his injected organs with the microscope, he would have found that between the most delicate plexuses of the bloodvessels there is always an additional substance destitute of vessels; although these organs, when seen by the naked eye, appear to be stained in every direction with the coloured injection.* But even admitting what frequently happens from a too forcible injection, that the matter thrown into the arteries is found in the ducts, this does not prove that the small bloodvessels are continuous with the excretory canals; for after the sanguiferous vessels are filled, they easily become ruptured, and so allow their contents to escape into the ducts. It may further be objected, that in all the glandular organs which have been carefully inspected the commencements of the excretory ducts are larger than the least arteries;† indeed, Ruysch's own account of this imaginary continuity is very vague, and the plates designed to illustrate his theory, especially that of the kidney, are any thing but satisfactory. As Ruysch did not employ the microscope, it is impossible he could have *seen* that continuity which he so confidently described; indeed, as Haller remarks,‡ it is difficult, or rather as we should say impossible, to demonstrate, with the aid of the most powerful lens, the connexion of the last arteries with the coats of the ducts.

Not only did Ruysch adopt a most insufficient mode in prosecuting his inquiries, but he assumed as a fact what was in reality a mere hypothesis, that secretion can only take place from the *open mouths* or orifices of the secerning arteries. The only point, therefore, which he discussed was, whether the passage of the arteries into the excretory ducts takes place gradually and insensibly, or suddenly and by the intervention of a follicle; for it never occurred to the anatomists of those times, or even to Haller and his contemporaries, that canals closed at their end by cul-de-sac, and without open arterial mouths, could secrete.§

But the true opinions of Malpighi did not refer to the exact mode of termination possessed by the arteries; nor did he imagine that any particular machine or follicle was interposed between the arteries and the ducts: his observations were rather directed to the more important circumstances relative to the disposition, formation, and extent of the true secreting canals.

In concluding these remarks on the hypothesis of Malpighi, it is due to the character of that illustrious cultivator of anatomical science to state that his views are highly philosophic, and in a general manner correct—that they are supported by numerous observations made on the glands of the lower animals, as well as on the development of the liver during incubation—and that he had thus the sagacity to adopt the mode, which experience has shown is alone capable of resolving this difficult question.

It would be superfluous to enter into a detailed account of the opinions advanced by later anatomists, as they are for the most part simply modifications of the hypothesis either of Malpighi or of Ruysch. A few general observations will therefore suffice.

Ferrein has the merit of being the first writer who pointed out in a more distinct manner than had been done by Malpighi, the great importance of what are erroneously called the excretory ducts, but which constitute, as we have already shown, the true secerning structure. He remarks* that the cortical part of the kidney is composed of a collection of white cylindrical tubes, variously folded on themselves (*canales corticales*, or ducts of Ferrein,) and he thought he had seen the same tubes in the liver. The serpentine cortical canals have been seen in birds by Galvani, to be filled with cretaceous urine after the ligature of the ureter. Although the researches of Ferrein are very important, yet they want that support from comparative anatomy, by which means alone they could have been made subservient to establish any general principles.

To Rolando belongs the honour of having demonstrated the mode in which the glands are developed from the alimentary canal. By carefully conducted observations on the incubated egg, he discovered that each of these organs in the first instance consists of an elevation or tubercle of the intestine, which subsequently becomes hollowed and forms a canal directly continuous with that of the intestine. He also distinctly announced what has since been demonstrated in all its details, that the lungs are formed, like the glands, by a *pushing out* of the upper end of the intestinal tube; and he further describes the mode in which the bronchi and their subdivisions are developed. The error of those writers who contend

§ The existence of open mouths in the arteries of the serous membranes, where they are generally called *exhalants*, has never been proved; on the contrary, on examining, with a powerful microscope, the circulation of the peritoneum in rabbits, I have repeatedly observed that the small arteries, after ramifying in a very complicated manner, become distinctly continuous with the little veins.

* Mém. de l'Acad. Roy. des Sc. 1749, p. 492.

with Ruysch that the bloodvessels and the secreting canals are continuous with each other, is clearly shown; in short, Rolando was the first modern anatomist, who, following in the footsteps of Malpighi, pointed out the manner in which the inquiry ought to be prosecuted, and thus laid the foundation of those laborious and interesting researches for which science is principally indebted to the German anatomists, and by which, within the last few years, the subject of the glandular organization has been so strikingly elucidated.*

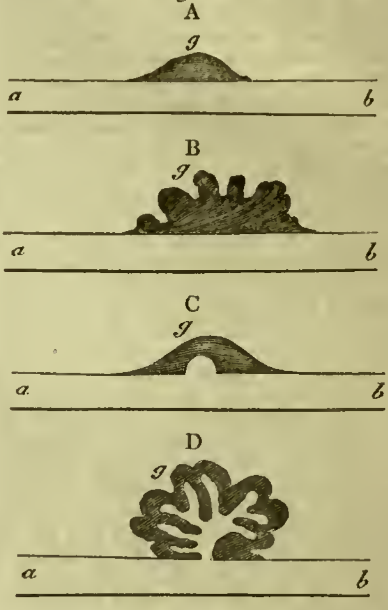
Development.—The investigations of Harvey, Malpighi, Rolando, Weber, Meckel, Bär, Valentin, Rathke, Müller, and many other anatomists, have very satisfactorily determined the manner in which the glands are in general developed. It is, however, necessary to premise that these observations principally *relate to those glandular organs which are appended to the alimentary canal*, especially the salivary glands, the pancreas, and liver; for as regards the development of those glands that are subordinate to the secretion of urine and to generation, comprising essentially the kidney and the testis, much uncertainty still prevails, although it is rather generally believed that the corpora Wolffiana, or false kidneys, are in some way or other connected with their primary formation.†

From the researches that have been made with so much care, we learn that, although there are many modifications of the formative process in the different classes of the glandular organs, there are yet certain fixed laws in obedience to which they are produced. As the development of the individual glands is, however, considered in the several articles on those organs, it is only requisite to describe in this place in a general manner, and without noticing the modifications of the general rule, the process of formation. In prosecuting this inquiry two different objects present themselves for examination,—the primitive substance in which the gland is developed, and the internal component parts, consisting essentially of the secreting tubuli and the bloodvessels.

1. Every gland is formed from a portion of the primary plastic and amorphous mass (*blastoderma*) of which the body of the embryo consists.

2. This mass is at first gelatinous, extremely delicate and diaphanous; it subsequently becomes thicker and less transparent. In the beginning it is solid, and in the case of those glands which are appended to the alimentary canal,—that is to say, the salivary glands, the liver, and the pancreas, (and the same laws are observed in the formation of the lungs,*) it appears as a projection on the mucous membrane. (*Fig.* 222, A.)

Fig. 222.



A plan designed to show the first origin of the glands.

a, b, alimentary canal; *g,* gland. (The letters have the same signification in A, B, C, D.)

3. In a short time this rounded mass begins to project on its external surface, and thus forms a number of lobes, or, as it were, little islands, which, by the continuation of the same process, become more and more numerous and smaller in size; and thus, according to the character of the gland examined, are at length formed all the minute lobes of which it consists. (*Fig.* 222, B.)

4. Simultaneously with this development of the outer surface of the plastic mass, but quite independently of it, a metamorphosis is going on within, by which the internal canals, which subsequently become the secreting tubes, are formed. In the first instance a hollow or cavity is noticed communicating with the tube of the intestine, and which subsequently becomes the principal or excretory duct. When it first appears it is a simple sac, (*fig.* 222, C,) but in proportion as the projections or lobes are formed on the external surface, lateral branches are added to the principal duct; and these again become more and more ramified, till an indefinite number of tubes are formed. (*Fig.* 222, D.)

* Journ. Comp. des Sc. Méd. xvi, p. 54, p. 57. P. 63. The honour of discovering the mode in which the glands appended to the alimentary passage are formed by *pushings-out* of that tube has been by Burdach improperly attributed to Rathke.

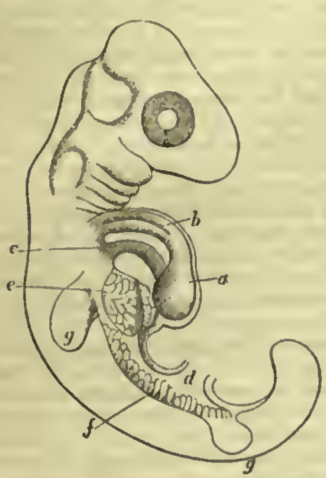
† It would be inconsistent with the perfection of the formative process to conceive that either the kidney or the testis requires the aid of any other glandular organ for their development; besides which it may be mentioned that there is no actual connexion between the above glands and the corpora Wolffiana. Rathke observes. " Although they (corpora Wolffiana) are not organically connected with the kidneys and genital organs, they appear to be, in an early period of the life of the embryo, the precursor or representative of the kidney." Burdach, II. Band. p. 646.

* Rathke, in Burdach's Phy. II. Band. p. 580, edit. 1837. Valentin, l. c. p. 501 et seq.

This development of cœcal tubuli is seen in the liver of *Limnæus stagnalis* in the embryo state, (*fig.* 223). In the embryo of *Lacerta viridis*, (*fig.* 224,) the rudimentary liver with its blind secreting canals (*e*) are observed; the elongated heart (*a*) furnishing the aorta (*b*) dividing into its right and left trunks, together with the principal venous trunk (c), are represented; *d* is the intestine, *f* the rudiment of the corpora Wolffiana, and *g g* the rudiments of the upper and lower extremities.

Fig. 223.

Fig. 224.



One of the most remarkable differences observed in the development of the several glands relates to the proportion between the mass of the primary plastic substance, and the extent and number of the contained tubes; thus, in the evolution of the liver there is seen a thick layer of the primitive matter; whilst, on the contrary, the parotid gland in the embryo of a calf two inches seven lines long, consists of a tube visible to the naked eye, and not at all covered by parenchyma.

5. The mode in which the secondary tubes are developed has been observed with great care; and it is distinctly established that *they do not proceed as mere elongations of the primary cavity*, but are formed in an independent manner. One of the latest writers on the development of the body, Valentin * has given a very exact account of the process in all the glands. He states that in the neighbourhood of the chief duct or of a branch of it, small oblong accumulations of the plastic mass are formed, which become hollowed in the interiur, and these hollows, *at first independent of the principal cavity*, subsequently communicate with it. It is also observed by Müller that in the kidney of Batrachian Amphibia, the secreting tubes first appear as vesicles which are formed before the ureter, and therefore independently of the principal duct.* As the tubes become more developed, the plastic substance around them, by acquiring greater firmness, constitutes their walls, and thus determines their exact form and limits. It is necessary to state that in every instance without an exception, the newly-formed canals end in cœcal extremities, which are often rather swollen, presenting a pedunculated appearance.

6. In proportion as the canals become formed in the substance of the plastic mass, this latter gradually diminishes in quantity, till ultimately, when all the tubuli are formed, it is so much reduced that it merely fills up the interlobular fissures, and is in fact converted into the interstitial cellular tissue.

7. At the same period of time that the tubes are thus being formed, the bloodvessels are being developed; and, as Müller and Valentin remark, a very close parallel is presented in the generation of these the essential parts of the gland. As in the case of the tubes, there are at first little masses, or islands, of the plastic substance, which subsequently join together, and their interior becoming liquified, a number of little channels are formed containing a circulating fluid, and which channels, by the subsequent consolidation of their walls, are at length formed into perfect bloodvessels. Like the tubes these vessels are at first independent; they afterwards open into larger trunks and ultimately into the heart. It is proper to remark that, although there is such a correspondence in the process of development in each instance, the bloodvessels are formed quite independently of the canals; that they occupy a different part of the plastic mass; and that they never present that continuity which ought at this epoch to have been very apparent, if the theory of Ruysch had been founded in truth.

8. The several glands are not developed equally early, some having their organization much more advanced than others; thus at the time when the pancreas is so far formed as to contain an immense number of canals, the parotid presents only a single duct or a few ramifications.† The principle which regulates the relative degree of development has evidently reference to the importance of the organ during the fœtal life; and in this respect the liver is most remarkable, for that body being, as I conceive, *the true decarbonising organ in the animal kingdom*, and therefore its functions being doubtless necessary in the fœtus, very quickly acquires a high degree of organization, so much so that, as we learn from all observations, it very speedily fills the greatest part of the abdomen.‡

* De Gland. Struct. p. 87.

† Rathke in Burdach's Phy. II. Band. p. 576. Valentin, l. c. p. 225.

‡ In the embryo of a sheep five lines in length, Valentin has found the liver filling half of the abdominal cavity; and in the embryo eight lines long, that organ constitutes three-fourths of the bulk of the viscera contained in the peritoneum:

Lastly, The laws in obedience to which the glands are developed, are as universal as to their existence in the animal kingdom, as those which regulate the formation of the nervous, osseous, and vascular systems; and thus it may be noticed that the complex glands of man and the mammalia, such as the parotid, the pancreas, and the liver, pass, in the various epochs of their development, through those forms, which in the lower animals, and especially in the invertebrated tribes, constitute the permanent structure. It may also be stated, that when any particular gland first appears in the animal series, it presents the most simple structure, although the same gland in the higher classes acquires the highest degree of complexity. Thus, the liver in insects is tubular, and in many of the amphibia excavated into large cells; the pancreas in fishes consists of separate tubuli; the salivary glands of birds are extremely simple; so also are the mammary glands in the Cetacea, and the prostate glands in many of the Mammalia.

GLOSSO-PHARYNGEAL NERVE (*nervus glosso-pharyngeus*; part of the sixth pair of Galen and the older anatomists; part of the eighth pair of Willis; the ninth pair of Soemmerring and some of the modern anatomists). The glosso-pharyngeal, par vagum, and spinal accessory nerves were long considered as forming a single nerve. Willis first clearly pointed out the origin and course of the spinal accessory, separated it from the par vagum, and termed it the nervus accessorius. The glosso-pharyngeal appears to have been generally described at the time of Willis as a branch of the par vagum. The term glosso-pharyngeal was not applied to it until the time of Huber.* Previous to the time of Willis, however, some anatomists, more particularly Fallopius,† Eustachius,* Bauhinus,† had shown that this nerve was really not a mere branch of the par vagum. The same thing was stated, more or less strongly, by many subsequent anatomists, more particularly by Winslow,‡ Haller,§ and Vicq D'Azyr.‖

Soemmerring¶ and Andersch** were, however, the first who fairly separated the glosso-pharyngeal from the par vagum, and ranked it as a distinct nerve. The glosso-pharyngei form the ninth pair of Soemmerring's classification of the encephalic nerves, and were termed the eighth pair by Andersch. There can be no doubt that if we adopt the numerical method of naming these nerves, the glosso-pharyngei properly form the ninth pair. To avoid, however, all the misunderstanding which is apt to arise from the use of numerical names when applied to these nerves, the best designation for the nerve at present under our consideration is the glosso-pharyngeal, derived from its being principally distributed upon the tongue and the pharynx. I need scarcely state that, under the term eighth pair, as it is most generally used in modern writings, is included the glosso-pharyngeal, par vagum, and spinal accessory nerves.††

Origin.—The glosso-pharyngeal nerve arises by from two to six filaments from the restiform body of the medulla oblongata, closely upon the groove which separates the restiform from the olivary body. At its origin it is placed immediately above and in the same line with the par vagum nerve, and between it and the portio dura of the seventh pair. Its lower margin is generally separated from the upper margin of the par vagum by a few small bloodvessels.

From its origin it first proceeds outwards along with the par vagum and spinal accessory to reach the foramen lacerum posterius. Through the anterior and inner part of this foramen it escapes from the interior of the cranium, and is enclosed in a strong and separate sheath furnished by the dura mater.‡‡ In its passage through the foramen lacerum it is placed anterior to the par vagum and spinal accessory and the commencement of the inter-

(l. c. p. 517.) Similar observations have been made in other animals and in the human embryo by Meckel.

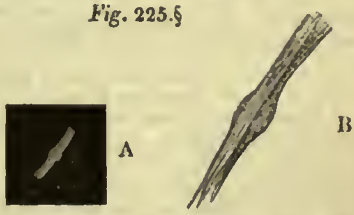
‡‡ According to Morgagni (Adversar. Anat. vi. Animad. xii.) and Wrisberg (De Nervis Pharyngis, in tom. iii. p. 52 Ludwig. Script. Neur. Sel. Min.) this septum separating the glosso-pharyngeal from the par vagum is sometimes osseous.

nal jugular vein, which lie in the order here enumerated. As the nerve issues from the lower part of the foramen lacerum it forms a small rounded chord, close to, but still quite separate from the par vagum, and is situated between the internal jugular vein and internal carotid artery. It now leaves the trunk of the par vagum, proceeds downwards, inwards, and forwards, passing in front of the internal carotid artery and behind the styloid muscles, and joins itself to the stylo-pharyngeus muscle. It runs at first along the lower margin of this muscle, and rests on the superior constrictor of the pharynx which separates it from the tonsil; it then mounts on the anterior surface of the stylo-pharyngeus muscle, and passes between it and the stylo-glossus to reach the base of the tongue, upon which it is ultimately distributed. Occasionally, instead of turning over the lower edge of the stylo-pharyngeus, it perforates this muscle. In following the course here described, it forms a slight curve, the convexity of which looks downwards, and it sends off several branches, which are principally distributed to the pharynx and isthmus of the fauces. These branches vary very considerably in size and in number in different subjects, but the general distribution of the nerve is in all cases nearly the same. When the branches are few in number, this is compensated for by their increased bulk, and when they are more numerous they are of diminished size. This nerve generally anastomoses with the par vagum within the cranium by a pretty distinct branch.* As the nerve lies within the foramen lacerum it presents two swellings or ganglia upon it, and gives off some small branches. The superior of these two ganglia is considerably smaller than the inferior, and has been termed the *ganglion jugulare* by J. Müller, (*fig.* 225). It is described by Müller† as generally present, though small, placed upon the posterior or external side of the nerve, and situated at the cranial end of the foramen lacerum. It can only be distinctly seen after the dura mater has been removed, and the upper margin of the opening chiseled away. I have repeatedly observed this ganglion jugulare in the human subject. In one case which I lately dissected, where it was comparatively large, very distinct, and presented undoubtedly all the appearance of a true ganglion, it appeared to me, after careful examination, that this swelling does not include the whole of the nerve, but is confined, as Müller states, to the posterior filaments. These posterior filaments do not seem to differ otherwise in appearance from the anterior. This ganglion was first pointed out by Ehrenritter, and mentioned by Soemmerring on his authority.‡ Very little attention seems to have been paid to this ganglion, so that when it was lately re-described by Müller,§ it was supposed that its existence in the human subject had been hitherto unknown.* Mayer, of Bonn, had, previous to this (1833), described two small swellings upon the root of the glosso-pharyngeal in the ox, but he failed to detect any similar ganglion in the human species. No nervous filaments either leave or join that part of the trunk of the nerve upon which the ganglion jugulare is placed. The inferior ganglion (ganglion petrosum, ganglion of Andersch) is considerably larger than the superior, is of an oblong shape, and includes all the filaments of the nerve. It is described by Andersch† as about five lines in length, and commencing about four lines below the place where the nerve perforates the dura mater. No doubt, if we include all that portion of the trunk of the nerve which appears to be somewhat increased in size, it may sometimes measure five lines, but the true gangliform enlargement is considerably less. As Wutzer‡ remarks, it is rarely found to exceed two lines in length. This ganglion lies in a distinct depression in the petrous portion of the temporal bone, which Andersch terms receptaculum ganglioli petrosi.

Fig. 225.§



Natural size. *Magnified about four times.*

Some branches both proceed from and join that portion of the nerve occupied by this ganglion petrosum. The most important of these is a small branch which proceeds from the ganglion into the tympanum (*ramus tympanicus nervi glosso-pharyngei;* nerve of Jacobson). The course and distribution of this branch were partly known to Schmiedal, Andersch, Ehrenritter, and Comparetti,‖ but were more fully

* I find that Wutzer, in his Monograph "De Corporis Humani Gangliorum Fabrica atque Usu," p. 92, after describing the inferior ganglion of the glosso-pharyngeal, says, "secundarium ganglion quod nonnumquam adesse Ehrenritter contendit mihi non sub oculos cecidit."

† If Andersch is not to be considered the discoverer of this ganglion, it cannot be denied that he first gave a full and clear description of it. (Op. cit. p. 115.) Kilian (Op. cit. p. 30 and 75) contends that the existence of this ganglion was known to Winslow. In evidence of this he quotes the following sentence from his Exposit. Anatom. tom. iii. "les deux portions (nervus glosso-pharyngeus et nervus vagus) sont édroitement collées ensemble et communiquent de part et d'autre par des filamens qui grossissent un peu la petite portion (glosso-pharyngeal.)"

‡ Op. cit. p. 91.

§ [This figure is taken from a dissection by Mr. Walker in the Webb-street School of Anatomy. The Editor is indebted for it to the kindness of his friend Mr. Grainger.]

‖ Vide Müller's Archiv. für Anat. und Physiol. &c. No. ii. 1837. p. 281.

described by Jacobson.* The nervus tympanicus enters a canal in the petrous portion of the temporal bone, and there anastomoses with the Vidian and the carotid plexus of the sympathetic. The orifice of this canal is placed between the jugular fossa and carotid canal, and external to the termination of the aqueduct of the cochlea. The ramus tympanicus is figured and described by Arnold† as dividing into six filaments: 1. a filament to the fenestra rotunda; 2. one to the fenestra ovalis; 3. one which anastomoses with the sympathetic; 4. one distributed upon the Eustachian tube; 5. one, which he terms nervus petrosus profundus minor, anastomosing with the spheno-palatine ganglion; 6. one, the nervus petrosus superficialis minor, which anastomoses with a branch from the otic ganglion or ganglion Arnoldi. The nerve of Jacobson thus forms an anastomosis among the glosso-pharyngeal, the second and third branches of the fifth pair, and the superior ganglion of the sympathetic.‡ A small branch arises from the ganglion petrosum, as delineated by Arnold,§ which unites itself to the auricular branch of the par vagum.‖

Two other filaments are generally found connected with that part of the trunk of the nerve occupied by the ganglion petrosum. These are a communicating twig between the ganglion petrosum and ganglion of the par vagum, and an anastomosing filament of the sympathetic. As these filaments are very minute, and lie in a dense fibrous sheath, they can only be displayed by an exceedingly careful dissection. The communicating filament between these two ganglia of the glosso-pharyngeal and par vagum is short, and passes directly from the one ganglion to the other. The communicating filament from the sympathetic comes from the superior cervical ganglion, mounts up between the trunks of the par vagum and glosso-pharyngeal, and divides into two portions,—one of these connecting itself to the ganglion petrosum, the other to the ganglion of the par vagum. The course and mode of termination of this communicating filament of the sympathetic is represented differently by Wutzer¶ from the description here given. I have adopted that given by Arnold,** since it exactly agrees with my own dissections. Another branch has been described as arising from the ganglion petrosum immediately below the ramus tympanicus, and passing backwards behind the styloid process, to anastomose with the trunk of the facial after its exit from the stylo-mastoid foramen.* We here see that the anatomy of that portion of the glosso-pharyngeal nerve which lies within the foramen lacerum is very complicated, but it must be at the same time obvious that it embraces considerations of great interest in a physiological point of view.

What the true nature of these two ganglia is, we cannot at present venture positively to decide. I may mention, however, that Müller† states that he is satisfied, that the superior ganglion or ganglion jugulare resembles the Casserian ganglion upon the trigeminus or fifth pair, and those upon the posterior roots of the spinal nerves, for while one portion of the nerve swells into a ganglion, the other passes by without assisting in its formation. On the other hand, he believes that the inferior ganglion differs decidedly from those upon the posterior roots of the spinal nerves, and resembles the swelling which is occasionally found upon a nerve where it is joined by branches from the sympathetic. The ramus tympanicus, according to his view, belongs to the sympathetic system of nerves.‡

On escaping from the foramen lacerum the glosso-pharyngeal occasionally forms direct anastomoses with the par vagum, spinal accessory, and superior ganglion of the sympathetic; at other times it only anastomoses with these through its branches.

Digastric and stylo-hyoid branch. — The origin of this branch is far from being regular. It frequently arises from the external side of the nerve soon after its exit from the foramen lacerum. It ramifies, as its name implies, in the digastric and stylo-hyoid muscles. The filaments of this nerve anastomose in the substance of the digastric muscle with the digastric branch of the portio dura.§

Carotid branches are two or more in number, and pass from the convexity of the nerve or from some of its pharyngeal branches, and proceed upon the surface of the internal carotid, where they form a very evident anastomosis with the sympathetic, with the pharyngeal, and other branches of the par vagum, and assist in forming the plexuses around the carotid arteries. They have been traced downwards for a considerable extent, and found to anastomose with the superior and even with the middle cardiac nerves.

Pharyngeal branches.—The nerve next furnishes the pharyngeal branches, which are from two to four in number. The largest of these proceed downwards, and their ramifications can be traced over the whole of the pharynx, but more particularly over its upper and middle

* Acta Reg. Soc. Havniensis Medic. tom. v. Copen. 1818.

† Icones Nervorum Capitis, tab. vii. 1834.

‡ Cruveilhier (Anatomie Descriptive, tom. iv. p. 952, 1835) states that, in one subject he found this ramus tympanicus formed by two branches, one from the par vagum, the other from the glosso-pharyngeal. In another subject it was formed by a branch from the auricular of the pneumo-gastric united with one from the glosso-pharyngeal.

§ Op. cit. plates iii and v.

‖ It appears that the ramus auricularis of the par vagum was described even to both its branches by Comparetti, p. 129, De Aure Interna, &c.

‡ Handbuch der Physiol. Erster Band.

§ Mr. Swan, in plate xvii. *fig.* 2 and 3, of his "Demonstrations of the Nerves of the Human Body," figures this communication as formed by a filament of the digastric branch of the facial going to join the trunk of the glosso-pharyngeal.

portions. One or generally more of these pharyngeal branches perforate the stylo-pharyngeus muscle, and can be traced partly downwards upon the middle constrictor, partly upwards upon the superior constrictor and mucous membrane of the fauces, and also partly forwards upon the surface of the tonsils. I have traced one of these pharyngeal branches through the posterior part of the hyo-glossus muscle into the mucous membrane at the side of the posterior part of the tongue. These pharyngeal branches, by their anastomoses with the pharyngeal branches of the par vagum and pharyngeal branches of the sympathetic, form what is called the *pharyngeal plexus of nerves.** A distinct swelling is frequently found over the internal carotid artery, formed by the confluence of the principal pharyngeal branches of the glosso-pharyngeus, of the superior pharyngeal branch of the par vagum, and the pharyngeal branches of the superior ganglion of the sympathetic. This swelling varies considerably in size and appearance. Hubert† describes a small ganglion in the pharyngeal plexus. Haase‡ shortly describes this swelling as a gangliform enlargement. Wrisberg§ states that a ganglion, of the size of the ophthalmic, is placed at the confluence of these nerves. Scarpa|| describes and figures it as a gangliform plexus more particularly connected with the pharyngeal branch of the par vagum. Wutzer¶ states that he has been unable to detect this pharyngeal ganglion. Kilian** and Arnold,†† but more particularly Kilian, figure it as a plexus. Though I would not deny the occasional existence of a small ganglion in this region, yet I believe it will be found that this swelling is generally formed by the cellular tissue binding together these branches as they anastomose with and cross each other.‡‡

Lingual branches.—After the trunk of the nerve has furnished the pharyngeal branches, it sends off from its concave side some small twigs upon the surface of the tonsils. It then forms the lingual portion of the nerve, passes into the base of the tongue below the stylo-glossus and posterior margin of the hyo-glossus muscle, where it divides into three or four branches. The superior of these is principally distributed upon the posterior part of the sides of the tongue, and sends some twigs backwards upon the palato-glossus muscle and mucous membrane of the fauces, where they anastomose with the other tonsillitic twigs. The middle part of the termination of the nerve passes through the lingualis and hyo-glossus muscles to reach the mucous membrane and papillæ at the side of the base of the tongue. The remainder of the nerve perforates the genio-hyo-glossus to reach the mucous membrane and papillæ in the middle of the base of the tongue. The distribution of these twigs is confined to the mucous surface at the base of the tongue, and do not extend beyond an inch in front of the foramen cœcum. They pass through the muscles of the tongue without giving any filaments to them.*

Tonsillitic twigs.—The different twigs of this nerve which we have described as passing to the tonsils, form an intricate plexus, posterior to and around these bodies, which has been called the *circulus tonsillaris.* These tonsillitic twigs are ultimately intermixed with the ascending filaments of the pharyngeal branch of the par vagum, and pass in considerable numbers to the isthmus of the fauces and soft palate. They anastomose also with the posterior palatine branches of the second branch of the fifth pair, and, according to Wrisberg,† with a filament from the third branch of the fifth.

In repeated dissections, both upon the human subject and the dog, I have found, in tracing the branches of this nerve to their ultimate distribution upon the pharynx and fauces, that those branches of the glosso-pharyngeal which do not anastomose with the pharyngeal branch of the par vagum are principally distributed upon the mucous membrane, and that comparatively a small number of these filaments seem to terminate in the muscular fibre. The uncombined twigs of the pharyngeal branches of the par vagum are, on the other hand, distributed entirely to the muscular fibre. In a dissection of this kind care must be taken to select those twigs only which proceed to their distribution without exchanging filaments with any other nerve. It can be made more favourably in the dog than in the human species. The glosso-pharyngeus is still distributed upon the tongue in birds, in the frog, and certain of the amphibia, while this organ receives no branch from the fifth pair, and from this circumstance it has been considered the nervus gustatorius of these animals.‡ In fishes there is a branch of the par vagum called glosso-pharyngeal, which escapes from the base of the cranium by a separate opening, and is distributed upon the gills, and also upon the tongue as far as the skin of the mouth.

Physiology.—It is only to the labours of anatomists and physiologists within the last few years that we are to look for any thing

* A small twig from the hypo-glossal nerve can sometimes be traced into this plexus. As the superior pharyngeal branch of the par vagum is partly formed by the spinal accessory, this last nerve must assist in the formation of this plexus.

** Op. cit. tab. ii. fig. 5.

†† Op. cit. tab. iv.

‡‡ The glosso-pharyngeal in the dog is generally considerably increased in size where the principal pharyngeal branches are given off.

* In tracing these nerves, it has appeared to me that a few minute filaments terminate in the muscles of the tongue, but these are exceedingly few and small. The statement of Wrisberg, that the deep branches of the lingual portion of the glosso-pharyngeal are distributed to the muscles of the tongue, is opposed to the observations of the best anatomists, who have since his time examined the ultimate distribution of this nerve.

† Op. cit. p. 51.

‡ Handbuch der Physiologie, etc. Erster Band, p. 590, 772.

like accurate data in enabling us to judge of the functions of this nerve. Its deep situation, its proximity to important parts, and the consequent difficulty of exposing it in the living animal, have until very lately deterred physiologists from making it an object of experimental investigation. Some have supposed that it supplies the nervous filaments upon which the sense of taste at the root of the tongue depends, while the third branch of the fifth pair furnishes those of the anterior part of this organ. Mr. Mayo* states that "when this nerve is pinched in an ass recently killed, a distinct convulsive action ensues, apparently including and limited to the stylo-pharyngeus muscle and upper part of the pharynx." He concluded from this that the glosso-pharyngeal is in part, probably, a nerve of voluntary motion; and from its distribution upon the surface at the root of the tongue, that it is also partly a nerve of common sensation. Sir C. Bell believes that this is the respiratory nerve of the tongue and pharynx, associating the movements of those organs with the muscles of respiration in speech and in deglutition. And we find it stated by Mr. Shaw † that its power of combining the movements of the tongue and pharynx in deglutition "has been shown by several experiments, the results of which were very curious, and corroborative of the views deduced from comparative anatomy." Panizza ‡ has undertaken an experimental investigation into the functions of the nerve, and obtained very unexpected results.

From these we are led to believe that when this nerve is pricked in a living animal, this is attended by no indications of suffering and no convulsive movements; that section of both nerves is followed by loss of taste, while the tactile sensibility of the tongue and the muscular movements of deglutition and mastication remain unimpaired; that section of the fifth pair is on the contrary followed by loss of common sensation without any apparent effect upon the taste. From these and other experiments upon the nerves supplying the tongue, he concludes that the glosso-pharyngeal is the nerve upon which the sense of taste depends, and is therefore the true *gustatory nerve.* Dr. M. Hall and the late Mr. Broughton § had, from experiments performed previous to the publication of those of Panizza, arrived at the conclusion that this nerve is not a nerve of common sensation. These gentlemen likewise reported at the meeting of the British Association for 1836 an experiment, the results of which were in exact accordance with those obtained by Panizza upon this nerve, but no details of these experiments have yet been published. Mr. Mayo* has stated several objections to these conclusions of Panizza. He rests his grounds of dissent principally upon the fact that the distribution of this nerve is confined to the posterior part of the tongue; while the sense of taste, he maintains, is also present in the anterior part of that organ, and consequently it cannot, in that part at least, depend upon the glosso-pharyngeal. The persistence of the sense of taste after section of the fifth pair may, Mr. Mayo supposes, depend upon the palatine twigs of the second branch of the fifth pair distributed upon the palate and isthmus of the fauces. Mr. Mayo attempted to decide the matter by experiment, but he did not carry this sufficiently far to obtain any satisfactory results. Dr. Alcock † has also lately examined into the functions of this nerve experimentally, and has arrived at conclusions at direct variance with those of Panizza; for according to Dr. Alcock, when this nerve is exposed and irritated in the living animal, it excites pain and spasmodic contractions of the pharynx and muscles of the throat. When divided on both sides, the animal's taste, "to say the least of it, did not appear to be much affected." He believes that the sense of taste enjoys "two media of perception, and that these are the glosso-pharyngeal nerve and the lingual and palatine branches of the fifth." He also states that the muscular movements of deglutition are very much impaired after section of the nerve on both sides. He concludes, then, that the glosso-pharyngeal are sentient nerves, and also influence muscular motion. He, however, is doubtful in what manner these muscular movements are excited by irritation of this nerve, for though "disposed to regard the result in question as the effect of a sentient impression excited through the nerve, and referred to the interior of the pharynx," from the fact that this movement extends to muscles not supplied by this nerve, and forms an associated movement, he admits "that the circumstance may be as well explained by an exalted degree of muscular excitement, or by a higher one than that necessary to produce the simple starting." Professor Müller ‡ believes that an examination of the position of the ganglion jugulare will decide that the glosso-pharyngeal is a mixed nerve, and he maintains that the distribution of this nerve, partly for sensation (mucous membrane of the root of tongue), partly for the movements of muscles (stylo-pharyngeus and pharynx), exactly resembles that of the two roots of the nervus trigeminus. Unable amidst these discordant statements to come to any satisfactory conclusions upon the proper functions of this nerve, I entered into a lengthened experimental and anatomical investigation for this purpose. The experiments were twenty-seven in number, and were performed upon as

many different dogs. Seventeen of these were upon the living animal, with the view of ascertaining if this nerve were to be considered both a nerve of sensation and motion, and what are the effects of its section upon the associated movements of deglutition, and on the sense of taste. The other ten were performed on animals immediately after they had been deprived of sensation, for the purpose of satisfying myself to what extent it was to be considered a motor nerve. The most remarkable effect witnessed in these experiments was an extensive convulsive movement of the muscles of the throat and lower part of the face on irritating this nerve in the living animal, provided the irritation was applied to the trunk of the nerve before it had given off its pharyngeal branches, or to one of these pharyngeal branches separately. These movements were equally well marked upon pinching the cranial end of the cut nerve after it had been divided at its exit from the foramen lacerum, as when the trunk of the nerve and all its branches were entire. In some of these experiments we observed a remarkable difference between the effects of irritating this nerve before and after it had given off its pharyngeal branches, which is valuable on this account, that it may explain the discrepancies between the results obtained by Panizza, Dr. M. Hall, and the late Mr. Broughton on the one hand, and Dr. Alcock on the other. For though I do not mean to affirm that pinching the lingual portion of the nerve is never followed by indications of suffering, (for from the irregularity in the origin of the pharyngeal twigs, and the difficulty of judging at the bottom of a deep wound in the living animal at what particular part these are all given off, it is generally impossible to decide where the lingual portion may be said to begin,) yet I have no hesitation in saying that if in several of these experiments we had operated only on that portion of the nerve which first presented itself, and not proceeded to dissect it backwards towards its place of exit from the cranium, we should have gone away with the impression that the irritation of this nerve was followed by no convulsive movements, and little if any indications of suffering.

From a review of all the experiments which I have performed upon the glosso-pharyngeal nerves, I am inclined to draw the following conclusions:—

1. That this is a nerve of *common sensation*, as indicated by the unequivocal expression of pain by the animal, when the nerve is pricked, pinched, or cut.

2. That mechanical or chemical irritation of this nerve before it has given off its pharyngeal branches, or of any of these branches individually, is followed by extensive muscular movements of the throat and lower part of the face.

3. That the muscular movements thus excited depend, not upon any influence extending downwards along the branches of the nerve to the muscles moved, but upon a reflex action transmitted through the central organs of the nervous system.

4. That these pharyngeal branches of the glosso-pharyngeal nerve possess endowments connected with the peculiar sensations of the mucous membrane upon which they are distributed, though we cannot pretend to say positively in what these consist.

5. That this cannot be the sole nerve upon which all these sensations depend, since the perfect division of the trunk of the nerve on both sides does not interfere with the perfect performance of the function of deglutition.

6. That mechanical or chemical irritation of the nerve, immediately after the animal has been killed, is not followed by any muscular movements when sufficient care is taken to insulate it from the pharyngeal branch of the par vagum. And we here observe an important difference between the movements excited by irritation of the glosso-pharyngeal and those of a motor nerve, for while the movements produced by the irritation of the glosso-pharyngeal are arrested as soon as the functions of the central organs of the nervous system have ceased, those from irritation of a motor nerve such as the pharyngeal branch of the par vagum, continue for some time after this, and when all connexion between it and the medulla oblongata has been cut off by the section of the nerve.

7. That the *sense of taste* is sufficiently acute, after perfect section of the nerve on both sides, to enable the animal readily to recognize bitter substances.

8. That it probably may participate with other nerves in the performance of the function of taste, but it certainly is not the special nerve of that sense.

The sense of thirst which is referred to the fauces and pharynx does not appear to depend entirely upon the presence of this nerve. The animals in which it was divided lapped water of their own accord. I observed one of those in which the nerves were found satisfactorily divided, rise, though feeble, walk up to a dish containing water, lap some of it, and return again to the straw upon which he was previously lying.

In all experiments upon the glosso-pharyngeal nerve in the dog, too great care cannot be taken to avoid the pharyngeal branch of the par vagum, which is sometimes situated in immediate contact with it, at other times one or two lines below it, and is frequently united to it by a considerable communicating branch, so that it may readily be mistaken for a large pharyngeal branch of the glosso-pharyngeal. This precaution is the more necessary, as I am confident that these two nerves differ from each other in function, and this must consequently seriously affect the results. I attribute the difficulty of deglutition after section of this nerve in the living animal, and the muscular movements on irritating it in the animal recently killed, observed by two of the preceding experimenters, to a want of sufficient precaution in separating these nerves from each other. These results were only observed by me when the pharyngeal branch of the par vagum was implicated in the experiment.

With regard to the argument in favour of the motal properties of this nerve, drawn by Müller from its anatomy, it appears to me that this analogical mode of investigation, valuable though it is, must be permitted to yield to the more positive observations obtained from experiment. And though it may be granted that the apparent limitation of the ganglion jugulare to the posterior filaments of this nerve causes it here to resemble closely the double roots of the spinal nerves, yet we must be wary in drawing analogies between the glosso-pharyngeal and spinal nerves, since we have another ganglion situated immediately below this, viz. the ganglion petrosum, which involves the whole of the nerve, and to this assuredly we have no analogical structure in the spinal nerves. No doubt Müller supposes that this inferior ganglion differs from those placed upon the posterior roots of the spinal nerves, and that it belongs to the sympathetic system. But as nothing like conclusive proof is advanced in support of this opinion, we may in the mean time reasonably suspend our belief as to the probable influence which this lower ganglion may exert upon the functions of the nerve.

Of course the fact that some of the filaments of the glosso-pharyngeal terminate in the muscular fibre, is no proof that these filaments are motal, for the muscular bundles have their sensitive as well as their motal filaments.

(John Reid.)

GLUTÆAL REGION, (Surgical Anatomy.) (Fr. *region fessiere.)* The glutæal region may be defined with tolerable precision to be all that space external to the pelvis which is covered by the glutæi muscles of each side. Its boundaries seem naturally to be the crista of the ilium above; behind, the mesian line as low down as the point of the coccyx; before, a line drawn from the anterior superior spinous process of the ilium to the trochanter major; and below, a line drawn from the point of the coccyx to the insertion of the glutæus maximus; in fact, the inferior margin of this muscle forms the boundary line. These limits, better defined than those of most of the anatomical regions, separate this tract from the lumbar and iliac regions above, from the superior anterior region of the thigh in front, from the perineal and posterior regions of the thigh below, and from the corresponding part of the opposite side at the posterior mesian line. This space, which does not comprise many points of importance in surgical anatomy, is yet not without interest. Here are the glutæal and ischiadic arteries, also the commencement of the course of the great sciatic nerve. The internal pudic artery also skirts along the inferior edge of the glutæal region, but this will be best considered as part of the region of the perineum.

The first thing that strikes us in the examination of this region is the great density and thickness of the integuments; they are inferior in this respect only to the sole of the foot. This density is, however, found greater proportionally in the true skin than in the cuticle, which retains much of the softness and pliability of the same covering in other parts of the body, and the end of this is evident, since whatever the pressure may be upon the glutæal parts, a dense state of the cuticle in any degree similar to the sole of the foot would, in the varied positions and movements of the trunk, be quite incompatible with comfort. On the other hand, the true skin, though pliant, is remarkably dense and strong, its fibres almost tendinous in structure, interlacing each other in every direction, and united underneath to a strong but rather loose cellular tissue which connects it to the glutæus muscle. It is to the laxity of this cellular connexion that the integuments of this part are partly indebted for that pliability which enables us to rest with ease and comfort upon surfaces of various degrees of hardness and inequality. It contains a considerable quantity of fat, which adds to the softness and elasticity of this cushion, and is very different from the granular hard fat found in the plantar region. The density of the integumental covering of the glutæal region varies somewhat in different parts. It is greatest where it covers the tuber ischii, and gradually diminishes on all sides except on the side next the perineum, where the change is very abrupt from its characteristic density to the extreme thinness and delicacy of the perineal covering. The peculiarity of structure of the integument covering the glutæi should be borne in mind by the surgeon in the treatment of diseases of this part. Abscesses should on this account be earlier opened from the obstacle thus presented to their pointing. It is on this account also, probably, that we so generally find abscesses here accompanied with sloughing of the cellular tissue, which is best obviated by an early opening.

The fleshy fibres of the glutæus maximus are covered by a somewhat denser stratum of cellular tissue, forming an aponeurosis distinct from the fascia lata of the thigh, though continuous with it at the anterior edge of the muscle, where the fascia lata lies upon the anterior half of the glutæus medius. The great glutæus is composed of coarse and loosely connected fasciculi, running in a direction downwards and forwards. It commences by a somewhat semicircular line of origin from the posterior two-thirds of the crista ilii, from the side of the sacrum and of the coccyx. From this origin the fibres run somewhat converging towards the great trochanter and upper part of the linea aspera. This direction of the fibres should be borne in mind in connexion with all remedial manipulations on this part, that the position in which the limb should be placed may be chosen most favourably for the relaxing of the muscle. The other muscles which are in this neighbourhood, and all of which move the thigh-bone, are so much smaller than this great muscle that the relaxing of this is of the first importance, and the position must be chosen with reference almost entirely to this.

On reflecting the glutæus maximus the following parts are brought into view:—1st, several large branches of arteries and veins, which were divided in reflecting the muscle, and which passed into the substance of the great glutæus muscle; these are from the glutæal and ischiatic arteries, and appear principally at the upper and posterior part of the glutæus medius; 2d, the whole of the glutæus medius, the posterior two-thirds of which had been covered by the larger muscle; 3d, at the posterior edge of the glutæus medius is the pyriformis muscle partly concealed by it, and coming out of the superior sacro-sciatic foramen; 4th, next below the pyriformis lie the two gemelli, with the tendon of the obturator internus between them, and below these is the quadratus femoris, having underneath it the strong tendon of the obturator externus; 5th, the great sciatic nerve is seen emerging from the superior sacro-sciatic foramen near the sciatic artery. Sometimes it comes out entirely below the pyriformis; sometimes it descends in two branches, one of which perforates that muscle, and they then unite. The trunk passes directly downwards, crossing the rotator muscles of the hip, and passing between the projecting tuberosity of the ischium and the trochanter major. In this part of its course it is accompanied by the sciatic artery, which is seen about half an inch to the internal or sacral side of the nerve, and sends one considerable branch to supply the nerve, and runs tortuously imbedded in its neurilema. The course which the nerve and artery here take will be represented by a line drawn from the posterior superior spinous process of the ilium to a spot midway between the tuber ischii and trochanter major. Lastly, in this view are exposed the bursal sacs, of which there are several between the glutæus maximus and the subjacent parts. The most considerable is found between it and the external surface of the trochanter major. A considerable but smaller one is placed between its broad tendinous expansion and the upper part of the vastus externus, and two smaller ones commonly between the muscle and the os femoris at the upper and back part of the thigh. The ischiatic artery at the commencement of its course is smaller than the glutæal, and comes down over the pyriformis muscle, and makes its exit from the pelvis through the lower part of the sciatic notch, between the pyriform and levator ani muscles, above the lesser sciatic ligament, and in front of the sciatic nerve; it sometimes passes between the roots of this nerve. On the dorsum of the pelvis the sciatic artery is covered by the glutæus maximus muscle, and may be seen by a similar dissection to that which exposes the glutæal artery, excepting that it is found about an inch and a half lower down than the last-named vessel.

The glutæal artery comes out of the pelvis at the upper part of the sciatic notch in company with the superior glutæal nerve and vein. It immediately winds upwards upon the dorsum ilii, keeping close to the bone, and shortly after its arrival upon the dorsum it divides into branches principally distributed to the glutæal muscles. To expose this artery and its branches in dissection, it is necessary to proceed as in the dissection of the glutæus maximus muscle. Next divide this muscle in a line from the posterior superior spine of the ilium to the tuberosity of the ischium. In making this dissection several large arteries and veins must be injured. If the edges of the muscle be now separated and the subjacent cellular membrane removed, the glutæal artery, accompanied by one or two large veins and by the glutæal nerve, may be seen escaping from the sciatic notch above the pyriform muscle, between it and the glutæus medius. This artery, as it escapes from the pelvis, lies three inches and a half from the mesian line, or from the spinous processes of the sacrum.

The glutæal and ischiadic arteries, as we have seen, are covered by the glutæus maximus muscle, and lie at such a depth from the surface that they are not very liable to injury. Wounds, however, of this part do occasionally implicate these vessels, either in their large branches or even the trunks themselves, and they have been affected with aneurism, an instance of which is mentioned by Mr. J. Bell,* and which attained a considerable size. In the case of a wound, its direction will lead us to the situation of the artery; and in the instance of aneurism just mentioned, Mr. Bell ventured to lay open the sac and thus reach the mouth of the glutæal artery, which he secured by ligature, and this perhaps might be accomplished in a very emaciated person; but generally speaking the artery lies so deep, and the vessels which must be wounded in making the necessary incisions would by their bleeding so obscure the operation, that the most experienced surgeons do not recommend the attempt under ordinary circumstances, but prefer the operation of tying the internal iliac.† As a guide, however, to the situation of the glutæal artery, whether in the examination of a wound or in operating upon it, its position on the dorsum of the pelvis may be ascertained by drawing a line from the posterior spinous process of the ilium to the middle of the space between the tuberosity of the ischium and trochanter major. If this line is divided into three, the glutæal artery will be found emerging from the pelvis at the juncture of its upper and middle thirds.‡

To return to the consideration of the anatomical structures which we expose in succession. We are struck with the difference in texture of the three glutæi muscles. The fibres of the two smaller glutæi are of moderate size and strength, while those of the larger glutæus are remarkable for their coarseness and large dimensions. The relative situation of the three muscles is also important. The position and direction of the glutæus maximus is just in that line in which the greatest vigour of action is required to erect the body by drawing the back part of the pelvis towards the trochanter major. In this operation it is assisted by the position of the glutæus medius and minimus,

* Principles of Surgery, vol. i. p. 421.

‡ See Harrison's Surgical Anatomy of the Arteries, vol. ii. p. 100.

the posterior fibres of which are covered by the glutæus maximus. These anterior fibres have a different action, varying in the different positions of the body in relation to the thigh, and, according to this, consisting either in rotation inwards, abduction, or flexion of the femur, or, this bone being fixed, assisting in the various anterior movements of the pelvis upon the thigh.

At the posterior edge of the middle glutæus is the pyriformis coming out of the upper opening of the sciatic notch. Here, as we have seen, the glutæal artery is also emerging from the pelvis and winding round the upper edge of the notch. This, therefore, will be the situation of an aneurism of this artery, and a pulsating tumour being detected in the situation just indicated by measure, as the seat of this vessel, will be a very strong ground for deciding both as to the disease and the vessel diseased. A case lately came under our notice of a very obscure character in which a swelling was situated precisely in the position of the glutæal artery, but without pulsation or any other symptom of aneurism. The swelling was at first indistinct, but as the surrounding parts wasted under the effect of disease it became more prominent. It was firm to the touch and rather moveable, and about the size of a hen's egg. But the principal part of the disease showed itself within the pelvis in a tumour consisting almost entirely of coagulum, as was proved by puncture, situated behind the rectum, and pressing it forward so as to occupy nearly the whole pelvis, and obstructing the passage both of fæces and urine. As there was no decided symptom of aneurism no operation was attempted for the relief of the case, and as the girl, who is eighteen years of age, still lingers, the nature of the disease is not yet cleared up. But this part also occasionally gives exit to a hernial tumour, part of the intestines or even the bladder or ovary becoming thus displaced and being lodged in the sac.* The superior opening of the sciatic notch is bounded above by the notch of the ilium, before by the descending ramus of the ischium, and below and behind by the superior sacro-sciatic ligament; and so large is the opening thus left that we might expect to find the protrusion of some of the viscera of the pelvis much more frequently than we do. Yet so completely is this part covered and defended by the pyriform muscle, the plexus of nerves, the glutæi maximus and medius, that this form of hernia is an extremely rare occurrence. When it does occur in the adult, the diagnosis is very difficult while the hernia is small, owing to the great depth at which it is situated. When, however, it is congenital, the nature of the swelling is larger in proportion to the size of the surrounding parts, and the depth of the superjacent parts less; yet even here Professor Schreger did not at first detect the nature of the swelling. In fact nothing but the actual feeling of the guggling of the gas of the intestines under the finger seems sufficient to discriminate the case, and this is of course not to be expected when the gut is strangulated. Indeed, in Dr. Jones's case* the symptoms were not at all referred by the patient to the true seat of the disease, and the surgeon was in consequence never led to make any external examination of this part. It may be well to state here the anatomical relations of the hernial sac in this case, which was carefully dissected. "A small orifice in the side of the pelvis, anterior to but a little above the sciatic nerve and on the fore part of the pyriformis muscle, led into a bag situated under the glutæus maximus muscle, and this was the hernial sac, in which the portion of intestine had been strangulated. The cellular membrane which connects the sciatic nerve to the surrounding parts of the ischiatic notch had yielded to the pressure of the peritoneum and viscera. The orifice of the hernial sac was placed anterior to the internal iliac artery and vein, below the obturator artery and above the obturator vein. Its neck was situated anterior to the sciatic nerve, and its fundus, which was on the outer part of the pelvis, was covered by the glutæus maximus. Anterior to but a little below the fundus of the sac, was situated the sciatic nerve, behind it the glutæal artery. Above, it was placed near the bone, and below appeared the muscles and ligaments of the pelvis."

We must not conclude this article without a few words on the general form of the glutæal region as affording an important means of diagnosis in disease. In examining this region in a healthy person we observe, 1st, the thick rounded prominence of the nates, formed by the posterior and inferior margin of the glutæus maximus; 2d, the projection of the trochanter major, only covered by the integuments and the thin tendon of the last-named muscle; 3d, the projection of the crista ilii, forming the upper boundary of the region; 4th, a depression, perpendicular in direction, between the nates and the trochanter major; 5th, another depression, slighter than the last and transverse in direction, between the trochanter and crista ilii.

Now almost all these points become altered in character and relation in disease. In dislocation of the femur they of course are changed by the difference in position which the trochanter assumes in common with the head of the bone; and according to the unnatural situation which this occupies, so will the alteration in the general form of the parts be modified. But we now speak particularly of the changes of disease. Even in the inflammatory stage of disease of the hip-joint, it is surprising how great is the effect produced upon the nates. The roundness and fulness gradually go, the nates looks wasted, and the depression between this and the trochanter disappears. This wasting, arising from interstitial absorption of the glutæus and parts adjacent, is the more striking as it occurs too rapidly upon the affection of the joint to be the effect of inaction of the

* See a summary of cases of ischiatic hernia in Cooper's First Lines of Surgery.

* See Sir A. Cooper on Hernia, part ii. p. 67.

muscle, as we have seen it occur in a marked degree in a rather severe attack of inflammation of the joint, which readily yielded to treatment.* Then in the more advanced stages of disease of the joint, the depressions above mentioned are not only lost, but from morbid depositions in the neighbourhood of the hip they become elevated and swollen, and the sharp prominences of the trochanter lost in the general fulness of the part.

(A. T. S. Dodd.)

GROIN, REGION OF THE, (Surgical Anatomy.) (Fr. *l'aine, region inguinale.*) The limits of this region, as understood by most surgical writers, seem to be wholly artificial. The groin constitutes the confines of the abdomen and the thigh; and Poupart's ligament forms a natural line of division between its femoral and its abdominal portions. A line drawn horizontally, the subject being erect, from the anterior superior spinous process of the ilium to the linea alba, forms the superior limit of this region, while below it may be defined by a line parallel to the former one, and extending from the pubis to the outer part of the thigh. For the particulars of this region, see HERNIA, FEMORAL ARTERY, ABDOMEN, and THIGH, REGIONS OF THE.

(R. B. Todd.)

HÆMATOSINE, (αιμα, *blood*, and πιπτω, *to fall.*) The colouring matter of the blood.† This principle separates with the fibrine of the blood when that fluid coagulates, and may be obtained free from adherent albuminous matter by the process recommended by Berzelius, which is as follows. The coagulum is first to be sliced in thin pieces with a sharp knife, and then carefully washed in separate portions of distilled water; by these means we separate the adherent serum, and if the washing is gently performed, but little hæmatosine becomes washed away with it. The slices thus prepared are placed on a filter and allowed to drain: when the draining is complete, the slices are to be thrown into a glass vessel and broken up in distilled water; we thus procure a solution of the colouring matter while any fibrine present gradually subsides. The liquor when poured off is a tolerably pure solution of hæmatosine. If it is wished to procure the principle in the solid form, the solution may be evaporated at a temperature not exceeding 100° Fahrenheit.

Engelhart prefers heating the solution after filtration to about 150° Fahrenheit, which determines the precipitation of the hæmatosine, while any albumen which may possibly exist in solution with it, remains dissolved at that temperature. Engelhart's process yields us hæmatosine in its purest form, but when thus obtained it is no longer soluble in water, whereas, if procured by evaporation at 100° Fahrenheit, it is still soluble, and what is very extraordinary, dry hæmatosine procured at that temperature, though it be afterwards subjected to a heat of 212° Fahrenheit, does not lose its property of dissolving in water. Hæmatosine may be described under two forms, viz. in solution and in the dry state.

The aqueous solution of hæmatosine is precipitated by alcohol and the acids. The alkaline hydro-sulphurets and sulphuretted hydrogen change the colour of the solution to green; nearly all the metallic and earthy salts precipitate it. Infusion of galls produces a pale red precipitate; gallic acid, however, does not show this effect. Chlorine passed through a solution of hæmatosine decolorizes it. Bromine produces a similar result, but it is some time before the effect is observed. Iodine will also decolorize the solution after some hours, and produces a brown precipitate, which is found to contain iodine.

Hæmatosine when dry is of a dark red colour and exceedingly hard, having a vitreous fracture. Its chemical properties in many respects resemble those of fibrine, and albumen in the coagulated state. Berzelius remarks that, like fibrine, it contains a fatty matter peculiar to itself which can be separated by ether; this is one point of resemblance in the opinion of that chemist. The action of acetic acid on hæmatosine is a very striking point of resemblance between that body and fibrine; for when the acid in the concentrated state is allowed to remain in contact with hæmatosine for a few hours, we observe that it is converted into a tremulous brown mass which is more or less soluble in water, and which during solution evolves nitrogen gas. The nitric, hydrochloric, and sulphuric acids, if diluted with an equal bulk of water, and digested on hæmatosine, become coloured yellow and disengage nitrogen; but they do not dissolve the principle even at a boiling heat. The results of such digestions, however, in the hydrochloric and sulphuric acids, are soluble in water; but that which has been digested in nitric acid remains insoluble.

Potash, soda, and ammonia dissolve hæmatosine with facility, and it is precipitated from such solution by the addition of an acid. The acetic acid acts thus, but re-dissolves the precipitate if added in excess, as it would albumen or fibrine.

Tannin precipitates hæmatosine from solution in alkalies.

Tiedemann and Gmelin have observed that boiling alcohol will dissolve hæmatosine; this is also the case to a considerable extent with its combinations with several of the acids which precipitate it. When hæmatosine is incinerated and decarbonized, it yields an ash amounting to 1.3 per cent. of its weight: this, according to Berzelius, is composed of the following substances:—

* There seems to be a law of the animal economy that when a joint is diseased the muscles moving it immediately lose tone and bulk, and there is no more marked symptom of disease of an articulation than this wasting of the muscles which belong to it.

† Lecanu considers that hæmatosine is a compound of albumen with a substance which he believes to be the true colouring matter of the blood, and which he calls *Globuline*.

Carbonate of soda, with traces of phosphate	0.3
Phosphate of lime	0.1
Caustic lime................	0.2
Subphosphate of iron	0.1
Sesqui-oxide of iron	0.5
Carbonic acid and loss........	0.1
	1.3

The ultimate analysis of hæmatosine approaches very nearly to that of fibrine. Michäelis declares to have found a difference of ultimate constitution between the colouring matter of arterial and venous blood: his analyses are as follows:—

	Arterial.	Venous.
Nitrogen........	17.253	17.392
Carbon	51.382	53.231
Hydrogen	8.354	7.711
Oxygen	23.011	21.666

It will be observed, on examining these analyses, that the difference of constitution is so small that we may reasonably conclude it has been produced by a difference in manipulation or some other extraneous cause capable of modifying the result: indeed, ultimate analyses of identical substances have, when in the hands of different chemists, often yielded results far more discrepant than these, and that too when each operator stood high as an analyst. Berzelius, in remarking on these experiments, observes that it is impossible for the chemist to fix the state of blood whether arterial or venous; for it will lose its condition with respect to the colouring matter long before the chemist can procure its hæmatosine for analysis. Thus the venous clot becomes of a bright red colour when exposed to air, and arterial blood soon loses its vermilion hue. A great contrariety of opinion exists as to the cause of the red colour of hæmatosine, some chemists supposing that the iron contained in it takes an active part in its coloration, while others maintain that though iron is present it cannot be considered as the cause of colour. Winterl imagined he had discovered the secret when he formed sulphocyanic acid (blut säure) by carbonizing blood with carbonate of potash and precipitated salt of iron with the lixivium—an experiment quoted by Treviranus; but we are unable to detect the sulphocyanic acid in blood, so this formation of a ferruginous colouring matter must not be considered as in any way assisting in the inquiry, although it simulates the tint of blood most completely. Fourcroy asserted that subphosphate of iron was capable of imparting a red colour to serum, which is not the case, and went so far as to declare that the colourless globules of the chyle contained neutral phosphate of iron, which, when mixed with the blood, was decomposed by the alkali present into a subphosphate, which on reaching the lungs became a per-salt and imparted colour to the fluid. This idea is quite hypothetical, and in discordance with facts as observed by other chemists.

Engelhart's experiments on hæmatosine tend to shew that iron is in some way influential in producing the red colour of the blood. He showed that, though albumen and fibrine yielded no iron on incineration, the metal existed in considerable quantity in hæmatosine. He found that a solution of red particles impregnated with sulphuretted hydrogen became of a violet colour and then passed to a green, it being impossible to restore the original red tint. Chlorine when passed through the solution bleached it, having previously produced a green colour; when decolorization was complete, white flocculi were observed to fall, which on being examined yielded no appreciable ash, while the clear solution gave evidence of iron by the usual reagents. The white flocculi were supposed by Engelhart to be the colouring matter changed to white by the abstraction of its iron. It is evident that even if the colour of the blood were owing to some peculiar animal matter and not to iron, we should still expect decolorization by chlorine; but yet the change of colour from red to green which that re-agent produces previous to decolorizing the solution, renders it probable that its action is on iron in some form of combination as yet unknown. Rose has shown that many organic matters interfere with the action of the tests for iron when present in solution with that metal, and quotes this to account for the failures in procuring the reactions of iron from the blood in a fluid state. Some experiments of Berzelius, however, have proved that the artificial combinations of iron with albumen which Rose formed, can be precipitated by ferrocyanate of potassa if they are previously treated with acetic acid: as this does not happen with blood, it is very properly contended that Rose's experiments are not to be looked upon as an explanation of the difficulty. In a paper published by Mr. Brande in the Philosophical Transactions for 1812, that gentleman proposes to consider hæmatosine as an animal dye, which like cochineal is capable of uniting with metallic oxides; thus the oxides of mercury and tin are active precipitants of this colouring matter, and woollen clothes previously impregnated with a solution of bichloride of mercury have been permanently dyed by steeping them in a solution of hæmatosine. The question as to whether or not iron be really necessary to the existence of the red colour of the blood cannot be considered as determined, and it is difficult to imagine any line of experimenting which could afford results sufficiently satisfactory to settle the point. Mr. Brande's experiments, by which he concluded that hæmatosine contained iron in no greater proportion than fibrine or albumen, would have placed the matter beyond doubt if other chemists had confirmed his observations; but the experiments of Dr. Engelhart published in 1825, and which have received very general confirmation, show that fibrine and albumen when pure contain no iron, and that the metal exists in considerable quantity in hæmatosine.

HAIR. See TEGUMENTARY SYSTEM.

HAND, BONES OF THE, (Human Anatomy.) The hand (χειρ, *manus*; Fr. *la main*; Germ. *die Hand,*) is the inferior segment of the upper extremity. Its presence is characteristic of man and the Quadrumana.

Although formed on the same general type, the hand will be found to exhibit many points of difference from the foot—characters strongly indicative of the diversity of use for which it is designed. In examining the skeleton of the hand, we observe subdivisions analogous to those which exist in the foot—the *carpus* corresponding to the tarsus, the *metacarpus* to the metatarsus, and the *phalanges* of the fingers in every way analogous to those of the toes. Independently of the lightness and mobility which are such prominent features in the mechanism of the hand, when contrasted with that of the foot, the divergence of the first or radial finger *(the thumb)* from the line of direction of the other four, is peculiarly characteristic of the hand. Whilst the four fingers, properly so called, are parallel to the middle line of the hand, the thumb, when extended, forms with it an angle of rather more than 45°. To this position of the thumb is due in the greatest part the facility of opposing it to one of the fingers, a movement so necessary in the prehension of minute objects.*

The general form of the hand is oval, the obtuse extremity corresponding to the tips of the fingers, the unequal lengths of which occasion the curvature in this situation. On its posterior surface or *dorsum*, the hand is convex; on its anterior surface or *palm*, it is concave: both these surfaces correspond to, and in the recent state are supported by, the bones of the carpus and metacarpus.

I. *Carpus* (Germ. *die Handwurzel)*. The carpus bears a much less proportion in size to the whole hand than the tarsus does to the foot; it forms scarcely more than one-fourth of the hand. Its outline is oval, the long axis being transverse: if examined in a hand to which the ligaments are attached, the carpus will be found to form the posterior and osseous portion of an osseo-ligamentous ring, which gives passage to the tendons of the fingers. It is consequently hollowed from side to side, and is bounded on each side by a bony ridge, which gives attachment to the ligament *(annular ligament)* which forms the anterior part of the ring; on the radial side the ridge is formed by a process of the os trapezium and of the scaphoid; on the ulnar, where there is a more prominent ridge, by a process of the unciform bone, and by the os pisiforme.

Seven bones, arranged in two rows, form the carpus. The superior row consists of the *os naviculare*, *os lunare*, and *os cuneiforme*, to which last is articulated a bone, constantly reckoned as a carpal bone, but which, I conceive, may be more correctly regarded as a sesamoid bone, the *os pisiforme*. The second or inferior row is formed by the *os trapezium*, *os trapezoides*, os *magnum*, and *os unciforme*.

1. *Os naviculare (os scaphoideum*; Fr. *le scaphoide*; Germ. *das Kahnbein)*. The navicular or scaphoid is the largest of the upper row, and likewise the most external. Its superior surface is convex, oval, with long axis transverse, articular, and is adapted to the outer part of the carpal articular extremity of the radius. The hollowed surface, to which it owes its name *(boat-like)*, is directed downwards and inwards; this is likewise articular and receives the head of the os magnum: continuous with and to the inner side of this hollow surface, there is a plane one of a semilunar form, with which the os lunare is articulated. The scaphoid bone articulates with the trapezium and trapezoides, by a convex surface directed downwards and outwards. Externally this bone terminates in a pointed extremity which receives the external lateral ligament of the wrist-joint and the annular ligament *(tuberculum ossis navicularis*, s. *eminentia carpi radialis superior)*. The anterior and posterior surfaces of the bone are rough, and give attachment to the anterior and posterior radio-carpal ligaments.

2. *Os lunare, (os semilunare* v. *lunatum*; Fr. *le semilunaire*; Germ. *das Mondbein)*, situated between the scaphoid and the cuneiform bones, it presents four articular surfaces; an upper one, convex and somewhat triangular in its outline, articulated with the radius; an inferior one, very much hollowed from before backwards (to the crescentic form of which the bone owes its name), articulated with the os magnum; an external surface, plane and square, adapted to the cuneiform bone; and, lastly, an internal surface, by which it articulates with the scaphoid.

3. *Os cuneiforme (os triquetrum* s. *pyramidale*; Fr. *le pyramidale*; Germ. *das dreiseitige Bein)*. This bone terminates the superior carpal row on the ulnar side; its upper surface is partly smooth, encrusted with cartilage in the recent state, where it is in contact with the triangular ligament of the wrist-joint, and partly rough where it gives attachment to ligaments. Externally it articulates with the cuneiform bone, and inferiorly with the unciform by a large and concave suaface. The inner half of its anterior surface articulates with the pisiform bone, and the radial half of the same surface is rough for ligamentous insertion.

The three bones just described, constituting the superior row of the carpus when united, present on their superior aspect a convex articular surface which forms the carpal portion of the radio-carpal joint, the scaphoid and lunar being articulated with the radius, while the cuneiform glides upon the triangular cartilage of the wrist.

4. *Os pisiforme* (from *pisum*, a pea; Fr. *le pisiforme*; Germ. *das Erbsenbein)*. This little bone projects at the anterior part of the ulnar extremity of the superior carpal row; it forms what some anatomists designate *eminentia carpi ulnaris superior*, being part of the bony ridge already referred to on the ulnar side of the carpus. The prominence produced

* See the prefatory observations to the article FOOT.

by this bone is easily felt during life, more especially during flexion of the wrist-joint. It is round every where, except posteriorly, where it presents a flat circular surface, by which it is articulated with the cuneiform bone. This bone is intimately connected with and as it were inclosed in the terminal portion of the tendon of the flexor carpi ulnaris.

5. *Os trapezium (os multangulum majus;* Fr. *le trapeze;* Germ. *das grosse vielwinkliche Bein).* This bone is situated at the radial extremity of the inferior carpal row, having the scaphoid above it and the metacarpal bone of the thumb below it. We may describe six surfaces upon it, four articular and two non-articular. *a.* A large articular surface, situated on the external and inferior aspect of the bone. This surface is for articulation with the metacarpal bone of the thumb: it is somewhat oval in form, the long axis passing from without inwards and downwards; in this direction it is concave, from before backwards it is convex. The three remaining articular surfaces are on the internal and superior aspects of the bone. *b.* Internally, a very small plane surface, adapted to a corresponding one on the radial side of the carpal extremity of the second metacarpal bone. c. Above the last described surface and separated from it merely by a slight ridge, we find one of a somewhat triangular form and slightly concave, articulated with the radial side of the trapezoid. *d.* Quite on the superior aspect a small semicircular surface, adapted to the scaphoid. Of the non-articular surfaces, one is on the palmar aspect of the bone, and is easily distinguished by the prominent ridge or tubercle at its outer part, which gives attachment to the annular ligament, *(tuberculum, eminentia carpi radialis inferior;)* and on the ulnar side of this ridge a groove in which the tendon of the flexor carpi radialis glides. The second non-articular surface is on the dorsal aspect: it is more extensive than the last, rough and tuberculated, affording insertion to ligaments.

6. *Os trapezoides (os multangulum minus;* Fr. *le trapezoide;* Germ. *das Kleine vielwinkliche Bein).* This is the second bone of the inferior carpal row; it has the os trapezium on its radial and the os magnum on its ulnar side, the scaphoid above and the second metacarpal bone below it. We describe four articular surfaces and two non-articular. *a.* The inferior one the largest, quadrilateral, much narrower in front than behind, convex from side to side, slightly concave from before backwards, is entirely devoted to articulation with the second metacarpal bone. *b.* On the radial side, a slightly convex surface for the trapezium. c. Superiorly a quadrilateral concave surface for articulation with the scaphoid. *d.* On the ulnar side a very small surface, adapted to a corresponding one on the radial side of the os magnum. The palmar surface is non-articular, five-sided, slightly excavated, and rough from the insertion of ligaments. The dorsal surface, also non-articular, is of greater extent, convex, and likewise rough.

7. *Os magnum (os capitatum;* Fr. *le grand os;* Germ. *das Kopfbein).* This bone is, as its name implies, principally characterized by its excess in size over the other carpal bones, and from the number of bones with which it is connected, it may be regarded as the key-bone of the carpus. Superiorly it is in the form of a rounded head *(capitulum)*, flattened on the ulnar side, where it articulates with the unciform bone. The superior prominent portion of this head is received into the excavation of the lunar bone, and by its radial side it articulates with the inferior hollow surface of the scaphoid. The inferior portion of the bone is cuboid, and has been called *the body;* it is rough and convex on its palmar surface, also rough but irregular on its dorsal, both these surfaces affording insertion to numerous ligaments. Inferiorly we notice an extensive articular surface, which is adapted in the centre to the third metacarpal bone, on the radial side to the second, and by a very small portion on the ulnar side to the fourth metacarpal bone. On the ulnar side of its inferior portion it articulates a second time with the os unciforme by a small circular articular surface, the circumference of which nearly equals that of the flat surface of a split pea. Lastly, on its radial side it articulates with the trapezoid bone. Thus the os magnum articulates with seven bones; three metacarpal bones, two carpal bones in the inferior row, and two in the superior row.

8. *Os unciforme* (from *uncus*, a hook, *os hamatum;* Fr. *l'os crochu ou unciforme;* Germ. *das Hakenbein, oder Keilformiger Knochen).* This bone has received its name from that which allows of its being easily distinguished from all the carpal bones,—namely, the hooked process, which projects from the radial edge of its palmar surface. This process constitutes a considerable prominence on the ulnar side of the carpus *(eminentia carpi ulnaris inferior)*, and affords insertion to the annular ligament. Its concavity looks towards the radial side of the carpus; the remainder of the palmar surface is rough for ligamentous insertion. The dorsal surface is likewise rough, convex, and of considerable extent. This bone articulates inferiorly with the fourth and fifth metacarpal bones, on its radial side with the os magnum, and on its superior surface with the cuneiform bone.

Structure of the carpal bones.—These bones are chiefly composed of the reticular osseous tissue, to which their extreme lightness is attributable, the surface being invested by a thin layer of compact texture, in this respect perfectly resembling the bones of the tarsus.

Developement.—The carpal bones are very late in their developement; at birth they are completely cartilaginous. According to Cruveilhier, each bone is developed by a single point of ossification. The os magnum and os unciforme are the first in which the ossific process commences, about the end of the first year; between the third and fourth years it begins in the cuneiform, a year later in the trapezium and lunar, and between the eighth and ninth years in the scaphoid and trapezoid bones. The ossification of the pisiform does not begin till between the twelfth and fifteenth years, and Cruveilhier states that of all the bones of the skeleton it is the last in which the process of ossification is completed.

II. *Metacarpus* (Germ. *die Mittelhand*). Five bones constitute the metacarpus, the four internal ones being parallel to each other, the external one diverging outwards at an acute angle with the middle line of the hand. These bones vary in length from about two inches and a half to one inch six-eighths. They articulate inferiorly with the superior or metacarpal phalanges, and superiorly with the carpus.

Each metacarpal bone presents two extremities, and a shaft or body between them. The *superior* or *carpal* extremity is expanded and wedge-shaped, the broader part being towards the dorsal aspect. Three articular surfaces exist on each; one, the most extensive, on the superior or carpal surface, for articulation with a carpal bone; the other two on the radial and ulnar surfaces, adapted to the adjacent metacarpal bone or to a carpal bone. The palmar and dorsal surfaces are rough and irregular, and afford insertion to the ligaments which strengthen the carpo-metacarpal joints. The *inferior* or *digital* extremity is in the form of a rounded head, flattened on each side, where we notice a depression, and behind it a tubercle which affords insertion to the lateral ligament of the joint. The smooth articular surface of the head extends further upon the palmar surface of the bone than upon its dorsal surface, or, as in the case of the metatarsal bones, more on the side of flexion than on that of extension. The *shaft* or *body* is prismatic and slightly curved, so as to present a concavity towards the palmar surface, and a convexity to the dorsal.

The metacarpal bones are numbered from without inwards. The *first*, or that of the thumb, is the shortest of all and likewise the thickest. Its carpal extremity will likewise serve to distinguish this bone; it wants the cuneiform shape, and is rather wider on its palmar than its dorsal surface. It has no articular facets on its sides, being articulated with the trapezium alone by means of a surface which is concave from before backwards, and convex from side to side; the body of this bone is flatter on its palmar and dorsal surfaces than any of the others.

The *second* metacarpal bone is the longest; it, however, exceeds the third by a very slight difference. It is further distinguished from the third by the diminutive size of the articular facet on the radial side of its carpal extremity.

The *third* metacarpal bone, though shorter than the second, is manifestly thicker and stronger; this excess of developement being attributable to its affording insertion to one of the most powerful muscles of the hand,—namely, the adductor pollicis.

The *fourth* and *fifth* metacarpal bones are shorter and in every way smaller than the preceding ones. The fifth is shorter and somewhat thicker than the fourth: it has no articular facet on the ulnar side of its carpal extremity, but presents a prominent tubercle in that situation for the insertion of the extensor carpi ulnaris.

The *structure* of the metacarpal bones is the same as that of the long bones in general.

Developement.—There are two points of ossification for each metacarpal bone, one for the body and the carpal extremity, the other for the digital extremity. The first metacarpal bone, however, according to Cruveilhier, offers an exception to this, inasmuch as its carpal extremity is developed from a point of ossification distinct from that of the body. In some instances there are three points of ossification for each metacarpal bone. The bodies of the metacarpal bones are completely ossified at birth. Between the second and third years appear the points for the inferior extremity in the four inner bones and the superior extremity in the first, but the complete fusion of the extremities with the shafts does not take place till near the twentieth year.

III. *Fingers (digiti;* Fr. *les doigts;* Germ. *die Finger).* The fingers differ strikingly from the toes as regards their length, to which, indeed, is due their greater mobility. They are numbered in proceeding from the radial to the ulnar side of the hand. All except the thumb are composed of three phalanges, the *superior* or *metacarpal*, the *middle*, and the *inferior* or *ungual:* in the thumb the middle phalanx is absent. The fingers differ considerably in length; the thumb is by far the shortest, and the middle finger is the longest. Next in length is the ring finger, then the index, and last and least the little finger.

The *metacarpal* phalanges have the following general characters:—1st, a body slightly concave from above downwards on the palmar surface, and convex on the dorsal; 2d, a superior or metacarpal extremity more expanded than the inferior, hollowed into an articular surface for the head of the metacarpal bone; and 3d, an inferior extremity, having a pulley-like surface for articulation with the middle phalanx. The metacarpal phalanges are the longest.

The *middle* phalanges present the same characters as the preceding as regards the body. The superior extremity has a pulley-like articular surface, *convex* transversely; that of the inferior extremity being *concave* in the same direction.

The ungual phalanges are readily distinguished by the inferior or ungual extremity, which is rough, non-articular, horseshoe-shaped, with the convexity directed downwards. It is this part of the bone which supports the nail. The superior extremity is articulated with the middle phalanx by a pulley-like surface, concave transversely. The ungual phalanx of the thumb is considerably larger than that of any of the other fingers.

In point of structure and developement the phalanges scarcely differ from the metacarpal bones. There are two points of ossification, one for the body and inferior extremity, the other for the superior extremity. This last is late in making its appearance, not until between the third and seventh year, while the ossification of the body commences at an early period of intra-uterine life.

Although the perfect prehensile hand is peculiar to man and the Quadrumana, the inferior segment of the anterior extremity will be found to possess many interesting analogies throughout the mammiferous series. On this point we refer to the articles OSSEOUS SYSTEM (Comp. Anat.) and SKELETON.

JOINTS OF THE HAND.

Joints of the carpus.—The bones constituting each row of the carpus are firmly connected by strong ligaments, so that their combined surfaces form one extended surface adapted to the radius, or to the metacarpus, or to each other. Thus the union of the superior articular surfaces of the upper carpal row constitutes the convex surface that contributes to the formation of the wrist-joint, whilst the united inferior articular surfaces of the same row are adapted to the united superior surfaces of the inferior carpal row. Again, the inferior articular surfaces of this last row enter into the formation of the carpo-metacarpal joints.

The several articulations of each row are strengthened by two sets of ligaments, one on the palmar, the other on the dorsal surface of the joints, *palmar and dorsal ligaments;* they extend transversely from one bone to the other. The palmar ligaments are considerably stronger than the dorsal. The synovial membranes which exist in these small articulations are merely offsets from the large synovial membrane which is interposed between the two rows of the carpus.

In the articulation between the scaphoid and lunar bones, as well as in that between the lunar and cuneiform, we observe a remarkable fibro-cartilaginous lamina interposed in the whole extent of each articulation from before backwards, although not extending over the entire articular surfaces. These laminæ are readily seen on opening the radio-carpal joint in the interval between the bones above mentioned; they are attached to the palmar and dorsal ligaments by their anterior and posterior extremities. When dissected out they will be found to be wedge-shaped, the thick edge being directed towards the wrist-joint, and adherent to the synovial membrane of that joint. These laminæ are described by most anatomists as ligaments, under the name of *interosseous ligaments.* Of their fibro-cartilaginous nature, however, I have no doubt from repeated and careful examinations; they may therefore be more correctly denominated *interosseous fibro-cartilages.* Feeble interosseous ligaments exist on either side of the os magnum between it and the unciform on one side, and the trapezoid on the other; they are best seen when these bones are torn from each other.

Articulation of the two rows of carpal bones to each other.—The superior articular surfaces of the four bones composing the inferior carpal row are adapted to the inferior articular surfaces of the scaphoid, lunar, and cuneiform bones. The head of the os magnum and the superior articular surface of the unciform bone form a prominent convexity, which is received into a deep concavity formed on the ulnar side by the cuneiform bone, on the radial side by the scaphoid, and in the centre by the lunar bone; whilst external to the projection of the os magnum, a superficial oblong concavity receives the convexity on the inferior and outer surface of the scaphoid. Thus the line of this articulation has somewhat of the course of the roman S placed horizontally, ∽. That part of the articulation which is to the ulnar side, then, partakes more of the nature of enarthrodia or ball and socket joint, while that to the radial side is arthrodia with almost plane surfaces.

This articulation is strengthened in front by an *anterior* or *palmar* ligament which is of considerable strength and thickness. Most of the fibres of this ligament are attached inferiorly to the palmar surface of the os magnum, whence they diverge to be inserted into the scaphoid, lunar, and cuneiform bones; some few fibres extend from the trapezoid and trapezium to the scaphoid, and from the unciform to the cuneiform. Behind we find a *dorsal* ligament, also strong, although much less so than the palmar. This ligament extends obliquely from the bones of the first row to those of the second, but is stronger on the ulnar than on the radial side. The extent and connexions of both these ligaments are best seen when the joint is opened, by cutting through the dorsal ligament to view the palmar, and vice versa. The ligaments called *lateral* by some anatomists are merely the continuation of the lateral ligaments of the wrist-joint; nor do those described by Cruveilhier under the name of *glenoid ligaments* deserve to be separated from the anterior and posterior, of which they constitute that portion most intimately connected with the anterior and posterior notches of the hollow cavity in which the head of the os magnum is lodged.

In opening this joint in the manner already described, it will be seen how extensive is its synovial membrane. It extends some distance on the palmar and dorsal surfaces of the neck of the os magnum, and sends two processes between the bones of the first row (between the scaphoid and lunar, and the lunar and cuneiform), and three processes between those of the second row, (one on each side of the os magnum,) and one between the trapezium and trapezoid.

Motions of the carpal articulations.—An examination of the dissected carpus will at once show how limited are the motions between any two of the carpal bones of each row. The movement of one row upon the other, however, is more extensive, but only in the direction of flexion and extension, the former being considerably greater in consequence of the less resistance of the dorsal ligaments. Solidity and strength, a power of resistance to violence which might easily occasion fracture, were the carpus one solid bone, are gained by the number of small bones of which it is composed, the arthrodial form of its articulations, and the strong ligaments by which the motions of these joints are restricted.

Articulation of the pisiform bone.—The pisiform bone is so little connected with the mechanism of the carpus that its articulation with the cuneiform bone demands a separate consideration. A plane oval surface on the posterior part of the pisiform is articulated with a corresponding one on the palmar aspect of the cuneiform, and several strong ligaments strengthen the joint. Two lateral ligaments pass from the pisiform to the cuneiform bone, the internal, which is also anterior, being of considerable strength. This bone is further connected to the unciform by strong ligamentous fibres; and a strong bundle, which bears the same relation to the tendon of the flexor carpi ulnaris as the ligamentum patellæ does to the tendon of the rectus femoris, extends to the carpal extremity of the fifth metacarpal bone. This joint is provided with a loose synovial membrane; its motions are those of gliding in the directions of the axis of the articular surfaces.

Carpo-metacarpal joints.—These are very strong articulations, and, with the exception of the first and fifth, enjoy a very limited extent of motion. The four internal ones are nearly planiform arthrodiæ, restricted on the palmar and dorsal surfaces by strong and short ligaments *(palmar* and *dorsal ligaments)*, the latter being much better developed. The *second* metacarpal bone is articulated with the trapezoid in an extremely firm manner: its *palmar* ligament extends from the extremity of the metacarpal bone to the trapezium internal to the ridge, and covered by the tendon of the radial flexor of the wrist. There are three *dorsal* ligaments, an external attached to the trapezium, and an internal to the os magnum. These two ligaments are oblique in their direction; the third or middle one is vertical and attached to the trapezoid. The *third* metacarpal bone is articulated with the os magnum: here we find three strong *palmar* ligaments, an external one which extends obliquely outwards to the trapezium, an internal one which passes in front of the carpal extremity of the fourth metacarpal bone, adhering to it, and inserted into the unciform and the fifth metacarpal bone, and a middle one which passes vertically to the os magnum. This joint has two dorsal ligaments, both inserted into the os magnum. The *fourth* metacarpal bone is articulated with the radial portion of the inferior articular surface, and with a very small portion of the os magnum; it has a single palmar and dorsal ligament. The *fifth* metacarpal bone is articulated with the outer part of the inferior surface of the unciform; this surface is convex transversely and concave from before backwards, while that on the metacarpal bone is convex from before backwards and concave transversely. The proper ligaments of this joint are very feeble, being merely a few fibres attached to the anterior and posterior surfaces of the synovial membrane. The joint, however, is protected in front by the prominence of the unciform process, which descends a little below the line of the articulation, and limits the forward motion of the carpal extremity of the bone; and posteriorly it is strengthened by the tendon of the extensor carpi ulnaris, while its motion ulnad is restricted by the strong internal palmar ligament of the third metacarpal bone, which we have already described as passing from that bone to the fifth metacarpal and the unciform bones. The fifth carpo-metacarpal articulation approaches in many particulars to the first; it has a greater latitude of motion than the three immediately preceding it, and its articular surfaces very much resemble those of the first.

Besides the palmar and dorsal ligaments already described, these metarcarpal bones are very firmly connected to each other by short but strong ligaments, extending transversely from one to the other on the palmar and dorsal aspects.

A common synovial membrane extends throughout the four joints above described; this synovial membrane is continuous with that between the two rows of carpal bones.

The digital extremities of the four inner metacarpal bones are connected by their transverse ligaments situated at the palmar surface and extending from one to the other.

Carpo-metacarpal joints of the thumb.—The main feature by which this articulation is distinguished from the other carpo-metacarpal joints is its great mobility. It is an arthrodia, and in many particulars resembles very much the sterno-clavicular joint. The trapezium presents a surface concave from within outwards, and convex from before backwards, that on the metacarpal bone being convex in the transverse, and concave in the antero-posterior direction.

The ligamentous apparatus of this joint has very much the appearance of the capsular ligament of an enarthrosis, and has indeed been described as such by many anatomists; but on a careful examination it will be found to consist of separate bundles of ligament placed at those situations in which the greatest tendency to displacement exists in the various motions of the joint. Four principal bundles may be described: one very thick and strong, situated at the posterior and outer part of the joint, *(lig. dorsale,* Weitbr.) extending from the metacarpal bone to a prominent tubercle on the outer part of the dorsal surface of the trapezium; this ligament limits flexion of the joint. A second ligament is situated directly in front of the joint, *(lig. palmare,* Weitbr.) is inserted into the trapezium immediately internal to its prominence; extension is limited by this ligament. The third and fourth bundles *(lig. laterale ext. et int.* Weitbr.) are situated on the radial and ulnar sides of the joint: they are less distinct as well as less strong than those last described. That on the ulnar side is considerably the stronger; it limits abduction of the thumb, whilst that on the radial side limits adduction.

The synovial membrane of this joint is lax; it is perfectly distinct from the general synovial membrane of the other carpo-metacarpal articulations.

Motions of the carpo-metacarpal joints.—In the second, third, and fourth joints the motions are limited to a very slight, and during life scarcely appreciable gliding forwards or backwards: the strong transverse ligaments, as well as the close manner in which the carpal extremities of the metacarpal bones are impacted together, render lateral motion impossible; in the fifth joint the forward or backward motion is somewhat more extensive, but this joint is equally limited with the others in lateral movement.

The carpo-metacarpal joint of the thumb enjoys motion forwards, backwards, inwards, and outwards, producing the movements of flexion and extension, abduction and adduction. The power of opposing the thumb to any of the fingers is due to the oblique direction of flexion in this joint: the bone moves forwards and inwards, passing through a line which would be concave inwards. This is by far the most extensive motion of the thumb, and it is by an excess of this motion that the dislocation of the metacarpal bone backwards is generally occasioned. Cruveilhier observes that the weakness of the posterior ligament favours the occurrence of this luxation. I cannot, however, admit the weakness of this ligament; on the contrary, it appears to me to be the strongest of all the ligaments of this joint; which opinion, I find, is that of the accurate Weitbrecht.

The motion of adduction is, on the other hand, the most limited, in consequence of the proximity of the second metacarpal bone; that of abduction is very extensive, and when carried too far may occasion luxation inwards.

JOINTS OF THE FINGERS.

1. *Metacarpo-phalangeal joints.*—The first phalanges are articulated by an oval concave surface, with the rounded oblong heads of the inferior extremities of the metacarpal bones: it is remarkable that the long axis of the oval concavity of the phalanx has a transverse direction, while the long axis of the head of the metacarpal bone is directed from before backwards, and consequently at right angles with the former; whence the great extent of lateral motion enjoyed by these joints.

Each of these joints is strengthened by two lateral ligaments, of considerable strength, inserted into the tubercle behind the depression on each side of the head of the metacarpal bone; the point of insertion into the phalanx is anterior to this, and consequently the direction of the lateral ligaments is downwards and forwards; as they descend, these ligaments spread out, and their anterior fibres become identified with the anterior ligament.

A third ligament, the *anterior* ligament, or *glenoid* ligament of Cruveilhier, seems destined more to increase the extent of the phalangeal articular concavity anteriorly, than to maintain the integrity of the joint or limit its motions. This ligament is, as Bichat expresses it, a thick and dense fibrous bundle, in shape half a ring, placed in front of the palmar surface of the head of the metacarpal bone, composed of transverse fibres which adhere inferiorly to the anterior edge of the concavity on the phalanx, and on each side are identified with the lateral ligaments and the transverse ligaments by which the metacarpal bones are connected. If the ligaments and synovial membrane of this joint be cut all round close to their attachment to the head of the metacarpal bone, and that bone be removed, the synovial capsule and ligaments remaining attached to the phalanx, a very clear idea of the relative positions of the ligaments may be formed. The synovial membrane will then appear protected on three sides by ligament; on the radial and ulnar side by the lateral ligaments, and in front the anterior ligaments, whilst posteriorly it is unprotected save by the sheath of the extensor tendon.

In the metacarpo-phalangeal articulation of the thumb two sesamoid bones, developed in the substance of the anterior ligament, protect the joint in front.

2. *Phalangeal joints.*—These joints are all ginglymoid, the articular surfaces being pulley-like; they are provided with lateral ligaments similar to those of the metacarpo-phalangeal joints, and also with anterior ligaments similarly disposed.

Motions of the joints of the fingers.—In the phalangeal joints these motions are only flexion and extension; the former are considerably more extensive, and are favoured by the inferior insertion of the lateral ligaments being on a plane anterior to their superior insertion. In addition to flexion and extension the metacarpo-phalangeal joints enjoy considerable lateral motion, which is due to the glenoid form of the phalangeal articular surface, and to the enarthrodial form which the joint derives from the extension of that articular surface by the anterior ligament.

(R. B. Todd.)

HAND, ABNORMAL CONDITIONS OF THE. Deviations from the normal condition of the different structures which enter into the composition of the hand are very numerous, and may be classed into those which are the result of, first, accident; second, disease; third, congenital malformation.

I. ABNORMAL CONDITIONS, THE RESULT OF ACCIDENT.

Fractures and luxations. — Simple fractures of the bones of the hand are seldom followed by any notable deformity; but luxations of these bones require from us some attention here.

Luxation of the bones of the carpus.—The bones of the carpus are united to each other so solidly, and their movements seem so limited, that, without experience, we should be disposed to pronounce luxation of any of these bones impossible; nevertheless, the head of the os magnum may be dislocated from the cavity formed for it by the scaphoid and semilunar bones. The first range of the bones of the carpus is articulated with the bones of the second range in such a manner that slight gliding movements of flexion and extension of the hand are permitted, which augment a little the movements of flexion and extension of the hand upon the forearm, and add somewhat, as Cruveilhier says, to the grace of the movements of this portion of the upper extremity. In flexion, the head of the os magnum, which is somewhat inclined backwards, raises up the thin capsule which surrounds its articulation, and, if this movement be carried very far, the capsule and accessory fibres which support the bone posteriorly are broken, and the os magnum escapes from the cavity in which it is naturally placed; the dislocation cannot be called complete, yet the os magnum passes somewhat the level of the posterior surface of the other bones of the carpus. The accident is more common in women than in men, no doubt because the ligaments are weaker and the bones enjoy greater motion in the former than in the latter; the luxation backwards of the os magnum, the only one which can occur, is always the result of a forced and violent flexion of the wrist, such, for example, as a fall on the back of the hand would produce.

We recognize the luxation of the os magnum by the history of the accident, and by the deformity produced. We perceive a hard circumscribed tumour which has suddenly appeared on the back of the hand in the situation which corresponds to the head of the bone. This tumour becomes more prominent when the hand is flexed, and diminishes when it is extended; we can make it disappear entirely by a slight compression. This luxation causes but little inconvenience, but the head of the os magnum always remains more salient when the hand is flexed, and forms a tumour more or less marked according to the extent of the displacement.

We can easily reduce this luxation by extending the hand, or by exercising a slight pressure on the head of the os magnum; but, although it is easy to make the bone resume its position in the cavity formed for it by the scaphoid and semilunar bones, it is very difficult to maintain it there, and the inconvenience and deformity resulting from the luxation are so trivial that few persons will submit with patience to the means usually recommended.

Luxation of the bones of the metacarpus.—Luxation of the metacarpal bone of the thumb. The carpal head of the metacarpal bone of the thumb, notwithstanding the range of motion it enjoys, is rarely dislocated. Sir A. Cooper, in his extensive experience, has seen but one species of this accident, viz. luxation of the metacarpal bone of the thumb upon the os trapezium, inwards. "In the cases I have seen of this accident," says Sir Astley, "the metacarpal bone has been thrown inwards between the trapezium and the root of the metacarpal bone of the fore-finger; it forms a protuberance towards the palm of the hand; the thumb is bent backwards, and cannot be brought towards the little finger: considerable pain and swelling are produced by this accident."

Luxation of the carpal head of the metacarpal bone of the thumb *backwards*. Some surgeons seem to doubt that the metacarpal bone of the thumb is capable of being dislocated in any other direction than that inwards; but the following case is given on the highly respectable authority of the experienced Boyer. Madame De la P—— luxated the metacarpal bone of her left thumb backwards on the dorsum of the trapezium by falling on the external or radial border of her hand; the luxation was at first mistaken. When Boyer saw it six months after the accident, the superior extremity of the metacarpal bone of the thumb formed posteriorly a very remarkable prominence on the trapezium, and this bone and the phalanges of the thumb were inclined towards the palm of the hand. On pressing posteriorly on the prominence formed by the superior extremity of the dislocated bone, it could be made to resume its natural place and the prominence disappeared; so long as the pressure was continued, the bone retained its place and the thumb enjoyed its natural powers of flexion and extension; but as soon as the pressure was remitted, the bone became displaced anew, and the movements of the thumb impossible. The lady was unwilling to submit to any treatment, and the condition of the joint remained unaltered. These luxations of the metacarpal bone of the thumb, whether backwards or inwards, must be rare, as the causes which are calculated to produce them must act through the first phalanx of the thumb, which, it is manifest, will be much more disposed to yield than the metacarpal bone.

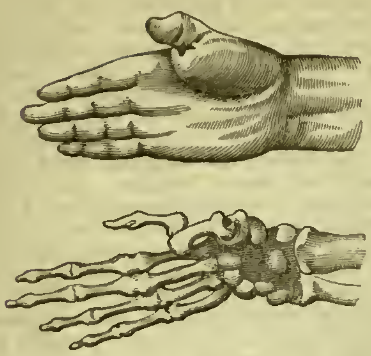
Luxation of the phalanges of the fingers.—The first phalanx of the thumb as well as the first phalanx of any of the fingers may be luxated *backwards;* the luxation *forwards* of the phalanx is very rare and perhaps impossible, except in the index finger and the thumb.

The mutual support which the first phalanges of the fingers afford each other laterally, and the strength of the lateral ligaments render the luxation *outwards* or *inwards* very difficult.

Luxations of the first phalanx of the thumb from the metacarpal bone. The first phalanx of the thumb may be luxated *forwards* to the palmar surface of the metacarpal bone, but this form of luxation is very rare, while the luxation of the same phalanx on the dorsum of the metacarpal bone is the most common and important displacement of any to which the bones of the hand are liable. We shall therefore consider this accident in detail.

In some persons the first phalanx of the thumb can at will be dislocated backwards, solely by the contraction of the muscles. The displacement produced by accident, however, is much more extensive than this, which may be termed the *voluntary luxation*. When the first phalanx of the thumb is in a state of extreme extension, accident may dislocate it on the dorsum of the metacarpal bone. The signs of the injury are so evident that mistake appears impossible; the first phalanx is thrown back as if pulled by its two extensors, and forms nearly a right angle with its metacarpal bone (*fig.* 226); the head of the latter forms a remarkable tumour at the anterior part or palmar aspect of the articulation, while a prominence behind points out the situation of the base of the first phalanx: the last or distal phalanx is (in recent cases) flexed, and it soon becomes difficult or impossible to extend it, or to flex the first phalanx.

Fig. 226.



Luxation of the first phalanx of the thumb on the back of the metacarpal bone.

Anatomical characters of this accident. Opportunities of ascertaining by dissection the actual condition of the parts when luxation backwards of the first phalanx of the thumb has recently happened, of course do not occur, but from the dissection of old unreduced injuries of this kind,* and from experiments on the dead subject, we are led to infer that the immediate effects of the injury are, extensive laceration of the anterior part of the synovial membrane, and of one or both the lateral ligaments, while the posterior portion of the capsule remains entire; the base of the first phalanx is dragged to a considerable extent upon the dorsum of the metacarpal bone, elevating with it the tendons of the extensor primi and secundi internodii pollicis; the tendon of the flexor pollicis longus is carried inwards and under the head of the metacarpal bone. As the extensor ossis metarcarpi and opponens pollicis are not attached to the first phalanx, they are little affected by the luxation, but the condition of the three remaining muscles which are inserted into the base of the first phalanx requires consideration. These short muscles are the abductor pollicis, the flexor pollicis brevis, and the adductor pollicis.

When the dislocation backwards of the first phalanx of the thumb has occurred, the large head of the metacarpal bone is at the same time thrown inwards towards the palm, and having forced its way between the two origins of the flexor pollicis brevis, the shaft of this bone, which is comparatively much narrower than the head, becomes tightly embraced by the two fleshy columns of the muscle. This is a state of things which should be taken into account when the obstacles to the reduction of this dislocation are considered, nor should it be forgotten that the direction and relative position of the points of attachment of all the muscles concerned must be altogether changed when the complete luxation has occurred; their origins and insertions are more than naturally approximated, and the line of direction of their action is thrown much behind the longitudinal axis of the metacarpal bone; the tendons of the extensor primi and secundi internodii, and of the flexor pollicis longus are of course carried by the dislocated bone behind their usual line of action; hence the action of all these muscles, after the luxation has occurred, becomes materially altered, their contraction will no longer be resisted by the lateral and capsular ligaments, and the bone will be drawn upwards and backwards by them, a considerable distance on the dorsum of the metacarpal bone (*fig.* 226). The flexors have their direction so altered and so thrown behind the longitudinal axis of the metacarpal bone of the thumb, that they now no longer act as flexors of the first phalanx to approximate it to the palm; on the contrary, they now have become extensors of the dislocated phalanx, and tend much by their contraction to increase the deformity.*

This dislocation is difficult to reduce, particularly if the nature of the accident have not been speedily recognized. Various causes have been assigned for the opposition to the return of the bone; some think with the late Mr. Hey of Leeds, that a transverse section of the head of the metacarpal bone presents in its outline somewhat of a cuneiform figure; and that, in consequence of the narrowest part of the wedge being thus placed anteriorly, it can easily under the influence of accident glide towards the palm by passing between the lateral ligaments which remain unbroken, and resist all return of the bone backwards to its original situation. Others imagine that the interposition of the anterior ligament and sesamoid bone attached to it between the articular surfaces constitutes the principal obstacles to the reduction of this luxation. Again it has been asserted that the tendon of the flexor longus pollicis has been twisted spirally under the metacarpal bone, while some with more appearance of truth have supposed that the muscles are the principal sources of resistance. The learned author of the First Lines of Surgery has expressed his opinion that the return of the dislocated phalanx to its place is opposed by a combination of causes, viz.—the cuneiform shape of the bone and the resistance of the lateral ligaments, as suggested by Hey, the force of the muscles, and, lastly, he adds, because the surface for the application of the extending means is very limited. To most of these observations we have reason to object, particularly to the last, because we believe that all the force which it is justifiable to use may be easily applied; and we should

* See London Medical Gazette for Oct. 14, 1837, J. A. Lawrie, Glasgow.

* In the experiments made by my colleague Mr. Mayne and myself on the dead subject, when we forcibly dislocated the first phalanx backwards, we found the anterior part of the synovial membrane and the external lateral ligament torn across; the first phalanx was placed as in *fig.* 226. We found the head of the metacarpal bone driven between the two heads of the flexor pollicis brevis in such a way, that the external head of the muscle was placed upon the outside of the shaft of the bone in company with the abductor pollicis, while the internal was situated at the inside of it, along with the adductor and long flexor tendon.

ever keep in mind a case given on the authority of Mr. Hey, who informs us that the celebrated Mr. Bloomfield reported to his class of pupils at St. George's Hospital, London, that he knew a surgeon increase the force of extension to such a degree in attempting reduction of this dislocation, that he tore off the thumb at the second joint.

The idea that a transverse section of the head of the metacarpal bone presents an outline of a cuneiform figure with the narrowest part of the wedge towards the palm, or forwards, was first advanced by Mr. Hey, and has subsequently been adopted with too little reflection by many writers: for our part we do not think that the head of the metacarpal bone does present this form assigned to it by Hey. But even although it be conceded that it has occasionally a form which would answer to the description given by Mr. Hey, and that its cuneiform figure would facilitate its gliding between the lateral ligaments and forbid its return, surely such an obstacle to the return of the bone would suppose a state of integrity of both lateral ligaments. In our experiments on the dead subject, we found one of these lateral ligaments invariably torn whenever a complete luxation was effected; but with the theory of Hey, which seems to us quite unsupported by the normal anatomy of the bone or the anatomy of the accident, how can we reconcile the observation, that when the first phalanx of the thumb is dislocated to the palmar instead of the dorsal aspect of the metacarpal bone, equal difficulty of reducing the luxation has been experienced by very eminent surgeons! For example, Velpeau says, "we have seen but once the first phalanx of the thumb pass in front of the first metacarpal bone. The subject of this accident was a woman aged forty-five years; the bone had been out for three days, there was no inflammation." I thought, says Velpeau, "that it was owing to some want of skill in myself that I could not succeed in reducing the luxation; but M. Professor Bougon also made fruitless efforts to effect it; finally, M. Roux, with his well-known address and ingenuity, was not more successful, and the bone remained ever afterwards unreduced."*

Upon the whole it would appear to us that in the case of the dislocation of the first phalanx of the thumb on the dorsum of the metacarpal bone, the cause of the difficulty we experience in reducing it will not be found either in the mechanical resistance of the lateral ligaments or in the interposition of muscular or fibrous parts between the extremities of the dislocated bones, but that, whether the luxation be the common one backwards or the more unusual one forwards, the *vital contraction* of numerous muscles on a small and yielding bone (whose ligaments have been lacerated) will be the principal opposing force we have to contend with. Most of these muscles will be found to be favourably circumstanced for the opposition, for they are either inserted into or attached very close to the bones of the first phalanx of the thumb: they are six in number; some of them are of considerable length, and the aggregate force of both long and short muscles constitutes a very powerful means of maintaining displaced the first phalanx of the thumb; nor should it be forgotten, in estimating their force, that the very large supply of blood-vessels and nerves which these muscles receive, must add much more to the energy of their contraction than the size and number of their composing fibres would lead us to suppose.

If such a view of the abnormal condition of the different structures which compose this articulation be correct, we should derive from it the important practical precept, that when we have one of those difficult cases to contend with, our first effort should be to reduce, as much as practicable, the irritability and vital force of the muscles which act on the dislocated bone before any of our mechanical appliances be resorted to. When the general system of the patient has been under the depressing influence of the usual means, viz. tartarized antimony, &c., and under these favourable circumstances the surgeon has with patience and perseverance used all the force that he deems expedient or justifiable, and has not succeeded in replacing the bone, our experience would induce us to recommend that in such a case no further measures should be had recourse to. We have, in the museum of the Richmond Hospital, a cast of the hand of a man who had suffered this luxation sixteen years before the cast was taken. The history he gave the writer was briefly that he consulted an eminent surgeon, who used all the means in his power to reduce the dislocation, but could not succeed; that the surgeon then proposed to the man an operation which he explained, and which from the patient's description of it we may conclude consisted in laying bare the head of the metacarpal bone and removing it, as had been about that time recommended by Mr. Evans, of Kettley near Wellington; the man, however, refused to consent to the proposal, and had good reason to be content with his own determination, as he can now oppose the point of the thumb to the other fingers, and can follow his business, which is that of a plasterer, with very little inconvenience, affording us a proof that the advice given by Sir A. Cooper relative to irreducible dislocations of the metacarpal bone, may be well extended to the common dislocation backwards of the first phalanx, viz. "that if the bone cannot be reduced by simple extension, it is best to leave the case to that degree of recovery which nature will in time produce, rather than divide the muscles or run any risk of injuring the nerves or the bloodvessels."

The first phalanges of any of the other fingers may be luxated backwards. The little finger appears to us, after the thumb, the most liable to this accident; it is sometimes difficult to reduce. Mr. Romer, a pupil of the Richmond Hospital, lately brought to the writer a patient who was the subject of luxation of the

* Velpeau, Traité d'Anatomie des Regions, tom. i. p. 475, edit. 1825.

first phalanx of the little finger on the back of its metacarpal bone. This patient was a female about thirty-five years of age; the bone had been only a few hours luxated, and some ineffectual attempts had been previously made to reduce it. The reduction was effected with some little difficulty by at first increasing the extension, and then by forcibly flexing the last phalanx. In this case the long extensor tendon of the little finger was displaced from its sheath and groove, and lay on the ulnar side of the metacarpal bone and luxated phalanx, and never afterwards could be maintained in its proper place. This accident is very easily recognized, yet it has been occasionally left unreduced.

It has been stated already that luxation of the first phalanx of the thumb forwards may occasionally happen, and we have also good authority for supposing that a similar luxation may occur to the phalanx of the index finger. These accidents, however, are very rare; the middle, ring, and little fingers have never been seen thus displaced; indeed, Boyer seems to think such an accident in these last, impossible from the nature of their articulation with their metacarpal bones.

Luxation of the second, and third or distal phalanges.—The articulations of these phalanges being only covered by the skin and the tendons of the flexor and extensor muscles, their luxations are also very easily recognized. In the luxation backwards, the only one which we have had occasion to observe, the luxated phalanx is turned to the side of extension, and forms with the phalanx above it an angle more or less open. When it is the second phalanx which is luxated, the third is flexed by the elongation of the tendon of the deep flexor, and it is impossible to extend it or flex the second. The reduction of these luxations is generally easy if time be not allowed to elapse between the occurrence of the luxation and the period of attempting its reduction.

II. DISEASED CONDITIONS.

Caries and necrosis occasionally affect the bones of the hand, but the complete descriptions of these diseases, which have been elsewhere given in this work,* render superfluous here any special observations on these morbid actions when they manifest themselves in the region of the hand. The bones of the metacarpus and phalanges are very frequently deformed by a disease which (although it cannot be said to be exclusively observed in these bones) produces on the hand and fingers appearances too remarkable to be left unnoticed in this place.

The disease which we wish to describe as we have seen it in the bones of the hand would be by some designated as exostosis,† by others as benign osteo-sarcoma, and others‡ would be disposed to preserve the somewhat objectionable but ancient name of spina ventosa.

The metacarpal bones and the phalanges of the fingers are the usual seat of this disease, and in general many of them are simultaneously engaged in it; the shafts of the affected bones are usually swelled out by the disease into tumours somewhat of a globular form, the articular extremities of the bones remaining perfectly free. It is by no means unusual to see the first and second phalanx of a finger forming two distinct globular swellings, while the last or distal phalanx is perfectly free from enlargement.

It has been already mentioned that these tumours, when viewed externally, seem to have a spheroidal form; but when the integuments of the bony shell which incloses the tumours are removed, we discover on their palmar aspects the flexor tendons buried in deep grooves. This is of course best seen when the disease has existed long, and the tumours have attained a considerable size.

If we have an opportunity of examining anatomically the phalanges while the disease is yet in its early stage, we shall find reason to conclude that the morbid process had commenced deep in the interior of the bone, and that the tumour proceeding outwardly presented itself first on that aspect of the phalanx, or metacarpal bone, where there was the least resistance opposed to it; hence we usually notice these tumours, when small, shewing themselves most on the dorsal aspect of these bones. As the disease increases they swell out laterally, and the whole circumference of the phalanx would be equally expanded were it not for the support given on the side of flexion by the flexor tendons and their strong fibrous sheaths. The integuments of these tumours preserve their natural sensibility, and are at first freely moveable over them; but as the swellings gradually increase and undergo a species of softening in certain points, the integuments become adherent at these points, and circular openings are formed in them which correspond to similar circular apertures in the shell of the bone, and through which the bony cysts discharge their contents; these swellings of the bones of the hand, as far as we know, never degenerate into any disease of a malignant nature; but when they attain a considerable size, and are excavated by these cysts, and have large fistulous orifices, the irritation they produce and the discharge cause some febrile excitement of the constitution, and amputation may become necessary. The following very remarkable case clearly proves the non-malignant nature of this disease; the history of it will serve well to illustrate the natural progress of this form of disease in the hand.

A countryman of rather a delicate appearance, aged twenty-four years, was admitted into Jervis-street Hospital, July 22, 1828, under the care of Dr. O'Beirne. This man had an enormous enlargement of the left hand, which arose from a tumour, the principal seat of which was in the first and second phalanges of the middle finger, but the ring and index finger

* See BONE, *morbid anatomy*.

† See Scarpa, De Anatomia et Pathologia ossium, cum tabulis æneis, tab. vi. *fig*. 1, Exostosis ossium plerorumque manus dexteræ.

‡ Boyer, Maladies Chirurgicales, vol. iii. p. 579.

were also involved in the disease, and the three metacarpal bones supporting the three fingers already mentioned were also much enlarged; in a word, all the bones of the metacarpus and fingers, with the exception of those of the thumb and little finger viewed externally, seemed to enter into the formation of one morbid mass, the size and form of which may be best conceived by a reference to the annexed figure.

Fig. 227.

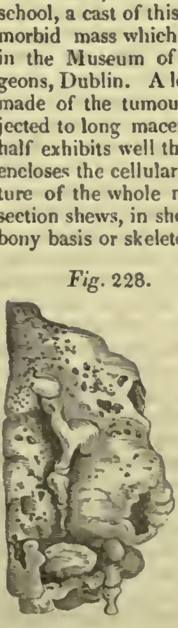
The chief bulk of this large bony tumour existed posteriorly, where it extended as high up as the line of the wrist-joint, and completely concealed the bones of the carpus. The tumour did not extend itself directly forward towards the palm of the hand, but passed downwards; at its remote extremity the last phalanx of the middle finger was to be seen projecting; this phalanx was itself, however, perfectly free from morbid change, and the integuments covering it possessed their natural sensibility. The circumference of the tumour measured accurately twenty-four inches; numerous very large protuberances shewed themselves every where on its surface, which yielded but little to pressure. Three of these tumours had ulcerated at their most prominent points, and by circular depressed openings (nearly an inch in diameter) gave exit to a thin fœtid ichorous matter, which continued to flow from the interior of the morbid mass. These orifices, which presented some loose granulations, readily admitted the introduction of a probe, which could be then freely moved in the interior of these cavities, each of which was large enough to contain an ordinary hen's egg. The integuments every where over the whole of this morbid growth had a perfectly healthy aspect, and were freely moveable on this immense tumour, except at the borders of the circular apertures already mentioned. The disease existed for many years, having begun, as the patient stated, when he was a boy.

The disease was unaccompanied by pain, and the man's health continued good until the period when the tumour had ulcerated; after which he became somewhat debilitated by the exhausting effect of the sanious discharge on his constitution, and his mind was depressed with the idea of his being afflicted with a disease so formidable in appearance, and which hitherto had resisted, nay increased under, all treatment, and deprived him altogether of the means of earning a livelihood. Although there was some difference of opinion as to the name by which this disease of the bone should be designated, it was agreed that there was nothing really malignant in its nature; most of those consulted on the case recommended amputation, but Doctor O'Beirne conceived the happy idea, and speedily put it into execution, of cutting out the morbid mass. Although it was rightly conceived that the index finger was but little diseased, and that the ring-finger was merely enveloped in the tumour, still the thought of preserving either of these fingers could not be for a moment entertained, as the metacarpal bones supporting them were known to be diseased. It was plain that the thumb and little finger only could be saved, and the lines of incision which were followed may be easily imagined. The operation was performed thus: one incision was commenced at the root of the little finger at its radial side, which was extended deeply through the soft parts upwards and backwards as high nearly as the wrist-joint; the termination of this incision here was met by another, which was commenced at the first interosseous space between the index finger and the thumb; the lines of these incisions were followed deeply, and, with the assistance of the knife and metacarpal saw, the whole of the morbid mass was removed; the hæmorrhage was soon arrested, and dressings applied with a bandage to approximate gradually the thumb and little finger. The wound was at first refractory, and cartilaginous granulations sprang up; to repress these, Dr. O'Beirne found nothing so effectual as the actual cautery, and under its influence the wound healed kindly.

It is now nine years since the operation was performed, and the man has, during that period, enjoyed vigorous health; the thumb and little finger have approached each other, and increased much in size, power, and usefulness, and he is fully competent to follow his occupation, which is that of a land-surveyor.

We have, in our collection at the Richmond school, a cast of this remarkable hand; and the morbid mass which was removed is preserved in the Museum of the Royal College of Surgeons, Dublin. A longitudinal section has been made of the tumour: one half has been subjected to long maceration, and dried; and this half exhibits well the thin osseous shell which encloses the cellular and reticulated bony structure of the whole mass;—this portion of the section shews, in short, the true structure of the bony basis or skeleton (if we can so say) of the disease (*fig.* 228). The other half of the section has been preserved in spirits, and in the line of division shews a smooth cartilaginous surface, and several excavations lined by a smooth membrane, which had enclosed an albuminous fluid. Some of these cavities were complete isolated cysts, buried deep in the interior of the cartilaginous mass; but the contents of three of these cysts had made their way ex-

Fig. 228.



ternally through the large circular apertures already mentioned.

We have thought it right to detail this remarkable case at length, as it is the history of an important fact, from which, it is true, different conclusions may be drawn; for our part, we consider the case a well-marked specimen of a disease described by some of the older writers as spina ventosa. Boyer adopts this appellation, and in his work will be found a good account of the disease; and, indeed, he so accurately depicts the appearances we observed in this case, and which were discovered by dissection, that we feel satisfied his description has been drawn from nature. Boyer says, "We understand by spina ventosa an affection of the cylindrical bones, in which the walls of the medullary canal are subjected to a slow, gradual, but sometimes enormous, distension; while, at the same time, they are considerably thinned, and even pierced in many points, in which their tissue undergoes a singular rarefaction,—a disease whose primitive seat would appear to reside in the medullary cavity," &c.

Sanson, from two careful dissections of recent specimens of this disease, considers it to originate in a degeneration of the membrane which lines the interior of the bone. The substance which is found to fill up the cavity of the bone can only proceed from the system of the medullary membrane, the action of which becomes so altered and diseased, as to produce the new growth which is found in the interior of these globular tumours. This product distends by degrees the walls of the medullary canal and reticular structure of the bones. The dilatation, in which the articular surfaces do not participate, is generally sudden, so that the part immediately near the point where the disease is situated preserves its natural dimensions. When the globular tumours thus formed are cut into, in the early stage of the affection, their interior presents a fibro-cartilaginous appearance, surrounded by a thin shell of bone. A section of one of those tumours of the fingers in the early stage appears to us to present a striking resemblance to the common fibrous tumour of the uterus, which is often encased in a similar bony shell. The description Mr. Crampton has given of the structure of the benign osteo-sarcoma may well be applied to this disease. He says, "the interior of the tumour presents a great variety of structure, but I should say, in general, that the cartilaginous character which the tumour exhibits in its origin prevails to the last. In the *early* stages of the disease, the tumour consists of a dense elastic substance, resembling fibro-cartilaginous structure; but the resemblance is more in colour than in consistency, for it is not nearly so hard, and it is granular rather than fibrous, so that it breaks short. On cutting into the tumour, the edge of the knife grates against spiculæ, or small grains of earthy matter with which the substance is beset. If the tumour acquires any considerable size, it is usually found to contain cavities filled with a fluid differing in colour and consistency; but in general the fluid is thickish, inodorous, and of the colour of chocolate. Sometimes the growth of the tumour, and the secretion of the fluid within its substance, is so slow, that the deposition of bony matter keeping pace with the absorption, the bone becomes expanded into a large thick bony case, in which the tumour is completely enclosed."*

Strumous osteitis of the metacarpal bones, and of the phalanges of the fingers.—It is by no means difficult to distinguish the disease last described under the name of spina ventosa, or benign osteo-sarcoma, from that enlargement of the metacarpal bones and of the fingers which we frequently witness in children of the strumous diathesis. The strumous affection of the phalanges we allude to seems little else than an osteitis, which terminates usually either in caries or necrosis. The disease, when fully formed, shows itself in the shape of either a pyriform or globular swelling of the phalanx of one or more of the fingers. There is at first no sensible alteration of the surrounding soft parts; the swelling has usually been preceded by pains of a dull and obtuse character; the movements of the part affected are for a long time preserved, and indeed are not at all restrained, except when the tumefaction of the bone becomes sufficient to turn aside the tendons from their natural direction, or to cause deformity of the articular surfaces, which rarely happens.

As the disease advances, the soft parts are distended, suppuration takes place, and the integuments of the swollen part always ulcerate at a point corresponding to some deficient part of the bony cylinder. Through the ulcerated opening a probe may be passed freely into a cavity which the bone contains; the opening becomes fistulous, and for a long time continues to give exit to a moderate quantity of thin, serous, and ill-conditioned matter; sometimes, however, we notice an improvement in the general health of the patient, and, at the same time, the local disease assumes a new and more favourable aspect, the discharge diminishes, and at length dries up. Such a decided amendment, however, seldom occurs, until a process of necrosis, or exfoliation of a part of the bone, has taken place; after which the wound heals up, the use of the finger is restored, and all that remains of the disease is an unseemly, depressed, and adherent cicatrix.

Malignant tumours of the hand.—Malignant osteo-sarcoma, and even fungus hæmatodes, are diseases which may show themselves in the region of the hand and fingers; but these diseases are readily distinguished from the spina ventosa, or benign osteo-sarcoma, above alluded to. The pains of the malignant disease are lancinating, the progress is more acute, the constitution and health are more quickly and deeply implicated; the prognosis, too, is very different. Although life may perhaps be prolonged by an amputation of the hand of a patient affected by either of these malignant diseases, the terrible disorder will almost uniformly recur. On the contrary, if the disease be spina ventosa, a portion of the hand may be amputated, or a finger removed, and the disease shall not recur

* Vide Dublin Hospital Reports, vol. iv. p. 542.

after these operations. Indeed, we feel persuaded that, in some cases of spina ventosa, (*fig.* 229) the tumour may be cut off from a finger or from a metacarpal bone, and that although the wound may for a while throw up cartilaginous granulations, still, under proper treatment, the ulcer of the bone will be got to heal kindly.

Fig. 229.

Abnormal conditions of the fingers the result of accidents and morbid affections of one or more of their constituent structures.—We occasionally find that the voluntary power of flexing or extending the joints of the fingers is lost. This loss of power may arise from a great variety of causes;—anchylosis of a joint from acute or chronic inflammation; the loss of an extensor or flexor tendon from a similar cause, or from a wound; congenital malformation of the brain; disease or accident affecting this organ, the spinal marrow, or the nerves connected with the movements of the upper extremity; any of these may at times be the source of this loss of the voluntary power over the fingers. Under these circumstances, although there may be but little external deformity, sometimes the fingers cannot be flexed; more frequently they cannot be voluntarily extended. An abnormal condition of the fingers, shewing itself in some distortion of these organs, may be traced to causes affecting—1, the skin; 2, the fascia; 3, the theca of the tendons; 4, the tendon itself; and 5, the bone. If a burn penetrate the skin on the palmar surface of the hand, a dense cicatrix will be formed; and much exertion will be necessary, on the part of the surgeon, to oppose successfully the gradual contraction of the "tissue of the cicatrix." Should contraction take place, notwithstanding these efforts, the functions of the hand will be impaired, and much deformity will remain. A burn on the back of the hand may be followed by analogous effects.

There is a peculiar form of contraction of the fingers, which Boyer seems to ascribe (we believe erroneously) to a shortening of the tendons. Adopting the language of the ancients, he denominates the affection "crispatura tendinum." This contraction of the fingers is never seen in very young persons. Most of those we have known affected by it were adults, who had been for a long time compelled to make laborious use of their hands. The disease will be ordinarily found to commence in a contraction of the little finger; the ring finger is next engaged, and then the middle finger. From day to day the fingers become more contracted, and the power of extending them is lost. When one hand is thus affected, it usually happens that the other soon becomes equally engaged. It is remarkable that neither the indicator nor the thumb have ever been seen affected with this disease.

When we examine the fingers the subjects of this species of contraction (*fig.* 230), we find that the first phalanx is moveable on the metacarpal bone, and is flexed at an angle more or less approaching to a right angle. We can flex it a little more towards the palm; but to extend it so as to efface the angle is impossible; "a weight," says Dupuytren, "of 150lbs. will not bring the finger into a straight line with its metacarpal bone." Boyer says, "our efforts to extend the fingers are resisted to such a degree, that if we continued them they would break before we could force them to yield."

Fig. 230.

Contraction of the fingers from disease of the palmar fascia.

This description, however, applies only to the metacarpal joint of the first phalanx, for the last phalanges of each affected finger, though moveable, habitually remain perfectly straight.

In these cases the integuments of the affected palm and the subjacent fascia seem to be more than naturally thick and consolidated, and we observe the lowest of the natural cutaneous lines of the palm thrown into a very deep crescentic fold, the concavity of which looks towards the fingers, and the convexity towards the wrist joint. We also invariably notice in these cases a rounded projecting chord which passes downwards from the middle of the palm of the hand to the basis of the first phalanx of the contracted finger. This chord feels hard, and is rendered more tense and salient whenever we make an effort to straighten the affected finger.

When in the living subject we examine carefully the palmar fascia, and explore, as far as we can, its connexion above with the tendon of the palmaris longus, and below, follow the prolongations it sends to the lateral aspect of the contracted fingers, we find them all continuous; in a word, when we press upon the tendon of the palmaris longus, we make tense the tendinous digitations above-mentioned. The continuity of all these fibrous structures is thus evident in the living. When we have opportunities of examining, in the dead subject, a hand in which this contraction of the palmar aponeurosis has existed, and have raised the skin in all its extent from the palm of the hand and palmar surface of the fingers, its folds and rugæ all disappear, and it then becomes evident that this defect does not reside in the skin. When the aponeurosis is exposed, it is found contracted, thickened, and diminished in length. From its inferior part, the tense fibrous chords which were already supposed to exist are now exposed, and seen to be inserted into the periosteum on the lateral aspects of the contracted finger.

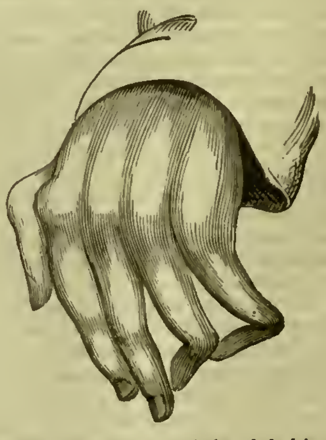
Dupuytren, by various anatomical and pathological investigations of this disease, satisfied himself that this peculiar contraction of the fingers depends essentially on this shortening, thickening, and organic alteration of the palmar aponeurosis and the digitations proceeding from it to the sides of the fingers; for he invariably found when he had opportunities of investigating this disease in the dead subject, that the tendons were of their accustomed volume and mobility. He cut them across, and then made efforts in vain to extend the finger. The bones were found of their natural form, and no alteration was perceptible in either the synovial membranes or lateral ligaments; but as soon as the section of the expansions of the fascia which go to the fingers was effected, the flexion disappeared, and the finger could be brought to its normal position. Finally, he infers, and indeed, as far as a few instances go, he proves, that a similar result will follow the division of the fascia in the living subject, and that the proper use and adjustment of a peculiar splint on the back of the forearm and hand, so as to keep the affected fingers for a time extended, will complete the cure of this disease.

Sir A. Cooper alludes to these deformities when he says, "The fingers are sometimes contracted by a chronic inflammation of the theca and aponeurosis of the palm of the hand, from excessive action of the hand in the use of the hammer, the oar, ploughing, &c.," evidently recognising two species, in one of which the aponeurosis is the cause of the contraction, and the contracted hand is narrow. "And this hand," he adds, "may with advantage be divided by a pointed bistoury, introduced through a small wound in the integuments; the finger may be then extended, and a splint applied to preserve it in the straight position." But he observes that "where the theca is contracted, nothing should be attempted for the patient's relief, as no operation or other means have succeeded."

Anchylosis of some of the joints of the phalanges sometimes succeeds to an attack of acute or chronic inflammation of one or more of these small articulations; this may have arisen from disease; for example, paronychia or accident; but from whatever cause the inflammation has arisen, anchylosis of a finger in the extended position, which cannot be contracted, or of a joint in the flexed position, which cannot be extended, is the too frequent result. The history of the case, and the actual state of the anchylosed joint, which cannot be overlooked, will prevent the surgeon from falling into any error in his diagnosis. A contracted state of the ring finger and little finger is frequently to be noticed in those who have suffered much from gout; but we are acquainted with no disease which more frequently produces deformity of the hand and fingers than *chronic rheumatism* (chronic rheumatic arthritis). This morbid condition of the joints of the hand is too cursorily alluded to by authors under the head of rheumatic gout, nodosity of the joints of the fingers, &c. &c. It is a complaint which is erroneously supposed to be met with only in elderly persons. We have, however, in the pauper department of the House of Industry in Dublin, examples of it in females under the age of 30; but of course it is more frequently observed in the aged and rheumatic patient. When the disease has existed long, the whole hand becomes greatly deformed, and the distortion the fingers have undergone in these cases is of itself calculated to impress us with a correct idea of the sufferings the victims of this disease have endured. The carpus is usually preternaturally convex on its dorsal aspect, owing to the thickening and distension of the synovial bursæ, which become like solid ganglions. All the joints of the hand and fingers become enlarged, particularly those which are formed by the junction of the first phalanges and metacarpal bones; at these joints the fingers are more or less flexed towards the palm, and are, at the same time, adducted or drawn to the ulnar side of the hand.

The head of the metacarpal bone, where it joins with the first phalanx of the index finger, seems particularly swelled and enlarged, and projects much towards the radial side and dorsal aspect of the hand, as is represented in *fig.* 231.

Fig. 231.



Chronic rheumatism, or nodosity of the joints.

The last phalanx of a finger is frequently flexed, while the middle phalanx is extended. Whatever be the faulty position which the fingers happen to have assumed, they are usually found to be remarkably rigid. All movements of them, whether voluntary or communicated to them, are painful; and in either case commonly a crepitus, produced by the contact of rough surfaces, is perceived both by patient and physician when making the examination.

When this disease exists in the hand to this amount, it will almost invariably be found that the distressing complaint has also extensively engaged most of the other articulations.

When we make an anatomical examination of the hand of those who have died with the condition of the joints of the fingers above described, we find that the synovial fluid is somewhat thicker than usual, and deficient in quantity. In some of the anchylosed joints we observe a species of fibro-cellular or ligamentous union of the bones; almost all the joints are deprived of their cartilaginous incrustation, which seems as it were to have been worn away by friction; the porous structure of the root of the phalanges is often exposed, and in some cases hollowed out, to accommodate the enlarged head of the metacarpal bone; a cup is formed in the base of the phalanx which is lined with a porcelainous deposit, while around this little cup an exuberant growth of new bone of a looser texture is thrown out. In the removal of the cartilage without suppuration—in the substitution for it of a porcelain-like deposit, and in the surrounding exuberance of new bone, we find this disease of nodosity of the joints of the fingers resembling accurately the analogous affection of the other joints, which has been supposed to be the slow effects of chronic rheumatism.—See Elbow, Knee, Hip, Abnormal Anatomy of.

III. Congenital malformations of the hand.

Children are occasionally born with one or two fingers more than the natural number. The supernumerary finger almost invariably is found to be an imperfect vegetation, growing from the ulnar side of the hand, and in general the deformity is found to exist on both hands. Examples, however, have been, though rarely, seen of a sixth finger parallel to the other fingers, and properly supported by a sixth metacarpal bone.

It frequently happens that children are brought into the world with their fingers united together. This union may be complete, or the connexion may be loose by means of the skin. It is known that up to the second or third month of intra-uterine life an interdigital membrane exists, and the abnormal condition of the fingers we are now considering is nothing but a persistence of the early condition of the fingers in the fœtal state. It seems pretty well proved that these congenital defects are very frequently hereditary, and that whenever the fingers are the seat of them, the toes are similarly affected.

The whole hand, or one or more of the fingers may suffer in utero what has been denominated spontaneous amputation, and the stump will present peculiarities already noticed.—See Fœtus, *fig.* 155, 159.

(R. Adams.)

HAND, MUSCLES OF THE. (Human Anatomy.)

The varied and beautiful movements of which the hand is capable are effected by muscles belonging to separate and distinct regions,—namely, one set of muscles which are the proper and intrinsic muscles of the hand itself, and a second set, which are continued into the dorsal or palmar region of the hand from the posterior or anterior surface of the fore-arm. In the present article it is proposed to describe the intrinsic muscles of the hand; but in considering the actions of that member or of any of its segments, it will be necessary to notice how far the second set of muscles contribute to or aid in their production.

The proper or intrinsic muscles of the hand may be divided into—1, those on the palmar; 2, those on the dorsal surface.

I. The muscles of the palm are fifteen in all. For convenience of description they may be classified into, *a*, those of the thumb, or *external palmar region*, constituting the *thenar* eminence; *b*, those of the little finger, or *internal palmar region*, forming the *hypothenar* eminence; c, those that occupy the hollow of the hand, or the *middle palmar region.*

a. Muscles of the external palmar region.—The muscles of this region, all of which belong to the thumb, are four.

1. *Abductor pollicis manus** *(scaphoido-phalangien*, Cruveilh.) short, flat, broader above than below; it arises from the anterior surface of the scaphoid and trapezium, the superior, anterior, and external part of the anterior annular ligament, and generally from a prolongation of the tendon of the extensor ossis metacarpi, by aponeurotic and fleshy fibres. It proceeds outwards and downwards to be inserted into the outer edge of the upper extremity of the first phalanx of the thumb. Sometimes the two origins of this muscle are not incorporated for some distance, giving the appearance of two muscles.

Relations.—It is covered by the skin and external palmar aponeurosis. It covers the opponens, a few fibres of which appear to its radial side, running in a transverse direction. It is separated by a thin cellular line from the short flexor, which is on the same plane.

The obvious action of this muscle is to draw the thumb forwards and inwards, thus separating it from the fingers.

2. *Flexor ossis metacarpi*, or *opponens pollicis (trapezo-metacarpien*, Cruveilh.), of a rhomboidal form; it arises from the trapezium, and from the fore part of the anterior annular ligament, anterior to the sheath for the radial flexor of the wrist, by long aponeurotic fibres; and posteriorly from a septum between it and the short flexor. From these attachments the fleshy fibres radiate downwards and outwards, being so much the shorter the higher and the more transverse they are. They terminate by

* Soemmering and Albinus divide this into two distinct muscles, the former giving them the names *abductores breves pollicis manus interior et exterior;* the latter calls the internal portion *abductor brevis alter.*

short aponeuroses along all the outer edge of the first metacarpal bone.

Relations.—With the exception of a small portion of its external border, this muscle is covered anteriorly by the preceding muscle. It covers the anterior surface of the first metacarpal bone, and its articulation with the trapezium.

It draws the thumb inwards, turning it upon its own axis, so that it opposes its palmar aspect to the other fingers.

3. *Flexor brevis pollicis manus (trapezo-phalangien,* Cruveilh.) is a larger muscle than the two preceding ones, triangular, bifid superiorly, having its anterior surface channelled; arises by aponeurotic and fleshy fibres, externally from the fore and under part of the annular ligament, and from the process of the trapezium, internally and posteriorly from all the reflected portion of the annular ligament, forming the sheath for the radial flexor and extending to the os magnum, and from the os magnum often by a distinct portion. From these various origins the fleshy fibres run downwards and outwards, are more oblique as they are more internal, and terminate in a strong fleshy bundle which is attached to the external sesamoid bone and outer side of the first phalanx.

Relations.—This muscle is covered by the external palmar aponeurosis, more internally by the tendon of the long flexor of the thumb, then by the common flexor tendons. It covers the first dorsal interosseous, the tendon of the radial flexor of the wrist, and a small portion of the external margin of the adductor of the thumb. Its outer edge corresponds to the abductor and is often confounded with the opponens, and its inner would be undistinguishable from the abductor near the first metacarpal bone, if it were not separated from it by the arteria magna pollicis,*—a fact that appears to have been overlooked by many anatomists, or the descriptions of the attachments of this muscle would never have been so much at variance: the foregoing description coincides with that of Meckel and Cruveilhier. Its tendon of insertion is covered by that of the abductor, which is external to it.

This muscle is badly named, at least if names be intended to denote action, for its power of flexing the thumb is very slight; but it has considerable power as an opposer of it, its insertion being especially favourable to that action.

4. *Adductor pollicis manus (metacarpo-phalangien du pouce,* Chauss.) is the largest muscle of the thumb as well as the most internal; in shape it is a perfect triangle, arising from all the anterior border of the third metacarpal bone, from its articulation with the magnum, from the anterior and superior portion of the trapezoid, and from the palmar interosseous aponeurosis in its central portion. From this extensive attachment the fibres run transversely outwards, the superior ones being most oblique; they converge to a strong fleshy bundle, which is inserted by means of the internal sesamoid bone into the first phalanx of the thumb.

Relations.—Its two internal thirds are covered by the lumbricales and common flexor tendons, also by a layer of the deep interosseous aponeurosis which constitutes its sheath. It covers the two first interosseous spaces. Its inferior border is subcutaneous, especially posteriorly, where it may be felt in the fold of skin extending from the index finger to the thumb.*

Its name implies its action; it draws the thumb towards the median line of the hand.

b. Muscles of the internal palmar region.—There are four muscles in this region also; one is a cutaneous muscle, the palmaris brevis; the others are proper to the little finger, and are inserted into the inner side of its first phalanx and the fifth metacarpal bone. They consist, as the last described set, of an abductor, short flexor, and an opponens minimi digiti.

1. *Palmaris brevis (peaucier de la main,* Cruveilh.) This muscle when it exists, (for in weakly subjects its fibres are often not to be distinguished, though on the other hand it acquires considerable volume in those that are muscular,) arises by aponeurotic intermingled with fleshy fasciculi which run horizontally inwards, forming a small quadrilateral muscle which terminates in the skin.

Relations.—Covered by the skin and imbedded in the adipose substance, it is spread over the muscles of the little finger and the ulnar artery and nerve, from which it is separated by the internal palmar aponeurosis.

It increases the concavity of the palm by puckering the skin over the part it occupies, thereby drawing the hypothenar eminence forwards and outwards, and rendering it more convex.

2. *Abductor minimi digiti (pisi-phalangien,* Cruveilh.) A long flat muscle, broadest at its centre, arising from the pisiform bone and from an expansion of the flexor carpi ulnaris, by strong aponeurotic fibres, which soon become fleshy, running along the inner edge of the fifth metacarpal bone. It ends in a flattened tendon, which is inserted in common with the short flexor into the inner side of the first phalanx, sending an expansion into the extensor tendon.

Relations.—It is covered by the internal palmar aponeurosis, itself covering the opponens.

Use.—It draws the little finger inwards and forwards, separating it from the others.

* Also deep in the palm, it is generally separated from the adductor by the deep palmar arch.

* Sometimes this muscle is separated into two bellies, the one superior and the other inferior, which are completely separate from each other, and of which the superior is by far the greater. In this case the first arises solely from the os magnum or from this bone and a small portion of the superior extremity of the third metacarpal bone, while the second arises from the inferior portion of the anterior head of the third, fourth, and sometimes even the fifth metacarpal bones; it runs transversely outwards and a little backwards to meet the superior head at the first phalanx of the thumb. This anomaly resembles the normal condition of the transverse and oblique adductors of the great toe. Meckel, Anat. vol. ii. p. 185.

3. *Flexor brevis minimi digiti (unci-phalangien*, Cruveilh.)—This muscle is external to the last; it arises from a small portion of the annular ligament and from the anterior part of the unciform process; it runs downwards and inwards to join the last described muscle, with which it is inserted.

Relations.—At its origin it is separated from the abductor by the ulnar vessels and nerve, but it soon becomes confounded with it. Chaussier described them both as one muscle. It is often wanting. In concert with the last, it abducts and slightly flexes the little finger.

4. *Adductor ossis metacarpi or opponens minimi digiti (unci-metacarpien*, Cruveilh.)—It resembles in disposition and form the opponens pollicis. Having the same origins with the preceding muscle, its fibres proceed downwards and inwards, the superior being nearly horizontal; they are inserted into all the internal border of the fifth metacarpal bone.

Relations.—It is covered by the two last muscles; its posterior surface is applied to the fifth metacarpal bone, the corresponding interosseous, and the tendon of the flexor sublimis going to the little finger.

It carries the fifth metacarpal bone forwards and outwards, thereby augmenting the cavity of the hand, and in a measure opposing the little finger to the thumb, but the articulation of the metacarpal bone with the os unciforme allows of so very little rotatory motion, that it is rather a motion of adduction and flexion than of opposition.

c. Muscles of the middle palmar region.—In the middle palmar region we have seven muscles, four connected to the tendons of the flexor profundus, the lumbricales, so called from their resemblance to earth-worms; and three deeper-seated muscles, the palmar interossei occupying a part of the second, third, and fourth interosseous spaces between the metacarpal bones, the remaining part of those spaces being filled up by muscles; we shall presently examine the dorsal interossei.

1. *Lumbricales (flectentes primum internodium*, Spig.) are four slender, elongated, fusiform, fleshy bundles, attached to the tendons of the flexor profundus, just after it escapes from under the annular ligament, distinguished into first, second, &c. from without inwards. The *first* arises from the fore and outer part of the flexor profundus tendon belonging to the index finger, sometimes also from the accompanying tendon of the flexor sublimis; the *second* lumbricalis arises from the radial side of the tendon of the same muscle destined to the middle finger; the *third* and *fourth* are double penniform arising from the opposed surfaces of the three internal tendons of the same muscle; from these attachments they proceed, the two middle vertically downwards, the outer outwards, the inner inwards, towards the outer side of the metacarpo-phalangeal articulations of the fingers, where they end in flat broad tendons, which are inserted into the outer border of the common extensor tendon, in common with the tendons of the corresponding interossei with which they are confused; they assist in completing the sheath which the extensor tendons form for the back of the fingers.

Relations.—Their anterior surface is covered by the tendons of the flexor sublimis, by the palmar aponeurosis, and collateral vessels and nerves of the fingers. Their posterior surface lies upon the interossei, the inferior transverse metacarpal ligament, and the phalanges.

Use.—They assist in the flexion of the fingers upon the metacarpus, at the same time drawing them outwards, they steady the extensor tendons, keeping them applied to the phalanges.

The *interossei*, of which there are seven in all, are small muscles situated between the metacarpal bones, to which they are attached superiorly, their inferior attachment being to the sides of the first phalanges and the extensor communis tendons; there are three on the palmar aspect, which are simple, and four on the dorsal aspect of the hand, which are bifid muscles; there are two to each interosseous space, excepting the first, which has only one: we shall first examine the palmar interossei.

2. *Interossei interni digitorum manus, (metacarpo-phalangiens lateraux palmaires*, Chauss.) Short, prismatic, and triangular; they arise, the first, or *posterior indicis*, from the root and inner side of the metacarpal bone of the fore-finger; the second, or *prior annularis*, from the root and outer side of the metacarpal bone of the ring finger; the third, or *interosseus auricularis*, from the root and outer side of the metacarpal bone of the little finger. They extend along the metacarpal bones, to which they are attached, and are inserted by short tendons; the second and third in common with those of the lumbricales, into the outer and upper, and the first into the inner and upper part of the corresponding first phalanges and side of the extensor tendons.

Relations.—Anteriorly they are covered by the deep flexor tendons and palmar muscles; posteriorly they correspond to the dorsal interossei, which are also connected with them along their unattached margin.

Use.—The simplest way of regarding their action, which is rather complex, is to refer it towards the axis of the hand or a central line drawn through the third metacarpal bone and the middle finger, in which case it is easily perceived that the palmar interossei are adductors towards the axis of the hand.

II. The only intrinsic muscles on the dorsal aspect of the hand are the dorsal interossei, *interossei externi digitorum manus.* Their common points are, that they appear both on the dorsal and palmar aspects of the hand; they are bicipital; arising from the opposed surfaces of two metacarpal bones, both heads terminating in a common tendon, which is attached to the sides of the first phalanges and extensor tendons that are not supplied by the palmar interossei. They are four in number; the first, or *adductor indicis*, alone merits a particular description. It is the largest; arising from the superior half of the external border of the first metacarpal bone, and externally from all the external surface of the second metacarpal bone;

these origins are separated by a fibrous arch, through which the radial artery passes; they are large and fleshy, and soon unite, forming a triangular flattened muscle, which is inserted into the external side of the first phalanx. The insertion of the other muscles are, the two middle into either side of the first phalanx; they are called the *prior* and *posterior medii;* and the last, or *posterior annularis,* into the internal side of the ring-finger.

Relations.—Posteriorly they correspond to the extensor tendons and skin; anteriorly they appear beside the palmar interossei, from which they are separated by a strong septum derived from the deep palmar aponeurosis. Their other relations are the same as the palmar interossei. The first, the abductor indicis, corresponds anteriorly to the adductor pollicis and part of the flexor brevis, which it crosses at right angles; its inferior and external margin is subcutaneous.

Use.—They are all abductors of the fingers from the axis of the hand, and by reason of their insertion into the extensor tendons, act best when the hand is extended. The same may be said of the palmar.

Before we enter on the general uses of this complex muscular apparatus, it would be well to remark that the proper muscles of the thumb and little finger appear to be nothing more than exaggerated and multiplied lumbricales and interossei. We may, in this light, view the short flexor of the thumb as the first lumbricalis, its abductor and opponens as a dorsal interosseus, while its adductor would represent a palmar interosseous muscle; again, as regards the little finger, its abductor and short flexor together personate a dorsal interosseus, while its adductor would be but an internal or palmar interosseous. Their principal use is, by acting on the carpo-metacarpal articulations of the thumb and little finger, which enjoy freer motion than the intermediate ones, especially that of the thumb, to oppose these extreme points of the hand to each other, more or less increasing its concavity, and thereby giving a firmer grasp, inasmuch as they adapt the cavity of the palm to the volume of the body grasped. The great use of this opposable faculty of the thumb (which action is the peculiar characteristic of the hand as distinguishing it from the foot) may be shewn by firmly clenching the fist, when the thumb, by its combined powers of opposition and flexion, is made to overlap the fore and middle, and in some the third fingers, pressing them firmly against the palm, while, at the same time, the thenar eminence is thrown forwards and inwards, meeting them in the palm, and by abutting against counteracts their tendency to fly open when a blow is struck, acting at the same time as a cushion to deaden the violence of the shock. We here see, also, the flexion of the fingers modified by the radial interossei and lumbricales, which, by their action, throw the fingers radiad, so as to bring the three outer ones to abut against the thenar eminence; the little finger is protected, in like manner, by the hypothenar, which is thrown forwards and outwards. The converse modification of the flexion of the fingers by means of the ulnar interossei may be seen in the action of the left hand of a fiddler, where the fingers are flexed and pointed ulnad to run up the scale.

It only remains for us to give a summary view of the muscles, extrinsic and intrinsic, concerned in the motions of the hand. These motions are flexion, extension, adduction or motion ulnad, abduction or motion radiad. First, the flexors of the wrist are six. 1. Flexor longus pollicis; 2 and 3, flexor sublimis et profundus; 4, palmaris longus; 5, flexor carpi radialis; 6, flexor carpi ulnaris. The extensors are six. 1, Extensor communis; 2, indicator; 3, extensor secundi internodii pollicis; 4 and 5, extensores carpi radiales longior et brevior; 6, extensor carpi ulnaris. The last three of the extensors as well as the last three of the flexors act directly on the wrist; the others act first on the phalanges. These also are the muscles that, in extreme flexion and extension, call into play the motion that exists between the two rows of the carpus, the two former extending, the three latter flexing the second row upon the first.

The adductors are five. 1, Extensor carpi ulnaris; 2, extensor communis; 3, flexor carpi ulnaris; 4, sublimis; 5, profundus.

The abductors are also five. 1 and 2, Extensores ossis metacarpi et primi internodii pollicis; 3 and 4, extensores carpi radiales longior et brevior; 5, flexor carpi radialis.

The following table is intended to exhibit at one view the motions of which the fingers are capable, and the muscles which effect them.

The movements of the fingers are—

1. *Flexion* performed by nine.
   - Flexor longus pollicis.
   - Flexor sublimis.
   - Flexor profundus.
   - Three internal lumbricales.
   - Three interossei interni.
2. *Extension* by eight.
   - Three extensores pollicis.
   - Extensor communis.
   - Indicator.
   - Three internal dorsal interossei.
3. *Adduction* by seven.
   - Three adductor, flexor brevis, and opponens pollicis.
   - Abductor minimi digiti.
   - Three interossei, viz. posterior indicis, posterior medii, posterior annularis.
4. *Abduction* by eleven.
   - Abductor pollicis.
   - Adductor et opponens minimi digiti.
   - Four lumbricales.
   - Four interossei, viz. abductor indicis, prior medii, prior annularis, interosseus auricularis.

We thus see that the hand is furnished with no less than thirty-three muscles, each capable of acting either singly or in conjunction with others. The most powerful of these are the flexors and opposers, both performing actions, as we have seen, peculiarly adapted for the prehension and retention of bodies.

But there is yet another function in which they are the chief agents, and of which the hand is the principal organ, that of touch, which may be regarded as a kind of sentinel by which we ascertain the nature of bodies; which without seeing warns the hand from too closely embracing what may prove hurtful to itself, or admonishes it to handle gently those delicate objects that would be destroyed by too rude a grasp. In the blind this sense, by constant exercise, becomes so perfect as in a great measure to compensate for the loss of sight. But by the combination of these two functions the hand is indeed rendered an organ worthy of, and admirably suited to the mind of man. With the one he plans, while through the other he performs and executes all that administers to the pleasures, the comforts, and the conveniences of life, and that establishes his superiority in the creation.

(F. T. M'Dougall.)

HAND, REGIONS OF THE. (Surgical Anatomy.) In the consideration of the surgical anatomy of the hand, we shall commence our description from an imaginary line encircling the fore-arm, at a point immediately below the insertion of the pronator quadratus, or about half an inch above the radio-carpal articulation. From this point downwards for about a finger's-breadth, the wrist is narrow and flattened like the fore-arm; from thence the hand, gradually expanding, acquires that remarkable breadth and flatness so necessary to it both as a tactile and prehensile organ; it is broadest inferiorly where it terminates in the fingers. In front, this region is concave and hairless; posteriorly, it is convex and slightly hairy.

In woman, the hand is smaller and more delicately shaped; it is also rounder and smoother, on account of the greater quantity of subcutaneous adipose tissue, softening down the harsher outline of bone and tendon displayed in the brawny hand of man.

In order to avoid needless prolixity, we shall not subdivide this inferior segment of the upper extremity into the three distinct regions of wrist, hand, and fingers; which, indeed, if we were considering its bony frame-work, would naturally present themselves. But as the soft parts, with which we have principally to do in the present article, exhibit no such natural distinctions in these separate parts, and are, for the most part, common to them all, we shall consider them as constituting one entire region, which is naturally subdivided into *palmar* and *dorsal regions.*

I. *Of the palmar region of the hand.*—The remarkable points on the exterior of this region are as follows:—Commencing from the presupposed imaginary line, and proceeding downwards, we perceive most externally a projection formed by the united tendons of the short extensors of the thumb; next in order, proceeding from without inwards, we notice a hollow, most visible when the hand is flexed, corresponding to the radio-carpal articulation, and in which the radial artery may be felt pulsating immediately before it passes under the tendons we have just noticed; bounding this hollow, on its inside, is a second eminence, formed by the tendons of the flexor carpi radialis and palmaris longus, and the projecting crests of the scaphoid and trapezium; more internally a second depression, corresponding to the ulnar nerve and artery, bounded internally by a third eminence, that of the flexor carpi ulnaris tendon and the pisiform bone, posterior to which may be felt the inferior extremity of the ulna and the interval between it and the bones of the carpus.

Lastly, in front of the wrist, owing to the thinness of the skin in this part of the palmar region, we perceive a blue network of veins, from which the median is formed.

More inferiorly, in the palm proper, we notice externally the thenar eminence, extending from the crest of the scaphoid to the base of the first phalanx of the thumb. On the inner side of the palm is the hypothenar eminence, longer and thinner, but less prominent than the last; it extends from the pisiform bone to the base of the first phalanx of the little finger. Separating these prominent parts, and extending from the inner furrow of the wrist towards the root of the index finger, is a deep excavation,—the hollow of the palm; next may be seen or felt four elevations, corresponding to the heads of the four metacarpal bones, about an inch in front of which the fingers free themselves from the skin of the palm, which is prolonged over them for that distance in a manner somewhat analogous to the web in the foot of a Newfoundland dog, or other swimming animals. Of the fingers themselves, the middle is the longest, the first and third are on a level, the little finger reaches the level of the last articulation of the annular, and the thumb terminates about three lines behind the second articulation of the index; the phalangeal articulation of the thumb being exactly on a level with the metacarpo-phalangeal union of the same finger.

There are likewise certain lines or furrows caused by the folding of the skin in flexion of the hand and fingers, some of which constantly occur, and are worthy of notice, inasmuch as they sometimes serve as guides or landmarks to the surgeon in operating on this region. They are as follows: two on the wrist; the superior one, extending between the styloid processes of the radius and ulna, corresponds to the radio-carpal articulation. Another, more remarkable, slightly convex downwards, projecting between the palmar eminences, separates the wrist from the hand, and corresponds to the articulation between the two rows of the carpus. In the palm, one commences from the metacarpo-phalangeal articulation of the index finger, which soon bifurcates, one of its divisions bounding the thenar on its inner side; the other runs obliquely across the palm, and terminates on the upper part of the hypothenar: this in a measure corresponds to the superficial palmar arch, having the same obliquity across the palm, but being three or four lines inferior to it; these lines are caused by the opposition of the thumb. There is yet another line running from the interval between the index and middle fingers to the base of the little finger; this traverses the hand about two lines above the metacarpo-phalangeal articulations. Opposite the joints of the fingers there are also transverse lines; the two first have double, the last joint but a single line;—an incision made perpendicular to it would fall about a line above the articulation. Of the middle joint, the superior transverse line is the most constant, and is placed about half a line above its articulation.

Of the lines corresponding to the first joint of the fingers, the superior is on a level with the termination of the interdigital web, and from ten lines to an inch below the articulation, excepting that of the thumb, which resembles the middle joint of the fingers, its line nearly corresponding to the articulation. There are many other inconstant folds, or markings of the skin, in this region, which, to the surgeon, are of little import, but which present a book of mystic lore to the gipsy and the cheiromancer, wherein (when opened by the necessary charms) they discern the future destinies of all that seek to be enlightened by them.

We shall now proceed to examine the various structures found in this region, and, for convenience of description, shall consider them as constituting the following layers:—1, skin; 2, subcutaneous cellular tissue, vessels, and nerves; 3, aponeurosis; 4, deep vessels and nerves; 5, muscles and tendons.

1. *The skin.*—The integument on the front of the wrist resembles that on the anterior surface of the fore-arm; but, on reaching the palm, it suddenly changes its character, and instead of the fine, smooth, yielding skin, we find it dense, resisting, exceedingly vascular, and covered with a very strong and thick cuticle; on the thenar, however, it preserves some degree of suppleness and elasticity. In those accustomed to hard manual labour, and in the aged, the cuticle becomes so thick and callous as to enable them to handle even hot coals without inconvenience; but in them, from this increased resistance, and from the difficulty of getting at matter, or freeing the parts by incisions, inflammations of the palm are the more dangerous. Corns are sometimes developed at the roots of the fingers, on the prominences formed by the heads of the metacarpal bones. There are no sebaceous follicles to be discovered in this region; but M. Velpeau thinks, from the fact of the occasional appearance of variolous pustules on the front of the fingers, that follicles there exist. The physical conditions of the skin of the hand, as to coolness or warmth, as to moisture or dryness, often furnish valuable signs in disease.

2. *Subcutaneous cellular tissue* is dense and serrated, more fibrous than cellular, enclosing in its meshes small rounded pellets of fat. On the wrist it binds the skin so closely to the subjacent parts, that, in cases of serous or other infiltration above this point, the effused fluids are arrested, and prevented from passing into the palm of the hand; also, in very fat and flabby people, and in young children, a kind of strangulation is observable at the wrist from the same cause. On the thenar this layer is laxer and less compact, permitting the skin to play freely. On the centre of the palm and hypothenar it is very dense and fibrous, enclosing larger pellets of fat, binding the skin very firmly to the palmar aponeurosis and sheaths of the fingers, towards the extremities of which it becomes more fatty, increases in thickness, forming a soft elastic cushion called the pulp of the fingers. This tissue is the seat of that painful phlegmonous inflammation, the true whitlow. The unyielding nature of the thick consistent skin on the one hand, and of the bones and sheaths on the other, whereby the swollen and inflamed pulp, together with its great number of vessels and the nervous expansion it encloses, are violently compressed, easily account for the violent symptoms, and call loudly for the prompt relief of the strangulation by means of the knife, and also indicate the great advantage of emollients.

The *subcutaneous nerves* are few, and derived from the palmar cutaneous branch of the median and some terminal branches of the internal and musculo-cutaneous nerves. The *veins* are also very few, and give rise to the median, and are accompanied by the superficial lymphatics.

3. *The aponeurosis.*—At the wrist the aponeurosis, derived from that of the front of the forearm, is interwoven with and inseparable from the anterior annular ligament, from the lower border of which, and from the tendon of the palmaris longus, the palmar fascia proceeds. Above the annular ligament the aponeurosis is attached to the extremity of the ulna, and the pisiform and the styloid process of the radius; it furnishes sheaths to the tendons that do not pass under the annular ligament, one to the ulnar and its nerve, and another to the radial trunk and its volar branch. The *anterior annular ligament* is exceedingly strong, attached internally to the pisiform and unciform, and externally to the scaphoid and trapezium. It consists of two layers, the one superficial, of divergent fibres, derived from the tendon of the palmaris longus when it exists, or belonging to the origin of the palmar fascia when it does not; the other deep, of transverse fibres, continuous with the fascia of the forearm. It forms, together with the concavity of the palmar aspect of the carpal bones, a sort of elliptical ring about two inches in its transverse, and one inch in its antero-posterior diameter, and gives passage to the common flexor tendons and median nerve, which are enveloped by a common synovial bursa which binds them together, and terminates in a common cul-de-sac above and below the ligament; also to the long flexor tendon of the thumb, which has a distinct bursa. This ligament, from its great strength, presents an insurmountable obstacle to the progress of tumours developed beneath it, forcing them to protrude on the forearm above the ligament in the hand below it. Thus, when the common synovial bursa of the tendons is distended, it forms two tumours, the one above, the other below the ligament; and upon compressing the fluid from one the other will be found to enlarge. Ganglia rarely occur here.

The annular ligament gives attachment inferiorly on either side to the muscles of the thumb and little finger, and in the centre to *the palmar fascia*, a dense fibrous layer binding down the flexor tendons in their passage along the hand.

The palmar fascia is chiefly derived from the expansion of the palmaris longus, which, when present, is its tightening muscle. It is strongest in the palmar hollow, where it is triangular in shape, its apex at the annular ligament, and is composed of divergent and longitudinal, interwoven with a few transverse fibres; the latter, becoming gradually fewer and more scattered, are lost on the tendons running to the fingers, and some few are at times continuous with the tendinous sheaths of the fingers. Near the roots of the fingers this portion of the palmar fascia divides into four bands, which subdivide each into two tongue-like processes, that embrace the heads of the metacarpal bones, and are attached to the sides of the first phalanges and the inferior transverse metacarpal ligament. At this point of division the transverse fibres are stengthened, and convert these slits into four distinct fibrous arches, through whicb pass the flexor tendons. Between these arches we find three lesser ones resulting from the primary division of the fascia. They transmit the collateral vessels and nerves, and the lumbricales. This fascia is intimately connected with the preceding layer anteriorly, its deep surface covering the superficial palmar arch, flexor tendons, ulnar and median nerves, from which it is separated by loose and very extensible cellular tissue, which permits the tendons to play freely. This portion of the fascia presents numerous apertures through which the deep fat and cellular tissue communicate with the subcutaneous, and when the parts beneath are swollen they protrude, forming small herniæ, which, getting strangulated in these apertures, give rise to great pain. It detaches from either side two processes, a superficial and a deep one. The two deep processes dive deep into the palm, to form the interosseous aponeurosis; of the superficial ones, the external, assisted by the tendinous expansion of the extensor ossis metacarpi, envelopes the thenar muscles; the internal stronger, and assisted by the flexor carpi ulnaris expansion, encloses the hypothenar muscles, and to it is attached the palmaris brevis. We next meet with the strong sheaths binding down the flexor tendons in their passage along the fingers. They are continuous above with the palmar fascia, by means of strong detached transverse fibres, which are prolonged over the tendons as they pass through the arches of the fascia; laterally they are firmly attached to the ridges on the sides of the phalanges. On the bodies of the two first phalanges these sheaths are very strong and resisting; but opposite the articulations they become very thin, and are often wanting; so that the synovial sacs of the tendons are in contact with the subcutaneous layer; and it is through these spaces that the inflammation in whitlow is propagated to the synovial membrane and joints. At the last joint of the fingers they become weak and thin, and are confounded with the pulp and periosteum. They each enclose a distinct elongated synovial sac, which reaches as far upwards as the fibrous arch of the fascia, but does not communicate with the synovial membranes of the joints, entirely enveloping the flexor tendons, lubricating them, and facilitating these motions in the sheaths. At the point where the tendon of the profundus passes through the divisions of the sublimis, there is a falciform process of the synovial sheath of considerable strength, attaching the tendon of the latter to the first phalanx, so that if the fingers be amputated at the second joint, the power of moving the first phalanx will still be retained, though the contrary has been stated. We may here likewise notice that the gradual contraction of the three last fingers occurring in adults, (*crispatura tendinum,*) formerly thought incurable, as it was supposed to be the result of a drying or contraction of the tendons, is stated by Baron Dupuytren to be nothing more than a band or strip of the palmar fascia, adhering to the sheath of the tendon, upon the division of which a complete cure may be effected; or it may be caused by a fibrous transformation of the subcutaneous cellular layer, depriving it of its elasticity, and causing it to contract, so that the finger cannot be extended. What favours this opinion is, that this malady generally occurs in labourers, boatmen, and those whose avocations necessitate constant flexion of the fingers, at the same time that firm pressure is kept up, especially against the roots of the three inner fingers, as in handling a spade, or grasping an oar.

4. *The vessels and nerves* are exposed on removing the fascia, being immediately underneath it. The palmar aspect of the hand being that of flexion, according to the general rule of arterial distribution, the principal trunks are there found; they are the ulnar and radial arteries, and a branch of the interosseous accompanying the median nerve.

The ulnar artery at the wrist lies on the annular ligament, to the radial side of the pisiform bone, where it is covered by the expansions of the flexor carpi ulnaris; it then curves towards the mesial line, and crossing the annular ligament, traverses the palm between the fascia and the flexor tendons, in a curved direction towards the centre of the metacarpal bone of the index finger. In this course it forms an arch, the convexity of which looks downwards and inwards, towards the ring and little fingers, its concavity being turned to the ball of the thumb. It then inosculates with two branches from the radial, the superficialis volæ, and the radialis indicis, forming thus the superficial palmar arch, from the convexity of which proceed four digital arteries which subdivide into the collateral branches at about two lines below the metacarpo-phalangean articulations; they supply the palmar and lateral surfaces of all the fingers except the thumb and the radial side of the index finger. They all run along the sides of the fingers external to the sheaths, to the last phalanx, where those of either side coalesce, forming an arch, from which arise numerous branches to supply the pulp of the fingers. When the artery arrives at the wrist, it sends off two regular branches, the arteriæ carpi ulnares anterior et posterior, to the fore and back parts of the joint. After crossing the annular ligament, it detaches also a deep communicating branch, which dips down between the flexor brevis and abductor minimi digiti, to join the deep arch from the radial.

The radial artery, just below the styloid process of the radius, passes round to the back of the wrist under the two external extensors of the thumb, to the cleft between the two first metacarpal bones, where it again passes into the palm between the heads of the first dorsal interosseous, and then between the short flexor and adductor of the thumb, to form with the communicating branch from the ulnar the deep palmar arch. In this course it lies upon the capsular and external lateral ligaments, and close upon the head of the first metacarpal bone; it is therefore generally divided in the amputation of that bone; but it would often be avoided, were the edge of the knife kept close to the inner side of the bone, as it is carried down to the joint. Before it curves round the wrist, this artery gives off the superficialis volæ, a branch which runs over the annular ligament to unite with the superficial palmar arch; also the anterior carpal branch, which anastomoses with the anterior interosseous and corresponding ulnar branch. At the back of the carpus it detaches the dorsalis carpi radialis, which inosculates with the corresponding branch from the ulnar; it runs beneath the extensor tendons, supplying the synovial membrane and the bones of the carpus; it also anastomoses with the posterior interosseous. This branch generally sends off the metacarpal artery, which forms a kind of posterior arch across the heads of the metacarpal bones, that supplies the integuments and interossei muscles;—this metacarpal branch sometimes arises from the trunk of the radial. The only remaining dorsal branches are, the arteriæ dorsales pollicis, in general two distinct branches, but sometimes arising by a common trunk. They run along the dorsum of the thumb, the one on the radial, the other on its ulnar side; this last sends a branch to the index finger, the dorsalis indicis. The radial artery then dips deep into the palm, as before described, and divides into its three terminal branches: the first is the magna pollicis, which runs along the ulnar side of the metacarpal bone of the thumb, and at its inferior extremity divides into two collateral branches, which are distributed similarly to those of the fingers. The next branch is the radialis indicis, which forms the external collateral artery of that finger; it receives a branch of communication from the superficial palmar arch. Lastly, the arteria palmaris profunda; this runs deeply into the palm, generally separating the flexor brevis and adductor pollicis muscles. It crosses the interossei and anterior part of the superior extremities of the metacarpal bones; it is covered by the deep flexor tendons and lumbricales; and opposite the fifth metacarpal bone inosculates with the communicating ulnar,—completing thus the deep palmar arch, the convexity of which is towards the fingers; and it gives four or five regular branches, which supply the interossei, and at the clefts of the fingers anastomose with the digital branches. This arch is less oblique, and farther from the fingers, than the superficial one.

Thus we see that the disposition of the arteries of the hand is peculiar, and is somewhat analogous to that of the venous system generally,—viz. that they are divided into a superficial and deep set. The question naturally occurs, whether it may not be for the same cause, viz. that when pressure obstructs the superficial vessels, the deep may still carry on the interrupted circulation? In the hand, as we have seen, the communications between the deep and superficial arches are frequent and free, while we daily experience with what violent and continued pressure the circulation through the superficial arch is liable to be interrupted.

The varieties of the arteries of the hand are numerous: sometimes the radial predominates, at other times the ulnar, in the share they respectively take in supplying the hand; they are always in an inverse ratio; and if both are small, then the artery of the median nerve derived from the interosseous is proportionably large.

From the constant call for vigorous and rapid, as well as sustained and powerful action, the hand, with the exception of the tongue, is the most vascular of the voluntary locomotive members of the human body. The communications between its arteries are so numerous and free, as, in cases of simple wounds of this region, frequently to prove a source of great embarrassment to the surgeon, and, in unskilful hands, of danger to the patient. Wounds of the integuments of the palm often bleed profusely, and are liable to secondary hæmorrhage. This may in some measure be accounted for by the peculiar density of the cellular tissue and skin, and its intimate connection with the subjacent fascia, which, as well as the numerous branches given off from the divided vessels, prevent their retraction, nor can a coagulum easily form around them; they are not generally vessels that require a ligature, (excepting in cases similar to one related by M. Velpeau, where the arteries of the hand were in a varicose state, and of an enormous size,) but where ordinary means fail, plugging the wound, the continued application of cold, and a tightish bandage up to the shoulder, in order to moderate the circulation in the whole limb, will usually stop even very severe bleedings. If these means should not succeed, and no large divided vessels can be seen in the wound, the surgeon must tie one or even both arteries above the wrist. The inosculations with the interosseous will sometimes even then allow the bleeding to continue, especially in cases where the median branch is large, or helps to form the arch; but pressure and cold will then soon stop the remaining hæmorrhage.

Veins.—The deep ones accompany their arteries; the superficial veins are very few on the palm.

The lymphatics accompany the veins.

The nerves of this region are superficial and deep: the former have been already noticed; the latter are the median and ulnar. The first passes under the annular ligament with the flexor tendons; it then divides into five branches, behind the superficial palmar arch. The first, or most external of these branches, supplies the short muscles of the thumb; the second sends one or two deep branches down to the interossei, to communicate with the deep palmar branch of the ulnar nerve; it then finishes on the outer side of the thumb; the remaining three branches soon bifurcate, and are distributed to the ulnar side of the thumb, to both sides of the index and middle, also to the radial side of the ring finger; giving likewise a branch to each corresponding lumbrical muscle.

The ulnar nerve passes over the annular ligament to the internal and posterior side of its artery; while passing over the ligament, it sends the cutaneous branch to the skin on the hypothenar, and then it divides into three branches: first, the deep palmar branch, which accompanies the communicating branch of the artery, and behind the deep palmar arch unites with the branch sent from the median to supply the deep muscles; the next branch supplies the ulnar side of the little finger and its muscles; while the remaining branches supply the collateral nerves not furnished by the median, to the radial side of the little, and the ulnar side of the ring fingers. All these collateral nerves accompany the corresponding arteries along the sides of the fingers, giving numerous branches in their course that terminate in the skin; and on the last phalanx they divide into two branches, a dorsal and palmar: the dorsal, or ungual branch, is lost in the skin, under the nail; and the palmar is expanded in the pulp of the fingers. It is remarkable that the nerves of the opposite sides of the fingers never anastomose.

The *muscles and tendons* with which the hand is pre-eminently endowed, lastly present themselves for our consideration. In the upper part of this region, or in front of the wrist, there are scarcely any muscular fibres, excepting a small portion of the origins of the thenar and hypothenar muscles; and sometimes the lower border of the pronator quadratus reaches as far, or a little below the imaginary line we have marked out as the superior boundary of this region. But we have no lack of tendons in this part; for we here find an assemblage of them more numerous, and more tightly packed, than in any other part of the body; they are also invested by synovial sacs, and pass through the carpal ring, which was described in speaking of the annular ligament in which they are closely bound down. There are, however, some that do not pass through this ring, and they are the following:—Most externally is the tendon of the supinator longus, which terminates by being inserted into the radius at the upper boundary of this region; then the tendons of the extensores ossis metacarpi, and primi internodii pollicis, running in the most external groove in the radius, which is converted into a sheath for them by a process of the posterior annular ligament. The radial artery passes under these, separating them from the joint in its passage to the back of the wrist.

More internally we have the tendon of the flexor carpi radialis passing into the palm, behind the external reflected portion of the annular ligament, in a canal destined for it in the scaphoid and trapezium; the next tendon is that of the palmaris longus, which here begins to expand on the anterior surface of the annular ligament, to which it is also attached; and lastly, we find the flexor carpi ulnaris tendon implanting itself into the pisiform bone. This tendon, and those of the short extensors of the thumb, form the lateral boundaries of this region, dividing it from the dorsal.

All the other tendons from the front of the fore-arm pass through the carpal ring; they are nine in number:—Four of the flexor sublimis; four of the flexor profundus,—these are all bound up in a common synovial sheath, along with the median nerve; the remaining tendon, that of the flexor pollicis, is situated more externally, and has a distinct synovial sac. All these tendons, after emerging from under the annular ligament, diverge towards the different fingers to which they are destined. In the palm they are placed beneath the aponeurosis, and lie upon the palmar interossei and the adductor pollicis.

As the muscles of the palm have already been described, (see HAND, MUSCLES OF,) we shall not notice them further than merely to observe, that the intrinsic muscles of the thumb and little finger constitute the external and internal regions of the palm, which they almost solely occupy; while the middle region, or hollow of the palm, is occupied not only by the remaining intrinsic muscles, (the interossei and lumbricales,) but also contains the tendons just described, with their synovial sheaths, as well as the principal vascular and nervous trunks of the hand. Wounds are therefore more dangerous in the middle of the palm than on either the external or internal regions, which are constituted principally of muscle, having but a thin aponeurosis and no important vessels or nerves. It is also worthy of remark, that the short muscles of the thumb, especially the abductor, flexor brevis, and adductor, though they act but indirectly on the first metacarpal bone, present a serious obstacle to its dislocation forwards; their action tending to throw its base backwards, whilst, by their bulk and tension, they repel its attempts to slip forwards.

Having now examined all the soft parts on the palmar region, as nearly as possible in the order in which they would have been exposed by the dissector, we proceed to the second division of our subject, and shall consider the various layers of the dorsal region in similar order.

II. *The dorsal region of the hand* is convex and irregular; the veins are large and prominent. When the hand is extended the extensor tendons stand out in strong relief, converging at the wrist; and when flexed the heads of the metacarpal bones and phalanges protrude. The other prominent external characters of this region are, at the superior and external part, when the thumb is extended and abducted, an elongated depression, bounded externally by the two short extensor tendons of the thumb, and internally by its long extensor and the tendon of the extensor carpi radialis longior. In this depression the pulsation of the radial artery may be felt, also the heads of the two first metacarpal bones: internally and about the same level there is a hollow corresponding to the union of the wrist and hand; and at this point we can feel the tendon of the extensor carpi ulnaris and the styloid process of the ulna. When the thumb is adducted the first dorsal interosseous projects considerably. The fingers appear longer on their dorsal aspect, the interdigital web that was noticed on their palmar surface being here wanting.

1. *The skin* is very loose and thrown into transverse folds; opposite the two last joints of the fingers may generally be seen three or more transverse furrows; the middle one is the deepest and most constant, and an incision made about a line and a half below it will hit upon the articulation. It resembles that on the back of the fore-arm, but it gradually thickens at the sides as it approaches the palmar surface. Hairs and sebaceous follicles are most abundant on the ulnar side of the back of the hand and on the first phalanges. On the ungual phalanx, the skin, as it approaches the nail, becomes tighter and glabrous, extends for about two lines over the root of the nail, and is then reflected back, so as to be continued over its anterior surface to its free border, where it becomes continuous with the skin of the pulp of the fingers. It is in this portion of the skin about the roots of the nails that the false whitlow, called by the French *tourniole*, takes place. It is an inflammation more of an erysipelatous than a phlegmonous nature, sometimes attacking several fingers successively or at once, therein differing from the true whitlow, which is generally confined to one finger. Warts also frequently occupy the skin of the dorsum of the fingers, especially in those that have to perform hard manual labour.

2. *The subcutaneous layer* is very lax, serous infiltration easily taking place; it contains no pellets of fat like that of the palmar surface.

The *veins* are subcutaneous, large and numerous; all the large veins of the hand being on its dorsal surface, the venous circulation is not interrupted by the effort of prehension. On the back of the fingers they form a complete net-work, which gives rise to the dorsal collateral veins of the fingers. At the interosseous spaces these unite as the arteries divide, and then proceed towards a kind of dorsal venous arch, the concavity of which is upwards, and from which arise larger branches; these, in conjunction with one from the little finger called the *vena salvatella*, and another from the thumb called the *cephalic*, form the basilic and cephalic veins described in the fore-arm. (See Fore-arm.) Some people prefer being bled on the back of the hand, but, owing to the laxity of the skin and subcutaneous layer, considerable extravasation of blood is apt to take place. The subcutaneous nerves, derived from the dorsal branch of the ulnar, and the terminal branches of the musculo-spiral accompany the veins, as also do the lymphatics.

3. The *aponeurosis* is continued from that of the back of the fore-arm; it is strengthened across the back of the wrist by strong parallel oblique fibres, forming a band of nearly an inch in breadth; which extends obliquely downwards over the extensor tendons from the styloid process of the radius to the internal lateral ligament of the wrist.* It sends down strong processes between the tendons that convert the grooves in the back of the radius and ulna into sheaths, which are as follows:—1st, that noticed on the palmar region for the short extensors of the thumb; 2d, for the radial extensors; 3d, for the long extensor of the thumb; 4th, for the extensor communis and indicator tendons; 5th, for the extensor minimi digiti; 6th and last, for the extensor carpi ulnaris. The metacarpal aponeurosis is very thin and split into two layers; the one separates the subcutaneous layer, vessels, and nerves from the tendons; the other covers the dorsal interossei, isolating them from the tendons.

4. The *nerves* are, externally, the radial, which sends one branch, that, bifurcating, supplies the thumb and radial side of the index finger; and another, which in like manner furnishes the inside of the index and the middle finger. Internally the posterior branch of the ulnar supplies the two remaining fingers. These branches receive frequent communicating ramuli from the anterior collateral nerves.

5. *Tendons and muscles.*—The former are less numerous on this region than on the palmar; the order in which they cross the wrist was mentioned in describing the aponeurosis. If the divisions of the extensor communis be enumerated, they are twelve in number; four of these are inserted at the base of the metacarpal bones of the thumb, index, middle, and little fingers; they are the extensor ossis metacarpi pollicis, extensores carpi radiales, and extensor carpi ulnaris. The other tendons proceed onwards to the phalanges. Those of the common extensor are flattened and riband-like; the three inner ones communicate with each other, while that going to the index is free. Opposite the metacarpo-phalangean articulation these tendons narrow and thicken, sending an expansion to either side of the articulation: they again flatten on the first phalanges, where they receive the tendons of the lumbricales and interossei. At the articulation of the first and second phalanges they divide into three portions: a middle one, that is inserted into the superior extremity of the second phalanx; and two lateral ones, that run along its sides, reunite at its inferior end, and are implanted into the upper part of the ungual

* Generally called the posterior annular ligament.

phalanx.* The remaining tendons of the index and little fingers are implanted into the phalanges of those fingers with those of the common extensor: those of the thumb are inserted separately. Having no sheaths, these tendons are firmly attached by means of a membranous expansion to the bones to prevent them slipping aside, nor have they here any synovial membranes, and are therefore in contact with those of the joints; but as they pass through the sheaths in the posterior annular ligament, they are all provided with synovial sacs. The largest is that of the extensor communis and indicator; they are less complex than those of the palmar region, and their inflammation less formidable and not so painful. The occurrence of ganglia is here very frequent. They sometimes attain a large size and produce considerable inconvenience. The puncture of them is not so dangerous here as in the palmar region.

6. *Arteries.*—The course of the radial over the back of the hand has been already noticed; its metacarpal and carpal branches run across the wrist beneath the extensor tendons, unite with the posterior carpal branch of the ulnar, forming a kind of dorsal arch, from which proceed the interosseous and perforating branches, to communicate with the deep arch; also the dorso-digital branches, one to either side of the fingers.

The *bones* and *ligaments* forming the firm, light, and compact skeleton of the hand have been elsewhere described. See article HAND, BONES AND JOINTS.

In the amputation of the metacarpal bone of the thumb, which is easily performed at its articulation with the trapezium, the edge of the knife should be kept close to the ulnar edge of the bone, in order, if possible, to avoid wounding the radial artery as it traverses the interosseous space. The metacarpal bone of the little finger may also easily be removed by an operation similar to that practised for the thumb; the articulating surfaces are nearly plane and inclined obliquely upwards and inwards. Disarticulations may also be performed of the other metacarpo-carpal joints; but the operations are very difficult and embarrassing, owing to the irregularity of the articular surfaces and their close connexions with each other, and in removing them singly a much neater and easier plan is, if their upper extremities are sufficiently sound, to saw through them in an oblique direction.

In amputating at the phalangeo-metacarpal articulations the flap is, if possible, made on the palmar surface. At the first joint of the fingers two flaps are preserved by making two semilunar incisions, which extend from the head of the metacarpal bones to the termination of the commissure of the fingers, meeting behind and before at the joint, which is an inch above. They may all be amputated together when a single flap is made on the palmar surface terminating at the line in the skin that bounds the commissure. In amputating at the other joints of the fingers it is necessary to recollect the marks, before alluded to when speaking of the skin, and to divide the lateral ligaments before entering the joints.

(F. T. M'Dougall.)

* It is not uncommon for these tendons to send a slip to the superior extremity of the first phalanx.

HEARING, ORGAN OF. The ear (in the wide acceptation of the term). *Organon auditûs s. auris.*—Fr. *L'organe de l'ouie au l'oreille.* Germ. *Das Gehörorgan oder das Ohr.*—As the apparatus of vision naturally admits of being divided into two parts, viz. the eye-ball and its appendages, so we can distinguish in the apparatus of hearing a fundamental organ, and parts accessory to the perfect performance of its function. The fundamental organ of hearing is what is commonly called the internal ear, or from the complexity of its structure, the *labyrinth.* The accessory organs consist of the middle ear or tympanum and external ear.*

If we extend our observations to the animal series, and trace the apparatus of hearing along the descending scale, we shall find that the accessory parts gradually disappear, and that the sense of hearing comes at last to have for its organ merely a representative of the labyrinth in the higher animals. This part even, having laid aside much of its complicated structure, presents itself under the form simply of a membraneous pouch containing a fluid, with a calcareous concretion suspended in it, on which the auditory nervous filaments are expanded.

The labyrinth being in the apparatus of hearing exactly what the eye-ball is in that of vision, may be distinguished by the name of *ear-bulb.* The ear-bulb, like the eye-ball, consists of a hard external case, in the interior of which are contained membraneous and nervous parts and humours. The accessory parts of the apparatus of hearing have also their prototypes in the accessory organs of the apparatus of vision.

The different parts of the apparatus of hearing are situated in the interior and on the surface of the temporal bone. See the description of the temporal bone in the article CRANIUM.

I.—THE EAR-BULB, *or fundamental organ of hearing.* (*Bulbe auditif,* Breschet.)

In man and the higher animals, the hard external case of the ear-bulb is of bone, and is called the *osseous labyrinth.* The soft textures contained in its interior bear the name of *membraneous labyrinth.* The interior of the osseous labyrinth, which we may with Breschet† call the *labyrinthic cavity,* is not completely filled by the membraneous labyrinth; the remaining space is occupied by a limpid watery fluid.

1. *The osseous labyrinth (labyrinthus osseus;* Fr. *Labyrinthe osseux;* Germ. *Das knöcherne Labyrinth.)*—The osseous labyrinth presents three compartments, distinguished by the names

* Haighton, in Memoirs of the Medical Society of London, vol. iii. p. 7. London, 1792.

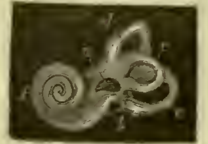
† Recherches anatomiques et physiologiques sur l'organe de l'ouie et sur l'audition, &c. chap. i. s. x. Paris, 1836.

of *vestibule, semicircular canals*, and *cochlea*. The semicircular canals and cochlea do not communicate immediately with each other, but only *mediately* through the vestibule. The latter may be considered the principal compartment.

The osseous labyrinth is imbedded in the substance of the petrous portion of the temporal bone, from the compact texture of which it is, in the adult, scarcely to be distinguished. In the early periods of life, however, its walls consist of a hard but brittle osseous substance, around which is the then less compact tissue of the petrous bone. Hence it is in a young bone only, and that by means of some little preparation, that the external form of the osseous labyrinth can be well demonstrated.

Of the compartments of the osseous labyrinth, the vestibule lies in the middle, the semicircular canals behind it, and the cochlea in front.

Fig. 232.



The exterior of the osseous labyrinth of the left side. Natural size.

a. Oval or vestibular fenestra; *b*. round or cochlear fenestra; *c*. external or horizontal semicircular canal; *d*. superior or anterior vertical semicircular canal; *e*. posterior or inferior vertical semicircular canal; *f*. the turns of the cochlea.

The vestibule, (vestibulum; Fr. *le vestibule;* Germ. *der Vorhof.)*—The vestibule is an irregularly shaped cavity, the diameter of which from above downwards, as also from behind forwards, may be stated to be about one-fifth of an inch. The distance between its inner and outer wall is somewhat more than one-tenth of an inch. In an anatomical sense we can distinguish in it three horns, one of which is towards the anterior and lower part, another towards the posterior and lower part, whilst the third composes the upper part of the vestibular cavity.

The anterior and lower horn leads by an oval opening directed forwards and downwards into the vestibular scala of the cochlea. This opening is called the vestibular orifice of the cochlea, *osteum s. opertura scalæ vestibuli cochleæ*. The posterior and lower horn of the vestibule corresponds to three of the orifices of the semicircular canals; the upper horn to the other two orifices.

At the under part of the inner wall of the vestibule, within the limits of its anterior horn and to the inside of the vestibular orifice of the cochlea, is a hemispherical depression, *fovea hemispherica s. sub-rotunda*. Its bottom, which corresponds to the posterior part of the lower depression at the bottom of the internal auditory meatus, presents a sieve-like spot, *macula cribrosa*, that is, it is perforated by minute apertures for the passage of filaments of the auditory nerve. On the upper wall of the vestibule, bordering the upper margin of the hemispherical fossa and within the limits of the upper horn, is another depression, of an oval shape, which is known by the name of *fovea hemi-elliptica*. The hemispherical and hemi-elliptical depressions are separated by a ridge or pyramidal eminence, *eminentia pyramidalis*, pervaded by small canals for the passage also of nervous filaments. On the inner wall of the vestibule, a little in front of the orifice common to the two vertical semicircular canals and within the limits of the posterior horn, there is, bordering on the hemi-elliptical and hemispherical depressions, below the former and behind the latter, another very small depression or sulcus, *fossa s. cavitas sulciformis*, which leads upwards and backwards to a small oblique orifice, that of the aqueduct of the vestibule, *osteum internum aqueductus vestibuli*. At the middle of the inner wall of the vestibule, where the boundary lines of these three depressions meet, there is a slight eminence.

The inner wall of the vestibule corresponds to the bottom of the internal auditory meatus, and is pervaded by small canals, some of which have been already mentioned, for the passage of fibrils of the auditory nerve and of blood-vessels.

In the outer wall of the vestibule there is an oval, or rather a kidney or bean-shaped hole, called *foramen ovale, s. fenestra ovalis, s. fenestra vestibuli*. The long diameter of this aperture, which is about one-tenth of an inch or perhaps a little more, is directed from behind forwards. Its vertical diameter is about half that of its long diameter. The upper part of the circumference of the hole is arched upwards, the lower part is slightly inclined in the same direction. The margin of the vestibular fenestra is turned in towards the vestibule. Viewed from the tympanum, into which it opens in the macerated bone, the vestibular fenestra appears situated at the bottom of a fossa, which was called by Cotugno *pelvis ovalis*. In the recent state the vestibular fenestra is closed in by the base of the stapes.

The semicircular canals, (canales semicirculares; Fr. *les canaux semicirculaires;* Germ. *die Bogengänge oder halbcirkelförmigen Canäle.)* These are three canals, which, describing more than the half of an irregular circle, open at each of their extremities into the vestibule; hence, if it was not for the circumstance that two unite by one of their extremities to form a common short canal, there would be in the vestibule six orifices of semicircular canals, instead of the five only which exist. The calibre of these canals is about one-twentieth of an inch in the direction from the concavity to the convexity of their curve; in the opposite direction they are somewhat compressed, so that a transverse section, instead of presenting a round orifice, presents an elliptical one. The semicircular canals are wider where they open into the vestibule, but especially so at one of their extremities, which presents a dilatation in the form of a bulb, called ampulla or ampullary sinus, *sinus ampullaceus*.

Two of the semicircular canals occupy a vertical position and one of them a horizontal.

Of the *vertical*, one is *anterior* and *superior*, the other *posterior* and *inferior*. The *horizontal* is *external*.

Superior vertical semicircular canal, canalis semicircularis verticalis superior. The superior vertical semicircular canal has its arch directed upwards, and its extremities, which are more widely divergent than those of either of the other two semicircular canals, downwards. Followed from its outer extremity, it describes its curve from without and upwards, then downwards and inwards, with an inclination from before backwards,—in a word, across the petrous bone. The convexity of the curve of this semicircular canal can always be recognized on the upper surface of the petrous bone. The concavity of it is free in the fœtus and in the adult of some of the lower animals, as the dog, hare, &c.

The inner extremity of the superior vertical semicircular canal and the upper extremity of the posterior vertical unite to form a common canal, *canalis communis*, which is about one-eighth of an inch long, and somewhat wider than either of the two which unite to form it.

Posterior vertical semicircular canal, canalis semicircularis verticalis posterior. Leaving the common canal, the posterior vertical semicircular canal describes its curve parallel to the inner and posterior surface of the petrous bone, perpendicularly from above backwards, then downwards and forwards. The convexity of the curve is thus directed backwards and slightly outwards, its extremities forwards and inwards.

Horizontal semicircular canal, canalis semicircularis horizontalis. This is the shortest of the three canals; traced from its anterior extremity, which is close to that of the superior vertical, it curves outwards and backwards, then inwards and forwards. Its convexity is outwards, its extremities directed inwards.

We described in the vestibule three horns, into the posterior and into the superior of which the semicircular canals opened. In the superior horn is observed the orifice of the external extremity of the superior vertical semicircular canal, and immediately below that and above the fenestra vestibuli, the orifice of the anterior extremity of the horizontal semicircular canal. Both of these orifices are dilated into ampullæ. In the posterior horn is the orifice of the canal common to the two vertical semicircular canals. Below and in front of this orifice is the opening of the inferior extremity of the posterior vertical semicircular canal. Above the latter and immediately outside the former is the opening of the posterior extremity of the horizontal. Of all these orifices in the posterior horn, that of the lower extremity of the posterior vertical semicircular canal is the only one which is dilated into an ampulla.

There are thus three ampullary dilatations, one at the outer extremity of the superior vertical semicircular canal, a second at the anterior extremity of the horizontal, and the third at the lower extremity of the posterior vertical. In the lower and anterior wall of the ampullary sinus of the posterior vertical semicircular canal is a small sieve-like spot indicating the entrance of nervous filaments.

The cochlea, (cochlea; Fr. *le limaçon*; Germ. *die Schnecke.)*—The cochlea does not exist in all its perfection except in the Mammifera. In birds it is in a very rudimentary state, but it is easy to trace parts analogous to what we find in the Mammifera. In regard to frequency of occurrence in the animal series, the cochlea does not stand next to the semicircular canals; the tympanum is found in a greater number of animals.

The cochlea forms the anterior part of the labyrinth, and is, perhaps of all the parts of the ear, that of which it is the most difficult to give, either by descriptions or delineations, a correct idea. If we can figure to ourselves a tube tapering towards one extremity where it ends in a cul-de-sac, and coiled, like the shell of a snail, round an axis or central pillar; and if we suppose this tube subdivided into two passages by a thin partition running throughout its length, and of course spirally round the axis, we shall have some conception of the disposition of the cochlea.

The tube of which the cochlea is composed, *canalis spiralis cochleæ*, is about an inch and a half long, about one-tenth of an inch in diameter at its commencement, and about one-twentieth of an inch at its termination. It describes two turns and a half, and that in a direction from below upwards—from left to right in the right ear, and from right to left in the left ear. The apex of the coil, which is also the apex of the tube itself, is directed forwards and outwards. The commencement of the first turn of the cochlea forms an eminence towards the cavity of the tympanum, called the *promontory*. The second turn lies at its commencement within the first, and only towards its termination rises decidedly above the level of it. By the base of the tube the cochlea is connected with the vestibule. The cul-de-sac at the apex forms a sort of vaulted roof called *cupola*.

The axis, or central pillar, modiolus s. columella cochleæ. The first turn of the cochlea takes a wider circular sweep than the rest, a sweep having an average diameter of a quarter of an inch, and is separated from the second turn by the interposition of a soft bony substance, which extends also a little way between the second and third. The axis, or central pillar, as has been pointed out by Ilg,* is nothing more than the internal walls of the tube of the cochlea and the central space circumscribed by their turns, in which space the filaments of the cochlear nerve, running in small bony canals, are contained. Now in consequence of the wide sweep the first turn of the cochlea takes in comparison with the rest, the axis is very thick, about one-seventh of an inch, where it is surrounded by the first turn, and rapidly becomes thinner from the second onwards to its termination. The last part of it is in fact formed merely by the fold which

* Einige anatomische Beobachtungen, etc. Prag. 1821, p. 7.

the internal wall of the tube of the cochlea necessarily forms where it bends abruptly at the last turn. This last part of the axis, viewed from the cavity of the second turn of the tube, has a funnel-like appearance, the wide mouth corresponding to the cupola; hence it is called *infundibulum* or *scyphus*. But viewed from the last turn, the so-called infundibulum is a mere free edge which proceeds directly to be confounded with the walls of the cochlea. But all this, if the disposition of a snail's shell, or a tube coiled round be rightly conceived, is understood of itself.

Exposed by the removal of the outer walls of the cochlea, the axis is somewhat like the common pictorial representations of the tower of Babel. It has a spongy porous appearance. It is pervaded by numerous small canals which run from its base onwards to orifices on its sides, corresponding to the spiral lamina, and transmit into the cochlea the ramifications of the cochlear branch of the auditory nerve and bloodvessels. The outermost of the canals are the shortest; towards the interior they gradually become longer, and there is one canal in particular wider than the rest, which runs throughout its whole length; it is called *tubulus centralis modioli*, and opens at the so-called infundibulum.

The base of the axis corresponds to the anterior part of the inferior depression at the bottom of the internal auditory meatus, and presents the commencing orifices of the small canals just mentioned, arranged in a spiral manner corresponding to the turns of the cochlea, *tractus spiralis foraminulentus* of Cotugno.*

Spiral lamina and scalæ of the cochlea.— The passages into which the tube of the cochlea is subdivided are called *scalæ*, and the partition *lamina spiralis*.

The spiral lamina is partly bony, partly membraneous; but as we are describing the osseous shell of the labyrinth only, it is with the bony part alone we have at present to do. The bony part of the spiral lamina, *zonula ossea laminæ spiralis*, is coiled round the axis or central pillar of the cochlea like the stairs in a spiral staircase. The internal or central margin of the bony spiral lamina is inserted on the axis. Its peripheral margin is free in the dry bone, so that the two scalæ are not found completely separated from each other, as in the recent state, when the membraneous extension of the spiral lamina exists. At the place where the spiral lamina is inserted on the axis, there is a sort of canal all round, which has been specially described by Rosenthal† under the name of *canalis spiralis modioli*.

The spiral lamina commences with a bend or sweep upwards and forwards at the base of the cochlea, below the hemispherical depression of the vestibule and opposite the bridge of bone which separates the vestibular fenestra from the cochlear fenestra. Its broadest part, which is about the middle of the first turn of the cochlea, is about one-twentieth of an inch. Towards the summit of the cochlea it insensibly contracts, and ceasing to be connected to the axis, where the latter presents the free margin already mentioned, terminates at the commencement of the third turn in a curved hook-like point. This hook, *hamulus laminæ spiralis*, has a free concave margin towards the axis, and a convex margin, which latter, however, like the rest of the peripheral margin of the bony spiral lamina, is not free in the recent state, but is continuous with the membrane which completes the partition.

In consequence of the above mode of termination of the bony spiral lamina by means of a free margin towards the axis of the cochlea, an opening of communication is left, even in the recent state, between the two scalæ of the cochlea. For this opening, which was called by Cassebohm* *canalis scalarum communis*, we adopt from Breschet† the name *helicotrema*.‡

The bony spiral lamina consists of two thin plates of bone, between which run numerous small canals from the central margin of the lamina to its peripheral—the continuation of those already described in the axis, and which therefore bend at a right angle in passing from the axis into the spiral lamina. At the free edge of the osseous part of the spiral lamina, the two plates of bone are intimately incorporated. This part of the bony spiral lamina, which is more delicate, denser, whiter, more transparent, and, in the recent state, more elastic than the rest, is what Breschet calls the middle zone. The surface of the spiral lamina corresponding to the tympanic scala is much marked with striæ running from the inner margin to the outer. The surface corresponding to the vestibular scala is less striated.

Of the two scalæ of the cochlea, one, *scala tympani*, communicates with the cavity of the tympanum through the fenestra rotunda or cochlear fenestra, which however, in the recent state, is closed by a membrane; the other, *scala vestibuli*, opens by an oval orifice freely into the vestibule, and it is only by means of the communication which the tympanic scala has with the vestibular scala through the helicotrema that the former communicates with the rest of the labyrinthic cavity. The tympanic scala is wider at the commencement than the vestibular, which on its part again is larger toward the termination. Near the fenestra rotunda there is in the tympanic scala a very minute orifice, that of the aqueduct of the cochlea. We shall return to the spiral lamina, the scalæ of the cochlea, and the mechanism of the helicotrema, when speaking of the membrane lining the labyrinthic cavity.

The aqueducts.—What are called the aqueducts are two canals of very minute calibre, opening by one extremity in the labyrinthic

* De aqueductibus auris humanæ internæ anatomica dissertatio, s. xxiv. pp. 36—38. Viennæ, 1774.

† Op. cit. s. xiv.

‡ Ελιξ, ελισσω, *volvere*, and τρημα, *foramen*.

cavity, and by the other on the surface of the petrous portion of the temporal bone. They are generally associated with the name of Cotugno,* who, though not their discoverer, was the first to give a complete description of them. One, called *aqueductus vestibuli*, communicates with the vestibule; the other, *aqueductus cochleæ*, with the tympanic scala of the cochlea.

The internal orifice of the aqueduct of the vestibule is observed to commence by a groove or sulcus, the *sulciform depression* already described in the vestibule, immediately below and in front of the opening common to the two vertical semicircular canals. From this the aqueduct turns itself round the inner wall of the common canal, and then follows a course downwards and backwards. Gradually widening, it opens under that sort of osseous scale observed a little behind the middle of the posterior and inner surface of the petrous bone, just above the jugular fossa; towards the latter there is usually a groove running on the surface of the bone from the orifice of the aqueduct. The length of the course of the aqueduct of the vestibule is about one-third of an inch.

The aqueduct of the cochlea commences by a very small orifice in the lower wall of the scala tympani immediately before the fenestra rotunda. It proceeds downwards, inwards, and forwards, in the inner wall of the jugular fossa of the temporal bone, and widening in its course it opens at the bottom of that triangular pyramidal depression, situated towards the middle of the edge which limits the inner and inferior surfaces of the petrous bone, and below the internal auditory meatus. The length of its course is about a quarter of an inch. The aqueduct of the cochlea is very wide in the pig. Of the aqueducts we shall observe farther in speaking of the membrane lining the labyrinthic cavity.

Membrane lining the labyrinthic cavity.—The cavities of the osseous labyrinth which we have just described are lined by a serous or fibro-serous membrane, extremely delicate and closely adherent to the surfaces. *The membraneous labyrinth must not be confounded with it.* This membrane, which may be compared to that serous pellicle on the inner surface of the sclerotica, known by the name of membrana fusca or arachnoidea oculi, is more manifest at an early age than in adults, and is nowhere so distinct as at the places where the nerves enter, and at the bottom of the tympanic scala of the cochlea. It is it which completes the spiral septum of the cochlea, by an arrangement immediately to be described.

The fenestra rotunda or cochlear fenestra is, in the recent state, closed by a membrane which shuts out the cavity of the tympanum from any direct communication with the cochlea. This membrane, called by Scarpa* the secondary membrane of the tympanum, *membrana tympani secundaria*, is concave towards the cavity of the tympanum, convex towards the tympanic scala of the cochlea, and is received at its circumference into a groove within the orifice of the fenestra rotunda. It is composed theoretically of three layers, the inner of which is nothing but the fibro-serous membrane under consideration. The outer layer is a continuation of that which lines the cavity of the tympanum. The third and proper layer is situated between the two mentioned. The same may be said in regard to that membrane, which, together with the base of the stapes, closes the vestibular fenestra.

The membrane lining the tympanic scala of the cochlea is continued into that lining the vestibular scala at the opening called helicotrema. The membrane of the vestibular scala is continuous with that lining the vestibule, which on its part is continuous with that of the semicircular canals. Lastly, the same membrane lines the aqueducts.

Such is a general description of the membrane lining the labyrinthic cavity; but to understand the disposition of the cochlea and aqueducts in the recent state, we must take a nearer view of this membrane such as it exists in those cavities, which, indeed, is the most important and difficult part of it.

Of the cochlea in the recent state.—The cochlea is the last addition made to the labyrinth in the ascending scale of the animal series. As was said, it is in birds in a very ru-

* Op. cit.

* De auditu et olfactu, cap. ii. s. 19. p. 35.

dimentary state. It is in fact a mere pouch or diverticulum not at all coiled up, in which, however, can be distinguished a part corresponding to a lamina spiralis, which is represented by a cartilage, and a vestibular and a tympanic scala, together with a cochlear fenestra. This analogy, much insisted on by Breschet,* I gave a brief notice of some years ago.†

The cochlea is richly supplied with nerves. The spiral lamina is that part of it on which its nerves expand; this must therefore be considered as forming a very essential element of the cochlea, and may be viewed as being in the economy of that part of the internal ear what the apparatus of the membraneous labyrinth is to the vestibule and semicircular canals.

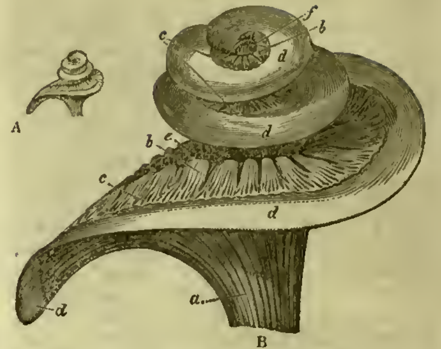
The bony spiral lamina is rendered a complete partition between the scalæ of the cochlea by a membraneous continuation, *zonula membranacea laminæ spiralis s. zona Valsalvæ*, formed by the application against each other of the membranes, which line the interior of the two scalæ, at the moment they are reflected from the free edge of the bony spiral lamina to the outer walls of the cochlea. Hence the spiral partition of the cochlea, when complete, is osseous at its inner or central part, and membraneous at its outer or peripheral.

The outer part of the osseous zone of the spiral lamina is thinner than the rest; it is semi-osseous, semi-membraneous, and the membraneous spiral lamina at its junction with it presents a fine cartilaginous stripe; hence Comparetti and Sömmerring described the spiral lamina as composed of concentric bands or zones. They admitted four, viz. 1, the inner thick part of the bony spiral lamina; 2, the outer thin part; 3, the cartilaginous stripe commencing the membraneous spiral lamina; and 4, the rest of the membraneous spiral lamina, or the membraneous spiral lamina properly so called. The first zone is continued into the hamulus cochleæ, the second ceases towards the second turn of the cochlea, and the third and fourth are continued beyond the hamulus cochleæ, forming of themselves the spiral partition in the last turn.

It is sufficient to admit, with Breschet,‡ only three zones; an osseous zone, a middle zone, and a membraneous zone; the third and fourth zones of Comparetti being comprehended under the latter.

The osseous zone of the spiral lamina we have already described, and alluded to the middle zone. The latter, when it still exists in the dry bone, appears merely as the outer margin of the former. It is the narrowest of the three zones, and is most distinct in the first

Fig. 234.



The axis of the cochlea and spiral lamina isolated, in order to show the disposition of the three zones. The vestibular lamina of the osseous zone is removed. (From Breschet.)

a. trunk of the cochlear nerve; *b.* distribution of the filaments of this nerve in the osseous zone; c. nervous anastomoses in the middle zone; *d.* membraneous zone; *e.* osseous substance of the axis; *f.* helicotrema or hole of communication betwixt the two scalæ.

turn of the cochlea. Breschet describes it as composed of the membranes lining the interior of the two scalæ, where they first meet each other in passing from the bony spiral lamina, together with osseous particles deposited between them. In this interstice between the membranes also are contained the last ramifications of the filaments of the cochlear nerve, still enveloped by their neurilemma, and sprinkled over by the small bony particles just mentioned.

Different from the middle zone, the membraneous zone goes on increasing in breadth, though not regularly, from the base to the summit of the cochlea. It is the longest and most extensive of the three zones. It is it alone which extends into the last turn of the cochlea. According to Breschet the membraneous zone should be composed of three layers, the two exterior of which should be, as already said, formed by the membranes lining the interior of the scalæ, and the middle one by the expansion and interlacing of the neurilemmatic sheaths from the middle zone; but these layers are so thin and so closely united that they are inseparable, and constitute a membrane of great thinness and transparency, on which, however, bloodvessels can be easily seen.

The membraneous zone presents a central margin continuous with the rest of the spiral lamina, except in the third turn of the cochlea, where this margin forms nearly the third of the circumference of the helicotrema, and where it runs into the peripheral margin at an acute angle. The peripheral margin, which is much thicker than the rest of the membraneous zone, is pervaded by a vascular sinus, like that which in the eye runs round the circumference of the cornea at the insertion of the iris.

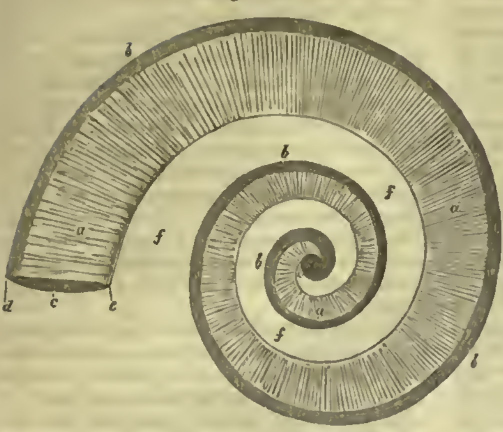
Fig. 235.



A diagram from Breschet, intended, according to him, to give an exact idea of the disposition of the helicotrema. The walls of the vestibular scala are supposed to be removed.

a a a. represent the osseous and middle zone of the spiral lamina; its termination in the hamulus or hook is seen; *b b b b.* this darker and narrower stripe represents the membraneous zone of the spiral septum; towards the summit of the cochlea it becomes a little broader, and at its termination constitutes by itself alone the septum between the two scalæ at their termination; *c.* the commencement of the tympanic scala; *d.* the external or great margin; *e.* the internal margin of the turns of the cochlea; the two margins *d* and *e* meet at *o*; *f f f.* the vacant space corresponding to the axis; it terminates at o, which corresponds to the summit of the axis; *x.* helicotrema or hole which establishes a communication between the two scalæ.

The section of the peripheral margin of the membraneous zone presents a triangular surface, the base of which is inserted on the osseous wall of the cochlea. This swollen margin of the membraneous zone is, according to Breschet, evidently continuous, at the origin of the spiral lamina in the base of the cochlea, with the osseous zone, a circumstance which is particularly to be remarked in very young fœtuses, where all these parts are still cartilaginous. This thickened margin of the membraneous zone Breschet therefore considers as analogous to the tympanic cartilage of the bird's cochlea, having exactly the same relations and uses.

Fig. 236.

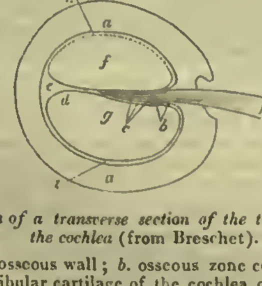


Diagram of a transverse section of the two scalæ of the cochlea (from Breschet).

a. a. osseous wall; *b.* osseous zone compared to the vestibular cartilage of the cochlea of birds; *c.* middle zone compared to the auditive lamellæ; *d.* membraneous zone; *e.* cartilaginiform swelling of the external margin of the membraneous zone, compared to the tympanic cartilage of birds; *f.* scala vestibuli; *g.* scala tympani; *h.* periosteum lining the vestibular scala, more vascular than fibrous; *i.* periosteum of the tympanic scala; *j.* nerve.

In vascularity and richness in nerves, the spiral lamina bears a great resemblance to the iris. Like it, also, it is the partition between two chambers, containing an aqueous humour, and communicating, like the aqueous chambers of the eye, by a single orifice.

The two scalæ of the cochlea have not the same length nor the same diameter. Toward the base of the cochlea the tympanic scala exceeds somewhat the vestibular; its diameter is, at the same time, also a little more considerable, as far as towards the middle of the first turn of the spire. The two scalæ have then the same diameter, and preserve the equality to the commencement of the last turn. There the tympanic scala contracts, and in particular flattens considerably, and is at last confounded, through the helicotrema, with the vestibular scala, which still continues for two-thirds of a turn, and then ends in a cul-de-sac. This is also to be noted in regard to the vestibular scala of the bird's cochlea, which indeed is very large, and proceeds considerably beyond the tympanic scala. It ends in a large cul-de-sac called *lagena*.

a. a. a. trunk of the cochlear nerve; *b. b.* filaments of this nerve in the osseous zone; *c. c. c. c.* nervous anastomoses in the middle zone; *d. d. d. d.* membraneous zone; *e. e. e. e.* swelling of the external margin of the membraneous zone; 1, 1, axis of the cochlea; 2, infundibulum; 3, 3, 3, 3, external osseous wall of the cochlea; 4, 4, 4, 4, osseous lamina separating the turns of the spire of the cavity of the cochlea; 5, 5, 5, 5, tympanic lamella of the osseous zone of the spiral lamina; 6. vestibular lamella; 7, hamulus or hook, which terminates the osseous zone; 8, helicotrema, with a bristle introduced into it.

Further observations on the aqueducts.—The aqueducts, the one leading from the vestibule, and the other from the tympanic scala of the cochlea, are lined by a continuation of the thin and delicate pellicle which invests the interior of those cavities.

Under the osseous scale, on the surface of the petrous bone, where the aqueduct of the vestibule ends, there is a small triangular pouch produced by a separation of the dura mater into two layers. Into this pouch the lining membrane of the aqueduct enters, and ends in a cul-de-sac. The pouch is called by Cotugno the *membraneous cavity of the aqueduct.* I found the structure just described of unusual size, in consequence of irregular development, in the ear of a man deaf and dumb from birth, which I examined some years ago. The triangular pouch in the dura mater was about one-third of an inch long at its sides, and was distended by a clear liquid. Every time pressure was made on the distended pouch, a fine jet of liquid issued through a small opening which had been made in the superior vertical semicircular canal. Similar cases have been described by Mondini* and others.

The lining membrane of the aqueduct of the cochlea ends, in like manner, in a cul-de-sac, which, however, is not so large as that of the aqueduct of the vestibule.

The liquid contained in the labyrinthic cavity, or liquid of Cotagna, or perilymph. (Aquula Cotunnii.)—The cavities of the osseous labyrinth contain a liquid, the secretion, probably, of their thin and delicate lining membrane. *They contain no air, as has been asserted.* The liquid called the liquid of Cotugno, or by De Blainville *perilymph*, must not be confounded with another which is contained in the interior of the *membraneous labyrinth.* Dominico Cotugno,† though not actually the discoverer of this liquid, yet took a more correct view of it than his predecessors in this branch of anatomical research, Valsalva,‡ Vieussens,§ Cassebohm,|| and Morgagni.¶ He in fact recognised in it a substance fulfilling some office in the exercise of hearing, a view of the matter which was admitted by Haller, and put beyond doubt by Ph. Fr. Meckel,** and since their time recognised by all physiologists.

The perilymph occupies, in the vestibule and semicircular canals, all the space not taken up by the membraneous labyrinth. The cochlea contains nothing but it; and as all the cavities of the osseous labyrinth communicate, it is the same humour in each.

In all fishes, except the cartilaginous with fixed gills, the labyrinthic cavity is very imperfect, being in many of them open towards the cranial cavity, or at the most separated from it only by a membraneous partition, as in the cod; hence the encephalic liquid in some of them is not distinct from the perilymph whose function it must perform. In the cartilaginous fishes with fixed gills, on the contrary, the labyrinthic cavity is completely separated from the cranial; therefore in them we meet with perilymph distinct from the encephalic liquid, and that, too, in pretty large quantity.

In birds the perilymph is in much less quantity than in the mammifera, in proportion to the size of the membraneous labyrinth. In reptiles the quantity of perilymph is still less.

Cotugno and Meckel supposed that the aqueducts were a sort of diverticula, or cavities which served to let off the superabundant perilymph, when necessary, during the act of hearing. This opinion is, however, now-a-days very much questioned, and several anatomists, Brugnone, Ribes, Breschet, &c., refuse to those aqueducts the uses which Cotugno assigned them, and consider them merely as canals destined for the passage of bloodvessels. Although they may be insignificant in a physiological point of view, still, if the description I have given of them be correct, they must be considered as something more than mere canals for the transmission of vessels. The constancy of the aqueducts, moreover, is another argument against their being mere vascular canals.

Breschet,* and in Hildebrandt's *Anatomie* by Weber† the same idea is concisely expressed, explains the mode of formation of the aqueducts by supposing that at first the labyrinthic cavity is nothing but a sac formed by a prolongation of the dura mater in the same way as the tunica vaginalis is of the peritoneum; that as development proceeds, the tube of communication between the labyrinthic sac of the dura mater and general cavity of the dura mater is gradually contracted and elongated; and that as ossification extends, the tube becomes surrounded by osseous substance, and presents itself under the appearance of an aqueduct. "This view," says Breschet, "is rendered probable, for in many fishes the labyrinthic cavity forms one with that of the cranium, and if, in these animals, a prolongation of the walls of the cranium tended to separate the brain from the ear, there would result a small canal establishing a communication between the two cavities, and this canal would be nothing but an aqueduct."

According to this view, the lining membrane of the labyrinthic cavity may be considered as a continuation of the arachnoideal layer of the dura mater, perhaps of the dura mater also.

osseous labyrinth is contained an extremely delicate and complicated membrano-nervous apparatus, called *membraneous labyrinth*, first properly described by Scarpa.* It does not extend into all the compartments of the osseous labyrinth, but only occupies the vestibule and semicircular canals. The cochlea, as has been said, contains in its cavity nothing but perilymph.

The vestibular part of the membraneous labyrinth, and of that perhaps one of the pouches only, is all that is really fundamental in the structure of an organ of hearing. In the Crustacea and Cephalopodous Mollusca in which the organ of hearing exists in its simplest form, and even in the Cyclostomatous fishes there is nothing but a small pouch containing a little liquid and a lapilliform body.

Much smaller than the cavities which contain it, the membraneous labyrinth is suspended as it were in the perilymph. It does not appear to adhere to the walls of the labyrinthic cavity except at the points where it receives nervous filaments.

The component parts of the membraneous labyrinth are:—

1. The common sinus. 2. The membraneous ampullæ and semicircular tubes. 3. The saccule.

Fig. 238.

The common sinus, membraneous ampullæ, and membraneous semicircular tubes.— These constitute but one apparatus which is just the counterpart of the vestibule, ampullary sinuses, and semicircular canals of the osseous labyrinth; the semicircular tubes opening into the ampullæ and common sinus in the same way

* De auditu et olfactu.

that the semicircular canals open into the ampullary dilatations and the vestibule.

The common sinus is an elongated, laterally compressed pouch, and lies in the posterior part of the vestibule. It extends into the upper horn to join the ampullæ of the superior vertical, and of the horizontal semicircular tubes; and into the posterior and lower horn, to join the ampulla of the posterior semicircular tube, and to receive the tubulus communis and cylindrical extremity of the horizontal tube, as they emerge from their respective canals. Its upper end, which is larger than its lower, lies in the hemi-elliptical cavity, to the bottom of which it is fixed by nervous filaments.

The membraneous tubes are only about a third part of the calibre of the semicircular canals in which they are contained. Like the latter they are distinguished by the epithets, superior vertical, posterior vertical, and horizontal. Each membraneous semicircular tube opens at one of its extremities, like its corresponding osseous canal, into an oval dilatation called *ampulla*, which on its part communicates with the common sinus. As the vertical semicircular canals unite at one of their extremities to form the common canal, so their corresponding membraneous tubes also unite to form a common tube, *tubulus communis*, which occupies the common canal.

At the place where the nervous filaments enter the common sinus, its wall presents a much more considerable thickness and consistence than elsewhere.

According to Steifensand,* who has examined the structure of the ampullæ very carefully, each ampulla presents a very much arched surface, *superficies convexa*, and opposite to this a concave or indented surface, *superficies concava s. inflexa*, which receives the nervous filaments. Where the nerve enters there is a transverse depression, *sulcus transversus*, by which this surface is divided into two parts. This transverse depression on the outside produces in the interior a fold of the membrane composing the wall of the ampulla, and through which the nerve enters. This fold forms a transverse septum, *septum transversum*, which divides the interior of the ampulla into two parts; one of which, the sinus part, communicates by the *osteum sinus* with the common sinus, and the other, the tube part, by the *osteum tubuli* with the membraneous tube.

Saccule, sacculus rotundus. This is a round membraneous bag, smaller than the common sinus in front of which it lies in the hemispherical depression of the vestibule. It is firmly fixed in its place by nervous filaments which proceed to it through the apertures observed in the bottom of the hemispherical depression. As has been mentioned in regard to the common sinus, the wall of the saccule presents an increase of thickness and consistence at the place where the nervous filaments enter it.

* Müller's Archiv. für Anat. Physiol. und wissenschaftl. Medecin. 1835. Heft. II. pp. 173, 174.

Small in the Mammifera, the saccule is very distinct and large in fishes.

The common sinus and saccule adhere to each other, but whether their cavities communicate has not been determined. They are fixed, as has been said, to the inner wall of the vestibule, by the nervous filaments which they receive through the apertures with which that part is perforated. Towards the outer wall they are nowhere in contact with the base of the stapes, the perilymph intervening. This circumstance, first distinctly pointed out by Scarpa,* and particularly insisted on by Breschet, shows that it is only by the intermedium of the perilymph that the movements of the stapes can have any impression on the nervous expansions of the membraneous labyrinth.

The common sinus, ampullæ, semicircular tubes, and saccule are composed of a firm transparent membraneous coat, within which is a nervous expansion, and outside which is a cellulo-vascular layer, in some places tinged black or brown. Of the nervous expansion we shall speak under the head of the auditory nerves. In the sheep, hare, rabbit, &c. the walls of the membraneous labyrinth present patches of black pigment, a circumstance noticed by Scarpa,† Comparetti,‡ and Breschet.§ Before I knew of the observations of these anatomists I had myself observed the fact. I was not, however, led to the discovery of it by accident; but, being engaged in researches on the pigment of the eye, and considering the analogy which the organs of sense bear to each other in their general anatomical structure, I was curious to know whether pigment did not exist also in the ear. Examination proved to me that it did; for I found, as Scarpa and Comparetti had previously noticed, pigment deposited in the form of small black spots in the membraneous parts of the labyrinth in different Mammifera. In some I have found a distinct cellulo-vascular layer of a black or brown colour forming the outer surface of the membraneous labyrinth. And, contrary to what Breschet asserts, I have found pigment in the membraneous labyrinth of the human ear also. It appears, especially on the ampullæ, under the form of a slight but perfectly distinct brown tinge, similar to what is seen around the ciliary processes in the eyes of Albinos.

Semicircular tubes are found in all the Vertebrate animals, with the single exception of the Cyclostomata. When they do exist there are never more nor less than three.

The common sinus, ampullæ, semicircular tubes, and saccule contain a limpid humour. Suspended in this humour there is found in the common sinus and also in the saccule a small mass of calcareous powder.

The liquid of the membraneous labyrinth,

§ Op. cit.

or endolymph or vitreous humour of the ear. (*Aquula labyrinthi membranacei. Humor vitreus auris.* Fr. *Vitrine auditive.* Germ. *Wasser des häutigen Labyrinths. Die Glasfeuchtigkeit des Ohres.*—This humour, first distinctly pointed out by Scarpa, fills exactly all the cavities of the membraneous labyrinth,—that is to say, in the human ear, the common sinus, ampullæ, the semicircular tubes, and saccule. Like the perilymph, it is almost as limpid as water. In the endolymph there are, as has been said, always found suspended calcareous concretions. The endolymph is in birds as limpid as in the Mammifera; but in reptiles it is in general more dense than water and a little viscid. It is viscid in all fishes, but especially so in the Chondropterygenous, in which it often presents itself in the form of jelly. It is also very decidedly viscid in the Cephalopodous Mollusca.

The masses of calcareous matter contained within the membraneous labyrinth.—In the ear-bulb of all animals which possess one, there are found small masses of a chalky nature; in some solid, in others pulverulent. Solid concretions are found in the osseous fishes, and in the Chondropterygenous fishes with free gills, such as the sturgeon. The chalky matter is in a pulverulent state in Mammifera, birds, reptiles, and in Chondropterygenous fishes with fixed gills. In the Batrachian reptiles and Cephalopodous Mollusca, the calcareous matter appears rather under a concrete form.

These calcareous masses are best known in osseous fishes, in which they are hard but brittle bodies of a determinate shape. In those animals, indeed, they have been erroneously considered as analogous to the tympanic ossicles of the higher Vertebrata. MM. Breschet* and Huschke† have lately called particular attention to the subject, and have described masses of calcareous matter in the ear of reptiles, birds, and Mammifera. Scarpa and Comparetti had observed them in the human ear, without, however, detecting their nature. But they had been unequivocally noticed before by De Blainville;‡ and previously to the first publication of Breschet's papers on the ear in the Annales des Sciences Naturelles, I had also studied them throughout the animal series.

Breschet has proposed for the solid masses the name of *otolithi*, from ους, auris, and λιθος, lapis; and for the pulverulent ones that of *otoconia*, from ους, and κονις, pulvis. Otoconia has been translated into German by Lincke § *Ohrsand.* Huschke calls the pulverulent matter ear-crystals, *Ohrkrystalle.* Krause, ear-chalk, *Ohrkalk.*

In the ear of man and the Mammifera in general there are two masses of calcareous matter; one in the common sinus and the other in the saccule. According to Huschke and Barruel they are composed of mucus, carbonate and phosphate of lime, and some animal matter. They are said to be more distinct in the fœtus than in the adult. From my own observations I should say that they exist in the human adult as distinctly as in the fœtus. Concretions are never found in the ampullæ or semicircular canals, either in man or any of the lower animals.

Examined in man and the Mammifera the concretions are suspended in the endolymph, and correspond to the points of the common sinus and saccule where the nervous filaments are implanted.

The grains composing the calcareous mass are held together by a soft mucous tissue.

Huschke describes the grains as crystalline, small six-sided columns, pointed at the ends with three surfaces. They appear to me, under the microscope, to have an oval form, more or less elongated, in man and the mammifera, passing into a spindle shape in birds and reptiles, and, though transparent, they do not present any very decided crystalline form. The particles of chalk examined through the microscope have a somewhat similar appearance, but much smaller. The grains of the ear are of different sizes. Of a mass which I removed from the ear of a middle-aged man, the greatest number had their longest diameter equal to that of the globules of the human blood, that is, about the three-thousandth part of an inch.

There is found in the cochlea of birds a mass of calcareous matter. Breschet says he has found, in cochleæ of the human fœtus, which had been dried but not macerated, small masses of cretaceous matter deposited near the summit of the cochlea; and Huschke* once found, in the fluid of the cochlea of a child, a collection of microscopical crystals.

Cruveilhier* asks, do the small masses of cretaceous matter, found in the ear of man and the mammifera, fulfil the same function as the stones in the ear of fishes? or must they be considered as a remains only of a part important in other animals? Breschet says, "the otolithes and otoconies have, for their use, to communicate to the nervous extremities a more vivid and energetic impression than a simple liquid like the endolymph could do; for the vibrations of a solid body are much more sensible for their force and degree of intensity than those of a liquid body." However this may be, it appears that the development of these concretions coincides, in some degree, with the medium inhabited by the animal; thus, they are stony in most animals living in water, and pulverulent in such as exist in air.

The auditory or acoustic nerve.—Nervus au-

ditorius s. acusticus.—Fr. *Nerf auditif ou acoustique.*—Germ. *Der Gehörnerv.*—The internal auditory meatus of the temporal bone appears to end in a cul-de-sac; but, examined more closely, the bottom is found divided into two unequal-sized depressions, an upper and a lower, by a crest, which extends backwards from the anterior and outer wall of the meatus. The upper depression, which is the smaller, is subdivided into two, an anterior and a posterior, by a small vertical pillar. The anterior leads into the aqueduct of Fallopius, and gives passage to the facial nerve. The posterior is almost funnel-shaped, and presents two or three pretty large apertures, and several smaller and less distinct ones. These are the mouths of small canals which lead into the vestibule, and their terminating orifices produce that sieve-like appearance in the pyramidal elevation between the hemi-elliptical and hemispherical depressions, and which extends towards the ampullary dilatations in the superior horn of the vestibule.

The lower and larger depression presents two subdivisions. The anterior and larger corresponds to the base of the axis of the cochlea; it presents a spiral groove or tract—*tractus spiralis foraminulentus*, answering to the turns of the cochlea, and perforated like a sieve by numerous apertures, which diminish in size towards the centre, where there is one opening larger than the rest. The posterior subdivision of the lower depression is a small superficial fossa, perforated by two or three larger, and a great number of smaller apertures, which open into the hemispherical depression of the vestibule, producing the sieve-like spot already mentioned as existing there. Below this superficial fossa there is a pretty large hole, leading into a canal in the posterior wall of the vestibule, which opens by several small orifices, forming the sieve-like spot within the mouth of the ampullary dilatation of the lower extremity of the posterior vertical semicircular canal.

The different minute apertures we have described give passage to the fibrils of the auditory nerve.

The internal auditory meatus is lined by dura mater.

The facial nerve enters the internal auditory meatus along with the auditory nerve. At the bottom of the meatus there is a communication between the two nerves, which was first pointed out by Mr. Swan. Separating from the auditory nerve, the facial leaves the internal meatus, by entering the aqueduct of Fallopius.

From its origin to about where it enters the internal auditory meatus, the auditory nerve presents most distinctly the delicate-walled tubular structure of brain. Within the meatus it assumes the ordinary thick-walled cylindrical tubular structure of nerves; a circumstance overlooked by Ehrenberg, when he adduced, as a peculiarity of the special nerves of sense, that they presented throughout their course the so-called varicose tubular structure.

The auditory nerve divides into two branches —an anterior, or cochlear; and a posterior, or vestibular branch,—which externally remain united together as far as the bottom of the meatus. The former is whiter, and has its filaments more compactly bound together than the latter. Examined under the microscope, the cylindrical tubules of the cochlear nerve appeared to me to be larger than those of the vestibular, and to contain, or at least to give out, a greater quantity of nervous medulla.

The anterior branch, or cochlear nerve, *nervus cochleæ*, is something like a flat tape rolled on itself longways. It proceeds forwards to that depression at the bottom of the internal auditory meatus, already described as corresponding to the base of the axis. Here it resolves itself into a number of fine filaments, which enter the apertures in the spiral tract of holes. Traversing the small bony canals leading from those apertures into the substance of the axis, they enter the bony spiral lamina according as their turn comes, by bending nearly at a right angle, and spread out upon it. The first filaments given off are the largest, the rest gradually diminish in size.

The first turn of the spiral lamina is supplied by those which enter the first turn of the spiral tract of holes; the second turn receives the filaments which traverse the bony canals, into which the fine apertures of the second turn of the spiral tract lead; and the last half turn is supplied by that large bundle of filaments terminating the nerve, and which, entering the axis by the large opening in the centre of the spiral tract, emerges at its summit.

The vestibular nerve, *nervus vestibuli*, which presents a small gangliform enlargement, divides into three branches. The uppermost, which is the largest, lies in the depression behind the entrance to the aqueduct of Fallopius. Its filaments having penetrated the vestibule by the small apertures of the canals already mentioned in the pyramidal elevation, arrange themselves into three fasciculi; of which one is distributed to the common sinus, and the other two to the ampullæ belonging to the superior vertical and to the horizontal semicircular tube.

The fibrils of the next branch enter the vestibule by the apertures at the bottom of the hemispherical depression, and terminate in the saccule.

The third, or lowest branch, which is the smallest, enters that canal described in the posterior wall of the vestibule, and which opens by a sieve-like spot within the ampullary dilatation of the posterior semicircular canal. Its fibrils are distributed to the ampulla of the posterior semicircular tube.

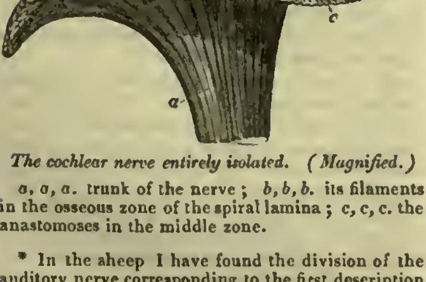
Such is the description of the divisions of the auditory nerve as given by most authors, and as it has appeared to me in the examinations I have made. Krause and Breschet, however, describe the mode of division differently. The former says the nerve of the saccule comes off from the cochlear nerve; the latter, that the cochlear nerve (which he calls the posterior fasciculus of the auditory nerve) gives off both the saccular nerve and the filaments to the posterior ampulla. I have not at present an opportunity to repeat my examination of the parts, to enable me to say positively which description is the most correct.*

The nervous fibrils of the cochlea, according to Breschet, traverse the osseous zone of the spiral lamina under the form of cylindrical bundles, which, in the *middle zone*, become flat, and anastomose by loops. These loops are intermingled with small osseous particles. Near the outer margin of the middle zone, the neurilemma leaves the nervous filaments, and goes to form the framework of the membraneous zone, whilst small globules are seen irregularly disseminated around the convexity of the loops which the filaments form by their anastomoses. All this, however, is not so unequivocally distinct as Breschet pretends. What I have been able to see in regard to the termination of the nerves on the spiral lamina, is simply this:— The tubular structure of the nervous filaments ceases, among grains of nervous matter arranged into a sort of expansion. There is nothing that can be called a termination in loops. Mueller thinks the nervous fibrils do not form loops in the bird's cochlea. "But," says Mueller, "it is of no consequence, in the present state of the physiology of the nerves, whether the nerves of sensation form at their terminations loops or not."

Treviranus† found a papillary termination of the nervous filaments, not only in the retina, but also in the nervous expansions of the ear and nose. The papillæ of the auditory nerve he saw on the spiral lamina of the cochlea in young mice. The osseous part is entirely covered with filamentous papillæ, lying close together. Gottsche also found the ends of the nerves of the cochlea in hares and rabbits club-shaped. In the hare, the nervous cylinders terminate in an oval knob.

The following figures from Breschet illustrate his views of the mode of termination of the nervous filaments of the cochlea.

Fig. 240.



The cochlear nerve entirely isolated. (Magnified.)

a, a, a. trunk of the nerve; *b, b, b.* its filaments in the osseous zone of the spiral lamina; c, c, c. the anastomoses in the middle zone.

B, *the same part considerably magnified to show the globular structure (?) of the nerves and the mode in which the neurilemma leaves them at the place where they form their anastomoses.*

a. Portion of the trunk of the cochlear nerve; *b.* fasciculi lodged in the osseous zone of the cochlea; c, *c.* anastomoses in the middle zone; *d, d, d.* the neurilemma leaving the nervous loops, interlacing and forming the basis of the membraneous zone.

As to the mode in which the nervous filaments enter and terminate in the membraneous labyrinth. The nervous filaments, according to Scarpa, before penetrating the vestibule of the small bony canals, lay aside their thicker sheath, and become softer and whiter. The filaments expand on the parts for which they are destined, appear to form a network, and, having penetrated into the interior, are resolved into a nervous pulp which lines the inner surface. Scarpa compares this nervous expansion in the saccule to the retina.

According to Breschet's account, the nervous filaments, in penetrating into the interior of the different membraneous pouches, are accompanied by a sheath furnished by the pouch itself, which is folded inwards, and accompanies them until these filaments spread themselves out. Hence it is that, at the entrance of the nerves, the walls of the pouch are always thicker, and form a more or less considerable projection in the interior. This prominence is slight in the saccule and common sinus, but very well marked in the interior of the ampullæ, where it forms a sort of incomplete septum across; a structure which is small in man and the mammifera, but very much developed in birds and the higher reptiles.

At those prominences the nervous filaments, says Breschet, present anastomosing loops, and the neurilemma leaving them to be incorporated with vessels, and thus to form the framework of the membraneous labyrinth, the nervous globules come into immediate contact with the mass of calcareous matter.

What I have said of Breschet's account of

* In the sheep I have found the division of the auditory nerve corresponding to the first description given above.

† Beiträge, &c. 1sten Bandes 2tes Heft. Neue Untersuchungen ueber die organischen Elemente der thierischen Koerper, p. 55. Bremen, 1835.

the terminations of the cochlear nerve is also applicable here. The filaments of the nerves of the common sinus and saccule expand in a fan-like manner on their walls, and having penetrated them, are resolved into a nervous layer like the retina, situated on the inner surface of the walls of those cavities. This nervous layer is, in the human ear, pervaded by extremely minute transparent fibres. In the rabbit I have distinctly seen, with a doublet magnifying 150 diameters, a fibrous or tubular structure similar to that of the retina first discovered by Ehrenberg.

As regards the entrance of the nerves of the ampullæ, Steifensand* gives a similar but more detailed account than Breschet. He says, the nerve, after having embraced in a forked manner about a third of the circumference of the ampulla, enters the wall of it.

Resolving itself now into infinitely fine filaments, the nerve penetrates the septum which lies quite close to the opening in the common sinus, and which resembles a semilunar eminence projecting into the interior. It now covers the surface of the septum and a circumscribed portion of the adjacent inner surface of the wall of the ampulla with an extremely delicate nervous pulp. The two ends of the semilunar septum, gradually flattening and spreading out, lose themselves in the wall of the ampulla.

Fig. 246, *(also from Steifensand.) The expansion of the nervous pulp over the septum.*

Bloodvessels of the labyrinth.—The principal artery of the labyrinth is the *arteria auditiva interior.* It is a branch of the basilar. It enters the internal auditory meatus along with the nerve of the seventh pair, and at the bottom of it divides into two branches, the cochlear and vestibular arteries, which enter the labyrinth with the corresponding nervous filaments.

The cochlear artery, *arteria cochleæ,* divides into a number of branches which enter the cochlea by the spiral tract of holes; one in particular, *arteria centralis modioli,* passes through the central canal of the axis as far as the apex of the cochlea.

The vessels of the walls of the cochlea are more numerous in the scala vestibuli than in the scala tympani. The arterial branches on the spiral lamina anastomose with each other at the outer margin of the osseous zone. From the convexity of the anastomotic arches numerous small arteries arise and run parallel as far as the outer margin of the middle zone, where they again anastomose, forming loops infinitely smaller, from the convexity of which capillary vessels run. These capillary vessels terminate in a sinus of a venous nature, lodged in the substance of the outer margin of the spiral lamina.

The vestibular artery, *arteria vestibuli,* supplies the vestibule and semicircular canals together with their contents, the saccule, common sinus, ampullæ, and semicircular tubes, and sends a branch along the surface of the spiral lamina corresponding to the vestibular scala. The *stylo-mastoid artery,* a branch of the *posterior auricular,* sends a twig to the external semicircular canal. The *occipital artery* also frequently sends twigs to the labyrinth.

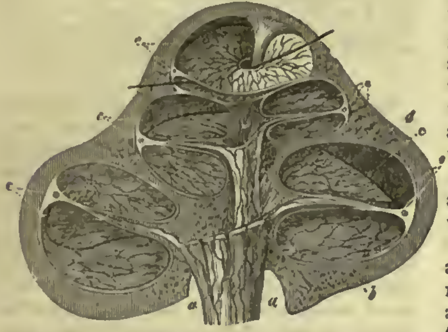
The bloodvessels form a beautiful plexus on the ampullæ, and considerable trunks run along the whole length of the semicircular tubes, supported on their surface by a delicate cellular tissue, which forms the vehicle for the passage of the small lateral branches given off to the walls of the tubes.

Not much is known of the veins of the labyrinth. The internal auditory artery is accompanied by a corresponding vein which carries away the blood from the labyrinth, and empties it into the superior petrosal sinus. Another vein, says Weber,* goes perhaps from the labyrinth through a small opening in the cleft of the aqueduct, and empties itself into the transverse sinus.

Of the veins of the cochlea, some, according to Breschet, accompany their arteries; others enter the sinus, lodged in the substance of the outer margin of the spiral lamina. Near the base of the cochlea, this sinus communicates with the veins of the vestibule.

Nothing is known of the absorbents of the labyrinth.

Fig. 247.



A section of the cochlea parallel to its axis, showing the distribution of the vessels in its interior. It is the veins that are delineated, but their distribution is almost the same as that of the arteries. Magnified. (From Breschet.)

a, a. Veins accompanying the trunk of the cochlear nerve, and penetrating the nervous branches across the spiral lamina; *b.* first anastomoses at the periphery of the osseous zone; *c, c.* second anastomoses at the periphery of the middle zone; *d.* last ramuscules, which are almost parallel, occupying the membraneous zone; *e, e, e.* venous sinus in the peripheral margin of the membraneous zone.

II. Accessory parts of the apparatus of hearing.

Of these parts, the auricle collects the sonorous undulations, and the auditory passage conducts them to the middle ear or tympanum, where they are modified and transmitted to the sensitive part of the apparatus, the ear-bulb.

A tympanum is found in reptiles, birds, and Mammifera, a perfect external ear only in the Mammifera. The lip-like folds of skin before the membrana tympani, in some birds and reptiles, may, however, be considered rudiments of an external ear. Among the Mammifera, the Cetacea have no auricle, and only a very contracted auditory passage.

It was said that the tympanum exists in a greater number of animals than the cochlea. This refers to a discovery made by Weber,† that a prolongation of the swimming-bladder in the herring, in the cyprinoid fishes, in silurus glanis, and in several species of cobitis, has a connexion with the membraneous labyrinth in the same manner that the prolongation of the mucous membrane of the throat, forming essentially the tympanum and Eustachian tube, is extended to the surface of the labyrinth; and moreover, that in all those fishes, with the exception of the herring, there exist bones analogous to the tympanic ossicles in the higher animals.

1. *The middle ear, or tympanum, and its appendages.*

The cavity of the typanum, cavitas tympani; Fr. *caisse du tympan ou du tambour;* Germ. *die Trommelhöhle oder Paukenhöhle.*—The cavity of the tympanum is a space lying at the peripheral surface of the ear-bulb, and measuring from above downwards as well as from before backwards about four-tenths of an inch, and from without inwards about three-twentieths of an inch. It is bounded internally by the outer wall of the osseous labyrinth; externally by a vibratile membrane, the membrana tympani, and that portion of the temporal bone into which it is framed. Anteriorly a canal, the Eustachian tube, leads from it into the throat; and posteriorly and superiorly it communicates with the mastoid cells.

The cavity of the tympanum is traversed by a chain of small bones, extending from the membrana tympani to the vestibular fenestra, and is lined by a very delicate membrane of a fibro-mucous character, which is prolonged into all its sinuosities and dependent cavities. This membrane is moreover reflected on the parts which traverse the cavity, and envelopes them. The lining membrane of the tympanum is continuous through the medium of that of the Eustachian tube, with the mucous membrane of the throat.

A condition essential to the due performance of the function of the tympanum is that the external air have free access to its cavity.

Examined on the dry bone, the *inner wall* of the tympanum presents a considerable eminence; behind and below which is an opening somewhat of a triangular form, and in a fossa above it another opening, about twice the size of the preceding, and of an ovoid shape. From the description which has been already given of the osseous labyrinth, it will be immediately perceived that the eminence in question, called the *promontory*, is that which the commencement of the cochlea forms; that the opening below and behind it is the *fenestra rotunda* or *cochlear fenestra*, and the opening above it the *fenestra ovalis* or *vestibular fenestra.*

The surface of the promontory is marked by a groove; sometimes instead of a groove there is a canal. This groove is continuous below with a canal, several lines in length, which opens in that depression in the partition betwixt the lower orifice of the carotid canal and the foramen lacerum posterius. Above, in front of the vestibular fenestra, the groove again runs into a canal which proceeds forwards and upwards between the canal for the internal muscle of the malleus and the commencement of the

* In Hildebrandt's Anatomie.

† De Aure et auditu Hominis et animalium, Lipsiæ, 1820.

aqueduct of Fallopius, and opens on the upper surface of the petrous portion of the temporal bone outside and in front of the hiatus of Fallopius. This canal, first accurately described by Arnold,* and called by him the tympanic canal, *canalis tympanicus*, is traversed by the nerve of Jacobson, which establishes a communication betwixt the glosso-pharyngeal and the otic ganglion. Besides this groove there are several others corresponding to the branches of the tympanic plexus of nerves.

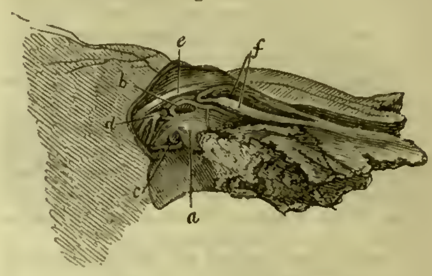
The opening below and behind the promontory, the *fenestra rotunda* or *cochlear fenestra*, leads, by a short infundibuliform canal directed obliquely inwards, into the lower or tympanic scala of the cochlea. Looking into this very short canal sideways, a groove is remarked encircling the margin of its inner orifice. This groove receives the circumference of the secondary membrane of the tympanum.

The opening above the promontory, the *fenestra ovalis* or *vestibular fenestra*, has already been described in speaking of the vestibule. All that we have to add here is that it is surrounded externally close to its edge by a small channel or groove.

Above the vestibular fenestra and running in much the same direction as its long diameter is a round elongated ridge, within which is the aqueduct of Fallopius. Below this ridge and behind the vestibular fenestra is a small mammillary or pyramidal eminence, called the pyramid, *eminentia papillaris s. protuberantia pyramidalis*. The apex of the pyramid, directed forwards and a little outwards, presents an opening leading into a canal, which extends backwards and downwards, then becoming vertical lies in front of the lower part of the aqueduct of Fallopius. In the thin lamina of bone which separates the two canals there is an aperture. The muscle of the stapes is lodged in the canal, and its tendon issues by the aperture in the apex, of the pyramid. About one-sixth of an inch behind the pyramid and close to the groove for the insertion of the circumference of the membrana tympani is the opening by which the chorda tympani, accompanied by an artery, enters the tympanum.

In front and a little above the vestibular fenestra, and on the anterior extremity of the prominence of the aqueduct of Fallopius, is a tubular projection with a wide open mouth directed outwards. This tubular projection, which is generally found incomplete in the dry bone, in consequence of being composed of a very thin brittle substance, is what has been called the *cochleariform process*. It is the continuation, bent at nearly a right angle outwards, of the canal or half canal, about half an inch in length, and destined for the reception of the internal muscle of the malleus, which lies above the osseous part of the Eustachian tube, and is separated from it merely by a thin lamina of bone, the continuation of that forming the tubular projection.

Fig. 248.



The inner wall of the tympanum.

a. Promontory; *b*. vestibular fenestra; *c*. cochlear fenestra; *d*. pyramid; *e*. eminence of the aqueduct of Fallopius; *f*. cochleariform process and half canal for the internal muscle of the malleus.

The outer wall of the tympanum is formed by the membrana tympani and the inner extremity of the osseous part of the external auditory passage, in which the membrana tympani is framed.

Osseous portion of the auditory passage.— This leads from the outside of the temporal bone. In front of it lies the glenoid cavity, and behind it is the mastoid process. It is about three-quarters of an inch long. Its course is from without inwards and from behind forwards, at first a little upwards and then downwards. It is wider at either extremity than in its middle. A cross section of the passage presents an elliptical orifice, the long diameter of which is directed from behind forwards and from below upwards. Its extremities are cut obliquely in such a way that internally the anterior wall exceeds the posterior, whereas at the outer orifice the posterior wall exceeds the anterior in length.

The margin of the *outer orifice* is rough and irregular to give attachment to the cartilaginous portion of the passage and to the auricle. Just within the *inner orifice* the osseous auditory passage is grooved all round except at its upper part. This groove is for the reception of the circumference of the membrana tympani.

In the fœtus the osseous portion of the auditory passage is a mere ring of bone, the *tympanic ring*, incomplete at the upper part where the groove in the adult is wanting. The tympanic ring serves as a frame for the membrana tympani. On the inner surface of the superior extremity of the anterior crus of this incomplete ring of bone there is a broad superficial groove, into which the processus gracilis of the malleus is received.

By-and-bye the tympanic ring is united to the temporal bone, and in process of time the part outside the groove grows outwards so as to form that plate of bone, thick behind, thin in front, rolled together in the form of an incomplete tube, which in the adult composes the lower, the anterior, and the posterior walls of the osseous auditory passage.

* Ueber den Canalis tympanicus und mastoideus, in Tiedemann's, Treviranus, und Gmelin's Zeitschrift für die Physiologie, B. iv. Heft 2, No. xxi. p. 284.

The tympanic ring lies immediately behind the glenoid cavity of the temporal bone, from which its anterior part is separated by a fissure. The middle part of this fissure, together with a line indicating the whole, remains permanent in the adult, and is known by the name of fissure of Glasser. Its internal orifice is, in the adult as it is in the young bone, in the outer wall of the tympanum, anteriorly of, and close to the groove for the reception of the membrana tympani. The fissure of Glasser gives passage to the ligament, or so-called great external muscle of the malleus, which is inserted into the processus gracilis of the malleus. The chorda tympani does not actually pass through the fissure of Glasser as commonly described, but as M. Huguier* has shown, through a particular canal, extremely narrow and about half an inch long, which runs in the line of the fissure, and opens at the re-entering angle between the squamous and petrous portions of the temporal bone.

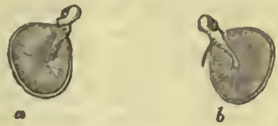
Membrane of the tympanum, (membrana tympani, Fr. *la membrane du tympan ou du tambour,)* Germ. *das Trommelfell oder Paukenfell.*—A proper membrana tympani exists only in birds and mammifera. In reptiles there is a very imperfect representation of one. In birds the membrana tympani is convex externally, in the mammifera, on the contrary, it is concave. The convexity externally in birds forms a very important distinguishing character of the class. In the cetaceous mammifera the membrana tympani is thick, and presents a prolongation like the tube of a funnel into the cavity of the tympanum.

The membrana tympani is situated at the bottom of the external auditory passage, between which and the cavity of the tympanum it is interposed like a partition. It is a thin, semi-transparent, glistening, dry-looking membrane. Its shape is an oval, truncated at one extremity, the upper. Rather more than the upper half of its vertical diameter is traversed by the handle of the malleus, which, when the membrane is examined on the living subject by means of the speculum auris, appears directed from above downwards and backwards.

The longest diameter of the membrana tympani, which is directed from above downwards, and from behind forwards, is about eight-twentieths of an inch, and its shortest, that from behind forwards, somewhat less than seven twentieths of an inch. It is fixed by its circumference in the circular groove already mentioned, at the inner orifice of the osseous part of the external auditory passage, or in the fœtus, the tympanic ring; and as in the adult the orifice is cut obliquely from behind forwards, from above downwards, and from without inwards, so is the direction of the membrane. Hence it forms, with the upper and posterior wall of the auditory passage, an obtuse angle, and with the lower and anterior wall, an acute angle.

Figure 249 represents the adult membrana tympani of the right side; *a.* as seen from the auditory passage; *b.* as seen from the tympanum. Its shape, size, the mode in which the malleus is connected with it, and the cartilaginous ring which forms its circumference, are sufficiently well shown.

Fig. 249.



The membrana tympani does not present plane surfaces. On the contrary its centre is drawn inwards, so that it is concave externally, and convex internally. This disposition of the membrana tympani depends on its connexion with the handle of the malleus. The latter being fixed in its whole length to considerably more than the upper half of the vertical diameter of the former, and having an inward direction inferiorly, the membrana tympani is, as it were, drawn inwards to it, hence the concavity externally.

As regards the composition of the membrana tympani, it consists of a proper membrane and two borrowed layers, one of which, covering the external surface of the proper membrane, is a delicate continuation, in the form of a blind end, of the lining of the auditory passage, and the other, situated on the inner surface, is a continuation of the delicate membrane which gives a lining generally to the cavity of the tympanum. The latter adheres very closely to the proper membrane, the other not so intimately, as it readily separates from it by putrefaction, and can be drawn out along with the rest of the epidermis of the external auditory passage in a cul-de-sac.

Structure of the proper membrane.—The proper membrane can be divided into two layers, an outer thin one, consisting of radiating fibres, and an inner thicker layer, which is less distinctly fibrous, though when torn it does indicate a fibrous disposition, and that in a direction opposite to the former. The radiating fibres run from its circumference towards the centre, to be fixed to the handle of the malleus along its whole extent. Towards the centre they become stronger, and being, of course, more aggregated, the layer which they compose is thicker and more compact in the centre than towards its circumference. The fibres which cross the radiating ones are also more aggregated at the centre. They run parallel with the handle of the malleus, and turn round its extremity. At the circumference of the proper membrane, there is a thick firm ligamentous or cartilaginous ring, (*fig.* 249,) which is fixed in the groove of the bone. This ligamentous ring appears to be formed by an aggregation of the circular fibres interwoven with the peripheral extremities of the radiating ones. The part of the membrana tympani midway between its centre and circumference is the thinnest.

The radiating fibres have been supposed to

* Cruveilhier, Anatomie Descriptive, tome iii. p. 508.

be muscular by Sir Everard Home and others, but this has not been confirmed by microscopical examination.

Mr. Shrapnell* describes at the anterior and superior part of the membrana tympani, above the short process of the malleus and its suspensory ligament, and where the groove in the bone is deficient, a flaccid tissue, composed of irregularly arranged fibres, to which he gives the name of *membrana flaccida*, in opposition to the rest of the membrana tympani, which he calls *membrana tensa*. This flaccid tissue is more developed in some of the lower animals, the sheep and hare for instance, than in man, and can be readily made to bulge out towards the auditory passage by blowing air into the Eustachian tube. But we cannot look upon it, with Mr. Shrapnell, as properly forming any part of the membrana tympani. It is merely a mass of dense, reddish, vascular cellular tissue, surrounding the neck of the malleus, and continuous with a similar tissue found under the lining integument of the upper wall of the osseous auditory passage. It is this same tissue which has been described as a muscle, and sometimes as a ligament.

The membrana tympani has been said to present in the natural state a perforation closed by a valve. Rivinus,† though not the first to mention it, dwelt on it, however, in a particular manner, hence the perforation has been called *hiatus Rivinianus*. The subject has been more recently taken up by Wittmann and Vest.‡

The membrana tympani receives a nerve from the third division of the fifth, which has communications with filaments of the chorda tympani.

To resume our description of the cavity of the tympanum:—In the upper wall of the tympanum there is an excavation for receiving the upper part of the incus, and leading from that, at the upper and back part of the tympanum, is a short, wide, triangular canal, with a rough cellular surface. This is the passage to the mastoid cells, through the medium of a large cell, *sinuositas mastoidea s. sinus mammillaris, s. antrum mammillare*, which already exists in the young bone between the squamous and petrous portions.

The mastoid cells are cavities in the mastoid process, all communicating with each other. They are quite irregular in regard to size, number, and relative situation. In early life, as the mastoid process is not fully formed, they do not exist, they are only found completely developed in the adult.

Inferiorly, the cavity of the tympanum forms a sort of furrow, which presents nothing particular. It is bounded by the plate of bone which forms the outer wall of the jugular fossa.

* On the form and structure of the membrana tympani, in London Medical Gazette, vol. x. p. 120. London, 1832.

† De auditus vitiis, Lipsiæ, 1717, 4, p. 32. Tab. adj. Fig. 1, *b*. et fig. 2, *b*.

‡ Ueber die Wittmannsche Trommelfellklappe, in den medizinisch. Jahrbüchern des oestr. Staates. Bd. v. Wien, 1819, p. 123, 133.

Anteriorly, the cavity of the tympanum opens into the osseous portion of the Eustachian tube.

The ossicles or small bones of the ear (ossicula auditus s. aurium, Fr. *osselets de l' ouie; Germ. die Gehörknöchelchen, or Gehörbeinchen).* In the upper part of the cavity of the tympanum, there are three small bones articulated with each other, and forming a chain which reaches from the membrana tympani to the vestibular fenestra. The bones are named *malleus, incus*, and *stapes*, from their resembling more or less respectively a hammer, an anvil, and a stirrup iron.

The innermost and most essential is the stapes; it is it alone which in birds and reptiles remains, when the others have disappeared, or been reduced to merely cartilaginous pieces. The stapes is engaged in the vestibular fenestra.

The outermost of the chain, the malleus, is in connexion with the membrana tympani.

The hammer bone, (malleus,) Fr. *le marteau*, Germ. *das Hammer*, presents a head, a neck, a handle, and two processes, one longer, and one shorter.

The head, *caput s. capitulum*, is round and smooth on one surface, and on the other presents a saddle-shaped depression, surrounded by a small elevated border. The depression articulates with the incus, and the border is for the attachment of the synovial capsule of this minute joint.

The neck, *collum s. cervix*, is flattened in one diameter, and joins the handle at an obtuse angle.

The handle, *manubrium mallei*, compressed from the side corresponding to the articular depression to the opposite side, and diminishing in thickness towards its extremity, forms, together with the short process, a double curve, like an Italic *f*. The extremity is also compressed, as if beaten flat, but in an opposite direction, so that the broad surfaces of the extremity correspond to the edges of the rest of the handle.

Short or blunt process, *processus brevis s. obtusus*. From the projecting side of the angle formed by the junction of the neck and manubrium, this process, which is short, thick and conical, rises.

The long or slender process, *processus longus, s. gracilis, s. spinosus, s. Folii*, springs from the neck, and from that side of it which corresponds with the non-articular surface of the head. The long process is of considerable length, and terminates in a broad, flat, spatula-like extremity, first described by Rau,* although the commencement or root of the process itself had been previously delineated and described by Folius. The long process is generally found broken off, either from its being so slender, or from its having been, especially in old subjects, united to the groove in which it is lodged.

The anvil bone, incus, Fr. *l'enclume*, Germ.

* Boerhaave Prælect. in Instit., Prop. iv. p. 358.

der Amboss.—This has been compared, also, to a bicuspid molar tooth. It is divided into a body, and two processes, or crura.

The body, *corpus*, presents a concave articular surface, by which it is joined to the malleus: around this surface is a groove, (particularly deep and broad on the side towards the labyrinth, that is, the side on which the lenticular process projects,) for the insertion of the articular capsule.

The shorter of the two processes, *crus s. processus superior s. brevis*, is blunt at its apex, and compressed from one side to another.

The longer process, *crus s. processus inferior s. longus*, is more slender, and becomes gradually thinner towards its extremity, where it is slightly curved, and where it presents, supported on a short bony pedicle, given off at a right angle from its side, the lenticular process, *processus lenticularis incudis*;*—a small oval plate so situated, that a line drawn through the long diameter of it would intersect obliquely a line corresponding to the long crus of the incus. The free surface of the lenticular process is convex, and is destined to articulate with the corresponding concave surface on the head of the stapes. The lenticular process has been, and is still, often described as a separate bone, under the name of *os lenticulare*.

The stirrup bone, (stapes). Fr. *L'etrier.* Germ. *Der Steigbügel.*—Exactly like a stirrup, this bone presents a base, two crura, and a head, where the crura unite.

The base, *basis*, the essential part of the bone, has precisely the same shape as the vestibular fenestra to which it is applied, only a little smaller. The arched margin of the base corresponds to the upper edge of the fenestra, and the indented margin to the lower edge.

The surface of the base corresponding to the vestibular fenestra is slightly convex. The other surface is grooved; but the groove is subdivided by a ridge, which extends obliquely along it lengthways, and which is continuous at its extremities with the upper margin of the groove on the inner surface of one crus, and the lower margin of the groove of the opposite crus. The margin of the base projects like a ledge beyond the insertion of the crura.

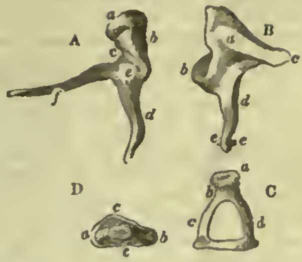
Of the two *crura*, one is shorter and straighter than the other; both are grooved on the surfaces regarding each other, and the grooves are continued into that just described in the base, in such a way that the groove of one crus is continued into one of the divisions, and the groove of the other crus into the other.

The head, *capitulum*, somewhat oblong and flat, presents a superficial depression on its top, oblique from above downwards, and from without inwards, for receiving the convex articular surface of the lenticular process of the incus. There is sometimes an appearance of a *neck* supporting the head.

Position, connexions, and articulations of the small bones of the tympanum.—The handle of

* Blumenbach, Geschichte, und Beschreibung der menschl. Knochen, s. 50, p. 145.

Fig. 250.



Small bones of the tympanum of the left side, magnified considerably more than twice. (From Soemmerring.)

A is the malleus seen from the side corresponding to the membrana tympani: *a.* head; *b.* articular surface; c. neck; *d.* handle; *e.* short process; *f.* long process.

B. The incus seen from its outer surface also: *a.* body; *b.* articular surface; c. short crus; *d.* long crus; *e e.* lenticular process.

C. The stapes: *a.* head; *b.* neck; *c.* anterior and less bent crus; *d.* posterior and more bent crus; *e.* base.

D. A fore-shortened view of the stapes: *a.* anterior and less curved crus; *b.* posterior crus, the two are seen uniting at the head, the articular surface of which is seen; c. base.

the malleus is fixed to the membrana tympani. The articular surface on the head of the malleus, to the corresponding surface on the body of the incus, and the long process of the incus, is through the medium of its lenticular process articulated with the stapes. These two joints are furnished with small articular capsules.

The head of the malleus lies in the upper space of the tympanum, above the upper margin of the membrana tympani. Its articular surface is directed obliquely backwards and inwards. The surface of the neck, corresponding to the prominence of the angle which it forms with the manubrium, is hitched like a shoulder under the upper part of the circumference of the inner extremity of the auditory passage. The handle of the malleus, it has been said, is compressed from one side to another, so that it presents two flat surfaces and two edges or ridges. That edge or ridge which is continued down from the short process is turned outwards, and corresponds to the membrana tympani; into it, indeed, along its whole extent, the central extremities of the radiating fibres of that membrane are inserted. The extremity of the handle of the malleus, which is curved forwards and outwards, is compressed, but in a direction contrary to the rest of the handle; so that one of the flat surfaces, that corresponding to the outer ridge of the rest of the handle, is connected with the membrana tympani at a point below its centre, and nearer its anterior edge. It is at this point that the bottom of the concavity is which the membrana tympani presents externally. At its upper part the membrana tympani is pushed outwards by the short process of the malleus, which projects towards the auditory passage.

The long process of the malleus is directed forwards, and lies in a groove within the anterior part of that for the reception of the membrana tympani, and close to the fissure of Glasser.

To the top of the head of the malleus, a ligament extends downwards from the upper wall of the cavity of the tympanum. Another ligament, known also under the name of the *great external muscle of the malleus,* proceeds from the spinous process of the sphenoid bone backwards and inwards, through the fissure of Glasser, and is inserted into the long process of the malleus. A third ligament has been described, as arising from within the upper and posterior margin of the inner orifice of the auditory passage above the margin of the membrana tympani, and proceeding downwards and inwards to be inserted into the handle of the malleus below the short process, close to the place where the connexion between the handle of the malleus and the membrana tympani ceases. Of this ligament, which has also been described as a muscle, *small external muscle of the malleus,* there is not much trace, except in the reddish cellular tissue already mentioned.

The body of the incus lies in the upper and posterior part of the tympanic cavity. Its articular surface, corresponding to that of the malleus, is directed forwards, and a little upwards and outwards. The articulating surfaces of the two bones are incrusted with cartilage, and the joint is provided with a synovial membrane, which is strengthened by ligamentous fibres. The short branch is directed horizontally backwards towards the entrance into the mastoid cells, and is there fixed by means of a short and broad ligament, which arises from a small pit in the outer wall, and embracing its extremity, is inserted on it. The long branch extends perpendicularly downwards, almost parallel with the handle of the malleus, but nearer the inner wall of the tympanum, towards which its extremity, bearing the lenticular process, is curved.

The *stapes,* situated lower down in the cavity of the tympanum than the other bones, lies with its base applied to the vestibular fenestra, to the circumference of which it is closely fixed by a circular ligament, *ligamentum annulare baseos stapidis.* This ligament springs from the margin of the vestibular fenestra, and is inserted into the jutting margin of the base of the stapes all round. Besides this ligament, there are reflections of the membrane lining the tympanum, and of that lining the vestibule. The connexions of the base of the stapes with the vestibular fenestra are such as to admit of some degree of movement, but not to any very great extent,—so little, that it would seem one object of the mechanism of the fenestra ovalis, and its closure by the base of the stapes, was merely to interrupt the continuity of the osseous walls of the vestibule.

The short branch of the stapes is in front; the long branch behind, and its head outwards, where it meets and articulates with the lenticular process of the long branch of the incus. This articulation presents also cartilages of incrustation, and a minute synovial capsule, together with strengthening ligamentous fibres.

Fig. 251.

The small bones connected together, and their relation to the osseous labyrinth. Left side. Magnified. (From Soemmerring.)

Muscles of the small bones.—Some anatomists admit four muscles: three attached to the malleus and one to the stapes. Of the three attached to the malleus, two are described as having for their action the relaxation of the membrana tympani; but these so called *laxatores tympani* are merely ligaments, and have been described above as such. I agree with Hagenbach,* Breschet,† and Lincke,‡ that two muscles only can be distinctly demonstrated, and these two are both tensors of the tympanum. A relaxation, or state of rest of the membrana tympani, takes place of itself, as Treviranus§ remarks, when the tensors cease to act; hence a relaxator muscle of the membrana tympani was not required.

Muscle of the malleus, *musculus internus mallei s. tensor tympani.*—This muscle occupies the canal, or half canal, which was described as lying above the osseous part of the Eustachian tube. It arises from the posterior and under part of the sphenoid bone, from the superior part of the cartilaginous portion of the Eustachian tube, and also from an aponeurotic sheath which lines the canal, or completes the groove in which it is lodged. Its fibres proceed from before backwards, and terminate in a slender tendon, which bending at a right angle, as a rope over a pulley, enters the cavity of the tympanum, through the tubular projection already described as a continuation of the canal in which it lies. Having entered the tympanum, it proceeds outwards, and is inserted into a slight elevation, sometimes remarked on the inner and anterior surface of the handle of the malleus below the long process, and also a little below and opposite the root of the short

* Disquisitiones anatomicæ circa musculos auris internæ hominis et Mammalium, &c. Basileæ, 1833, p. 20.

† Op. cit. s. xxxiii.

‡ Das Gehörorgan, &c. Leipzig, 1837, p. 140, s. 114.

§ Biologie, Band. vi. p. 376.

process. The muscle of the malleus receives a nervous branch from the otic ganglion.

By the action of this muscle, the handle of the malleus is drawn inwards and forwards, whilst the head is moved in the opposite direction, in consequence of the bone moving on its long process as on an axis. The result of this movement of the bone is, that the membrana tympani, which is attached to the handle of the malleus in its whole length, is also drawn inwards and stretched. Besides the tension to which the membrana tympani is thus subjected, the base of the stapes is forced against the vestibular fenestra, in consequence of the movement communicated by the head of the malleus to the incus, which tends to press inwards the long extremity of the latter.

Muscle of the stapes, M. stapedius.—This is lodged, and takes origin in the cavity of the pyramid already described. Much paler and smaller than the preceding muscle, it is inserted into the posterior and upper part of the head of the stapes by a slender tendon, which issues by the aperture in the summit of the pyramid, and proceeds downwards and forwards to its termination.

The stapedius muscle receives a nervous filament from the facial nerve.

The first effect of the action of this muscle will be to press the posterior part of the base of the stapes against the vestibular fenestra. At the same time the long branch of the incus will be drawn backwards and inwards, and the head of the malleus being, by this movement of the incus, pressed forwards and outwards, its handle will be carried inwards, and the membrana tympani thus put on the stretch. Breschet calls the muscle of the stapes a *laxator*, but I do not know on what grounds.

Magendie* mentions the circumstance that in the stapedius muscle of the ox and horse, there is imbedded a small lenticular bone. Professor Berthold of Göttingen† has more lately called attention to the same circumstance. Berthold has not found this bone in man, nor sheep, nor deer, nor goats, nor swine. In the ox and calf it is about one-half to three-fourths of a line in its longest diameter, and one-third in the shortest, and lies surrounded by the muscular and tendinous substance where the former passes into the latter. In the horse it is a little nearer the lower margin of the muscle and tendon, and is much smaller than in the ox; moreover, it is not round, but is a longish plate, somewhat thicker in the middle.

At the place where the stapedius muscle is inserted into the stapes, Hyrtl‡ has sometimes found in the human ear a small process of bone which in some cases was so long as to extend into the belly of the muscle itself. Teichmeyer* has described this free bone of the stapedius muscle as constant in man.

* Sur les organes qui tendent ou relachent la membrane du tympan et la chaine des osselets de l'ouie dans l'homme et les animaux mammifères. In Journal de Physiologie experimentale, t. 1., p. 346. Paris, 1821.

‡ Beiträge zur pathologischen Anatomie des Gehörorgans, in the Medicin. Jahrbücher des k. k. oestr. Staates. Wien 1836. Bd. xx. p. 439.

Having described the walls and contents of the cavity of the tympanum, we come now to speak of the membrane which lines it.

The lining membrane of the cavity of the tympanum is in continuity with the mucous membrane of the throat, through the Eustachian tube. Extremely delicate, and in some parts very vascular, it is not merely a mucous membrane, but is theoretically a combination of periosteum and mucous membrane, being what Bichat called fibro-mucous. It invests all the elevations and depressions observed on the walls of the tympanum, and extends into the mastoid cells. The outer layer of the membrane of the fenestra rotunda, *membrana tympani secundaria*, is a continuation of it.

The base of the stapes is fixed by its circumference to the outer edge of the groove, which encircles the vestibular fenestra, by a membrane or ligament. The lining membrane of the vestibule, continued over the base of the stapes from within, also invests the inner surface of this annular ligament, whilst the outer surface of it is covered by the membrane lining the tympanum as it is reflected on the stapes.

The membrane lining the tympanum invests the small bones and the tendons of their muscles where they run free in the cavity. A fold of it fills up the space bounded by the crura and base of the stapes. The chorda tympani, also, in its passage across the tympanum, is enveloped by it. Lastly, it forms the inner borrowed layer of the membrana tympani, covering and adhering closely to the handle of the malleus.

The Eustachian tube, (tuba Eustachii, s. canalis palatinus tympani; Fr. *la trompe d'Eustachi;* Germ. *die Eustachische Röhre oder der Gaumengang des mittleren Ohrs.)* — The Eustachian tube is a passage of communication betwixt the cavity of the tympanum and the throat. In length about an inch and a half, it is directed from behind forwards, from without inwards, and from above downwards. Its guttural orifice is wider than that by which it opens into the tympanum.

Proceeding from the tympanum, its first part is an osseous canal, *the osseous part of the Eustachian tube;* the walls of the remainder of it are composed partly of cartilage, partly of fibrous membrane, *the cartilaginous and membraneous portion of the Eustachian tube.*

The osseous part of the Eustachian tube, *pars ossea tubæ Eustachii*, begins at the anterior and lower part of the tympanum, by a funnel-like orifice, and runs forwards and inwards on the outside of the carotid canal, and below that for the reception of the internal muscle of the malleus. It is about half an inch in length, and ends by a notched and irregular edge at the re-entering angle, between the squamous and petrous portions of the temporal bone. Its calibre contracts in its course forwards, and is compressed from without and below inwards

* Vindiciæ quorundam inventorum anat. in dubium vocatorum. Jenæ 1727. 4.

and upwards. In the dry bone it is wide enough to admit the end of a quill stripped of its feathery part, about one-twelfth of an inch thick. In the recent state, when lined by its mucous membrane, it is very much narrower.

The cartilaginous and membraneous portion of the Eustachian tube, pars cartilaginea et membranacea tubæ Eustachii.—In the skull it is observed that the osseous part of the Eustachian tube is continuous with a sort of gutter which is formed by the outer and anterior side of the petrous bone, and the posterior inner and lower margin of the great wing of the sphenoid bone. To this gutter the external wall of that part of the Eustachian tube under consideration, which is partly cartilaginous and partly fibro-membraneous, corresponds at its tympanic extremity; towards the guttural orifice of the tube, the membraneous wall is applied against the circumflex muscle of the palate. The inner, and also the upper wall of this portion of the Eustachian tube, is formed of a grooved cartilaginous lamina of a triangular form, fixed by dense cellular tissue to the irregular extremity of the osseous portion, to the apex of the petrous bone, and to the root of the inner plate of the pterygoid process of the sphenoid. At the guttural orifice of the Eustachian tube, it forms a semilunar prominence with its convexity turned upwards and backwards. The cartilaginous plate of the outer wall does not extend to the mouth of the tube, but only fills up that place where the outer wall of the bony groove above-mentioned as continuous with the osseous part of the Eustachian tube is defective, that is, from before the foramen spinosum of the sphenoid to the scaphoid fossa at the root of the inner plate of the pterygoid process.

The cartilaginous and membraneous portion of the Eustachian tube is about one inch long. Being compressed from within outwards, a section of it is an elliptical fissure. From its junction with the osseous portion, it goes on widening, so that the point of junction is the narrowest part of the tube;—in the recent state, about one-thirtieth of an inch in diameter, just sufficient to admit a small probe.

The mouth of the Eustachian tube in the throat forms an oval-shaped fissure, about three-eighths of an inch long, bounded anteriorly and posteriorly by prominent swollen edges. The fissure is directed obliquely from above downwards, and from before backwards, and is situated at the upper and lateral part of the pharynx behind the soft palate. In reference to the nasal passage, my observation agrees with that of Kramer,* that the *lower angle* of the guttural orifice of the Eustachian tube *lies a very little deeper* than the *horizontal line of the lowest meatus*, whilst *the upper angle is a little deeper than the horizontal line of the middle meatus.*

The Eustachian tube is essentially a tegumentary canal; through it atmospherical air is admitted into the tympanum, a condition which, by keeping up an equable pressure on either side of the membrana tympani, and giving free scope to the play of the small bones upon each other, is necessary for the perfect exercise of hearing. Its lining membrane is continuous with that of the throat on the one hand, and with that of the tympanum on the other. At the guttural orifice of the tube, it has all the properties of the mucous membrane of the nose and throat; as it approaches the tympanum it becomes thinner and finer, until it assumes all the characters of the fibro-mucous lining of the tympanum. Within the osseous portion of the tube, it no longer presents any of the mucous glands which are found in the mucous membrane of the prominent edges of the guttural orifice, and in that lining the cartilaginous and membraneous portion—mucous glands, which perform so important a part in the economy, and particularly the morbid states, of the Eustachian tube and apparatus of hearing generally.

2. *The external ear, including the auditory passage.*

A. The auricle or the ear, (auricula s. pinna,) Fr. *pavillon de l'oreille;* Germ. *das Ohr.*—The human auricle, as is known, presents on the surface directed outwards, prominences bounding gutter-like depressions, which wind like a maze in different directions; but all lead at last into the auditory passage. Considered in a general way, the surface directed outwards is concave. The surface turned towards the side of the head is, on the contrary, generally speaking, convex, but it is depressed at the places corresponding to the elevations on the outer surface, and more elevated where the depressions are.

The hem-like fold of the edge of the ear all round is called *helix*. The eminence within the helix is called *anthelix*, and the gutter-like depression between the two is called the *navicular fossa*. At its upper extremity the anthelix divides into two branches, between which is a triangular depression called *fossa innominata*. The lower extremity of the anthelix runs into a projection called *antitragus*, opposite which, and under the anterior part of the helix, is a broad projecting plate called *tragus*, which lies over the entrance of the auditory passage

* Die Erkenntniss und Heilung der Ohrenkrankheiten. Berlin, 1836. p. 243.

like a valve. The posterior margin of the tragus, and anterior margin of the antitragus, meet inferiorly; but superiorly they are separated by a considerable notch. Bounded by the anthelix, tragus, and antitragus, and traversed horizontally by the commencement of the helix, is a deep cavity, called *concha*, at the anterior part of which is the auditory passage leading from it, as the pipe from the mouth of a funnel. The lower pendulous part of the ear is called *lobule*.

Fig. 253.

The auricle of the left side (reduced in size). (From Soemmerring.)

Stripped of the skin which invests it, the auricle is found to be composed of a cartilaginous skeleton, on which its elasticity depends. The skeleton presents, with some modifications, all the eminences and depressions we have described, except the lobule, which consists merely of a prolonged fold of skin, between the layers of which is cellular and adipose tissue.

In the skeleton of the auricle, the *helix* commences by an acute point in the excavation of the concha. Gradually becoming broader and more elevated, it proceeds obliquely upwards and forwards, then turning round the upper margin of the ear, contracts in breadth; and about the middle of the posterior margin, its hemlike fold having ceased, its simple edge is continued into a free tail-like process of cartilage, which is separated by a fissure from the antitragus. On the anterior part of the helix above the tragus, there is a mammillary process of cartilage which gives attachment to a ligament. Behind and below the root of this mammillary process, there is a small vertical fissure in the helix, *incisura helicis*.

Regarding the *anthelix* there is little more to be said, except that the lower branch of its upper extremity forms a very prominent crest; and that inferiorly the anthelix is continued into the same tail-like process that the helix runs into, and is also partly continued into the antitragus.

The *antitragus* is a small plate of cartilage, forming an angle, directed upwards and forwards. It is continuous by its base with the cartilage of the concha. The lobule hangs from the antitragus, and the tail-like process of cartilage common to the helix and anthelix.

Tragus.—Between the helix and tragus there is no connexion by cartilage. The space is merely filled by a continuation of the fibrous cellular tissue which constitutes the upper and posterior part of the cartilaginous and membraneous portion of the auditory passage.

The cartilage of the ear is covered by perichondrium, which imparts considerable strength to it. When the perichondrium is removed by dissection, the cartilage is found to be very brittle.

Fig. 254.

a. a. a. a. helix; *b.* anthelix; *c.* two crura of anthelix; *d.* cavity of the concha; *e.* antitragus; *f.* tragus; *g.* fissure between the tragus and commencement of cartilaginous portion of the auditory passage, the larger fissure of Santorini.

Skeleton of the cartilage of the external ear (diminished). (From Soemmerring.)

The skin covering the cartilage of the ear adheres intimately to its unequal surface, less so to its back and circumference. The lower part of the hem-like fold of the helix is formed entirely by it; also the lobule, as has been already said. The skin of the auricle contains a number of sebaceous follicles, particularly in the concha, and around the entrance of the auditory passage.

On the tragus is observed, especially in old people, a small tuft of hair, which has been compared to a goat's beard; whence the name tragus, (τραγος, hircus,) which the Germans translate *Bock*. The *antitragus* they call *Gegenbock*.

Ligaments of the ear. Anterior ligament, (ligamentum auriculæ anterius).—This proceeds from the root of the zygomatic process to the lower and anterior part of the helix, and to the tragus.

Posterior ligament, (ligamentum auriculæ posterius).—Extends from the outer surface of the mastoid process to the posterior surface of the cartilage of the ear, where the concha runs into the auditory passage. Besides the above ligaments binding the ear to the head, there are others which extend from one point of the cartilage of the ear to another.

Muscles of the ear.—The muscles of the ear fall into two classes: viz. those which, arising from the head, are inserted into the ear, and move it as a whole; and those which, extending from one part of the cartilage to another, are calculated, were they strong enough, to produce a change in the general form of the auricle.

Muscles which move the ear as a whole, or the extrinsic muscles.—The elevator, or superior muscle of the ear, (M. attollens auriculam s. superior auriculæ), is a broad thin muscle, composed of fibres spread out on the upper part of the side of the head. It arises from the middle part of the epicranial aponeuroses, and also from the temporal aponeuroses; thence, to its insertion into that elevation of the ear-cartilage on the surface next the head, which corresponds to the fossa innominata, the fibres become more aggregated, so that the muscle is much narrower, but thicker inferiorly than superiorly. By elevating the upper part of the ear, it will widen and straighten the auditory passage.

The retractor or posterior muscles of the ear, (M. retrahentes auriculam, s. posteriores auriculæ.) These ordinarily consist of three bundles, sometimes only two, which, taking their origin from the mastoid process, run forwards to the cartilage of the ear, into which they are inserted at the eminence on the back of the concha, corresponding to the commencement of the helix on the other side.

In drawing the ear backwards, these muscles will dilate and flatten the concha, and widen the entrance to the auditory passage.

The anterior muscle of the ear, (M. attrahens auriculam s. anterior auriculæ,) arises from the zygomatic process, and, in its course backwards to the ear, gradually contracts, until it ends in a short tendon, which is inserted into the anterior surface of the helix, immediately above the tragus. It draws the ear forwards.

Fig. 255.

The cartilage of the left auricle from behind, and the extrinsic muscles (diminished). (From Soemmerring).

a. m. attollens auriculam; *b.* m. anterior auriculæ; *c. d.* two m. retrahentes auriculam.

Intrinsic muscles of the ear.—These muscles are very delicate and weak, little adapted to produce any sensible change in the form of the ear. Five are admitted:—

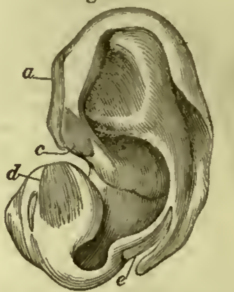
The larger muscle of the helix, (M. helicis major,) arises from the lower and anterior part of the helix, on the outer and anterior surface of which it ascends for about three quarters of an inch, and then is inserted into the helix above the point where the ear becomes free from its attachment to the head.

The smaller muscle of the helix, (M. helicis minor.)—This lies farther down and more behind than the preceding. It begins at the place where the helix rises from the concha, and is inserted into the posterior margin of the ascending portion of the helix.

The muscle of the tragus, (m. tragicus).—Of an oblong square form, this muscle covers the outer surface of the tragus, from the lower part to the upper margin of which its fibres run.

The muscle of the antitragus, (m. antitragicus).—The fibres of this muscle arise from the outer surface of the antitragus, and are inserted by a small tendon to which they converge into the lower extremity of the anthelix.

Fig. 256.

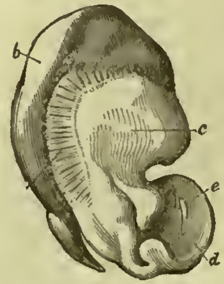


a. m. helicis major; *c.* m. helicis minor; *d.* m. tragicus; *e.* m. antitragicus.

The intrinsic muscles situated on the concave side of the auricle (diminished). (From Soemmerring).

The transverse muscle of the ear, (m. transversus auriculæ,) is situated on the back of the ear. It is composed of fasciculi not very distinctly muscular, which run from the dorsum of the concha to the back of the anthelix, and the elevation which corresponds to the navicular fossa.

Fig. 257.



a. transversus muscle; *b.* helix; *c.* back of the concha; *d.* tragus; *e.* fissure of Santorini.

B. The external auditory passage, (meatus auditorius externus s. porus acusticus; Fr. *Le conduit auditif ou auriculaire;* Germ. *Der Gehörgang.)*—Like the Eustachian tube, the external auditory passage is composed of an osseous portion, and a portion partly cartilaginous and partly membraneous. The osseous portion has been already described as a part of the outer wall of the tympanum; the other portion comes to be noticed here as a continuation of the cartilage of the auricle. The passage will then be considered as a whole.

Cartilaginous and membraneous portion of the external auditory passage, *meatus auditorius cartilagineus-membranaceus.* This portion of the auditory passage, about half an inch long, is formed in front and below by cartilage, above and behind by dense fibro-membraneous cellular tissue, in which many ceruminous glands are imbedded.

The plate of cartilage which forms the anterior and lower wall of this portion of the auditory passage is of a triangular shape with a fissure running through its base to near the apex. The base is below; the apex above. The base corresponds to the anterior surface of the mastoid process. One side is attached to the anterior and lower part of the circumference of the outer extremity of the osseous passage, by dense and strong cellular tissue. The other side corresponds to the base of the tragus. The apex or angle formed by the two sides runs into the upper part of the base of the tragus, and corresponds to the root of the zygomatic process. The angle formed by the base, and that side which is attached to the osseous part of the passage, is extended into a broad pointed tongue, which is fixed into the deep and rough depression at the lowest part of the margin of the orifice of the osseous passage. The angle formed by the base and the other side is continued into the concha.

The dense fibrous cellular tissue, which completes the passage above and behind, extends from the cartilage of the concha to the upper and posterior part of the margin of the external orifice of the osseous part of the passage.

What are called the fissures of Santorini, *incisuræ Santoriniona*, are: — 1. that fissure extending through the base of the triangular plate of cartilage to near its apex; and 2. that between the outer margin of the cartilage and the base of the tragus. These fissures are closed by fibrous cellular tissue which, particularly over the second fissure, appeared to Santorini to consist of muscular fibres. These fibres have, therefore, received the name of the muscle of the largest fissure, or the muscle of Santorini, *m. incisuræ majoris s. Santorini*. Haller considered their action to be, by approximating the cartilaginous pieces, to shorten the length of the passage.

Viewed as a whole, the auditory passage is a canal of an oval calibre. It leads from the auricle to the tympanum, from the cavity of which it is separated by the interposition of the membrana tympani. In front of it lies the joint of the lower jaw, behind is the mastoid process. In the adult its length is about an inch and a quarter, and its direction is at first somewhat forwards, then upwards and backwards, and lastly downwards and forwards again. Its lower wall is from one-tenth to one-fifth of an inch longer than the upper.

The auditory passage is lined by a continuation of the skin of the auricle. This skin becomes more and more delicate as it approaches the osseous part of the passage,—extremely so where it is continued on the outer surface of the membrana tympani. The skin of the auditory passage is covered with fine hairs, and in old persons close to the entrance, hairs like those on the tragus, sometimes of considerable length, are enrooted.

The skin of the auditory passage is connected to the subjacent cartilage and bone by rather dense and sparing cellular tissue. The epidermis readily separates by putrefaction, and may be drawn out like the finger of a glove, the blind end being the part which forms the outer borrowed layer of the membrana tympani.

From about a tenth of an inch within the auditory passage to about one-fifth of an inch from the membrana tympani, the lining integument is perforated by numerous small apertures, the terminations of the excretory ducts of the glands which secrete the ear-wax. These excretory orifices are most numerous about the middle of the passage, towards the termination of the cartilaginous and membraneous portion.

The ceruminous glands, *glandulæ ceruminosæ*, are small round or oval bodies of a brownish yellow colour, and very vascular. They are imbedded in the areolæ presented by the dense cellular tissue which connects the skin of the auditory passage to the subjacent cartilage or bone.

The ear-wax, *cerumen*, is, as is known, a thick orange-coloured or yellowish brown viscid substance, of an extremely bitter taste, and somewhat aromatic odour. When first secreted, it is a thin yellowish milky fluid. (See Cerumen.)

The auditory passage, especially in the middle, is usually covered with a more or less thick layer of it. It consists principally of a butter-like fat and albumen in combination with a peculiar animal matter; of a yellow, bitter, alcoholic extractive matter, with lactate of potass and lime and a watery extractive matter.

In irritation or diseased states of the glands, the ear-wax is changed in its properties, and is thrown out in larger quantities than usual, so that it collects and comes sometimes to fill completely the auditory passage, and thus give rise to dulness of hearing.

Fig. 258.

Skin of the face in front of the ear; *b.* lobule of the auricle; *c.* the antitragus; *d.* the tragus cut; *e.* anthelix; *f.* helix; *g.* anterior part of the osseous auditory passage, cut; *h, h.* anterior part of the cartilaginous portion of the passage, cut; *i.* posterior part of the cartilage of the ear; *k.* membrana tympani; *l.* section of the mastoid process; *m.* dura mater; *n.* skin behind the ear. It is seen continued over the auricle, and from that into the auditory passage; *o.* first or greater curve of the auditory passage; the end of which is directed forwards; *p.* the second or smaller curve, directed backwards; *q.* third and smallest curve; at *o.* and *p.* are seen the orifices of the ceruminous glands.

Nerves of the accessory parts of the apparatus of hearing.

Nerves of the tympanum.—The tympanum receives nerves from different sources—from the fifth, the seventh, eighth, and ninth pairs of cerebral nerves. Moreover, its nerves have communication with the sympathetic system.

The facial nerve or portio dura of the seventh pair rises from the brain by two roots, which unite together in the meatus auditorius internus, but before uniting, the smaller root sends off a delicate filament, which forms a communication, as has been mentioned, with the auditory nerve. This communication, first pointed out by Swan, has recently been very fully investigated by Arnold. According to the latter, in the middle or at the bottom of the internal auditory meatus, one or several delicate filaments go off from the smaller branch of the facial, and join the auditory nerve. After this the facial nerve enters the aqueduct of Fallopius, and issues from the cranium through the stylo-mastoid hole. In this course it receives, at the place where it forms the knee-like bend into the aqueduct of Fallopius, the superior branch of the Vidian or superficial petrosal nerve, *nervus petrosus superficialis, s. major*.

The superficial petrosal nerve comes off, along with the inferior branch of the Vidian or deep petrosal nerve, from the posterior part of the spheno-palatine ganglion or ganglion of Meckel. Leaving the deep petrosal nerve at the posterior orifice of the Vidian canal, the superficial petrosal proceeds upwards through the cartilaginous substance in the foramen lacerum medium, and then runs backwards in the groove on the anterior surface of the petrous bone leading to the hiatus of Fallopius. Having entered the latter, it joins the facial nerve, and forms, with its external fasciculi, a gangliform swelling, *intumescentia gangliformis nervi facialis*, of a grayish appearance and soft consistence.

From this swelling a filament arises by one or two roots, and runs backwards into the internal auditory passage to join the upper portion of the auditory nerve, where the first filament joined, and forms with it a small reddish gray elevation, known to and delineated by Scarpa.

Another branch, which arises from the ganglionic swelling, is the *chorda tympani*. The chorda tympani thus in reality derives its origin both from the facial and the superficial petrosal nerves. The chorda tympani accompanies the facial nerve along the aqueduct of Fallopius till within a little of the exit of the latter by the stylo-mastoid hole. The chorda tympani then leaves the facial nerve at an acute angle, and proceeds upwards in a proper canal in the bone, enters the cavity of the tympanum by the opening just within the posterior part of the groove for the membrana tympani already described. From this opening it proceeds forwards between the long process of the incus and the handle of the malleus, to the fissure of Glasser, through the canal beside which, already described, it makes its exit from the cavity of the tympanum. It then descends by the inner side of the ascending ramus of the lower jaw, and joins at an acute angle the lingual nerve. In its passage across the cavity of the tympanum, the chorda tympani anastomoses by one or several filaments with the nerve which the fifth pair sends to the membrana tympani.

Fig. 259.

The membrana tympani from within, and the course of the chorda tympani across the tympanum, together with the connexions of the malleus and incus (magnified). (From Soemmerring).

a. Membrana tympani; *b.* handle of the malleus and tendon of the internus mallei cut near its insertion; *c, c.* the chorda tympani.

To return to the facial nerve. It gives off, a little below the pyramid, a branch to the stapedius muscle.

The *pneumogastric nerve*, in its passage through the base of the skull, forms a small ganglion, from which springs a nerve which goes to the ear, *ramus auricularis nervi vagi*. This nerve is joined by a filament from the petrous ganglion of the glosso-pharyngeal; it then runs, according to Arnold, in a groove in the jugular fossa, and at last arrives at the aqueduct of Fallopius. Here it divides into three branches, the smallest of which runs upwards in the aqueduct of Fallopius towards the origin of the facial nerve, and unites with it; the second branch, which is somewhat larger, runs downwards, and also anastomoses with the facial. The third and most considerable branch will be noticed along with the nerves of the auricle and auditory passage.

The nervous anastomosis in the tympanum.—The principal nerve of this anastomosis is the nerve of Jacobson, or tympanic nerve of Arnold.

The tympanic nerve, *nervus tympanicus*, extends between the petrous ganglion of the glosso-pharyngeal nerve and the otic ganglion or ganglion of Arnold. To follow it from the glosso-pharyngeal, we find it arises from the upper part of the petrous ganglion, along with another filament, which goes to communicate with the *ganglion cervicale supremum*, and also with the pneumogastric. The tympanic nerve enters, by the tympanic canal already described, the cavity of the tympanum. Here the nerve appears near the anterior margin of the fenestra rotunda, traverses the groove on the promontory, arrives in front of the vestibular fenestra, then enters the proper osseous canal, into which the groove on the promontory is continued superiorly, and which opens on the surface of the petrous bone outside, and in front of the hiatus of Fallopius. From this the nerve advances between the anterior margin of the petrous bone and the posterior angle of the great wing of the sphenoid, between the internal muscle of the malleus and the superficial petrosal nerve. There it approaches the nerve of the internus mallei, and proceeds parallel with it, and under the name of *nervus petrosus superficialis minor Arnoldi*,* goes to join the otic ganglion.

Fig. 260.

Nervous plexus of the tympanum (from Breschet.)

a. Internal carotid artery; *b.* glosso-pharyngeal nerve; *c.* petrous ganglion of the same nerve; *d.* the principal trunk of the nervous plexus of the tympanum which extends to join, *e.* the otic ganglion or ganglion of Arnold; *f.* lower maxillary nerve to which the ganglion adheres; *g.* filaments of communication between the nerve of Jacobson and the carotid plexus; *h.* carotid plexus; *i.* filament to the fenestra rotunda, or cochlear fenestra; *k.* filament to the vestibular fenestra; *l.* filament going to anastomose with the facial nerve; *m.* filament running alongside the Eustachian tube; *n.* portio dura of the seventh pair; *o.* chorda tympani cut; *p.* nervous filament from the otic ganglion to the muscle of the malleus.

The branches given off and the communications formed by the tympanic nerve in the course described, are the following. On entering the tympanum, the tympanic nerve divides into two branches, a lower and an upper. The lower branch first gives twigs to the Eustachian tube, and then passes out of the cavity of the tympanum into the carotid canal, through a passage in the bone, where it anastomoses with the sympathetic nerve. The upper branch, the continuation of the nerve, gives a twig to the secondary membrana tympani. According to Varrentrapp, there arises from it, by two roots, a twig which runs on the inner wall of the cavity of the tympanum, then into the Eustachian tube, the cartilage of which it penetrates anteriorly, and at last loses itself in the mucous glands around its guttural orifice. A little higher up a third branch goes to the vestibular fenestra, and, according to Lauth, the tympanic nerve receives, immediately on its entrance into the canal in the upper part of the petrous bone, a filament from the facial nerve. Moreover, the tympanic nerve receives a filament of communication from the external branch of the *nervus caroticus*, the anterior and stronger branch of the first cervical ganglion of the sympathetic.

From the otic ganglion a nerve goes to the internal muscle of the malleus, *ramus ad tensorem tympani*. It arises from the upper and posterior part of the ganglion, and runs backwards on the inner side of the middle meningeal artery to the muscle.

2. *Nerves of the auricle and auditory passage.*—The auricle and auditory passage derive their nerves from the cervical plexus, from the facial, from the third branch of the fifth pair, and also from the pneumogastric.

The nerve from the cervical plexus is the great auricular nerve, *nervus auricularis magnus*. It comes off from the anterior branch of the third cervical nerve, and is distributed principally to the skin on the back of the auricle and to the posterior muscles. One branch passes between the antitragus and the tail-like process of the helix to the other surface of the ear and ramifies there.

The *facial nerve* on its exit from the stylomastoid hole gives off the posterior, inferior or deep auricular nerve, *nervus auricularis posterior, profundus inferior*, which receives a twig from the pneumogastric and another from the great auricular branch of the third cervical and then divides into two branches, a posterior larger, and an anterior smaller. The former gives twigs to the skin of the mastoid process and the retrahentes auriculam muscles, the latter spreads on the lower and posterior part of the cartilaginous auditory passage and the concha, giving twigs to the skin of these parts and the retrahentes auriculam. It sometimes sends a branch through the cartilage into the auditory passage to ramify in the integument lining that part.

The temporal branches of the facial nerve send filaments to the skin of the anterior part of the auricle, and to its anterior and superior muscles.

The superficial temporal nerve, a branch of the posterior and inferior fasciculus of the third division of the fifth pair, gives off two branches, *nervi meatus auditorii externi, inferior et superior*, the ramifications of which are distributed to the integument of the auditory passage and concha. There is one branch, *nervus tympani*, which runs under the upper wall of the osseous

* Bidder (Neurologische Beobachtungen. Dorpat, 1836,) has recently discovered a new nervus petrosus superficialis, which, for the sake of distinction, he calls *tertius*. It proceeds from the plexus accompanying the middle meningeal artery into the cavity of the cranium, passes through a proper fissure in the anterior surface of the petrous bone and under the entrance of the canal of Fallopius into the petrous bone to join the facial. It is not always present.

auditory passage to the membrana tympani, between the layers of which it glides and separates into very delicate filaments, by one or two of which it anastomoses with the chorda tympani. The last branch of the superficial temporal nerve sends filaments to the auricle and its anterior and superior muscles.

The third and most considerable branch of the auricular nerve of the pneumogastric, *ramus auricularis nervi vagi*, gets into the *canaliculus mastoideus* of Arnold, through an opening near the lower aperture of the *canalis chordæ tympani*. It here divides into two branches, one of which joins, as has been said, the posterior auricular branch of the facial nerve; the other, which is stronger, arrives at the posterior wall of the external auditory passage, gives filaments to the ceruminous glands, and in company with a branch of the posterior auricular artery penetrates the cartilage of the ear to ramify on the skin covering its convex surface.

Arteries of the external ear and tympanum. The *posterior auricular artery.* This supplies branches which ramify on the convex surface of the auricle, and also turn over the helix to spread out on the other surface. Twigs are also given off to the auditory passage.

A remarkable branch of the posterior auricular is the *stylo-mastoid artery.* This enters the stylo-mastoid hole and runs along the aqueduct of Fallopius, and ends by anastomosing with a branch of the middle meningeal, called the Vidian artery, which enters by the hiatus of Fallopius. In its course the stylo-mastoid artery transmits twigs to the mastoid cells, the external auditory passage, the membrana tympani, the stapedius muscle, and the external semicircular canal.

The twig to the membrana tympani is called *arteria tympanica superior.* This artery, together with the *arteria tympanica inferior* from the internal maxillary, supplies the membrana tympani. The arteries run round the circumference of the membrane and down along the handle of the malleus, and branching out form by their inosculations a fine net-work.

The *temporal artery* sends branches to the anterior part of the auricle, the external auditory passage, and to the ceruminous glands. It also gives off a branch which enters the tympanum by the fissure of Glasser, and ramifies in the mucous membrane of the outer wall of that cavity.

The *occipital artery* gives twigs to the auricle.

The *internal maxillary artery.*—This artery gives off a branch to the joint of the lower jaw, a twig of which, the *arteria tympanica inferior,* just mentioned, passes through the fissure of Glasser into the tympanum and inosculates on the membrana tympani with the twigs of the superior tympanic artery of the stylo-mastoid. The internal maxillary also sends a branch, the deep auricular artery, *arteria auricularis profunda,* to the cartilaginous portion of the auditory passage, where it supplies the lining integument and glands. It moreover sometimes gives small branches to the Eustachian tube.

The *middle meningeal artery* in the first part of its course gives branches to the Eustachian tube. In the cranium it sends a branch, *arteria Vidiana,* into the Fallopian canal, which has been already described as anastomosing with the stylo-mastoid. It also sends branches to the tympanum, which ramify in the mucous membrane of that cavity and in the muscles of the small bones.

The *accessory middle meningeal artery,* when present, gives branches to the Eustachian tube. The *inferior pharyngeal artery* also gives branches to the Eustachian tube, to the pyramid and cavity of the tympanum. The Eustachian tube also receives twigs from the *inferior palatine branch of the facial artery.*

The internal carotid, before entering the cranium, sometimes gives a small twig to the Eustachian tube and sends another, through a small passage leading from the carotid canal into the tympanum, to the promontory.

In some animals, such as the mole, the squirrel, the guinea-pig, the marmot, &c. there is an osseous canal like a bar of bone extending over the vestibular fenestra and running through between the crura of the stapes. This was first observed by Sir Anthony Carlisle in the marmot and guinea-pig, who describes it as "an osseous bolt to rivet it (the stapes) to its situation."* The canal is for the passage of an artery and nerve which in some other animals are unprovided with an osseous canal in their course through the stapes. The artery running through the stapes was observed about ten years ago by Professor Otto† in hybernating animals; but Professor Hyrtl of Prague‡ has shewn that the artery is by no means peculiar to those animals, as it does not occur in all, and as it occurs in animals which do not hybernate.

Mr. Shrapnell § describes in the human ear an artery accompanied by a nerve, passing through the membrane which fills up the space between the arms of the stapes. Mr. Shrapnell was led to this observation from what he had seen in the rat, viz. a nerve and artery passing through the stapes and supported by a minute channel of bone. Professor Hyrtl || has more recently described three modes of distribution of the arteries in man, which he has met with, analogous to the artery running through the stapes in the animals above mentioned.

The arteries of the external and middle ear are accompanied by corresponding veins. As to lymphatics, there are some small glands behind the auricle and in front of the mastoid process. The lymphatic vessels of the external ear accompany the arteries and veins, but principally the latter. Little or nothing is known of the lymphatics of the tympanum.

III.

1. *Development and irregular conditions of the organ of hearing.*

A. Development and irregular conditions of the ear-bulb.—Our knowledge of the early formation of the ear-bulb is not very precise. This much we know, that it has quite a separate origin from the rest of the apparatus of hearing. Hence, in the irregular conditions of the organ depending on defective development, there is no constant and necessary relation betwixt the labyrinth and the accessory parts of the ear; for the latter may be imperfect while the former is in its natural state, and *vice versâ*. In many cases, however, it has been found that imperfect development of the one attended an irregular condition of the other. The earlier a part is formed the fewer deviations it is subject to, so a greater number of malformations affect the accessory parts than the ear-bulb, as the former are developed subsequent to the latter.

The development of the ear-bulb commences very early, soon after the appearance of the eye. It takes place by the springing forth of the auditory nerve in the form of a tubular prolongation of the brain. At its central extremity the cavity of the cerebral prolongation is continuous with that of the fourth ventricle. Its peripheral extremity, which extends into the muscular layer of the embryo, and particularly into the osseous part of it, forms a vesicular dilatation which is gradually separated from the brain. To this vesicle of nervous substance, which is the labyrinth, there grows inwards a reflection of the tegumentary layer to form the accessory parts of the organ of hearing.

Such is Baer's account of the development of the ear in the chick. Huschke, on the contrary, says that the membraneous labyrinth does not arise from the brain, but is originally a blind sac of the skin with an excretory duct, which gradually contracts, until the blind sac of skin is completely cut off from the rest of the tegumentary system.

However this may be, the labyrinth, according to the observations of Valentin* made on the embryo of the sheep, exists at a very early period, under the form of a simple elongated tube with an oblong cavity, which is the vestibule. This cavity becomes broader, assumes a rounder form, and presents in the interior a somewhat uneven surface. Soon after this, its inner end is elongated and begins to make a circular turn, which is the first rudiment of the cochlea. The turns of this cochlear vesicle become gradually more developed. A short time after the commencement of the development of the cochlea, the semicircular canals begin to show themselves as processes or diverticula of the vestibule. There first appears the posterior over and behind the vestibular fenestra; it becomes elongated from within and below outwards and upwards, then bending in the form of an arch returns to the vestibule. In a similar manner the superior and inferior semicircular canals are formed. The semicircular canals are at first proportionally very wide, but gradually contract, till at last the ampullæ present the only trace of their former width. The vestibule itself has diminished in breadth and length, and acquired a more trapezoidal form. The vestibular fenestra, which was before not very distinct and still round, has become more evident and exhibits an oval shape.

What Valentin here describes is only the basis of the future osseous labyrinth. There exist as yet no observations bearing on the mode of development of the membraneous labyrinth.

The irregular conditions which the labyrinth has been found to present, as well as the structure permanent in the lower animals, correspond in a remarkable manner with the above-described stages of development. Thus in a monstrous fœtus, Hyrtl* found, instead of a vestibule, cochlea, semicircular canals, and internal meatus, a single very capacious cavity, containing a membraneous sac, in which the auditory nerve, sufficiently well developed, terminated. There was no trace of vestibular or cochlear fenestra, and the accessory parts of the organ were entirely wanting. Röderer† describes a somewhat similar case, in which, however, some of the accessory parts presented themselves, though in a very rudimentary and imperfect form.

The cochlea has presented itself as a mere subdivision of the vestibule without any windings, a state of parts which is permanent in birds. In other cases, though presenting windings, these have been found fewer than natural, and sometimes the spiral lamina has been wanting or not extending throughout all the turns of the cochlea, so that no subdivision into scalæ or but a very imperfect one presented itself. The semicircular canals are sometimes smaller and narrower than usual; one or all of them have been found wanting or but partially present. In the latter case, after running a short way, they have been observed stopping short and terminating in a cul-de-sac. The semicircular canals, as they are formed later, more frequently present deviations from the regular structure than the vestibule and cochlea.

Our knowledge of the ear-bulb in the human embryo commences at about the third month, when the membraneous labyrinth is already very perfectly developed and surrounded by a cartilaginous shell, having a structure as complicated as at a more advanced period the bony shell presents. The membraneous labyrinth is at this early period so firm that it is not very difficult, by means of careful dissection and manipulation, to extract the whole from its cartilaginous case.

According to Meckel,‡ the membraneous labyrinth is composed at first of two perfectly

distinct membranes, the one simply inclosed within the other, but not connected farther. The inner membrane is thinner but firmer and more elastic than the outer. The latter, which does not adhere to the cartilaginous case any more than it does to the osseous labyrinth which succeeds it, gradually becomes thin, until at the seventh month there is no longer any trace of it. The inner membrane, on the contrary, becomes proportionally thicker and firmer.

Meckel has never found the membraneous labyrinth in a more simple form, nor has he been able to determine whether it ever exists naked in the cranium.

At a very early period the pulpy mass of the auditory nerve becomes converted into nervous bundles, and grows either by lateral additions or by an increase of its filaments. The cochlear part of it, according to Valentin,* lies free in the tube of the cochlea under the form of a thick white cord; it follows the turns of the cochlea, but gives no considerable lateral fibrils to the walls of it. As to how the auditory nerve ends in the membraneous labyrinth at this period nothing is known.

In an anencephalous fœtus described by Hyrtl,† the cochlea was represented by a cavity, from the base of which, corresponding to the internal meatus, there rose a pyramid composed of canals and extended to the roof of it. This pyramid and the canals composing it were the representative of the axis and its canals for the transmission of the fibrils of the cochlear nerve. There was no trace of a turn of the cochlea nor of a lamina spiralis.

We now enter into a more explored region, viz. the progress of ossification in the labyrinthic shell, and for the knowledge we possess on the subject we are chiefly indebted to the late J. F. Meckel.‡

The osseous labyrinth is at first merely membraneous; by-and-bye it becomes cartilaginous, and lastly ossifies. The membraneous labyrinth has not been properly distinguished from it. The former at first lies free in the cavity of the cranium; the latter has never been observed in an uncovered state.

The development of the osseous labyrinth is quite distinct from the formation of the bony substance of the petrous bone. The latter commences before the former.

Ossification commences in the labyrinth towards the end of the third month round the fenestra rotunda, first at the upper part, then at the lower part; and when a ring of bone has thus been produced, ossification extends forwards. At the same time that the process just described takes place, another osseous nucleus, quite distinct from the preceding, is developed at the outer extremity of the superior vertical semicircular canal; there then appears a third small scale nearly in the middle of the posterior vertical semicircular canal. Proceeding from the first nucleus of bone, ossification makes rapid progress backwards and downwards; whence the floor of the labyrinth is formed. The second nucleus enlarges perhaps even more quickly than the first, so that the whole superior vertical semicircular canal is soon ossified, with the exception of its lower concave surface. From the inner extremity of this semicircular canal ossification extends on the inner surface of the petrous bone, circumscribes the internal auditory meatus, penetrates into its interior, and forms the base of the cochlea. In the fifth month ossification extends from the two first nuclei to the horizontal semicircular canal.

In the ossification of the cochlea, that of the petrous bone has but a very small share. All that the petrous bone contributes is merely a thin prolongation which it sends between the turns of the cochlea. This process is at first broader than at a subsequent period. From the third month, as the cochlea widens from without inwards, the process in question becomes thinner, and, at the same time, are developed the less considerable projections which separate externally the first external turn and a half of the cochlea from each other.

The ossification of the labyrinth has been found imperfect; thus Krombholz* relates a case in which he found the semicircular canals, as well as both scalæ of the cochlea, presenting the same thinness of walls as is remarked in the fœtus. Some places were merely membraneous. I have already mentioned that the aqueducts are sometimes unusually wide, a circumstance conceivable when we consider the mode in which most likely they are developed, and which was spoken of when considering them. In certain of the lower animals, such as the pig, they are naturally wide.

At first the osseous labyrinth is quite distinct from the mass of the petrous bone, in which it is, as it were, embedded. Its outer surface is, up to the fifth month, quite smooth; the corresponding inner surface of the osseous mass of the petrous bone is smooth also, but not so much so. The two surfaces are soon confounded together, although the spongy cellular structure of the petrous bone can still, even for some time after birth, be easily enough removed from around the hard bony substance of the labyrinth. Afterwards they become inseparable, though it is still possible to perceive a trace of the line of demarcation between them, especially in the cochlea.

All the above circumstances show that the osseous labyrinth, though in the petrous bone, is not of it; and that, as has been already said, it cannot be affirmed to belong to the skeleton, but to be merely embedded in a bone which does. Moreover as Weber† remarks, the osseous labyrinth is not in all animals enclosed in the same bone of the skull; for in fishes, when a trace of the osseous labyrinth is yet to be found, the semicircular canals, or the rudimentary representative of them, are situated in the occipital bone.

B. Development and irregular conditions of the tympanum and external ear.

1. *Of the tympanum and its contents.*

1. *The cavity of the tympanum.*—A prolongation or diverticulum of the mucous membrane of the throat, extending to the peripheral surface of the labyrinth, and forming, with its blind end, a dilatation there, gives us the simplest idea of a tympanum and Eustachian tube. According to Huschke*—and his views are more or less supported by Burdach,† Rathke,‡ and Valentin,§—the cavity of the tympanum with the Eustachian tube is a metamorphosis or remains of the first branchial fissure. Hence, in its origin, the tympanum has nothing in common with the labyrinth.

Valentin|| found the Eustachian tube and cavity of the tympanum, in an embryo at the seventh week, under the form of a conical or pyramidal fossa. This fossa gradually extends into a tube, at first short and wide, but afterwards longer and narrower in proportion as the cavity of the tympanum becomes developed, and recedes from the cavity of the mouth. The Eustachian tube is at first simply membraneous. About the middle of pregnancy, according to Meckel¶ and Burdach,** the third month according to Valentin, it acquires a cartilaginous investment.

The blind membraneous pouch which represents the cavity of the tympanum is at first very small and contracted, and is to be distinguished from the walls of the tympanum, which it invests. The peripheral surface of the labyrinth forms, as is known, the inner solid wall of the tympanum, and the tympanic ring and membrana tympani the outer wall. In proportion, therefore, as these parts, and also the mastoid process are developed, so does the tympanic cavity acquire its proper form, and is more and more withdrawn, both from the cavity of the mouth and the lateral surface of the head, with the integument of which it is, at an early period, in contact.

The prolongation of the mucous membrane of the pharynx forming the Eustachian tube and cavity of the tympanum, is at first very vascular, soft, and loose, like the mucous membrane of the nasal and guttural cavities; but after birth it loses its vascularity, and assumes a more simple character. United by loose cellular tissue to the subjacent osseous wall, it applies itself over all the elevations, and dips into the depressions of it, and moreover forms folds in which the ossicles are enveloped. The cavity of the tympanum is in the fœtus filled with a mucus, sometimes transparent, sometimes bloody, and varying from the consistence of water to that of a thick jelly.

The cavity of the tympanum has been found sometimes unusually contracted; sometimes, on the contrary, very much dilated. Non-development of the Eustachian tube would be necessarily attended by non-development of the tympanum, but not contrariwise. Absence of the Eustachian tube and cavity of the tympanum has only been found in fœtuses, in other respects monstrous.

In describing the development of the osseous labyrinth, it has been already mentioned that its peripheral surface, which forms the inner solid wall of the tympanum, begins to be ossified towards the end of the third month. An ossific point first appears on the promontory at the circumference of the cochlear fenestra, and gradually extends upwards, downwards, forwards and backwards. At this time there is no trace of mastoid process: In the fourth month the *sinuositas mastoidea* begins to appear, and the cavity of the tympanum becomes somewhat wider. The aqueduct of Fallopius is not yet ossified, nor the canals for the muscles of the stapes and malleus, a state of parts found permanent in most of the lower mammifera, and also frequently met with in the irregular conditions of the ear in man. When the cochlea is arrested in its developement, the promontory is small in proportion or entirely wanting.

In the fifth month the aqueduct of Fallopius and the canals for the muscles of the stapes and malleus are ossified. In this month, also, the vestibular fenestra is found completely formed, and appears proportionally larger than in the adult. In the sixth month, the temporal bone being altogether more developed, and the mastoid process having begun to appear, the cavity of the tympanum increases in capacity, especially its upper part, and the *sinuositas mastoidea.* The direction and situation of the cochlear fenestra vary much at the different periods of formation, which is owing chiefly to the degree of development of the promontory.

The vestibular and cochlear fenestræ are sometimes found unusually small, or even entirely wanting, the latter being obliterated by an extension of osseous substance, the former by the same cause, or by anchylosis of the base of the stapes. The cochlear fenestra sometimes appears to open into the vestibule, but this is when the cochlea is in a very rudimentary state. Such a condition may be compared with the state of parts found in the bird's ear.

Little or nothing is known of the origin and development of the membrana tympani. It may be looked upon as the persistence of that septum which exists at an early period at the opening of all mucous canals, and which is produced by the meeting of the indentation inwards of the skin with the diverticulum of the mucous cavity of the blastoderma. The membrana tympani is larger in proportion, and more vascular the younger the fœtus is. The form, situation, and direction of it in the fœtus is dependent on the tympanic ring, and is quite different from what is found in the adult. In regard to form, it is rounder. As to situation

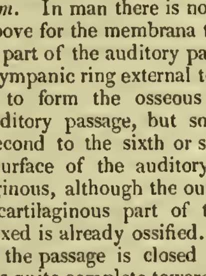
** Op. cit. Bd. ii. p. 465.

the osseous portion of the auditory passage not being yet developed, the membrana tympani is found at first closer to the surface than afterwards; and its direction is oblique from above downwards, and from without inwards, so that it has a more or less horizontal position, corresponding to the base of the cranium.

More is known of the origin and development of the tympanic ring in which the membrana tympani is framed. It appears later than the membrana tympani and the ossicles. A specimen of the tympanic ring before me, which was removed from an embryo at about the third month, is an incomplete ring of bone about one-tenth of an inch in diameter. It is about the thickness of a hair, except at its anterior extremity, which is broad and flat like a spatula, for the extent of about one-twelfth of an inch. The groove for the membrana tympani can be perceived with a magnifying glass. From the fifth month the tympanic ring is found more or less adherent to the rest of the temporal bone. In the lower Mammifera there are three parts developed from the tympanic ring, viz. 1, the groove for the membrana tympani, 2, the *bulla ossea*, and 3, the osseous part of the auditory passage. In birds the tympanic ring is represented by the *os quadratum*. In man there is no bulla ossea, only the groove for the membrana tympani and the osseous part of the auditory passage. The side of the tympanic ring external to the groove shoots out to form the osseous part of the external auditory passage, but so slowly that from the second to the sixth or seventh year, the lower surface of the auditory passage is still cartilaginous, although the outer orifice to which the cartilaginous part of the auditory passage is fixed is already ossified. About the twelfth year the passage is closed in by bone, and becomes quite complete towards manhood. The inner surface of the ring grows a little at the lower part, and helps, together with a process which extends from the petrous bone, to form the lower wall of the tympanic cavity. It is to be remarked that this inner part of the tympanic ring always remains distinct and is never changed so much as the external.

Fig. 261.



The tympanic ring, and the membrana tympani framed into it. The handle of the malleus is seen shining through the membrane.

The whole outer wall of the cavity of the tympanum has been found wanting in a monstrous fœtus. Hyrtl, who mentions the case, says that the cavity of the tympanum itself was represented only by a very shallow depression in the petrous bone, in which the skin of the auditory passage formed a cul-de-sac. The Eustachian tube was present. Hyrtl mentions another case in which the tympanic ring was much smaller than usual, and in which the membrana tympani presented in the direction of one of its radii, a large opening as if a piece had been cut out. The so-called *hiatus Rivinianus* ought, perhaps, to be looked upon, as Huschke observes, as a defect in original formation. The membrana tympani has been sometimes found congenitally too large, sometimes too small, sometimes of an elongated form, sometimes of a triangular form. A thickening and parchment appearance of the membrane, or ossification of it to a greater or less extent, if not always, appears to be more usually an acquired malformation.

2. *The small bones of the tympanum.*—The small bones are formed at a very early period. The malleus and incus appear before the stapes. The two former, according to Rathke and Valentin, appear like a small wart growing out from the posterior wall of the tympanum. The stapes is like a growth from the outer surface of the labyrinth; it appears as a small pyramidal wart flattened on the sides and thin in the middle, lying, according to Rathke, in a small funnel-like depression, the bottom of which is the future vestibular fenestra.

According to Weber* the ossicles are not developed in the cavity of the mucous membrane of the tympanic cavity, but in a sac which is a continuation of the dura mater, and comes through a fissure between the petrous bone and the squamous portion of the temporal into the tympanic cavity. This situation of the ossicles at an early period corresponds with that of those discovered by Weber in the fishes already mentioned. By this mode of development, as far as regards situation, may be explained the dislocated state of the ossicles so frequently found in the irregular conditions of the ear.

According to Meckel,† the ossicles are at the commencement of the third month proportionally very large, though still cartilaginous, and the stapes not to be distinguished from the incus. Thus, for example, the length of the malleus in a fœtus of the fourth month amounts to three lines, whilst the length of the body from the vertex to the coccyx measures four inches, hence the lenght of the malleus is to that of the trunk as one to sixteen; whereas in the adult the proportion is only as one to ninety, the malleus being four lines long, and the distance between the vertex and the coccyx amounting to two-and-a-half feet. At birth the ossicles are as large as in the adult.

Ossification of the small bones commences, according to Burdach,‡ about the twelfth week. Rathke and Valentin agree with Meckel; that ossification begins first and at the same time in the malleus and incus, and only afterwards in the stapes. In the malleus the first point of bone appears on the head, a second at the root

* Hildebrandt's Anatomie, Band. iv. p. 39.
† Op. cit. tom. iii. p. 197. s. 1948.
‡ Op. cit. Band. ii. p. 384.

of the long process. In the incus the first point of ossification occurs in the longer crus near the body, and from this point it extends during the fourth and fifth months, so far that the whole is ossified with the exception of the point of the short process. The long crus Meckel always found completely ossified, whilst the short crus was still cartilaginous.

The stapes is still cartilaginous when ossification has made considerable progress in the other two bones. According to Meckel ossification does not commence at any determinate point of the stapes; only he never observed it first on the head. According to Rathke there are three particular nuclei, one for each of the sides of the triangle which the stapes represents.

The opening between the crura of the stapes is at first very inconsiderable,—a condition analogous to what is found permanent in the Cetacea, &c.

The ossicles are not unfrequently irregular in their form, size, and situation. They may even be wanting. The stapes, as it is the last formed, presents the most numerous and most varied malformations; the malleus the fewest. The stapes has been found, by Tiedemann, as it is at first, like a pyramid without any opening; again, it has been found with but a very small opening, or presenting indeed the crura, but the space between them filled up by a thin plate of bone. Only one crus has been found rising from the middle of the base in the form of a slender pedicle of bone as in the bird, and presenting no trace of an articular cavity for the reception of the lenticular process of the incus, &c.

A remarkable circumstance connected with the early formation of the malleus is the existence, as Meckel* first observed, of a straight cartilaginous process, having the shape of a very elongated cone, which extends from the anterior part of the head of the malleus to the place where the two halves of the lower jaw unite in front. The cartilaginous process passes out of the cavity of the tympanum between the petrous bone and tympanic ring. This process, though having much the same situation, must not be confounded with the *processus gracilis*. The former lies above the latter, and both parts are quite distinct from each other. Moreover the cartilaginous process never ossifies, but disappears in the eighth month. Huschke† has discovered a similar process extending between the short crus of the incus and the superior horn of the hyoid bone through the medium of the styloid process.

The most interesting irregular formation of the malleus is what appears to be connected in some manner with the above described early condition of the malleus and incus. Such cases are related by Hyrtl,* Heusinger,† and Hesselbach.‡

2. *Of the external ear.*—The external ear soon disappears in the animal series. It is the last part of the apparatus of hearing which makes its appearance in the human embryo. It is very subject to irregular development. It is only about the middle of the second month that a trace of it can be observed. It is at first merely a slight elevation of the skin, broad above, narrow below. In the middle of this elevation is a longitudinal fissure of the same form, which is narrower and at the same time deeper from above downwards. The prominence soon becomes more elevated and thinner at its posterior part, and projects above the surface of the side of the head, from which circumstance the middle depression is a little exposed. At the same time or soon after, the anterior part of the prominence is found divided into two halves by a transverse fissure running forwards; the inferior half is the antitragus, and the superior the commencement of the helix. At the same time this anterior part of the external ear rises also, and the posterior spreads more out. In the third month the anthelix and tragus are developed; the concha is not yet perfectly distinct; it is only indicated by the middle depression. In the fourth and fifth month the hollow of the concha appears, and is completely formed in the sixth. The lobule is the last part which presents itself.

The cartilage begins to be formed in the third month, but is developed slowly. Towards the end of pregnancy, though thicker, harder, and firmer, it is still incomplete.

The cartilaginous portion of the auditory passage as well as the auricle is at first proportionally much smaller than afterwards. The skin lining the auditory passage is softer and thicker than in the adult, and is covered with a thickly set down. In the fœtus the auditory passage is rounder, straighter, and shorter than in the adult.

The auricles may not be formed at all, or their development may be so arrested that they shall be represented merely by unshapely folds of skin with or without cartilage, or they may deviate more or less from their usual form, size, and situation. Imperfect formation of the auricle is frequently accompanied by absence or closure of the auditory passage. Professor Samuel Cooper mentions the case of a child in which there was not the slightest trace either of external ear or auditory passage.

Sometimes, however, the auditory passage has been found regular though the auricles were wanting.

The auditory passage is sometimes found too wide, sometimes too narrow, sometimes too short. Closure of the auditory passage may be either partial or through its whole extent. It is more rarely the effect of disease than of irregular primitive formation. Partial closure may be by an extension of the skin over the mouth of the passage. Authors mention cases of a membraneous septum sometimes deep in the auditory passage and before the membrana tympani, sometimes nearer the entrance of the passage.

In monstrous fœtuses all the accessory parts of the apparatus of hearing together have been found wanting.

II. PARALLEL BETWEEN THE EAR AND THE EYE.

A parallel has often been drawn betwixt the ear and the eye. Breschet, in his memoir, already so often cited in the course of this article, compares the perilymph to the aqueous humour, the endolymph to the vitreous humour, and the calcareous concretions to the crystalline body.

The comparison which I should institute between the component parts of the ear and the eye is the following:—

The osseous labyrinth may be compared to the sclerotica, and the fenestra rotunda, or cochlear fenestra, to the cornea.

To find a part in the eye analogous to the vestibular fenestra, we must first consider that the latter is a yielding part of the otherwise solid wall of the labyrinth; that through the medium of it, the chain of small bones and their muscles in the tympanum exercise on the soft parts contained in the labyrinthic cavity, a certain degree of tension or compression fitted probably to accommodate in some manner the ear to the perception of different degrees of sound. In the case of the eye, the sclerotica, which corresponds to the osseous labyrinth, is thinner and more yielding at the middle of its circumference, (remarkably so in the Greenland seal). From this it has been supposed that the action of the muscles of the eye-ball might by their compression produce a change of shape fitted to accommodate the eye to distances. Hence the vestibular fenestra and middle thin part of the sclerotica might be compared to each other in as far as regards the function which each performs in the economy of its own organ. However this may be, the vestibular fenestra of the ear and the thin part of the sclerotica correspond to each other as far as can be in relative position; and if we admit the action just mentioned of the muscles upon the eye-ball, we have, as I shall immediately show, their counterparts in the muscles of the small bones of the tympanum.

The tympanic scala of the cochlea may be compared to the anterior chamber of the aqueous humour, and the vestibular scala to the posterior chamber.

The spiral lamina, considering its vascularity and richness in nerves, and its forming a partition between two chambers containing an aqueous humour, may, as I have already said in a former part of this article, be considered the counterpart of the iris, and the helicotrema that of the pupil.

The membrane lining the labyrinthic cavity bears the same relation to the latter as the *arachnoidea oculi** does to the sclerotica. The space filled with perilymph, between the osseous and membraneous labyrinth, may be considered analogous to that between the sclerotica and choroid. It however communicates with the scalæ of the cochlea, the parts analogous to the chambers of the aqueous humour, because there is nothing in the ear to be compared to the ciliary ligament.

Forming the membraneous labyrinth we find, 1. a delicate cellular tissue supporting the branches of the bloodvessels, and which is sometimes found containing black pigment; 2. a firm transparent membraneous coat, within which, 3. is a nervous expansion; 4. the endolymph; 5. suspended in the latter the mass of calcareous matter. The cellulo-vascular layer containing pigment, together with the rest of the walls of the membraneous labyrinth, may be compared to the choroid coat of the eye, the nervous expansion to the retina, the endolymph to the vitreous humour, and the calcareous mass to the lens.

In the lower animals the cochlea is the first part of the ear-bulb to disappear; in regard to the eye-ball, the aqueous chambers to which I have compared the scalæ of the cochlea, are in like manner the first parts which in the depreciation of the structure of the eye, in the animal series, disappear, e. g. the eye of the Cephalopodous Mollusca.

Is the cochlear nerve the same in function with the vestibular? The vestibular nerve is the special nerve of hearing; but does not the cochlear nerve perform some function in the economy of the ear analogous to what the ciliary nerves perform in that of the eye?

If an example is required in which the optic nervous filaments enter the eye separately as do the nervous filaments of the ear-bulb, it is to be found in the Cephalopodous Mollusca.†

As in front of the eyeball there is, or rather would be, if it was not that the eyelids are constantly in contact with the eyeball, a space lined by a mucous membrane, the conjunctiva, so at the peripheral surface of the ear-bulb, there is a space, the *tympanic cavity*, lined by a mucous membrane also. Moreover, as there is a passage into the nose from the space bounded by the conjunctiva, so does the tym-

* See my figure and description of a horizontal section of the human eye, in Mackenzie's Practical Treatise on Diseases of the Eye. *Second Edition.* London, 1835.

† See a paper "On the Retina of the Cuttlefish," in the London and Edinburgh Philosophical Magazine for January, 1836.

panic cavity communicate with the throat by the Eustachian tube. In the tympanic cavity there is a chain of small bones, articulated to each other and moved by muscles, which serves to produce some change in the state of tension of the soft parts of the ear-bulb; in the conjunctival space there is nothing analogous, although, without pushing the point too far, we might compare the muscles of the eye-ball with those of the ossicles of the tympanum, both being equally, in fact, *outside* their respective mucous membranes. In regard to the ossicles I would remark that, according to the views of Weber,* they must be reckoned among those which do not belong to the skeleton, and which are of very inconstant occurrence. Such are the bone of the penis in many animals, the teeth, *the ring of bony plates round the front of the sclerotica of the bird's eye, &c.*

A part in the composition of the appendages of the eye analogous to the membrana tympani is only to be conceived by supposing the existence of a *mediate anchyloblepharon*, that is, an irregular membrane stretched between the edges of the eyelids, uniting them together and closing in the space lined by the conjunctiva, which space would now communicate with the exterior, only by the lachrymal canalicules and nasal duct, in the same way that the tympanic cavity communicates with the exterior only by the Eustachian tube. A congenital fissure or total absence of the membrana tympani is an irregularity of structure in the ear, which may be compared to what is regular in the eye. A mind accustomed to trace analogies will perceive a resemblance :— to the external auditory passage in that short space at the opening of the eyelids extending from the inner edge of the tarsal margin to the outer; to the ceruminous glands in the Meibomian follicles; and to the hairs at the entrance of the auditory passage in the eyelashes. The auricle, if it is necessary to look for a part corresponding to it, may be placed in the same category with the eyebrows.

(T. Wharton Jones.)

HEARING (in Physiology,) *audition*; Lat. *auditus*; Fr. *l'audition, sens de l'ouie*; Germ. *das Gehör, Gehörsinn*.—Of all the senses, that of hearing is the most valuable to man in his social condition, for without it all interchange of ideas through the medium of a spoken language would be impossible. To it indeed, as a distinguished metaphysician has remarked, we are indirectly indebted for the use of verbal language. By the sense of hearing men and animals take cognizance of sounds and distinguish their varieties, the almost innumerable multitude of which may well excite our admiration of the sense. "Who," says the excellent Derham, "who but an intelligent Being, what less than an omnipotent and infinitely wise God, could contrive and make such a fine body, such a medium, so susceptible of every impression that the sense of hearing hath occasion for, to empower all animals to express their sense and meaning to others; to make known their fears, their wants, their pains and sorrows in melancholick tones; their joys and pleasures in more harmonious notes; to send their minds at great distances in a short time in loud boations; or to express their thoughts near at hand with a gentle voice or in secret whispers. And to say no more, who less than the same most wise and indulgent Creator could form such an œconomy as that of melody and musick is; that the medium should, as I said, so readily receive every impression of sound, and convey the melodious vibration of every musical string, the harmonious pulses of every animal voice, and of every musical pipe; and the ear be as well adapted and ready to receive all these impressions as the medium to convey them. And lastly, that by means of the curious lodgment and inosculation of the auditory nerves, the orgasms of the spirits should be allayed and perturbations of the mind in a great measure quieted and stilled; or to express it in the words of the last-cited famous author (Willis), 'that musick should not only affect the fancy with delight, but also give relief to the grief and sadness of the heart; yea, appease all those turbulent passions which are excited in the breast by an immoderate ferment and fluctuation of the blood.'"

*Preliminary observations on sound.**—Sound is the result of an impulse of any kind conveyed by the air to our ears. The analysis of what takes place on the production of various familiar sounds or noises abundantly explains this. If the ear be applied to one extremity of a long beam of timber and a person tap with his finger on the other, the impulse is distinctly perceived by the impression of sound which is conveyed. A fine probe introduced carefully through the meatus externus, and made to impinge upon the membrana tympani, however gently, will occasion the sensation of sound. To produce the sensation, then, of sound, an impulse is necessary either of some solid directly upon the membrane of the tympanum itself, or of the air which is always in contact with that membrane. The body by which the sound is produced, denominated by Professor Wheatstone† *a phonic*, occasions in the surrounding air vibrations or oscillations, corresponding in number and extent to those which exist in itself; and these vibrations or oscillations being propagated to the organ of hearing, give rise to the sensation. This agitation of the air surrounding the body from whence the sound emanates is manifest in numerous instances;—the report of a cannon, the rushing of waters, the rattling of carriages, which in the crowded thoroughfares of London communicate their vibrations to the walls and floors of the houses and even to the furniture. In the familiar instance of eliciting sound from a finger-glass partly full of water by rubbing the wetted finger round its brim, the vibrations which this friction excites in the glass are rendered evident by the crispations produced in the water immediately in contact with it. The vibration of the water, as indicated by these crispations, corresponds with that of the glass—the greater the intensity of the sound elicited, the more considerable are the vibrations in the glass, and consequently the more manifest are those of the water, and vice versâ. "In musical sounds we may also observe an agitation which is often felt communicating itself to the surrounding bodies. If, for example, we stand under or near a piano-forte when it is sounding, we feel a sensible tremor in the floor of the apartment. If we lay the finger or hand on the instrument or touch any other, such as a violin when it is sounding, or a bell, we feel the same sort of tremor in every part of them; and this is well observed in the case of any glass vessel, such as a tumbler or large cup. If we strike it so as to make it sound, and then touch the mouth of it with the finger, we feel a sensible tremor in the glass; and when this internal agitation is stopped, as it generally is by the contact with the finger, then the sound ceases along with it."*

The disturbance produced in the air by a sounding body has been from a very early period illustrated by a reference to the waves formed in still water by a stone falling into it. "Voice," says Vitruvius, "is breath flowing and made sensible to the hearing by striking the air. It moves in infinite circumferences of circles, as when, by throwing a stone into still water, you produce innumerable circles of waves, increasing from the centre and spreading outwards, till the boundary of the space or some obstacle prevents their outlines from going further. In the same manner the voice makes its motions in circles. But in water the circles move breadthways upon a level plane; the voice proceeds in breadth, and also successively ascends in height."† That the presence of air is necessary for the production of sound is proved by the experiment first tried by Hauksbee‡ and repeated by Biot. A bell was made to ring in the receiver of an air-pump, and in proportion as the air was exhausted it was found that the sound died away, and it again returned as the air was re-admitted. On the other hand, the bell sounded more strongly when the air within the receiver was condensed, and the greater the condensation of the air, the louder was the sound.

Any irregular impulse communicated to the air produces a noise, in contradistinction to a *musical sound*. This latter results from a succession of impulses, which occur at exactly equal intervals of time, and which are exactly similar in duration and intensity. When these impulses succeed each other with great rapidity, the sound appears continuous,

* It will be perceived that in the ensuing observations the writer has borrowed largely from Sir John Herschel's admirable essay on sound in the Encyclopædia Metropolitana. He has also to acknowledge his obligations to the article on Acoustics in Pouillet's Elemens de Physique.

‡ Phil. Trans. 1705.

in consequence of the duration of the impression upon the auditory nerve. The frequency of repetition necessary for the production of a continued sound from single impulses is, according to Sir J. Herschel, probably not less than sixteen times in a second, though the limit would appear to differ in different ears.

We distinguish in musical sounds, 1, the *pitch;* 2, the *intensity* or *loudness;* 3, the *quality.* The pitch of the sound depends on the rapidity with which the vibrations succeed each other, and any two sounds produced by the same number of vibrations or impulses in the same time are said to be *in unison.* The loudness or intensity depends upon the violence and extent of the primitive impulse. The quality is supposed by Sir J. Herschel to depend on the greater or less abruptness of the impulses, or generally, on the law which regulates the excursions of the molecules of air originally set in motion.

Sound may be communicated by air, aeriform fluids, liquids or solids, with variable degrees of velocity. In air at the temperature of 62° Fahr. sound travels at the rate of 1125 feet in a second, or 1090 feet in a second in dry air at the freezing temperature.

The velocity with which sound travels is, however, quite independent of its intensity or its tone; sounds of all pitches and of every quality travel with equal speed, as is proved by the fact that distance does not destroy the harmony of a rapid piece of music played by a band. If notes of a different pitch travelled with different velocities, they would not reach the ear in the order in which they were played. Moreover, Biot put it to the test of direct experiment; he caused several tunes to be played on a flute at the end of a pipe 3120 feet long, and found that they could be distinctly heard without the slightest derangement.

Neither is the velocity of sound affected by an increase of density in the air. It is, however, greater in warm than in cold air in consequence of the greater elasticity of the former. In the different gases much variety has been observed in the velocity of sound; through carbonic gas the rate of the velocity is said to be one-third slower than ordinary, but through hydrogen gas, which is twelve times more elastic than common air, the speed exceeds the usual rate three and a half times. A more striking difference is as regards the intensity of sound or the impression it is capable of producing on our organs of hearing. This varies considerably with the increase or diminution in the density of the transmitting gas. By means of a piece of clock-work, which caused a hammer to strike at regular intervals, the conducting power of the gas could be estimated, the clock-work being placed in a glass receiver filled with the gas. It was thus that Priestley ascertained that in hydrogen the sound was scarcely louder than in vacuo; in carbonic acid and in oxygen it was somewhat louder than in air.

Water can transmit sound, as the anatomist would infer must be the case from the fact that fishes are provided with distinct and highly developed organs of hearing. Hauksbee, Anderon, the Abbé Nollet, and Franklin have abundantly proved this by their experiments. M. Colladon, by means of a tin cylinder three yards long and eight inches in diameter, closed at its lower end but open to the air above, plunged vertically in the water, was enabled to hear the sound of a bell at a distance of about nine miles, and from numerous observations he concluded that the velocity of sound in water at about 46° Fahr. was equal to 4708 feet in the second.

Solids convey sound as well as or even better than air or liquids. Elasticity and homogeneousness are the qualities which best adapt solids for the conveyance of sound: hard substances, then, which are the most elastic, conduct sound best. An interesting experiment of Hassenfratz and Gay Lussac, in the quarries of Paris, affords a striking contrast of the relative conducting powers of air and solids. A blow of a hammer against the rock produced two sounds which separated in their progress; that propagated through the stone arrived almost instantly, while the sound conveyed by the air lagged behind. A more remarkable experiment was that of Herhold and Rahn, related by Chladni:—a metallic wire 600 feet long was stretched horizontally, and at one end a plate of sonorous metal was attached; when the plate was slightly struck, a person at the opposite end, holding the wire in his teeth, heard at every blow two distinct sounds, the first transmitted almost simultaneously by the metal, the other arriving later through the air. Biot, with the assistance of Messrs. Boulard and Malus, concluded the velocity of sound in cast iron at the temperature 51° Fah. to be 11,090 feet in a second.

Reflexion of sound.—Sonorous undulations in passing from one medium to another always experience a partial reflexion, and when they encounter a fixed obstacle, they are wholly reflected; and in both cases the angle of incidence is, as in the reflexion of light, equal to the angle of reflexion.

Echos are sounds reflected from some obstacle which is placed in their way, as the wall of a house, or those of an apartment, or the surface of a rock, or the vaulted roof of a church, &c.; and a sound thus reflected may, by meeting another similar obstacle, be again reflected, and thus the echo may be repeated many times in succession, becoming, however, fainter at each repetition till it dies away altogether. The phenomena of echos illustrate beautifully the analogy between sound and light. Thus, the reflexion of sound from concave and convex surfaces takes place exactly as in the case of light: if a reflecting surface be concave towards an auditor, the sounds reflected from its several points will converge towards him, exactly as reflected rays of light do; and he will receive a sound more intense than if the surface were plane, and the more so the nearer it approaches to a sphere concentric with himself; the contrary is the case if the echoing surface be convex. If the echo of a sound excited at one station be required to be heard most intensely at another, the two stations ought to be *conjugate foci* of the reflecting surface, i. e. such that if the reflecting surface were polished, rays of light diverging from one would be made after reflexion to converge to the other. Hence, if a vault be in the form of a hollow ellipsoid of revolution, and a speaker be placed in one focus, his words will be heard by an auditor in the other, as if his ears were close to the other's lips. The same will hold good if the vault be composed of two segments of paraboloids having a common axis, and their concavities turned towards each other; only in this case sounds excited in the focus of one segment will be collected in the focus of the other after two reflexions.

The most favourable circumstances for the production of a distinct echo from plane surfaces is when the auditor is placed between two such exactly half-way. In this situation the sounds reverberated from both will reach him at the same instant, and reinforce each other: if nearer to one surface than the other, the one will reach him sooner than the other, and the echo will be double and confused.*

We propose to enquire the part which each portion of the complex auditory apparatus of man performs in the function of hearing.

I. *Of the internal ear.*—The fact that a part, answering precisely to the vestibule, is to be met with in every class of animals in whom an auditory apparatus can be detected, affords a strong presumption that this portion of the labyrinth is the essential part of the organ. Here is the seat of the principal expansion of the auditory nerve upon the saccule and common sinus, which floating in the perilymph communicate, through the medium of that fluid, with the membrane of the fenestra ovalis, and consequently with the air contained in the tympanum. Any vibrations or oscillations then excited in the membrane of the fenestra ovalis, cannot fail to affect the perilymph to a proportional extent, and through it the membranous vestibule. In the simple ear of Crustaceans as well as that of Cephalopods and the lowest Cyclostomous fishes, the sonorous impressions are conveyed directly to the vestibular cavity through the solid material in which that cavity is formed, or, as in some Crustaceans, through the vibration of an external membrane.

In the higher organized fishes, too, the labyrinth constitutes the whole of the auditory apparatus, nor has it any kind of opening to or communication with the external air, being lodged in the walls or cavity of the cranium, the sonorous impressions must be conveyed through the solid cranial parietes; for, in truth, there is no other mode in which they can be conveyed, and we know that solids are even better conductors of sound than either liquids or aërial fluids.†

As to the function performed by the *otolithes*, or the calcareous dust, *otokonies*, which are found in the sacculus vestibuli of the ears of Cephalopods and Fishes, no satisfactory theory has as yet been offered by any physiologist. Although it is now admitted that similar calcareous particles exist in the vestibules of all vertebrated animals, still they are only in a rudimental condition when compared with those of fishes; indeed it seems not unreasonable to suppose that the calcareous dust or otokonie of cartilaginous fishes (the ray or shark for example) is rudimental of the hard, porcellaneous, and artfully formed otolithe of the osseous fishes.* A sort of loose notion seems to prevail, that the presence of this hard body in the vestibule favours the communication of sound, by impinging upon the expansion of the auditory nerve. The following observations of Camper no doubt propagated this idea, if they did not originally give rise to it: "Pour être convaincû," says this distinguished physiologist, "qu'un corps plus ou moins dur, mais flottant dans une substance gélatineuse reçoit la plus légère commotion ou mouvement extérieur, on n'a qu'à remplir un verre de gelée de corne de cerf, et y plonger quelque corps, on sentira aux doigts le mouvement de ce corps dès qu'on remuera le verre, ou qu'on lui donnera un petit choc avec un doigt de l'autre main. Quand on enferme dans une petite vessie quelque corps dur, le moindre mouvement de la vessie fait branler ce corps, qui produit une sensation très forte sur le doigt qui tient la vessie."†

Sir A. Carlisle thinks that the nature of this substance has reference to the habits of the particular class of fishes in which it exists. "Fishes," he says, "are only provided with more simple organs of hearing, ordained to inform them of collisions among rocks and stones, or the rushing of water or moving bodies in that element: and since the collisions of stones or of water are only variable in their magnitude or intensity, fishes are provided with these dense ossicles to repeat the semblable acute tones of similarly dense substances, such as rocks, stones, gravel, &c." Again, "There is an especial sac of calcareous pulp given to skates and some other cartilaginous fishes in the place of the dense ossicles, apparently intended to respond to the movements of sand and muddy strata on which they are doomed to reside; and it is remarkable that the sturgeon has its auditory ossicles consisting partly of hard substance and partly of calcareous pulp."‡

Weber believes that the otolithes in fishes supply the place of the cochlea which is wanting in these animals: the auditory nerves being connected with them receive the vibrations

* Herschel, Encycl. Metrop.

† Hunter, Monro, Weber, and Treviranus, however, describe a communication with the exterior in Rays and the Shark by two long canals; but Scarpa, Bell, and Blainville positively deny that these ducts perform the office of auditory canals.

* So definite does the form of these otolithes appear to be in osseous fishes, that Cuvier says the osseous fishes may be determined by their otolithes as well as by any other character.

† Mém. de l'Acad. des Sciences, an. 1779, and quoted in Scarpa De auditu et olfactu, p. 23.

‡ Quoted from a Mss. Essay on sound, in the Hunterian Catalogue, vol. iii. p. 193. Müller calls the otolithe "Eine freier solider Schwingungen repercutirender Körper."

direct from them, or sometimes the otolithes are so placed with reference to the expansion of the vestibular nerve, as to be able to compress it against the cranium.

But in man and those animals in whom, in addition to a more complicated labyrinth, there is also an external auditory passage and tympanum, it would appear that the sonorous vibrations are conducted in two ways; first, through the meatus externus and tympanum to the vestibule and semicircular canals; and, secondly, through the bones of the head directly to the auditory nerve. Sounds proceeding from external bodies, as Weber observes, are conveyed in the former way; but the oscillations of one's own voice, although they in part find their way by the external passage, are chiefly conducted by the cranial bones; and, as Professor Wheatstone has remarked, those sounds are best heard which are articulated most in the mouth, and with that cavity least open, as *e*, *ou*, *te*, *kew*. Closing both ears by firmly pressing the hands upon them, one's own voice is not heard less distinctly, but on the contrary more loud and clear than when both ears are left open; and if only one ear be closed, the voice is heard more distinctly and louder in that ear than in the open one.*

The observations and experiments of Weber render it very probable that the cochlea is that part of the labyrinth which is more particularly suited to appreciate sounds communicated through the solid case of the head, or, to use his words, that sounds propagated through the bones of the head are heard specially by the cochlea, but that sounds conducted through the external meatus are perceived by the membranous vestibule and semicircular canals more easily than by the cochlea. The following considerations favour these views.

It is an admitted fact in acoustics that sounds are most perfectly conducted by substances of uniform elasticity, and that when propagated from air or water to a solid, or from a solid to air or water, they are conducted much less completely. Now, inasmuch as the cochlea may be regarded as part and parcel of the cranial bones, the sounds which are propagated by these bones would reach the nervous expansion in that portion of the labyrinth by the most direct route; whereas, to affect the remaining parts of the labyrinth, the sound must be conducted from the bone through the perilymph to the membranous vestibule and semicircular canals. Moreover, when it is considered that the cochlear nerves are disposed in a radiated manner in the lamina spiralis, it will appear evident that the oscillations propagated to the petrous portion of the temporal bone must exert a direct influence on the cochlear portion of the auditory nerve.

One or two experiments with the tuning-fork show not only that the cranial bones do conduct, but also that sounds, inaudible or imperfectly audible through the meatus externus, may be distinctly heard when the sounding body is brought into contact with a bone of the cranium or face. When the tuning-fork is put into vibration by striking it against any solid body, if held near the external ear its vibrations are heard distinctly, but let the handle be applied to the teeth or to the superior maxilla, and the sound appears much louder; or if the fork be held near the ear until the sound has almost died away, and then its handle be applied to the superior maxilla or the teeth, the sound seems greatly to revive and continues for a considerable period, the handle being kept in contact with the bone.

When the conducting stem of the sounding tuning fork is placed on any part of the head, if both ears be closed by being covered with the hands, a considerable augmentation of the sound will be observed.* If the sounding-fork be kept in contact with the head for a short time, both ears remaining open, and then one ear be closed, the sound will be greatly augmented in the closed ear, and will appear to be heard exclusively by it. This experiment is more striking if the stem of the tuning-fork be applied to the mastoid process on one side: when both ears remain open, the sound seems to be heard chiefly by the ear in the vicinity of which the stem is placed, but when the opposite ear is closed, it appears as if the sound were transferred from the open to the closed ear; and if the ear be alternately opened and closed, the sound will alternately appear to be transferred from the one to the other. Similar phenomena may be observed if both ears are closed on the first application of the tuning-fork. The sound is at first heard in the adjacent ear, and either remains in it or is transferred to the opposite one, according as the former remains closed or is opened. Mr. Wheatstone adds that if the meatus and concha of one ear be filled with water, the sound from the tuning-fork will be referred to the cavity containing the water in the same way as when it contained air and was closed by the hand.

These phenomena afford obvious examples of the communication of sound through the bones of the head. The augmentation of the sound in the closed ear appears to result, as Mr. Wheatstone explains,† from the reciprocation of the vibrations by the air contained within the closed cavity, and this explanation is confirmed by the fact that when the meatus is closed by a fibrous substance, such as wool, no increase is obtained.

The following rationale may be offered of what occurs when the sound from the tuning-fork is communicated to a closed ear, in accordance with the views of Weber respecting the function of the cochlea. The vibrations of the fork are propagated by the bones of the head to the cochlea, the fluid of which being thus thrown into vibration causes the membrane of the fenestra rotunda to vibrate,

* E. H. Weber De Auditu in Annotat. Anatom. et Physiolog. Lips. 1834.

* These experiments were first suggested by Professor Wheatstone.—See his experiments on audition in the Journal of the Royal Institution for July 1827.

† Loc. cit.

by which as well as by the vibrations of the bones, the air in the tympanum is made to vibrate, and that cavity being closed the sonorous vibrations are reflected from its walls so as to give rise to the augmentation of the sound.

Autenrieth and Kerner believed the cochlea to be that part of the auditory apparatus by which we perceive what the French call the "timbre" of sounds; that quality, namely, which depends on the nature of the material of which the sounding body is constituted, as well as on its form and size, and in some degree on the manner in which sound is elicited from it; and they considered it the office of the vestibule to convey to the sensorium the pitch and strength of sounds. Their opinion as to the function of the cochlea was founded on some experiments as to the extent to which certain of the lower animals were affected by particular instruments of music: the results obtained from these experiments, when taken in connexion with certain differences in the form and other characteristics of the cochlea in those animals, led these authors to the conclusion that "those animals alone seemed to perceive a difference of the 'timbre' of sounds of pretty uniform pitch and loudness, in whom the cochlea was very long and projected considerably into the cavity of the tympanum, and was not much concealed by the surrounding bony substance. Thus it appeared that a dog (the cochlea of dogs being longer than that of cats), upon hearing a certain note of the clarionet, set up a howl, but seemed in no way affected at hearing the same note from the flute or violin; but the cat continued undisturbed, although a variety of instruments was sounded in her hearing. A rabbit (in which the cochlea is prominent) ran away at the note C elicited from a glass tumbler or from a string, but remained still when the same note was sounded even more loudly by the flute."* But it is abundantly evident that these experiments do not fairly lead to the conclusion which these physiologists endeavoured to establish; for, as Weber has remarked, it is one thing to be disagreeably affected by the peculiar tone of a given note in an instrument of music, and another thing to distinguish the timbre of the notes of different musical instruments. As well might we conclude that dogs excel in the power of distinguishing scents and savours, because the smell and taste of spirits of wine seem to be peculiarly disagreeable to them, and they reject instantly, although hungry, any food offered to them with which that has been mixed.

It seems evident that the cochlea is an indication of a very advanced condition of the organ of hearing; beyond this we can arrive at no definite conclusion in the present state of our knowledge, unless indeed we admit the very general one of Weber, that it is the primary seat of those auditory impressions which are conveyed through the vibrations of the cranial bones. But this view, however probable, and supported by much sound reasoning, throws no light on the object of the peculiar form and mechanism of the cochlea. We must not omit to notice that a portion of the vestibule is regarded by Weber as performing a similar function to that of the cochlea, and on similar grounds. That portion which is known under the name of the *sacculus* is so adherent to the bony wall of the vestibule, corresponding to the *fovea hemispherica*, according to Scarpa, that it cannot be separated without laceration, and consequently it seems to be better adapted to receive the sonorous vibrations which are conveyed by the cranial bones.

The remaining parts of the labyrinth, namely, the three semicircular canals and the common sinus, are most affected by those sounds which are conveyed through the external meatus: it seems evident at least that they must be more affected than the cochlea from the connexion between the membrana tympani and fenestra ovalis through the chain of tympanic ossicles, by which that membrane is brought into direct communication with the perilymph surrounding the membranous labyrinth. On the other hand these parts are badly adapted to receive the impression of vibrations direct from the cranial bones, being separated from the corresponding osseous parts by the peri lymph, and that part of the auditory nerve which is distributed to them, having no connexion with the bone. An experiment of Weber illustrates the relation of the perilymph to the membranous labyrinth, and shows that an impulse upon the membrana tympani is capable of affecting it. In some birds, the falcon for example, the semicircular canals are so large, that the membranous canals may be easily seen. If in such a bird one osseous semicircular canal be opened by a small opening, care being taken not to injure the membranous canal, and then we press the membrane of the tympanum inwards, at each com pression we observe the water contained in the bony canal to flow out with a jerk. He therefore concludes that the sonorous undulations conveyed by the cranial bones are communicated more immediately to the nerve of the cochlea, but those conveyed by the external meatus to the nerve of the vestibule.

The semicircular canals are remarkable for the constancy of their number, and of their relative position with respect to each other, in all animals in whom they are found. They exist in almost all fishes, and in all the other vertebrate classes, and in these they are never less than three in number, two of which are always placed vertically and one horizontally. The opinion that the arrangement of these canals has reference to conveying the sensation of the direction of sounds, I find expressed by Autenrieth and Kerner in the paper already referred to. "In no animal," they say, "are these canals ever more or fewer on each side than

* See these experiments quoted at greater length in Weber's paper before referred to. Autenrieth's paper is to be found in Reil's and Autenrieth's Archiv. fur die Physiologie, B. ix. 1809; and contains much valuable and highly interesting matter relative to all the parts of the organ of hearing in several of the Mammalia.

three, which are so situated that they correspond to the three dimensions of a cube, its length, breadth, and depth, and that every sound arriving in one of these three directions will always strike one canal at right angles to its axis, and another in its length. The position of these canals is likewise such, that the corresponding canals of opposite sides cannot be parallel, and that therefore any sound which strikes the head in any given direction affects the semicircular canal of one side much more than the corresponding one of the opposite side, whereby it may be determined whether the sound coming in a straight line (from west to east for example,) has really moved from west to east, or from east to west."* They state that in animals in whom the semicircular canals are highly developed, the power of distinguishing the direction of sounds is marked to a proportionate degree. Thus in the mole, the development of these canals is very considerable, and from a simple experiment it appears that this animal readily distinguishes the direction of sounds. A mole was introduced into a wide but flat vessel filled with earth, in which he was allowed to burrow, and it was found that the mole could be made to move about by sounding an instrument outside the vessel; if the instrument were sounded on one side, the animal would always immediately turn to the other.† The fox seemed to distinguish the direction of sounds better than cats: if at the same time, and at opposite sides, the high tones of a little bell and the deep tones of a bass viol were sounded, the fox always turned to the side whence the high notes came. Cats seem to be sensible of the direction of high notes only. When upon a violin, or a flageolet, or upon a glass goblet containing water, high notes were sounded, the cats always turned towards the place whence the sound came, even although the instrument was concealed from them: on the other hand, when a person seated on the ground sounded the low notes of a bass viol before several cats in a garden, they seemed to seek in all directions for the place of the sounding body, without hitting upon the right one. The cow, the horse, the pig, and the rabbit seemed to manifest particularly little sensibility to the direction of sounds. The dog appears to have less power to distinguish the direction of sound than man; his smell seems to assist him, and it is well known that when a dog is called by his master, he commonly runs backwards and forwards for some time before he finds out the right direction. The human semicircular canals greatly exceed in width all others examined by Autenrieth and Kerner, but this excess is more as regards the canals properly so called, but does not apply to the ampullæ. Scarpa had already remarked, that although the canals of oxen and horses were narrower than those of man, the ampullæ were scarcely at all smaller than in the human subject. These observers further remarked, in many animals they examined, an inverse ratio between the width of the ampulla and that of the canals; that the former were wider in proportion as the latter were narrow. In fine, they conclude that the wider the semicircular canals, the size of the animal being taken into account, the greater is the power of distinguishing the direction of sound. Of the lower animals, the first in order as regards this power is the hedge-hog, which, after the human subject, has, relatively to its size, the widest semicircular canals; we may form some idea of the width of these canals from the fact that in their centre they are nearly as wide as the semicircular canals of the pig, which is so very much larger an animal. Next to the hedge-hog stands the mole, whose canals are, proportionally to the size of the animal, both remarkably wide and long; they are peculiar also as projecting free (visible without any prepation) into the cavity of the cranium. The mouse and the bat come next, then the fox and the dog,* the rabbit, the cat, the pig, the cow, the horse, and lastly the sheep.

Professor Wheatstone advocates the theory that our notions of audible direction depend upon the excitation of those portions of the auditory nerve which belong to the semicircular canals. He conceives that we distinguish best the direction of those sounds which are sufficiently intense to affect the bones of the head, and that it is from the portion which is transmitted through those bones that our perception of the direction is obtained. Thus, we always find it difficult to tell by the ear the position whence the feeble tones of the Œolian harp proceed. The three semicircular canals, then, being situated in planes at right angles with each other, are affected by the sound transmitted through the bones of the head with different degrees of intensity according to the direction in which the sound is transmitted; for instance, if the sound be transmitted in the plane of any one canal, the nervous matter in that canal will be more strongly acted on than that in either of the other two; or if it be transmitted in the plane intermediate between the planes of this canal and the adjacent one, the relative intensity with which those two canals will be affected will depend upon the direction of the intermediate plane. The direction suggested to the mind will correspond with the position of the canal upon which the strongest impression has been made.†

* Op. cit. p. 363.

† This experiment, however, was repeated by Esser, who assures us that the direction of the movements of the mole was not influenced by the direction of the tones of the instrument. Kastner's Archiv. fur die gesammte Naturlehre, B. 12, s. 56. quoted in Treviranus, Erschein. und Gesetze des Organischen Lebens.

* The width of the canals in dogs was found to vary in the different races. Autenrieth and Kerner, loc. cit.

† Dr. Young thought that the semicircular canals seemed very capable of assisting in the estimation of the acuteness or pitch of a sound by receiving its impression at their opposite ends, and occasioning a recurrence of similar effects at different points of their length, according to the different character of the sound; while the greater or less

No conclusions can be derived from the experiments of Flourens with respect to the functions of the several parts of the labyrinth. The effects of disease had already sufficiently indicated the relative importance of the different parts of the ear, and even to a certain extent of those of the labyrinth. Thus we knew that stoppage or destruction of the external parts does no more than impair the sense of hearing, and that so long as the labyrinth remains perfect, or at least the vestibule, the sense is not destroyed. Sound may be conveyed to the auditory nerve through the bones of the head, as may be proved by the sensation of sound produced by the application of a tuning-fork in vibration to the teeth or to some one of the cranial bones. By a parity of reasoning, Flourens having successively destroyed the several parts of the ear in pigeons, inferred that the nervous expansion in the vestibule was the part of the organ most essential to audition: "that in strictness, it is the only indispensable part, for all the others may be removed; yet if this continue, audition is not destroyed." Partial destruction of the nervous expansion in the vestibule only partially destroys the sense, and complete destruction of this expansion involves total deafness. The vestibule may be laid open without any very considerable alteration in the sense; but rupture of the semicircular canals rendered the hearing confused and painful, and was moreover accompanied with a quick and violent tossing of the head.*

One can scarcely imagine vivisections less likely to lead to useful results than those which involve the exposure of the deep-seated internal parts of the ear, a dissection which even on the dead subject demands no ordinary skill; nor can we refrain from expressing our opinion that had M. Flourens never attempted these experiments, physiology would have been none the worse, and our respect for his humanity would have been all the greater.

II. *Of the accessory parts of the organ.*—We shall consider in succession the parts which the external ear—the tympanum, its membrane and ossicles, and the Eustachian tube, play in the process of audition.

The external ear may be regarded as consisting of two parts, the auricle and the meatus auditorius externus. The complete developement of the former is found only in Mammiferous animals, and exists pretty generally throughout the class; with, however, considerable diversity of form, varying from an almost flat cartilaginous lamella, scarcely at all under the influence of its muscles, to an elongated funnel-shaped ear-trumpet, very moveable and completely at the command of numerous large muscles. Man and the Quadrumana are at one extremity of this scale; the Solipeds, Ruminants, and Cheiroptera at the other. Some, however, are devoid of the auricle, as the mole, the zemni-rat, the mole-rat, the seal, the walrus, &c. It is said that those animals which are remarkable for the large developement of the auricle are almost all timid or nocturnal, and consequently require an acute sense of hearing.

That the auricle performs the office of an acoustic instrument to collect and reinforce the sounds which fall upon it, cannot be doubted in those cases in which it is large and fully developed, as in the horse, ass, &c. Here, indeed, we see that the animal employs it as we might expect such an instrument would be used; the open part is directed towards the quarter whence the sound comes, and continues so directed as long as the animal appears to listen. So far, however, from this part being mainly the instrument for enabling the animal to judge of the direction of sound, it appears to me that it cannot be applied to its full use until the direction of the sound has been in some measure determined; until the hearing-trumpet has been favourably placed with respect to the quarter whence the sound emanates, its value is not fully experienced. If we watch the movements of the auricle of a horse, we shall see that he uses it altogether for concentrating sounds from particular quarters: when he moves it about quickly, it often seems as if he were feeling for sounds coming from certain directions, having already acquired a tolerable notion, if I may so speak, as to what those directions are. Treviranus,* however, thinks that the reinforcement of the sound is not its principal use: "to what end," he asks, "have its various eminences and depressions been formed, if it have no other use than this, and why are these particularly developed in the human ear, which can have little or no influence as an ear-trumpet in increasing the influence of sounds?" He supposes that in the lower animals, but *especially in man*, the auricle serves more for forming a judgment respecting the direction of sounds than for assisting in hearing. We cannot understand in what way the fixed auricle of man can aid for this purpose, being almost immoveable, and indeed altogether so for the purposes of collecting sonorous undulations from different quarters; nor indeed does it appear that the opinion in question of Treviranus is any thing more than a mere hypothesis. A remark of Mr. Gough, the author of a highly interesting paper in the Manchester Memoirs "on the method of judging by the ear of the position of sonorous bodies," offers a strong argument against this notion. He observes that whatever may be the direction of a sound in the open air, as soon as it enters the auditory passage, it is compelled to follow the course of that duct until it reaches the apparatus in which the sense of hearing resides.†

The experimental researches of Savart throw some light upon the function of this part of the auditory apparatus.‡ These experiments

pressure of the stapes must serve to moderate the tension of the fluid within the vestibule, which serves to convey the impression. The cochlea seems to be pretty evidently a micrometer of sound.—See Med. Lit. p. 98.

† Manchester Memoirs, New Series, vol. v.

‡ Majendie's Journal de Physiologie, tom. iv.

were suggested by the result of several observations which he made upon the communication of vibrations through the air from a vibrating body to one placed even at a great distance from it, and susceptible of undergoing vibrations. The effect is best seen by using a thin membrane, such as very fine paper, carefully stretched in a horizontal position over the mouth of a glass, or of a small delft basin: a thin layer of sand is spread on this, and a glass thrown into vibration by a violin bow is held at a little distance from it; that the paper immediately begins to vibrate is shewn by the motions excited in the sand, the particles of which arrange themselves into figures, which are sometimes perfectly regular, and which form with so much rapidity that the eye can scarcely follow "the circumstances which accompany the transformation of the thin layer of sand into a greater or less number of lines of repose."

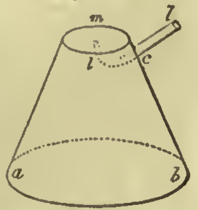
By a series of experiments to be hereafter detailed, Savart showed that the tympanic membrane is capable of being thrown into vibrations by the sonorous impulses from a vibrating body communicated to it by the interposed air. How far the external ear and auditory canal serve to increase these vibrations of the tympanic membrane, he sought to ascertain by the following experiments. He formed a conical tube of pasteboard, with a very wide mouth at its base, the opening at the smaller end being closed by a thin paper stretched over it and glued to the margins of the opening. This tube is placed resting on its base, the membrane being upwards and perfectly horizontal, so that a layer of sand may be spread over it. When a vibrating glass is brought near and parallel to the upper surface of this membrane, it immediately begins to vibrate, and the grains of sand are tossed about but raised but very slightly from the surface. If, however, the vibrating glass be placed near the base or the wide and open extremity of the tube, the vibrations of the membrane will be found to be much more manifest, and the excursions of the grains of sand so considerable, that they are often raised to a height of three or four centimetres; so that there is a manifest difference in the influence produced upon the membrane by the sonorous undulations excited in the air according as they impinge upon the external surface of the membrane or upon that which is turned towards the interior of the tube. This phenomenon, Savart adds, may depend upon two causes, namely, upon the concentration of the sonorous undulations by the tube, or upon the communication of motion to the parietes of the tube, which again would communicate it to the membrane. With a view to ascertain which of these causes was the effective one, a second conical tube, open at both ends, was held with its narrow extremity a little above and corresponding to the narrow extremity of the former one, but so that there was no contact between them. If now the glass is made to vibrate successively at the large orifices of the two tubes, it will be found that when placed at the orifice of the tube to which the membrane is attached, the oscillations of that membrane are considerably greater than when the aerial undulations reach it through the other tube. Whence it may be inferred that in all probability the external ear and auditory canal have, besides any influence they may exert in modifying the movements of the particles of the air, the additional function of presenting a large surface to the aerial undulations, consequently to enter into vibration under their influence, and thus to contribute to increase the excursions of the vibrating parts of the membrane with which they are immediately in contact; the auricle, by the variety of the direction and the inclination of its surfaces to one another, can always present to the air a certain number of parts, whose direction is normal (at right angles with) to that of the molecular movement of that fluid.

We get a general notion of the value of this external part of the auditory apparatus in collecting and directing the sonorous undulations, from the assistance often derived in hearing from increasing the concavity of the external ear by placing the hand behind it, so as to draw it forward and shorten it by pressure at its upper and lower part; by the dulness of hearing which it is said follows the loss of the auricle, and from the fact, so stated, that the seal and walrus are extremely dull of hearing. As regards the loss of the auricle, it is said by Kerner that this loss is followed by the greatest dulness of hearing in those animals in whom the osseous meatus is wanting. In a cat, from whom the right ear was cut close to the skull, after the wound had healed without any stoppage of the meatus, there was a remarkable disposition always to keep its head turned so as to be ready to receive sounds with the left ear, and this continued even after the tympanic membrane of the opposite side had been frequently perforated, that of the right side remaining whole; and when the left ear was stopped (although the right tympanic membrane was sound, and the only injury on that side was the removal of the auricle,) a total deafness was manifested except to the loudest and clearest sounds.

The tympanum and its contents.—We have already stated that Savart had demonstrated that the membrana tympani is thrown into vibrations by undulations of the air excited by a sonorous body. This he demonstrated experimentally upon the membrana tympani itself. The temporal bone having been separated, he sawed away the osseous meatus so as to expose the membrane on a level with the rest of the bone, and when it was sufficiently dry, he covered it with a thin layer of sand. A vibrating glass held parallel and very near to the surface of the membrane occasioned a slight movement of the grains of sand; but owing to the slight extent and the shape of the membrane, it was impossible to determine the existence of any nodal line. In a second experiment, the cavity of the tympanum was opened, so as to expose the ossicles of the ear and their muscles; and it was observed that when the internus mallei muscle acted and rendered the membrane tense, it was much more difficult to produce manifest movements in the grains of sand; thus affording much reason to suppose the tensor tympani muscle is analogous in its use to the iris, and destined to preserve the organ from too strong impressions. This experiment can be best tried on the membrana tympani of the calf.

In imitation of the mechanism by which the tension of the membrana tympani is effected, and with a view to determine more decisively the effects produced by variation of the tension of that membrane, Savart constructed a conical tube (*fig.* 262), with its apex truncated and covered by a layer of very thin paper (*m*), which was glued to the edge of the opening. A little wooden lever (*l l*), introduced through an opening in the side of the tube, and resting on the lower margin of this opening (*c*) as a fulcrum,

Fig. 262.



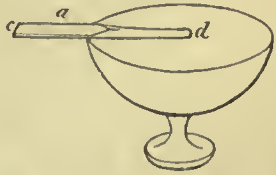
was used to vary the tension of the membrane, one of its extremities being applied to the under surface of the membrane. It is evident that, by depressing the extremity of the lever that was external to the tube, the inner one would be raised, and thus the membrane stretched to a greater or less degree according to the force used; on the other hand, by elevating the outer extremity, the inner one was separated from the membrane, which was accordingly restored to its original tension. This little lever was employed in imitation of the handle of the malleus, which under the influence of its muscles causes the variation in the tension of the membrana tympani. The artificial tympanic membrane then having been covered with a layer of sand, it was found that, under the influence of a vibrating glass, used as in the former experiments, a manifest difference was produced in the movements of the grains of sand, by increasing the tension of the paper; the greater the tension, the less the height to which the grains of sand were raised; and these movements were most extensive when the lever was withdrawn from contact, and the membrane left to itself.

From these experiments Savart concludes that the membrana tympani may be considered as a body thrown into vibration by the air, and always executing vibrations equal in number to those of the sonorous body which gave rise to the oscillations of the air. But what is the condition of the ossicles of the tympanum whilst the membrane is thus in vibration? The result of the following experiment affords a clue to the answer of this question. To a membrane stretched over a vessel, as in *fig.* 263, a piece of wood (*a b*) uniform in thickness is attached, so that the adherent part shall extend from the circumference to the centre of the membrane, while the free portion may project beyond the circumference. When a vibrating glass is brought near this membrane, very regular figures are produced, which

Fig. 263.

however are modified by the presence of the piece of wood, and the vibrations of the membrane are communicated to the piece of wood, on which likewise regular figures may be produced. The more extensive the membrane, the longer and thicker may be the piece of wood in which it can excite oscillations, and Savart states that, with membranes of a considerable diameter, he has produced regular vibrations in rods of glass of large dimensions. The oscillations of the piece of wood are much more distinct when the adherent portion is thinned down, as in c *d*, *fig.* 264, by which it

Fig. 264.



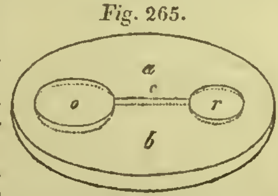
seems, as it were, more completely identified with the membrane, and consequently the oscillations of this latter are communicated directly to the thinned portion of the wood, and thence extended to the thick portion *a*: sand spread upon *a* will exhibit active movements, and will produce very distinct nodal lines. Thus it may be inferred that the malleus participates in the oscillations of the tympanic membrane; and these vibrations are propagated to the incus and stapes, and thus to the membrane of the fenestra ovalis. The chain of ossicles then evidently performs the office of a conductor of oscillations from the membrana tympani to the membrane of the fenestra ovalis; but the malleus likewise has the important function under the influence of its muscles of regulating the tension of the tympanic membrane; and to allow of the changes in the position of this bone necessary for that purpose, we find it articulated with the incus by a distinct diarthrodial joint, and between this latter bone again and the stapes there exists another and a similar joint. This mobility then of the chain of bones, and the muscular apparatus of the malleus and stapes are totally irrespective of the conducting office of the bones, but have reference to the regulation of the tension of the membrane of the tympanum as well as of that of the fenestra ovalis.*

We have already seen how the muscle of

* The experiments of Savart above detailed have been several times carefully repeated by me with results precisely similar.

the malleus regulates the membrana tympani, increases its tension, and thus limits the extent of the excursions of its vibrations. The contraction of the stapedius muscle causes the base of the stapes to compress the membrane of the fenestra ovalis to a greater or less extent, so that the degree of tension of that membrane depends on the condition of this muscle. Compression exerted upon the membrane of the fenestra ovalis extends to the perilymph and through it is propagated to the membrane of the fenestra rotunda, and in this way the same apparatus which regulates the tension of the membrane of the fenestra ovalis performs that office for that of the fenestra rotunda, and Savart has devised a little apparatus which very prettily illustrates the manner in which this may take place. In a disc of wood (*a b*, *fig.* 265) of a sufficient thickness, he hollows out two cavities, *o* and *r*, which communicate at their bottoms with each other by a narrow canal (*c*) hollowed in the wood, but not open on its surface; a thin membrane is extended over each of the cavities. Thus, the air contained in these cavities may pass easily from one to the other, and may always maintain the same degree of elastic tension in both. If, then, a vibrating glass be brought near the membrane *r* covered with a layer of sand, it will be found to enter freely into vibration, as evinced by the active movements of the grains of sand. If now pressure be made with the finger on *o*, *r* will become convex in proportion as *o* is rendered concave by the pressure, and when in this state, the movements of the sand will be much less considerable than before, presenting an effect precisely similar to that produced on the tympanic membrane by an increase of tension. Thus, the extent of the excursions of the vibrations of the membrane *r* is limited by the pressure exerted upon *o*, and as the membranes of the two fenestræ are related to each other in an analogous manner, we may argue that pressure upon the larger one, that of the fenestra ovalis, will occasion tension of the smaller, that of the fenestra rotunda, thereby limiting the extent of the excursions of its vibrations.

Fig. 265.



Moreover it appears, upon reference to the anatomy of these parts, (see *fig.* 252, p. 550,) that the only muscles which have been satisfactorily demonstrated are tensors of the tympanum; and that at whatever extremity of the chain of ossicles muscular effort be first exerted, a corresponding effect will be produced at the other; that when the stapedius muscle acts, the malleus is thrown into a position favourable to the tension of the membrana tympani, and, on the other hand, the contraction of the internus mallei depresses the stapes, and consequently increases the tension of the membranes of the two fenestræ. The cessation of muscular action restores all three membranes to their original laxity, nor does it appear that they admit of any further degree of relaxation through the influence of any vital process. The incus forms a bond of connexion between the two other bones, and its motions depend entirely upon theirs in consequence of its articulation with both, while from the fixedness of its connexion with the mastoid cells, as well as its intermediate position, and its not having any muscles inserted into it, it is obvious that its motions must be much more limited than those of the other bones. Its use seems to be to complete the chain in such a way, that by reason of its double articulation with the malleus on the one hand and the stapes on the other, the tension of the tympanic membranes may be regulated without any sudden or violent motion, which could scarcely be avoided were the conductor between the membranes of the tympanum and fenestra ovalis one piece of bone.

But whence the necessity of at all adding to the ear this complex apparatus of tympanum and tympanic membrane, and why might not the sonorous impressions have been made directly upon the membranes which close the openings to the labyrinth? Upon this point Savart has offered a conjecture which seems to afford the most probable explanation as to the true object of these parts. If the membranes of the fenestra, he says, had been in immediate contact with the atmosphere, their elastic state would have been constantly undergoing changes, under the influence of the vicissitudes of temperature of the air, a circumstance which would, in all probability, impair the power of the organ in detecting differences of sounds. He presumes therefore that the membrana tympani prevents this contact of the atmosphere with the membranes of the labyrinth, and that the cavity of the tympanum and the mastoid cells form a kind of receptacle in which the air, which finds its way into the tympanum through the Eustachian tube, acquires the constant temperature of the body, and establishes in front of the openings of the labyrinth a sort of atmosphere proper to themselves, the temperature of which does not vary.

This same acute observer remarks that the size of the membrana tympani in all probability, in the different species of animals, exerts much influence upon the number of sounds which they can perceive, and at the same time upon the limits at which those sounds begin or cease to be audible. Were the tympanic membrane in man of greater size than it is, there is no doubt that instead of beginning to hear sounds which result from about thirty vibrations in a second, we should be able to hear only sounds of a higher pitch. Moreover it may be reasonably presumed that animals who have the membrana tympani much larger than that of man, hear much graver sounds than those which result from thirty vibrations in a second; and, on the other hand, there must be other animals who hear very acute sounds only.

Even in the human species, we observe in different individuals a similar variation in the limits of sensibility to sounds, that is, we find, in the words of Dr. Wollaston, that "an ear which would be considered as perfect with regard to the generality of sounds, may at the same time be completely insensible to such as are at one or the other extremity of the scale of musical notes, the hearing or not hearing of which seems to depend wholly on the pitch or frequency of vibration constituting the note, and not upon the intensity or loudness of the noise."* And we owe to this distinguished man the knowledge of the interesting fact, that an insensibility of the ear to low sounds may be artificially induced, by exhausting the cavity of the tympanum to a great degree. This may be effected by forcibly attempting to take breath by expansion of the chest, the mouth and nose being kept shut; after one or two attempts, the pressure of the external air is strongly felt upon the membrana tympani, which is thus from the external pressure thrown into a state of considerable tension. An ear in this state becomes insensible to grave tones, without losing in any degree the perception of more acute ones. This induced defective state of the ear, from exhaustion of the tympanum, may even be preserved for some time without the continued effort of inspiration and without even stopping the breath, and may in an instant be removed by the act of swallowing. In repeating this experiment as I sit writing at my desk, I perceive that a great degree of stillness ensues immediately the sensation of pressure upon the tympanic membrane is felt, owing no doubt to the low rumbling noise of the waggons and carriages in the street being imperfectly audible. A similar observation was made by Dr. Wollaston: "If I strike the table before me with the end of my finger," he says, "the whole board sounds with a deep dull note. If I strike it with my nail, there is also at the same time a sharp sound produced by quicker vibrations of parts around the point of contact. When the ear is exhausted, it hears only the latter sound, without perceiving in any degree the deeper note of the whole table. In the same manner, in listening to the sound of a carriage the deeper rumbling noise of the body is no longer heard by an exhausted ear; but the rattle of a chain or screw remains at least as audible as before exhaustion." Dr. Wollaston refers to the curious effect produced by trying this experiment at a concert: "none of the sharper sounds are lost, but by the suppression of a great mass of louder sounds the shriller ones are so much the more distinctly perceived, even to the rattling of the keys of a bad instrument, or scraping of catgut unskilfully touched." Another very interesting circumstance connected with this subject is the production of the same condition of the tympanum by the sudden increase of external pressure as well as by the decrease of that within, as occurs in the diving-bell as soon as it touches the water, the pressure of which, according to Wollaston, upon the included air closes the Eustachian tube, and in proportion to the descent occasions a degree of tension on the tympanum, that becomes distressing to persons who have not learned to obviate this inconvenience."

From one opportunity which I had of descending in the diving-bell now exhibiting at the Polytechnic Institution in Regent-street, I experienced this sensation very strongly, and exactly as Dr. Wollaston describes it. The first effect of the pressure on the tympanic membrane was the production of a crackling noise, which was immediately succeeded by a painful sense of pressure in both ears; but this is immediately relieved by the act of swallowing; it soon however recurs, and may be in a like manner again relieved. I had no means of judging exactly as to the limits of audition; but I distinctly observed in conversation with those who descended with me, that grave tones were those least distinctly heard; the grave tones of my own voice also were less distinct as well as the low notes in whistling.

In such cases then it would appear that from the strong compression exerted on the membrana tympani, that membrane cannot vibrate in unison with tones which result from a small number of vibrations. On the other hand we may infer, from Dr. Wollaston's observations, that "human hearing, in general, is more confined than is generally supposed with regard to its perception of very acute sounds, and has probably in every instance some definite limit at no great distance beyond the sounds ordinarily heard." The ordinary range of human hearing comprised between the lowest notes of the organ and the highest known cry of insects, includes, according to Wollaston, more than nine octaves, the whole of which are distinctly perceptible by most ears. Dr. Wollaston has, however, related some cases in which the range was much less, and limited as regards the perception of high notes; in one case, the sense of hearing terminated at a note four octaves above the middle E of the piano-forte; this note he appeared to hear rather imperfectly, but the F above it was inaudible, although his hearing in other respects was as perfect as that of ordinary ears; another case was that of a lady who could never hear the chirping of the gryllus campestris; and in a third case the limit was so low that the chirping of the common house-sparrow could not be heard. Dr. Wollaston supposes that inability to hear the piercing squeak of a bat is not very rare, as he met with several instances of persons not aware of such a sound.

The opinion prevailed for a long time that rupture or destruction of the membrana tympani is necessarily followed by the loss of the sense. But Sir A. Cooper proved distinctly that not only was hearing not destroyed, but that in some cases of deafness it might be punctured with considerable benefit to the patient.* The most frequent cause of destruction of the tympanum is otitis, and provided

* Wollaston on Sounds inaudible by certain Ears. Phil. Trans. 1820.

* Phil. Trans. for 1800 and 1801.

the suppurative process does not extend so far as to destroy the stapes, the hearing is only impaired; but should that bone and its attached membrane suffer, then a total deafness is the consequence. In one case, related by Sir A. Cooper, the membrana tympani was entirely destroyed on the left side, and partially so on the right, yet this gentleman, if his attention were excited, was capable, when in company, of hearing whatever was said in the usual tone of conversation, but it was remarkable that he heard better with the left ear than with the right, although in the former there were no traces of a membrana tympani. He could not hear from as great a distance as others, and he stated that, in a voyage he had made to the East Indies, while others, when ships were hailed at sea, could catch words with accuracy, his organ of hearing received only an indistinct impression. His musical ear was not impaired, "for he played well on the flute and had frequently borne a part in a concert." The external ear too had acquired a considerable degree of mobility under the direction of the will, so that it could at pleasure be raised or drawn backwards, and this motion was observed to take place whenever the attention was directed to sounds not very distinctly audible.

The Eustachian tube evidently performs a two-fold office:—it is the passage for the entrance of air into the tympanic cavity from the throat, thus affording a provision for keeping that cavity constantly full of air in order to allow of the free vibration of the membranes as well as of the chain of bones; and it seems obvious that the tube communicates with the throat in order that the air introduced through it shall have acquired the temperature of the body. It likewise affords an outlet for the escape of such sonorous undulations as do not impinge upon the labyrinthic wall of the tympanum, which, were there no such communication with the external air, would cause an echo, and in this respect it performs a function similar to that of the mastoid cells. The necessity of such a provision as is afforded by the first office which the Eustachian tube performs, is manifest from the frequency of deafness resulting from a stoppage either in the tube or at its extremity. Bressa supposed that the Eustachian tube conducted the sonorous impulses excited by one's own voice from the cavity of the mouth to the labyrinth;* but the incorrectness of this notion is abundantly proved by the fact that persons who labour under obstruction of this tube can hear their own voices plainly enough, while they are deaf to those of others. Moreover, if we introduce into the mouth a watch or a vibrating tuning fork, care being taken that they do not touch any of the walls of the mouth, they are heard gradually less distinctly as they are approximated to the Eustachian tube; indeed when held far back in the mouth they are totally inaudible. In some birds the air of the tympanum finds its way not only into the mastoid cells, but also between the two tables of the skull, as in the owl and in singing birds. The arrangement of the osseous structure corresponding to the diploë is exceedingly beautiful in the canary, in which I have examined it. The two tables seem as it were connected by very fine and numerous bony pillars, the extremities of which are attached to each table; cells freely communicating with each other surround these pillars every where, and the air from the tympanum thus traverses the whole of this cellular structure. The superfluous sonorous undulations find their way into these cells, and being repeatedly reflected from their parietes become greatly weakened, so that they can exert no further influence upon the hearing.

Functions of the nerves.—The nervous apparatus connected with the organ of hearing consists of the nerve which receives the sonorous impressions, and of other nerves which are connected with the mechanism of the organ. That the portio mollis of the seventh pair answers to the former office, anatomy alone abundantly proves. With respect to the latter nerves some few remarks seem necessary. The muscular apparatus of the tympanic ossicles receives its nerves partly from the facial and partly from the otic ganglion, thus exhibiting an analogous arrangement to that of the muscular structure of the iris. Such an analogy renders it extremely probable that the actions of the muscles of the ossicles are excited in a similar way to that in which the iris is prompted to act. The stimulus of sound conveyed to that portion of the nervous centre with which it is connected, excites by reflection the motor power of the facial nerve, which, through its connexion direct or indirect with the muscles of the ossicles, causes them to act, and the action is in proportion to the intensity of the sound, inasmuch as the more tense the membrane of the tympanum, the less will be the excursions of its vibrations; as in the iris the more intense the light, the more contracted will the pupil be. It is impossible in the present state of our knowledge to say what is the office of the chorda tympani, or whether indeed it has any office in connexion with hearing; but we may easily conceive that from its connexion with the facial, an irritation of it may excite that nerve. Equally ignorant are we of the function of the tympanic anastomosis.

I shall conclude with the following brief summary of the present state of our knowledge respecting the functions of the several portions of the organ of hearing.

* Reil and Autenrieth, Archiv. für die Physiologie, B. viii. This was a modification of an opinion expressed by Boerhaave, viz., that those sounds from without which entered the mouth were conveyed to the labyrinth through the Eustachian tube. An English physiologist advocates the opinion that some sounds are conveyed through the Eustachian tube, and particularly as he supposes in the Cetacea, from the great development of that tube in these animals compared with the external auditory passage, and the erroneous notion propagated by Home that the malleus had no connexion with the tympanum, but now disproved by the careful examination of Professor Owen. See Fletcher's Physiology, and Owen's Edition of Hunter's Animal Economy.

1. The *vestibule* is the essential part of the organ. It detects the presence and intensity of sound, and especially of those sounds conveyed through the external ear and tympanum.

2. The *cochlea*, lying in immediate connection with the bone, receives those sounds which are propagated through the bones of the head. According to Kerner it is the medium of the perception of the *timbre* or quality of sounds.*

3. Of the function of the *semicircular canals* we know nothing. That they aid in forming a judgment of the direction of sounds is conjectured by Autenrieth and Kerner, and more recently by Wheatstone.

4. The *tympanum* and its membrane render the internal ear independent of atmospheric vicissitudes, and the former affords a non-reciprocating cavity for the free vibration of the latter, as well as of the chain of ossicles.

5. The *chain of ossicles* acts as a conductor of vibrations from the membrana tympani to the fenestra ovalis, and under the influence of the muscles regulates the tension of the membrana tympani, as well as the membrane of the fenestra rotunda, so as to protect the ear against the effects of sounds of great intensity.

6. The *external ear* and *meatus* are conductors of vibrations; the former in some degree collects them as a hearing-trumpet would do, and probably assists in enabling us to judge of the direction of sounds.†

(R. B. Todd.)

HEART (in anatomy). Gr. κιαρ, καρδια; Lat. *cor;* Fr. *cœur;* Germ. *Herz;* Ital. *cuore.* The movement of nutritious juices through the texture or textures of which an organized body is composed, is a fundamental law in Physiology. In proportion as the vital actions become more complex and energetic, the more a rapid and certain circulation of these fluids, which is intimately connected with this condition, becomes indispensable, and for this purpose we have a pulsatory sac or sacs, called *hearts*, superadded to the circulatory apparatus. Another invariable concomitant of this energetic manifestation of the vital phenomena is the more perfect exposure of the nutritious fluids to the atmospheric air, and this, combined with the dissimilar media in which different animals live and move, necessitates very important modifications in the number, position, and structure of these pulsatory sacs. These hearts were until lately supposed to be exclusively confined to the sanguiferous vessels, but Müller and Panizza have discovered distinct pulsating sacs placed upon the lymphatic vessels in several of the reptile tribe, and these may be considered *lymphatic hearts.*

In the lowest organized plants, as the Fungi, Algæ, &c. and in the lower classes of animals, as the Polypi, Actiniæ, and a great part of the intestinal worms, the nutritious fluids are transmitted through their substance without any distinct canals or tubes; while in the higher classes of plants, and in the Medusæ, &c. among animals, vessels are present, but these are unprovided with any pulsatory cavities. In the articulated animals generally, the vessels are still without any pulsatory cavities; but to make up for the deficiency, the dorsal vessel itself has a distinct movement of contraction and relaxation. Various pulsatory dilatations are placed upon the vascular system of the common worm *(Lumbricus terrestris);* one or two upon the vascular system of the Holothuria; and one in the Talpa cristata, where the dorsal vessel is reflected upon itself at the posterior extremity of the body to become continuous with an analogous ventral vessel; all of which may be considered as rudimentary hearts.

As we rise in the scale of animals, we find that the heart consists of two distinct portions—of a stronger and more muscular cavity called a *ventricle*, and of a weaker and less muscular cavity called an *auricle.* The latter not only serves as a kind of reservoir to the former, but also, by the contraction of its muscular fibres, drives the blood into it. This heart is placed within a sac or pericardium, and possesses valves to prevent the regurgitation of the blood from the ventricle into the auricle, and from the aorta back again into the ventricle. This may be considered as a perfect *single heart.* This single heart in some of the Mollusca and in Fishes which have a double circulation, propels the blood not only through the lungs, but also through the body. In the Batrachian Reptiles, as in the Frog, though the circulation is single, the heart becomes more complicated; for instead of a single auricle we have two, one of which receives the blood returning from the respiratory apparatus, the other receives the venous blood of the body. The pulmonic and systemic circulations are here separated as far as the auricles are concerned; but a single ventricle in which the venous and arterialized blood are intermixed, still continues to propel the sanguineous current both through the lungs and through the body. In the Ophidia or serpent tribe the heart possesses the same number of cavities as in the Batrachian Reptiles; but we have a still nearer approach to the double circulation in the presence of a rudimentary septum ventriculorum. In some of the Sauria, as the Crocodile, the ventricle is divided by partitions into distinct chambers, which never-

* Muller, who seems to regard the cochlea as an apparatus for distinguishing the pitch of notes, accounts for its peculiar form thus:—He supposes it an organ in which the separate parts of the nerve may be exposed to excitation; for this purpose all the finest fibres of the nerve lie exposed to the influence of the sound-conducting medium, and that it has assumed the spiral form in order that the nerves may be arranged in the most convenient manner and within the smallest space. See his Fragment on the sense of hearing appended to his work, Zur vergleichenden Physiologie des Gesichtssinnes.

† Much remains to be done to determine the true means by which we judge of the direction of sound. The reader who may be interested on the subject will find some valuable observations and experiments in Autenrieth and Kerner's paper already quoted, Mr. Gough's paper in the Manchester Memoirs, vol. v., new series, and one by Venturi in Voigt's Magazin f. d. Neueste aus der Physik. Mr. Wheatstone's views are very briefly stated in Dr. Elliotson's Physiology.

theless communicate freely with each other. It would appear, however, from Meckel's description, that the ventricle is divided by a complete septum into two separate and distinct chambers in the *Crocodilus lucius*. In the Mammalia and Birds, where no intermixture of the venous and arterialized blood takes place, but where all the blood sent along the aorta has been previously subjected freely to the influence of the atmospheric air, we find two distinct hearts, which in the adult have no communication with each other; one the respiratory heart for the transmission of the blood through the lungs, the other the systemic heart for the transmission of the arterialized blood through all the textures of the body. These are not placed separate from each other, as in some of the Mollusca, which with a double circulation have an aquatic respiration, but are in juxta-position, and in fact many of the muscular fibres are common to both.

Human Heart *(normal anatomy)*.

Position.—The heart in the human species is lodged within the cavity of the thorax, occupies the middle mediastinum, and is enclosed in a fibro-serous capsule called pericardium. It is placed obliquely from above downwards and from behind forwards, in front of the spine and behind the sternum. The apex is directed downwards, forwards, and to the left side, projects into the notch on the anterior margin of the left lung, and in the quiescent state of the organ corresponds to the posterior surface of the cartilage of the sixth rib. The base looks upwards, backwards, and to the right side; is separated from the anterior part of the spine by the pericardium, œsophagus, aorta, and other parts which lie in the posterior mediastinum; and extends from about the fourth to the eighth dorsal vertebra. Its right margin rests upon the upper surface of the cordiform tendon of the diaphragm, by which it is separated from the stomach and liver; its left margin, which is more vertical, looks upwards and to the left side, and occupies an excavation on the inner surface of the left lung. Its posterior or flat surface rests partly upon the cordiform tendon of the diaphragm, having the pericardium interposed between them, and partly upon the inner concave surface of the left lung.* Its position corresponds to the union of the superior third of the body with the two inferior thirds. The lungs overlap the lateral, and part (rarely the whole) of the anterior portion of the heart, leaving only in general about an inch and a half or two square inches of the anterior surface of the right ventricle uncovered by the lung. It is of importance to remember this fact in percussing this region. The two sacs of the pleuræ, as they pass between the spine and sternum to form the mediastina, are interposed between the lungs and the heart. The heart is subject to slight change of position from the influence of the contiguous organs. It is carried a little downwards during violent contraction of the diaphragm, and is pressed upwards when the abdominal viscera are strongly compressed by the powerful contraction of the abdominal muscles. During expiration it has been seen to recede deeper into the thorax, and during inspiration again to come forward. When the body is bent to the right side, the apex recedes from the inner side of the left wall of the thorax; when bent to the left side, it is still more closely approximated to it.

* In the lower animals its position is vertical, occupying the mesial line of the body.

Form and external surface.—Its form is that of a flattened cone, and it is neither symmetrical as regards the mesial line of the body, nor (as we shall afterwards find) is the organ itself symmetrical. It presents an anterior and a posterior surface; a right inferior or acute margin; a left superior or obtuse margin; a base, and an apex. Its anterior surface, which is also turned towards the left side, is convex and considerably longer than the posterior and right, which is flattened. On the anterior surface of the heart we find a distinct groove, running nearly in the axis of the organ, passing from above downwards and from right to left, and containing the left coronary artery. A larger portion of the heart appears to lie to the right than to the left of this groove. There is a similar groove on the posterior surface, which is nearly vertical, shorter than the anterior, and contains a branch of the right coronary artery. These two grooves are connected with each other at or near the apex generally by a small notch, which is sometimes of sufficient depth to give the heart a bifid appearance.* These grooves mark the division of the heart into right and left sides. These terms are, however, more applicable when describing the organ in the lower animals; for in the human species the right side is also anterior and inferior, and the left side posterior and superior. Near the base of the heart and at the commencement of the longitudinal grooves, we find a circular groove deeper anteriorly than posteriorly, which contains in its posterior part the coronary vein and branches of the coronary arteries. This circular groove points out the division between the auricular and ventricular portions of the heart. Two large arteries are placed in front of the anterior part of this groove, the one posterior to the other. That nearest to the groove is the aorta, which springs from the base of the left ventricle; the one placed anterior is the pulmonary artery, which arises from the upper part of the right ventricle, and at its origin covers, along with that part of the ventricle to which it is attached, the commencement of the aorta. The ventricles form the principal part of the heart, and occupy the middle and apex, while the auricles are placed at the base. The base of the ventricles is connected to the base of the auricles. Two large veins, the superior and inferior venæ cavæ,

* This notch in the human heart looks like the rudiments of the fissure which in the Dugong and Rytina separates the two ventricles from each other nearly up to the base. This bifid form of the heart, which is merely a temporary condition in the human species, is permanent in the Dugong and Rytina. See *fig.* 264, vol. i. p. 576.

enter the right, and the four pulmonary veins pass into the left auricle. The apex of the heart is in general formed by the left ventricle alone. The base of the ventricles is cut obliquely from before backwards and from above downwards, and this explains how the anterior surface of the ventricles should be longer than the posterior. I have found the difference of length between the two surfaces in a considerable number of uninjected hearts to vary from half an inch, or rather less, to an inch. There is little difference between the length of the two ventricles in the uninjected heart. In the injected heart the anterior wall not only becomes elongated but much more convex, while the posterior wall is simply elongated, so that the difference in length between the anterior and posterior surfaces becomes increased. This change is more marked in the right ventricle than in the left. Cruveilhier states that he found the anterior surface of the left ventricle to exceed the posterior by nine or ten lines, and the anterior surface of the right to exceed the posterior by fifteen lines. These measurements have evidently been taken from injected hearts. On the surface of the heart, but more particularly upon the anterior surface of the right ventricle, a white spot, varying in size, is frequently observed. According to Baillie it is placed on the free or inner surface of the external serous membrane.* These spots are so common an appearance that it is somewhat difficult to believe that they are morbid. It is, however, very probable that they are the result of some inflammatory action.

Except in very emaciated subjects there is a greater or less quantity of fat occupying the auricular and ventricular grooves. This fat is generally in greater abundance in old subjects than in young, in accordance with the general law, that the adipose tissue in young persons is principally collected on the surface, and in old persons around the internal organs. When in greater quantity, it is deposited along the ramifications of the coronary vessels, and may, in cases of great obesity, almost completely envelope the surface of the heart. It is generally placed in greater quantities on the right side than on the left.

The human heart may be considered as consisting of two distinct hearts separated from each other by a fleshy septum, and which in the adult have in general no communication. The position of the fleshy septum separating the ventricles is marked by the ventricular grooves. Each heart consists of an auricle and ventricle which communicate by a large orifice. The right heart is occasionally termed the *pulmonic heart*, from its circulating the blood through the lungs; and as it circulates the dark blood it was termed the *cœur à sang noir* by Bichat. The left is occasionally called *systemic heart*, as it circulates the blood through the body generally, and is the *cœur à sang rouge* of Bichat. The auricles, from their immediate connexion with the large veins of the heart, sometimes receive the name of venous portion of the heart *(pars cordis venosa)*; and in the same manner the term arterial portion of the heart *(pars cordis arteriosa)* has been applied to the ventricles from their connexion with the large arteries. In describing the different cavities of the heart we shall take them in the order in which the blood passes through them.

Right auricle (auricula dextra vel inferior, atrium venarum cavarum). External surface.—To see the external form of the auricles properly it is necessary that they be first filled with injection. The right auricle is of an irregular figure, having some resemblance to a cube, and occupies the anterior, right, and inferior part of the base of the heart. It receives all the systemic venous blood of the body. Its inferior portion rests upon the diaphragm. Its largest diameter runs in a direction from behind forward, and from right to left. It is broadest posteriorly, becoming narrow and prolonged anteriorly, where it terminates in a small and free appendix, which, from its resemblance to the external ear of the dog, has been termed auricle. This appendix is generally serrated on the edges, more particularly on the external, and projects between the aorta and the upper and anterior margin of the right ventricle. To this smaller portion the term *proper auricle* has been given, while the larger portion has been called *sinus venosus*. This division of the auricle into proper auricle and sinus venosus is more distinct in the left than in the right auricle. The posterior surface of the right auricle is connected with the entrance of the two cavæ; its inferior with the base of the right ventricle; its internal with the left auricle; its outer surface is free; and anteriorly it is prolonged into the proper auricle. The junction of its internal surface with the corresponding surface of the opposite auricle is marked by an indistinct groove, which corresponds to the attachment of the septum separating the two auricles. Its external surface is placed on a plane internal to the outer edge of the right ventricle.

Internal surface.—The inner surface of the right auricle can be satisfactorily examined only when it is opened *in situ*. Its interior can be best exposed by making a longitudinal incision from the appendix to the orifice of the inferior cava, then opening the superior cava along its anterior surface and connecting the two incisions. The inner aspect of the right auricle presents four surfaces:—1. a posterior, where the two venæ cavæ enter; 2. an outer, upon which numerous muscular bands are seen standing in relief; 3. an internal, which is nearly smooth, forms the septum between the two auricles, and presents an oval depression, about the size of the point of the finger, called the *fossa ovalis*; 4. an anterior, formed by the appendix, and which also presents numerous muscular bundles. The superior or descending vena cava enters at the upper and posterior angle, the inferior or ascending cava at the

* In three hearts in which I carefully examined these white patches, I could distinctly trace the serous membrane over them. See the observations of M. Bizot (Mémoires de la Société Médicale d'Observation de Paris, tom. i. p. 347, 1836,) on these spots.

posterior and inferior. The entrance of the superior cava looks downwards and forwards in the direction of the body of the auricle; the entrance of the cava inferior is directed upwards, backwards, and inwards. These two orifices are circular, and that of the cava inferior is larger than that of the cava superior. The right margins of these veins are continuous with each other; the left or anterior margins are continuous with the auricle, which in fact appears at first sight to be formed by an expansion of the veins; hence the term sinus venosus. Around the left margin of the entrance of the cava superior there is a prominent band of muscular fibres; and around its right and posterior margin there is another but less prominent band placed at its angle of junction with the right margin of the inferior cava. This last band occupies the position of the supposed tubercle of Lower *(tuberculum Loweri)*. The cava inferior occasionally forms a dilatation immediately before it enters into the auricle. The venæ cavæ have properly no valves at their entrance into the auricles.* The fossa ovalis *(valvula foraminis ovalis, vestigium foraminis ovalis)*, which marks the position of the foramen ovale by which the two auricles communicated freely with each other in the fœtus, is seen at the lower and right portion of the auricle, partly placed in a notch in the posterior and lower part of the fleshy portion of the septum, and partly in the upper part of the vena cava ascendens as it passes in to form the sinus venosus. The upper and anterior margins of this depression are thick and projecting *(annulus seu isthmus Vieusseni, columnæ foraminis ovalis)*. This was supposed by Vieussens to prevent the blood of the cava superior from falling into the cava inferior, an effect which Lower also imagined might be produced by the tubercle which he supposed was placed at the junction of the two veins. We have already pointed out that the orifices of the two veins are placed in different directions, which is sufficient to prevent the descending column of blood falling directly upon the ascending. The posterior and lower margins of the fossa ovalis are ill-defined. The surface of the depression is sometimes smooth, at other times uneven and reticulated. Between the upper margin of the depression and the annulus or thickened edge of the fossa ovalis we frequently find a small slit passing from below upwards, and forming a valvular opening between the two auricles. The remains of the Eustachian valve *(foraminis ovalis anterior valvula)* may be seen running from the anterior and left side of the entrance of the cava inferior to the left side of the fossa ovalis, where it attaches itself to the annulus. This valve exhibits very various appearances in the adult: sometimes it is very indistinctly marked, at other times it is sufficiently apparent, and much more rarely it approaches the size which it presents in fœtal life. It is frequently reticulated. Its convex margin is attached to the surface of the vein and auricle; its concave margin is free; its superior and convex surface looks towards the auricle, and its lower and concave surface towards the entrance of the vein. Placed to the left of the Eustachian valve, and between it and the upper and outer part of the base of the ventricle, is the orifice of the coronary vein. A valve *(valvula Thebesii)*, the free and concave margin of which is directed upwards, covers the entrance of this vein. It is sometimes imperfect, occasionally reticulated. Instead of one coronary valve we may have two or more, one placed behind another. These two valves, viz. the Eustachian and Thebesian, are formed by a reduplicature of the lining serous membrane of the heart.

* The Eustachian valve cannot be considered as essentially connected with the cava inferior in the adult.

The Eustachian valve frequently, however, contains some muscular fibres at its fixed margin. A number of small openings *(foramina Thebesii)* may be seen on the inner surface of the auricle, some of which lead into depressions; others are the orifices of small veins. The muscular fibres projecting from the anterior and outer surface, already alluded to, pass vertically from the auricle to the edges of the auriculo-ventricular opening. These, from their supposed resemblance to the teeth of a comb, are termed *musculi pectinati*. Smaller bundles cross among the larger, giving the inner surface at this part a reticulated appearance. At the places where the transverse fibres are deficient, the outer and inner serous membranes of the heart lie in close contact. In the floor or base of the auricle there is a large oval opening leading into the ventricle *(right auriculo-ventricular opening)*, having its upper margin surrounded by a white ring. The upper part of this ring has a yellowish colour from the auricular tendinous ring being here translucent, so that the fat lying in the auricular groove is seen through it.

Right ventricle (ventriculus anterior, v. dexter, v. pulmonalis.) External surface.—The right ventricle occupies the anterior and inferior portion of the right side of the heart. Its form is pyramidal, the base looking towards the auricle, its apex towards the apex of the heart. Its walls are much thicker than those of the auricle. This thickness arises from the increased number of its muscular fibres.

Internal surface.—The right ventricle may be best opened by making an incision along its right edge from the base to the apex, and another from the root of the pulmonary artery along its anterior surface near the septum to join the other at the apex. On examining the interior, its internal and posterior walls are seen to be common to it and the opposite ventricle, the anterior and external walls to belong exclusively to itself. Its posterior and internal walls are convex, its anterior and internal concave. Its posterior and external walls are decidedly shorter than its internal and anterior. Its parietes are rather thinner at their attachment to the anterior margin of the septum than along its posterior margin. They are also considerably thinner at the apex than towards the base. A number of fleshy columns *(columnæ carneæ, teretes lacerti)* project from the inner surface. We will find that they present three different appearances in both ventricles. 1. The more numerous are attached to the walls of the ventricles by their two extremities, so that we can introduce a probe under the middle part. These divide and subdivide in a variety of ways. 2. Others are attached to the walls of the ventricles by the whole of their external surface, while their internal surface stands in relief from these walls. 3. Others are fixed to the walls of the ventricle by their lower extremities, are perfectly free in the rest of their course, and terminate either in a blunt extremity or in several short processes. These last are few in number, nearly vertical, and have received the name of *musculi papillares.* These columnæ carneæ form an intricate network on the inner surface of the ventricle, and some of them occasionally cross its cavity near the apex. They are more numerous on the anterior and external than on the posterior and internal walls. Two large openings are placed at the base of the ventricle. The larger, oval in the empty, somewhat circular in the distended heart, is the right auriculo-ventricular opening, the upper margin of which was already seen in the right auricle. The smaller is circular, is placed anterior and to the left, is about three-quarters of an inch higher than the larger, and is the orifice of the pulmonary artery. That portion of the ventricle from which the pulmonary artery springs is prolonged upwards above the level of the rest of the ventricle. To this prolongation Cruveilhier has given the name of the infundibulum.*

The inner surface, particularly the posterior part of this infundibulum, is smooth and deprived of columnæ carneæ. Around the auriculo-ventricular opening a valve is placed, the fixed margin of which is attached to the circumference of the opening; the free margin projects into the ventricle. This valve, which forms a complete ring at its attachment, terminates in several apices, three of which are much more prominent than the rest, and on this account it receives the name of the tricuspid or triglochin valve *(valvula triglochis v. tricuspis).* The anterior of these three portions, which is placed on the side nearest to the orifice of the pulmonary artery, is more prominent and broader than the posterior and internal portions, and is separated from them by deeper notches than these two are from each other. From this circumstance some are inclined to consider this valve as consisting of two portions only. It contains several small tubercles at its free margin. This valve, like the other valves at the arterial and left auricular orifices, to be afterwards described, is composed of a reduplicature of the lining membrane containing some tendinous fibres between them. It is translucent and of great toughness. A number of tendinous cords *(chordæ tendineæ)* pass between the apices of these valves and the inner surface of the ventricle. Though the arrangement of these chordæ tendineæ is not uniform in all cases, yet it is of importance to remark, as prominently bearing upon the discussions connected with the manner in which these valves at the auriculo-ventricular opening perform their office, that their general distribution is the same, and evidently intended for a specific purpose.* The greater part of these chordæ tendineæ spring from the free and blunt extremities of the third kind of columnæ carneæ *(musculi papillares)* which we have described; some from the other two kinds, and others again from the smooth portion of the septum, and more particularly from the lower part of the smooth surface which leads into the infundibulum. These tendinous cords diverge to reach their insertion, some of them dividing and subdividing two or three times, occasionally crossing each other, and are inserted principally into the apices and margins of the notches which separate the valve into its three portions. A few of these cords pass between the columnæ and inner surface of the ventricle without being attached to the valve. The internal lip of the valve has its lower margin tied more closely down to the surface of the ventricle by these cords than the other two lips; besides several short cords frequently pass between the internal surface of the ventricle and the ventricular surface of that portion of the valve. At the exit of the pulmonary artery from the upper, anterior, and left part of the ventricle, three valves are placed *(fig.* 268). These from their form have received the name of semilunar or sigmoid valves. Their fixed margins are convex, and adhere to the tendinous ring to which the origin of the artery is attached; their free edges, from the presence of a small triangular tubercle in the middle of each *(corpus Arantii, corpusculum Morgagni, corpus sesamoideum,)* form two slight semilunar curves *(fig.* 268). The extremities of the curved attached edges look in the course of the artery. When the blood rushes from the ventricle into the pulmonary artery, the valves are laid against the sides of the vessel, and the free edge becomes vertical; when, on the other hand, a portion of the blood falls back towards the ventricle, the valves are thrown inwards and completely occupy the calibre of the artery. At this time the concave surfaces of the valves are directed in the course of the artery, the convex surfaces towards the ventricle. These valves may be distinguished by the terms anterior, posterior or left, and superior or right. The suggestion of

* This part is very minutely described by Wolff under the term *conus arteriosus.* Under the term *infundibulum* Wolff included a larger portion of the ventricle, apparently that portion placed above a line drawn from the upper and right margin of the ventricle obliquely downwards to the anterior fissure. As the upper part of the right ventricle becomes gradually narrower, he supposed that it increases the velocity and impetus of the blood as it is driven from the ventricle.—Acta Acad. Imper. Petropol. pro anno 1780, tom. vi. p. 200. 1784.

* Mr. T. W. King states (Guy's Hospital Reports, no. iv. p. 123.) that there is a disposition in the chordæ tendineæ from each fleshy column to attach themselves to the adjoining edges of two lips of the valve, as in the left ventricle.

Fantonus, that as three circular valves meeting in the axis of a canal would leave a small space in the axis itself, so the use of these corpora Arantii may be to fill up the interval which would thus otherwise be left, has generally been adopted.* These valves are thin and transparent, yet of considerable strength. Their attached are thicker than their free margins. That portion of the pulmonary artery which is placed immediately above the attachment of the semilunar valves bulges out and forms three projections, named from their discoverer *sinuses of Valsalva.* These sinuses are more apparent in old than in young persons.

Left auricle (auricula sinistra; a. posterior; atrium seu sinus venarum pulmonalium, a. aorticum). External surface.—It occupies the upper, posterior, and left part of the base of the heart, and receives the blood brought back from the lungs by the pulmonary veins. The only part of the left auricle that can be fairly seen after the pericardium has been opened, and none of the parts disturbed, is the appendix. To see it properly the pulmonary artery and aorta must be cut through and thrown forwards. It is of a very irregular shape, some anatomists comparing it to an oblong quadrilateral, others to an irregular cuboidal figure. Posteriorly it rests upon the spinal column, from which it is separated by the parts mentioned in describing the position of the heart itself, and appears as if confined between the spine and base of the heart,—a fact which has been considerably insisted upon in some of the explanations of the tilting motion of the heart. Superiorly and to the right it is connected to the auricle of the opposite side. More anteriorly and still to the right it is free, and is separated from the right auricle by the aorta and pulmonary artery. Its base is connected to the base of the corresponding ventricle. The auricle is prolonged forwards at first to the left, but bends towards the right before terminating. This prolongation is the appendix or proper auricle. This appendix is longer, narrower, more curved, more denticulated on the edges, and more capacious than the corresponding part of the right auricle, and projects along the left side of the pulmonary artery, a little beyond and below the anterior margin of the left ventricle. The two left pulmonary veins enter the posterior and left side, and the two right pulmonary veins enter the posterior and right side of the auricle.

The left auricle, like the right, has been divided into sinus venosus and proper auricle. *Inner surface.*—The inner surface may be divided into, 1st, a posterior, which is smooth, and which belongs exclusively to itself; 2d, an anterior, which communicates by a round opening with the cavity of the appendix; 3d, a right, the anterior and greater part of which is formed by the septum of the auricles. Upon this is observed the fossa ovalis, but without the distinct depression which it presented in the right auricle. The upper margin of the valve, between which and the upper thick edge of the fossa ovalis the oblique aperture exists, which we formerly stated to be frequently observed here, is often distinctly seen in the left auricle. The valvular nature of this small slit must prevent any intermixture of the blood of the two sides. This margin, when present, looks forwards and to the left. The two right pulmonary veins open upon this surface immediately posterior to the septum, and between the septum and posterior surface. 4th, A left, into which the two pulmonary veins of the left side open.

The pulmonary veins of the two lungs are thus separated from each other by the whole breadth of the auricle. The veins of the same side open into the auricle, the one immediately below the other, so that they occupy the whole height of the auricle. The superior is generally the larger. The two veins of the same side occasionally enter by a common opening, or this may occur on one side only. At other times we may have five openings. These veins, like the cavæ, have no valves at their termination in the auricle. At the lower and anterior part of the auricle a large oval opening presents itself. This is the left auriculo-ventricular opening, and like that on the right side it has its upper margin surrounded by a white tendinous ring. This ring, unlike that of the right side, is everywhere sufficiently opaque to prevent the fat placed in the auricular groove to be seen through it.

The inner surface of the left auricle differs materially from that of the right in its greater smoothness, and the consequently smaller number of its musculi pectinati. In fact, the only place in which these are observed, and that too to a comparatively smaller extent than in the corresponding portion of the right, is the appendix. This arises from the greater strength of the left auricle, the muscular fibres being so closely laid together as not to leave any interval between them.

Left ventricle (ventriculus sinister, v. posterior, v. aorticus.) External surface.—It is of a conical shape, and occupies the posterior and left part of the heart. It is rounded and does not present the flattened appearance of the right ventricle. It projects downwards beyond the right, and forms the apex of the heart. Though the left proceeds lower down than the right ventricle, that portion of the right called infundibulum or conus arteriosus mounts higher than any part of the left. The left is on the whole a little longer than the right. The circumference of the base of the right ventricle is greater than that of the left, exceeding it in some cases in the injected heart by about two inches.

Internal surface.—This ventricle is best opened by making an incision close upon the

* I find that the late Dr. A. Duncan, jun. has justly remarked that there is no necessity for calling in the aid of the corpora Arantii to produce the complete obstruction of the calibre of the artery, as the free edges of these valves, when they are thrown inwards, do not exactly lie in close apposition but overlap each other. Besides these bodies are occasionally very indistinct, and frequently do not project beyond the free margin of the valves, especially in the pulmonary semilunar valves.

anterior fissure from the apex near to the commencement of the aorta, then another incision midway between the posterior fissure and left edge of the ventricle, commencing near the base and carrying it downwards to join the other at the apex. The anterior and right parietes of the internal surface are formed by the septum; the posterior and left belong exclusively to itself. The walls of the left ventricle are considerably thicker than those of the right, and remain apart, while those of the right fall together. As connected with this we may observe that the septum is concave towards the left ventricle and convex towards the right. As the obstacles to be overcome in transmitting the blood through the body are greater than those to be overcome in transmitting it through the lungs, so is the left ventricle thicker than the right. It is important to remark, as connected with the pathology of spontaneous rupture of the heart, that the walls of the left, like those of the right ventricle, are considerably thinner at the apex than towards the base.* The anterior and right parietes are longer than the posterior and left. The columnæ may be arranged into three kinds, such as we have described in the right ventricle. They are not so numerous in the left ventricle as in the right. The greater number are also smaller, and are principally placed upon the posterior and left wall, near the apex of which they form deep areolæ.† The upper part of the septum which leads to the aortic opening, which we shall presently describe, is quite smooth. In the base of the ventricle we find two openings placed closely together; one of these, the smaller, is placed to the right and a little anterior, is the commencement of the aorta, and occupies the upper and right corner of the ventricle; the other is larger and placed to the left and a little posterior, and is the auriculo-ventricular opening of this side. The aortic opening is only separated from the auriculo-ventricular opening by the tendinous ring, and from the orifice of the pulmonary artery by the upper part of the septum. A valve resembling the tricuspid is attached to the tendinous ring around the auriculo-ventricular opening, which, from being more decidedly divided into two lips, is termed *bicuspid*, and from its fanciful resemblance to a bishop's mitre has generally received the name of *mitral valve*. Like the tricuspid it forms a complete ring around the margin of the auriculo-ventricular opening. The anterior lip of the valve in the quiescent state of the heart hangs suspended between the auriculo-ventricular opening and the origin of the aorta, and is considerably larger and more moveable than the posterior, which is smaller and more limited in its movements. The mitral valve is formed in the same manner as the tricuspid, and is somewhat thicker and stronger, and like it contains a number of tubercles in its free margin. The large anterior lip of the mitral valve projecting downwards into the ventricle was described by Lieutaud and by others since his time as dividing the ventricle into two portions, an aortic and a ventricular. These are separated from each other at the upper part by the valve only; at every other part they communicate with each other. The same authors have described the larger lip of the tricuspid valve as effecting a similar division of the pulmonic ventricle. Two of the columnæ carneæ in the left ventricle belong to the third kind (musculi papillares) already described, and are much stronger than any to be found in the right ventricle. They are attached to the lower part of its cavity, pass upwards, and about the middle of the ventricle terminate in a blunt extremity, from which a number of chordæ tendineæ pass to be attached to the margins of the mitral valve. Bouillaud describes these two columnæ as uniformly occupying the same position, one being placed at the junction of its left and posterior walls to form the left margin of the heart; the other on the posterior wall near its junction with the posterior margin of the septum.* Each of these fleshy columns consists of two fasciculi, of an anterior and superior, and of a posterior and inferior. The posterior and inferior fasciculus is shorter and less strong than the anterior. The chordæ tendineæ of the two anterior or internal fasciculi proceed to attach themselves to the margins of the anterior or larger lip of the valves, those from one fasciculus passing to one edge of the lip, and those of the other fasciculus to the other edge. As these chordæ tendineæ proceed from the fasciculi to the valve, they diverge from those of the same fasciculus, but converge towards those of the other fasciculus. (*Fig.* 269 shews the attachment of the chordæ tendineæ of the two anterior or internal fasciculi.) The chordæ tendineæ from the posterior fasciculi pass in a similar manner to be attached to the posterior lip. The posterior lip is fixed closer in its situation than the anterior, by the chordæ tendineæ, and this is frequently increased by some of these cords passing from the walls of the ventricle to be attached to the ventricular surface of the valve, sometimes nearly as high as the fixed margin of the valve. These chordæ tendineæ are stronger, fewer in number, and less subdivided than those in the right ventricle. Several of them pass between the fleshy columns without being attached to the valves, as in the right ventricle. Though the description here given is not perfectly uniform in every case, but is liable to frequent varieties,—by the non-divi-

* The circular arrangement of the muscular fibres around the apex (*fig.* 274) must have the effect of rapidly approximating the inner surfaces of the ventricles at the apex during their systole, more particularly when the apex is elongated, as in the heart of the horse, and thus prevent the pressure from falling upon the extremity of the apex, where it is very weakly protected.

† Laennec has erroneously stated in general terms that the columnæ of the right ventricle are larger than those of the left.

* I have satisfied myself by numerous examinations, of the accuracy of Bouillaud's account of the position of these musculi papillares and the arrangement of the chordæ tendineæ in the human heart. I have found them occupying a similar position in the heart of the horse, ox, ass, sheep, pig, dog, rabbit, hedge-hog, and some birds, and suspect that this will be found a general law in all the warm-blooded animals.

sion of the musculi papillares into two fasciculi; by their subdivision, on the other hand, into several smaller bundles, but so grouped that the position of the smaller corresponds to the larger; and by the smaller columns furnishing a certain number of the cords usually given off by the larger; yet there appears to be a remarkable similarity between the course and arrangement of the chordæ tendineæ in all cases. The object of this we will afterwards see when inquiring into the precise manner in which these valves prevent regurgitation into the auricle during the systole of the ventricle. The origin of the aorta is furnished with three semilunar valves (*fig.* 269), which very exactly resemble in their position, shape, and appearance those placed at the commencement of the pulmonary artery. They are somewhat stronger, and have the corpora sesamoidea generally larger than those in the pulmonary artery. Behind these valves are three dilatations (*sinuses of Valsalva*) upon the commencement of the aorta, similar to, but more prominent, than those at the commencement of the pulmonary artery (*fig.* 269).

It was maintained by several of the older eminent anatomists that the semilunar valves must necessarily cover the entrance of the coronary arteries,* and that they were filled, not during the passage of the blood along the aorta, but by the falling back of part of it during the diastole of the heart, or as Boerhaave expressed it, "Hæ arteriæ sunt in diastole, dum reliquæ corporis arteriæ in systole constituuntur."† Haller mentions two circumstances which must satisfy every one, if any thing more than the bare inspection of the parts was necessary, that the coronary arteries are at least *generally* filled in the same manner as the other arteries which arise from the aorta, and these are—1st, the result of experiments on living animals, where the blood is seen to spring per saltum from the cut coronary arteries during the systole of the heart; 2d, when a fœtus is injected by the umbilical vein, the coronary arteries are also filled. More lately, however, Vaust‡ has maintained that the origin of the coronary arteries is generally covered by the semilunar valves. He states that he has injected a great number of hearts from the pulmonary veins; in some of these the injection passed into the coronary arteries, but in by much the greater number these vessels did not contain a single drop of injection. On examination of these cases he found that the semilunar valves entirely covered the origin of the coronary arteries. In attempting to ascertain this point on the uninjected heart, we must bear in mind the different conditions of the aorta in the living body and after death. In the dead body the sinuses of Valsalva are collapsed, so that the semilunar valves can be laid over the origin of the coronary arteries in some cases, where they would become free when the sinuses are distended as they are with blood in the living body. Making every allowance for this source of fallacy, I am satisfied that I have seen one or two cases in which these valves appeared fairly to cover the origin of the coronary arteries. Supposing that the origin of the coronary arteries were covered in some instances by the valves, it would in all probability be a matter of little moment, as far as the efficiency of the circulation through these arteries was concerned, as long as the aorta retained its elasticity, for the force with which it drives the distending fluid backwards during the diastole of the heart (a force which can be ascertained in the dead body) would be sufficient to carry on the circulation. The circumstances would, however, become very much altered in those cases which are sufficiently common in advanced age, where the aorta has from disease of its coats entirely lost its elasticity, and the coronary arteries have also become studded with calcareous matter, unless we suppose what could scarcely happen, that the blood contained in the sinuses is forced along the arteries when the valves are thrown outwards.*

Septum of the ventricles.—The septum between the ventricles is triangular, and the apex extends to the point of the heart. It is of considerable thickness at the base, but becomes thinner at the apex. Its position is oblique like that of the heart. It is concave towards the right ventricle, and convex towards the left. From the slight rotation of the heart on its axis, the anterior surface of the septum is directed towards the right side, and the posterior towards the left. It is composed, like the other walls of the ventricle, principally of muscular fibres, lined on the one side by the internal serous membrane of the right ventricle, and on the other side by the corresponding membrane of the left.

We have preferred considering the relative thickness of the parietes, the different capacities of the several cavities of the heart, the relative dimensions of the auriculo-ventricular, aortic, and pulmonary orifices, and the size and weight of the heart under distinct heads, not only as this enables us to obtain a more connected view than we could otherwise have done of points upon which there are many conflicting opinions, and upon which it is so frequently necessary to possess, as far as we possibly can, accurate notions in deciding upon the normal or abnormal state of the organ, but we were also afraid that if mixed up with the other parts of the descriptive anatomy they would have

* Morgagni was doubtful in this matter, and thought that he had observed them sometimes covered by the valves, at other times free. *Advers.* v., *Animadver.* xxv.

† Institut. Med. 183.

‡ Recherches sur la Structure et les Mouvements du Cœur, p. 22, (1821.)

* Among the numerous and striking examples which the history of medical science furnishes us of the powerful tendency which preconceived notions have, if not powerfully guarded against, of influencing our observations of the plainest facts, we may instance the statements of Petriolus on this question. He, apparently deeply imbued with the old hypothesis that the heart is the seat of courage, maintained that in bold and carnivorous animals the coronary arteries were above the valves; in timid and herbivorous animals, on the contrary, they arose behind the valves, while in man they were of uncertain origin, as he was bold or timid.

rendered it more complicated. We will find that considerable differences in these respects may exist between different hearts and between different parts of the same heart, which, to judge from the perfect regularity with which all its functions proceeded before death, must be considered as perfectly healthy; and it is from this want of uniformity in the different parts of apparently healthy hearts that we can in some measure account for the discrepant statements on this subject which exist in the works of the most celebrated and accurate anatomists.

Thickness of the walls of the several cavities of the heart.—The left auricle is somewhat thicker than the right, and the left ventricle very considerably thicker than the right. Bouillaud* found the average thickness of the walls of the left auricle in four healthy hearts to be $1\frac{1}{2}$ lines, and that of the right auricle to be 1 line. Lobstein has rather strangely stated that the right auricle is twice the thickness of the left. He makes the thickness of the right auricle to be 1 line, and that of the left to be only $\frac{1}{2}$ line. Laennec reckons the relative proportion of the thickness of the left ventricle to the right as rather more than 2 to 1. Bouillaud found the average thickness of the right ventricle at its base in a great number of cases to be $2\frac{1}{2}$ lines, and that of the left ventricle at the same part to be 7 lines. Cruveilhier† states the proportionate thickness of the right to the left ventricle as 1 to 4, or even as 1 to 5. According to Soemmerring,‡ the relative thickness of the two ventricles is as 1 to 3. Andral§ states that in the adult the thickness of the left to the right ventricle is as 2 to 1, but in infancy and in old age it is as 3 or 4 to 1.

M. Bizot has lately published the results of the careful measurements of the healthy heart in one hundred and fifty-seven individuals of all ages.‖ The greater part of these observations were collected at La Pitié, under the auspices of Louis. According to M. Bizot, the heart goes on increasing in all its dimensions—length, breadth, and thickness—up to the latest periods of life. The growth is, however, more rapid before twenty-nine years than after that age. While, then, the muscles of animal life are diminishing in size in advanced life, the heart is still increasing in bulk. The heart of the male is, on an average, larger than that of the female at all the different stages of life. M. Bizot remarks that the longitudinal section of the left ventricle is fusiform, the thickest part being situated at the junction of the superior third with the middle third.¶ The thickness of this ventricle goes on increasing from youth up to advanced age. The following are a few of the measurements of the thickness of the walls of the ventricles given by M. Bizot.

Left ventricle, male.

Age.	Base.	Middle part.	Apex.
1 to 4 years	3 lines.	$2\frac{9}{10}$ lines.	$1\frac{9}{10}$ line.
50 to 79 years ..	$4\frac{37}{38}$ „	$5\frac{29}{38}$ „	$4\frac{1}{39}$ „
Average from 16 to 79 years ..	$4\frac{65}{122}$ „	$5\frac{19}{122}$ „	$3\frac{95}{122}$ „

Left ventricle, female.

Age.	Base.	Middle part.	Apex.
1 to 4 years	$2\frac{9}{10}$ lines.	$2\frac{7}{8}$ lines.	$2\frac{1}{10}$ lines.
50 to 89 years ..	$4\frac{1}{2}$ „	5 „	$3\frac{3}{4}$ „
Average from 16 to 89 years ..	$4\frac{7}{8}$ „	$4\frac{1}{5}$ „	$3\frac{13}{30}$ „

Thickness of right ventricle.—The thickest portion of the right ventricle is not placed, as M. Bizot remarks, at the same point as in the left. In the right ventricle it is at the base of the heart, 4 lines below the tendinous ring. The thickness of the walls of the right ventricle, unlike the left, remains more nearly stationary at the different periods of life. They are, however, a little thicker in advanced age than at an earlier period of life.

Right ventricle, male.

Age.	Base.	Middle part.	Apex.
1 to 4 years	$\frac{9}{10}$ line.	$\frac{6}{10}$ line.	$\frac{5}{10}$ line.
30 to 49 years ..	$1\frac{39}{46}$ „	$1\frac{7}{23}$ „	$\frac{43}{46}$ „
50 to 79 years ..	$2\frac{1}{19}$ „	$1\frac{53}{100}$ „	$\frac{51}{64}$ „
Average from 16 to 79 years ..	$1\frac{113}{124}$ „	$1\frac{99}{244}$ „	$1\frac{2}{61}$ „

Right ventricle, female.

Age.	Base.	Middle part.	Apex.
1 to 4 years	$1\frac{3}{10}$ line.	$\frac{7}{8}$ line.	$\frac{13}{24}$ line.
30 to 49 years ..	$1\frac{19}{22}$ „	$1\frac{13}{31}$ „	$\frac{23}{27}$ „
50 to 79 years .	$1\frac{1}{4}$ „	$1\frac{1}{4}$ „	1 „
Average from 15 to 59 years ..	$1\frac{3}{5}$ „	$1\frac{7}{24}$ „	$\frac{673}{720}$ „

Care was taken to make all these measurements at points where there were no columnæ carneæ.

The thickness of the septum ventriculorum, according to Meckel, is 11 lines at its base. Bouillaud obtained the same results in the only case in which he appears to have measured the thickness of the septum. M. Bizot has given measurements of the ventricular septum at six different periods of life, from which I have selected the following.

	Male.	*Female.*
Age.	Middle part.	Middle part.
1 to 4 years......	$3\frac{1}{10}$ lines.	$2\frac{3}{5}$ lines.
16 to 29 years....	$4\frac{17}{18}$ „	$4\frac{11}{14}$ „
50 to 79 years....	$5\frac{1}{3}$ „	$5\frac{3}{19}$ „

The thickness of the septum ventriculorum goes on increasing in thickness from infancy to an advanced period of life.

Relative capacities of the several cavities.—The most conflicting statements exist upon this point, and we find it perfectly impossible to come to any satisfactory decision. Each cavity of the heart is supposed, when moderately distended, to contain rather more than two ounces of fluid. The auricles may be safely said to be of less capacity than the ventricles; and this disparity is strikingly marked in the larger animals, as the horse and ox. The right auricle is generally allowed to be larger than the left, and the difference,

¶ Op. cit. p. 269 and 284.

as stated by Cloquet and Cruveilhier, is as 5 to 4. The right ventricle is generally found larger than the left after death. This difference has been very variously estimated by different anatomists. Some, as Winslow, Senac, Haller, Lieutaud,* and Boyer, have maintained that there is a marked disparity between the capacities of the two cavities, while Meckel, Laennec, Bouillaud, Portal, and others believed that this difference is to a smaller extent. Lower was the first to maintain that both ventricles are of equal size. Sabatier, Andral, and others have supported this opinion; while Cruveilhier† states that he has satisfied himself, from comparative injections of the two cavities, that the left ventricle is a little larger than the right. Gordon has occasionally found both ventricles of equal size, and Portal has seen them of the same size in young persons. Santorini and Michelattus believed that, though the capacity of the left ventricle appears a little smaller than that of the right, yet that the superior force of the left auricle over the right dilates the left ventricle sufficiently to render it equal to the right.

The majority of anatomists, however, have always maintained that the capacity of the right ventricle is greater than that of the left, and have adduced the following arguments in support of this opinion: 1, that the right auricle, right auriculo-ventricular orifice, and origin of the pulmonary artery are larger than the auricle and corresponding orifices of the opposite side: 2, that when both ventricles have been filled with water, mercury, or wax, more of these substances is found contained within the right than the left: 3, the experiment of Legallois‡ shew that when an animal is bled to death, this disparity between the size of the ventricles is still found. Those who maintain that the capacity of these two cavities is equal do so on the following grounds:—1, that as the walls of the right ventricle are weaker than those of the left, when the same force is used in injecting both, the right must, as a matter of course, be more dilated than the left. 2. Sabatier ingeniously suggested that, as during the last moments of life the passage of the blood from the right side of the heart is generally impeded, producing engorgement of that side, while the left side was generally empty, this might account for the greater size of the right ventricle. 3. Sabatier and Weiss§ maintained that in those cases where the kind of death was such that the right side of the heart could not be engorged as in fatal hæmorrhage, no difference between the capacity of the two sides could be observed. 4. The experiments of Sabatier, in which, after tying the aorta and producing engorgement of the left side of the heart, while the right side was emptied by a wound made into the vena cava or pulmonary artery, the left ventricle was found to be of greater capacity than the right.

M. Bizot maintains that the capacity of the ventricles goes on increasing from youth up to old age; and that this, contrary to the opinion of Beclard, is not so rapid in old age as in the earlier periods of life. The following are a few of M. Bizot's measurements:—

Age.	Length.	Breadth.
Left ventricle, male.		
1 to 4 years	20 lines.	31 lines.
50 to 79 years	36 „	$56\frac{2}{3}$ „
Average from 15 to 79 years	$34\frac{24}{61}$ „	$54\frac{9}{61}$ „
Left ventricle, female.		
1 to 4 years	$18\frac{1}{2}$ lines.	$29\frac{5}{8}$ lines.
50 to 79 years	31 „	$49\frac{1}{2}$ „
Average from 15 to 89 years	$31\frac{1}{30}$ „	$48\frac{23}{30}$ „
Right ventricle, male.		
1 to 4 years	$20\frac{1}{5}$ lines.	$47\frac{4}{5}$ lines.
50 to 79 years	$37\frac{1}{3}$ „	87 „
Average from 15 to 79 years	$37\frac{14}{61}$ „	$82\frac{11}{60}$ „
Right ventricle, female.		
1 to 4 years	$18\frac{7}{8}$ lines.	$44\frac{1}{8}$ lines.
50 to 79 years	$35\frac{11}{19}$ „	76 „
Average from 15 to 89 years	34 „	$76\frac{2}{3}$ „

Every one must confess that the right ventricle is generally found larger after a natural death in the human subject than the left; and it appears exceedingly probable that these two cavities, in the healthy state of the organ, contain different quantities of blood during life. As the capacity of the auricles is rather smaller than that of the ventricles, it may be asked how can the auricles furnish blood sufficient to distend the ventricles? We shall afterwards more particularly explain that the blood passes from the auricles into the ventricles at two different times during the interval between each contraction, viz. at the moment of its relaxation, and again during the contraction of the auricles. Various attempts have been made by those who maintain that the right side of the heart is larger than the left, to explain how the equilibrium of the circulation can be maintained. Helvetius* supposed that this could be accounted for by the diminution which the blood suffered in passing through the lungs; and in proof of this he erroneously maintained that the pulmonary arteries were larger than the pulmonary veins. Legallois believed that this could be explained (as appears very probable) by the greater size of the right auriculo-ventricular opening, allowing a greater reflux of blood back again into the auricle, during the systole of the ventricles.

* Mémoires de l'Academie Roy. des Sciences, t. viii. p. 561, 1754. Lieutaud's authority is sometimes quoted in support of the opinion that these cavities are of equal capacity.

Relative dimensions of the auriculo-ventricular orifices.—The right auriculo-ventricular orifice is larger than the left, as was correctly stated by Portal.* According to Cruveilhier, the largest diameter of the right auriculo-ventricular opening which is antero-posterior is from 16 to 18 lines, and its smallest diameter is 12 lines; while the largest diameter of the left auriculo-ventricular opening, which is directed almost transversely, is from 13 to 14, and its smallest is from 9 to 10 lines. Bouillaud gives the results which he obtained from the accurate measurement of the circumference of these two openings in three perfectly healthy hearts. The average circumference of the left auriculo-ventricular opening was 3 inches $6\frac{1}{3}$ lines: the maximum was 3 inches 10 lines, and the minimum was 3 inches 3 lines. The average circumference of the right auriculo-ventricular opening was 3 inches 10 lines: the maximum was 4 inches, and the minimum was 3 inches 9 lines.

Circumference of the aortic and pulmonary orifices.—The circumference of the aortic and ventriculo-pulmonary orifices is sometimes nearly equal; more generally, however, the ventriculo-pulmonary is the larger. Bouillaud gives the following measurements of these openings taken from four healthy hearts:—Average circumference of the aortic opening, 2 inches $5\frac{1}{2}$ lines: the maximum 2 inches 8 lines, and the minimum 2 inches 4 lines. Average circumference of the ventriculo-pulmonary opening, 2 inches $7\frac{3}{4}$ lines: the maximum 2 inches 10 lines, and the minimum 2 inches 6 lines. I have found this difference between the circumference of these two openings marked distinctly at seven years of age. M. Bizot has given measurements of the arterial orifices, of which the following is the average.

Aartic orifice, male.

Average from 16 to 79 years.. $45\frac{17}{33}$ lines.

Aortic orifice, female.

Average from 16 to 89 years .. $41\frac{1}{3}$ lines.

Pulmonary orifice, male.

Average from 16 to 79 years .. $54\frac{17}{61}$ lines.

Pulmonary orifice, female.

Average from 16 to 89 years .. $48\frac{1}{4}$ lines.

Size and weight.—Laennec has stated that the *size* of the heart in general nearly corresponds to the closed fist of the individual. This can only be considered as a loose approximation, as the size of the hand may vary in different individuals otherways resembling each other, either from original conformation or from dissimilar modes of life; and, besides, the size and form of the healthy heart itself may vary sufficiently to effect an apparent difference in these respects.

The average length of the heart, according to Meckel, is $5\frac{1}{2}$ inches, of which about 4 inches are to be allowed for the ventricles, and $1\frac{1}{2}$ inch for the auricles. Bouillaud found that a line drawn from the origin of the aorta to the point of the heart ranged, in nine healthy hearts, from 4 inches to 3 inches $2\frac{1}{2}$ lines. The average length was 3 inches $7\frac{1}{2}$ lines.

The *weight* of the heart, according to Meckel, is about 10 ounces, and its proportionate weight to the whole body is as 1 to 200. Tiedemann is of opinion that the proportionate weight of the heart to the body is as 1 to 160.* The weight of the healthy and empty heart, according to Cruveilhier, is from 7 to 8 ounces. Bouillaud found the average weight in thirteen healthy hearts to be 8 ounces 3 drachms. According to Lobstein it weighs between 9 and 10 ounces. The size and weight of the heart must generally be to a great extent in conformity with the size and weight of the body. In an athletic male we would expect it to weigh about 10 ounces, in an ordinary-sized individual about 8 ounces, and in weakly persons, or in cases of protracted debility, it would be still more diminished in weight. For the same reason it is generally larger and heavier in males than in females.

Structure of the heart.—The heart consists of muscular and tendinous textures, of cellular tissue, of bloodvessels, of nerves, and of lymphatics, enclosed between two serous membranes.

Tendinous texture.—The tendinous texture of the heart is placed, 1, around the auriculo-ventricular and arterial orifices; 2, within the reduplicature of the lining membrane forming the auriculo-ventricular and arterial valves; 3, it forms the chordæ tendineæ.

Auriculo-ventricular tendinous rings.—Around each auriculo-ventricular opening we find a tendinous circle or ring, from the upper part of which the muscular fibres of the auricles arise, and from the lower part those of the ventricles, thus affording perhaps the only example in the human body of a strictly involuntary muscle having tendinous attachments. The tendinous ring surrounding the left auriculo-ventricular opening is stronger than that surrounding the right. These tendinous zones are thicker along the lower edge where the muscular fibres of the ventricle are attached, and become thinner along the upper edge where the muscular fibres of the auricles are attached, so that the fat occupying the auricular groove is seen through the upper portion of the ring on the right side. The right margin of the left auriculo-ventricular ring is connected with that surrounding the aortic opening. The existence of the auriculo-ventricular and arterial tendinous rings was well known to Lower.†

Arterial tendinous rings.—The form of the tendinous rings surrounding the arterial openings, and the manner in which the large arteries are attached to their upper edges, have not, I think, been described with sufficient accuracy. These textures are very plainly observed

* Anatomie Médicale, t. iii. p. 69.

* If we consider the ordinary weight of an adult heart to be 8 ounces, and the average weight of the whole body to be 150 lbs. the proportionate weight of the heart to the body would be as 1 to 225.

† Tractatus De Corde, p. 29. 1669.

in the heart of the ox and horse after a little dissection. The following description is drawn up from numerous dissections of these parts made on the human heart. The tendinous ring surrounding the aortic opening is stronger and thicker than that surrounding the orifice of the pulmonary artery. Both of them are stronger than the auriculo-ventricular rings. Each of the arterial rings appears as if composed of three semilunar portions placed on the same plane, the convexities of which are turned towards the ventricles and the concavities towards the vessels *(fig. 266, a a)*.* Each of

Fig. 266.

Appearance of tendinous ring at the origin of the pulmonary artery. In slitting open the artery, one of the three projecting extremities of the tendinous ring has been divided.

these semilunar portions has its projecting extremities intimately blended at their terminations with the corresponding projecting extremities of those next to it, *(fig. 266, b b,)* so that the three form a complete circle, with three triangular portions projecting from its upper edge. The semilunar portions approach fibro-cartilage in their structure, and have the intervals left between their convex edges filled with a texture more decidedly fibrous, *(fig. 266, d,)* and which is considerably weaker than the semilunar portions, more particularly on the left side of the heart.† The thinness of the tendinous structure filling up these intervals has led some anatomists erroneously to describe these portions of the heart as protected only by the two serous membranes. The right tendinous zone is broader than the left and very thin, particularly at its inner margin, at which part in both sides of the heart it assumes more of the tendinous than of the fibro-cartilaginous structure. These tendinous rings are placed obliquely from without inwards and from above downwards, so that the outer edge is on a plane superior to the inner. The sigmoid valves are attached to the inner edge of the upper surface, *(fig. 267, a,)* and the tendinous fibres placed in the fixed margins of these valves contribute to the thickening of the ring at this part; the middle coat of the arteries is connected to the outer edge of the same surface, and to the anterior part of the projecting extremities, *(fig. 267, b;)* while the muscular fibres of the ventricles *(fig. 266, f; fig. 267, f,)* are attached to the lower surface of the projecting portion of the convexity, and to the lower margin of the fibrous tissue filling up the space between the convexities of the projecting ends, *(fig.*

* These tendinous festoons are represented stronger in the woodcut than they are naturally.

† These intervals are occupied by muscular fibres in the heart of the ox and horse.

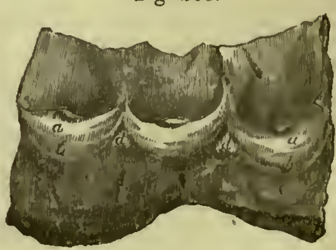
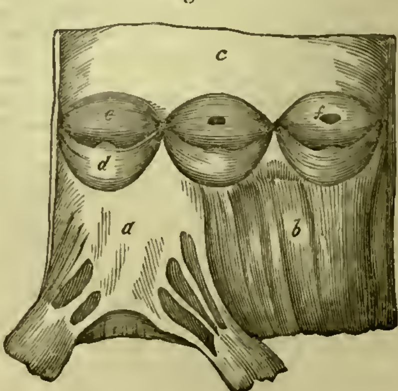
267, d.) There is, however, this difference between the right and left arterial openings with respect to the attachment of the muscular fibres;—on the right side the muscular fibres arise from the projecting portion of the convexity of the whole three tendinous festoons, *(fig. 268, c, c,)* while in the left side the mus-

Fig. 268.



cular fibres are attached only to one and part of a second, *(fig. 269, b b,)* as the larger lip of the mitral valve *(fig. 269, a)* is suspended

Fig. 269.



from the posterior or left, and a great part of the anterior,—in fact to that part of the tendinous ring which separates the aortic from the auriculo-ventricular opening. From the posterior part of that portion of the tendinous ring to which the mitral valve is connected, the anterior fibres of both auricles, near the septum, arise. As the left tendinous ring is thicker and narrower than the right, there is a larger space left between the fixed edge of the valves and the attachment of the middle coat of the arteries than there is on the left side. This space is of some importance, as upon it a considerable part of the pressure of the column of blood in the large arteries must be thrown during the diastole of the ventricles.

There is a good representation of these tendinous rings given in Tab. II. Opera Valsalvæ, tom. i. At page 129 they are thus described: "In horum sinuum ambitu quà valvulæ sinubus annectuntur quidem quasi Agger videtur occurrere substantiæ durioris ad similitudinem cartilaginis tarsi palpebrarum." I find also that Gerdy* appears to have had an accurate notion of the form and appearance of these tendinous rings. He was aware of the existence of the projecting angles of the tendinous ring which pass up between the festoons of the middle coat of the arteries, and which have been overlooked in succeeding descriptions. I find also that the late Dr. A. Duncan, jun. has, in his unpublished manuscript, given a very accurate account of these structures in the heart of the ox.

Tendinous structure in the auriculo-ventricular valves.—Distinct tendinous fibres exist in the auriculo-ventricular valves enclosed between the reduplication of the lining serous membrane. These are continuous with the auriculo-ventricular tendinous zones, and are most distinct and of great strength at the base. I could never observe any distinct traces of muscular fibres in these valves in the human heart either when fresh or after long boiling. Bouillaud has, from the examination of one inconclusive case, but principally from analogy with the corresponding valves of the heart of the ox, supposed that they may exist in some cases in hypertrophy of the valves. In making examinations of this kind we must be exceedingly careful not to mistake the tendinous fibres when tinged with blood for muscular fibres, for under these circumstances they certainly at all times assume the appearance of muscular fibres.†

* Journal Complementaire, tom. x.

† In the heart of the dog I have seen a distinct band of transverse muscular fibres in the base of the larger lip of the mitral valve, but could never satisfy myself of the existence of any longitudinal muscular fibres. In the heart of the ox and horse very distinct longitudinal muscular fibres are seen in the valves of both sides of the heart, principally, if not entirely, continuous with the inner layer of the fibres of the auricles. A greater part pass over the inner surface of the tendinous rings, and are firmly attached to the tendinous structure of the valves, reaching nearly to the lower margin of the smaller segments of the valves. The effect of these fibres upon the movements of the valves would form an interesting subject of investigation.

Tendinous structure in the arterial valves.—Distinct tendinous fibres also exist in the arterial valves, which must add considerably to their strength and prevent their more frequent rupture. Three of these tendinous bands in each valve are stronger than the others, and their position deserves attention, as they are often the seat of disease. One of these bands occupies the free margin of the valve, and passes between the projecting extremities of the tendinous festoons (*fig.* 270, *a*). Upon the middle of this band the corpus Arantii, which is formed of a similar texture, is placed. The other band comes from a point a little above the middle of the projecting end of the tendinous festoon (*fig.* 270, *b*), and passes up in a curved manner towards the corpus Arantii, leaving between it and the superior band a triangular space on each side, in which, if any tendinous fibres exist, they are exceedingly obscure. These two tendinous bands were well known to Morgagni. The third band is placed in the attached margin of the valve, and renders this part the thickest and strongest. Between the middle band and the attached margin of the valve a number of weaker bands are placed, which also pass upwards, generally assuming a curved form. Morgagni termed these lower and weaker fibres *fibræ carneæ*, but they evidently belong to the same structure as the stronger bands. The arrangement of these tendinous fibres is best seen in the aortic valves, and the appearance exhibited in the accompanying representation, (*fig.* 270,)

Fig. 270.

which has been taken from Morgagni, is not always distinctly observed, where the valves are perfectly healthy, but become sufficiently obvious in certain cases of disease.

Attachment of the middle coat of the arteries to the arterial tendinous rings.—The inner and outer serous membranes are continued from the heart upon the arteries; the one becoming the inner coat of the arteries, and the other is continued for a short distance upon their external surface. A thin layer of cellular tissue also passes from the heart along the arteries between their middle coat and their external serous membrane. These are, however, so far unimportant compared with the attachment of the middle coat of the arteries to the tendinous festoons which we have just described. The middle coat is so very firmly and strongly attached both to the external edges and to the anterior portion of the upper part of these projecting extremities, (*fig.* 267, *d*,) that it can be detached with great difficulty. Those fibres of the middle coat attached to the projecting extremities, which are apparently of the same number and thickness as in that portion of the artery immediately above, form a distinct curved edge (*fig.* 267, *e*), as they pass from the extremity of one festoon to the other. As we trace the middle coat of the artery downwards into the concavities formed by each festoon, we find that below this curved edge they become strikingly thinner and continue to diminish in thickness and in length, (since they can only stretch between the projecting extremities,) until we arrive at the bottom of the concavity. These three thin portions of the middle coat must then be placed behind the semilunar valves, and correspond to the sinuses of Valsalva.* The thinness of the middle coat at the sinuses of Valsalva will render this portion of the artery more dilatable, and predispose it to rupture when its coats are diseased.† The tendinous zones are distensible, but to a considerably less extent than the middle coat of the arteries. I am not aware that this account of the manner in which the middle coat of the arteries is attached to the tendinous rings has been previously given. I suspect, however, that Dr. Duncan must have been perfectly aware of it from some parts of his manuscript. The differences between these tendinous festoons and the yellow elastic coat of the arteries, and the manner of their attachment, can easily be made out in the human heart; they are, however, more apparent in the larger animals, as the horse and ox. The different characters of the two tissues are obvious at the first glance after boiling, even in the human heart.

Muscular tissue.‡—The greater part of the heart is composed of muscular fibres arranged in a very intricate manner. These fibres are connected together by cellular tissue,* which, however, exists in much smaller quantity in the heart than in the other muscles of the body. These fibres are attached generally by both extremities to the tendinous rings situated around the orifices of the heart; the fibres of the auricles pass upwards to form the auricles, and those of the ventricles downwards to form the ventricles, so that these tendinous rings must form the fixed points towards which all the contractions of the heart take place. None of the muscular fibres of the auricles are continuous at any part with those of the ventricles, and we will find that while some of them are confined to a single auricle, others belong to both. In the same manner a great part of the fibres of the ventricles are common to both, and are interwoven together, while others again belong exclusively to a single ventricle, or, as Winslow† expressed it, the heart is composed of two muscles enveloped in a third. The intimate arrangement of these muscular fibres, particularly those of the ventricles, is exceedingly complex, as the contraction of the organ is not in one particular direction only, but in all directions, and has long been considered as a kind of Gordian knot in anatomy. Vesalius, Albinus, and Haller‡ confessed their inability to trace them, and more lately De Blainville§ assures us, from his own experience, that we can only arrive at very general conclusions (*des choses très-générales*) on this subject. By adopting the method of long-continued boiling of the organ before commencing to attempt to trace the course and arrangement of its fibres, we will find that after a few trials several of the most important points connected with the distribution of these can be ascertained, and by perseverance they can be unravelled to a great extent. By long boiling the muscular fibres are rendered hard and firm, while the tendinous and cellular tissues are softened or dissolved, and the fat melted. Dr. Duncan, who employed this method to a great extent, states that the essential circumstance is to continue the boiling long enough, and that he has never been able to carry it too far. I have found from eighteen to twenty hours generally sufficient for this purpose. Some have recommended that the heart should be previously put for a short time into a strong solution of salt, and Vaust advises that it should be boiled in a solution of nitre, for the purpose of rendering the fibres firmer. The boiling is infinitely superior to the maceration in vinegar. By stopping the boiling before the tendinous rings are rendered too soft, we can easily see their form and their connexions to the muscular fibres.

The general connexion and distribution of

* So striking is the difference between the middle coat as it fills up the concavity of these festoons, and where it stretches between the projecting extremities in the hedgehog, that at first sight it appears to be deficient at that part.

† According to Valsalva aneurisms are frequently found in this situation: "Atque hic aortæ sinus maximus ille est, in quo sæpe aneurysmata circa præcordia contingunt, ut propria observatione edoctus sum." Valsalvæ Opera. Epist. Anat. ed. Morgagni, tom. i. p. 131. 1740. This greater tendency to aneurismatic dilatation must depend upon two circumstances. The increased calibre of the artery at this part will increase the pressure upon its walls from the well-known hydrostatic law, that "in a quantity of fluid submitted to compression, the whole mass is equally affected, and similarly in all directions," and the diminished thickness of the middle coat will materially favour this distending force.

‡ While I was engaged in examining the arrangement of the muscular fibres of the heart, Dr. Alison had the kindness to procure for me the manuscript of the late Dr. A. Duncan, jun. on this subject. It was well known not only in this country but on the continent that Dr. Duncan had for a very long period attended very particularly to this question, and was in the habit of demonstrating the parts he had ascertained to his pupils. Unfortunately his intentions of publishing on the subject were never carried into execution, and his papers referring to it were left in so confused a state that it is exceedingly difficult and in most parts impossible to make out the description. I have availed myself of those parts that are legible in the following pages, and these I have scrupulously acknowledged. Dr. Duncan's dissections of the heart were taken entirely from the ox and sheep.

* [This however is denied by other observers, and from very recent and careful examinations. See the succeeding article by Mr. Searle.—Ed.]

§ Cours de Physiologie, &c. tom. ii. p. 359.

the muscular fibres of the ventricles may be stated to be as follows. 1st, Most of these fibres are connected by both extremities to the tendinous structure of the heart, a fact well known to Lower,* though overlooked by many subsequent anatomists. 2d, The direction of these fibres is more or less oblique, a comparatively small part of them only being vertical, and that too for a limited part of their course. The degree of obliquity of these spiral turns is different in different portions of the heart: they are more oblique on the surface and less oblique as we proceed to the deeper fibres, more particularly at the base. The deeper fibres approach more to the circular form. 3d, As has been already stated, part of these fibres are common to both ventricles; while part only belong exclusively to a single ventricle, and that principally at the base. 4th, The external fibres are longer than the next in order, and after turning round the apex pass upwards into the interior, below the lower margin of the shorter fibres, and form the inner surface of the ventricles, while the deeper again turn up below the lower margin of the fibres next in succession, so that the longer enclose by their two extremities all the shorter fibres. By this arrangement we can explain how the base and middle part of the ventricles should be much thicker than the apex. This arrangement has been particularly insisted upon by Dr. Duncan and Gerdy, and to illustrate it Gerdy has given an ideal illustration, of which *fig.* 271 is a copy.

Fig. 271.

In examining the course of the fibres of the ventricles we shall not attempt to describe each particular band of fibres, but confine ourselves to their general arrangement.† In examining the surface of the ventricles the superficial fibres of the anterior surface are observed to run in a spiral manner from above downwards and from right to left, while those on the posterior surface, which are in general more vertical, run from left to right. Most of these bands are thin and broad at the upper part, and become narrower and thicker as they approach the apex, where they form a remarkable twisting, which has been termed the vortex, (of which *fig.* 272, taken from the human heart after boiling, is an accurate representation,) and then pass in to assist in forming the inner surface

Fig. 272.

of the left ventricle and the columnæ carneæ. The manner in which the external fibres turn in at the apex to form the inner surface of the ventricles and enclose the deeper fibres was well known to Lower, and he has illustrated it by an engraving, of which *fig.* 273 is a copy.

Fig. 273.

* Tractatus de Corde, p. 34 to 37. Lugd. Batav. 1669.

† Wolff has named and minutely described eight distinct bands of muscular fibres on the surface of the right ventricle: Acta Petropolit. pro anno 1781, tom. viii. p. 251, 1785.

This arrangement of the external fibres was also well known to Winslow* and Lancisi.† Winslow, however, denied that they described the figure of eight, as stated by Lower. More lately Gerdy has given a description of this arrangement, to which he has added an engraving, which approaches more to the appearance of the perfect figure of eight than that given by Lower. I, however, prefer that given by Lower, as it more nearly resembles the arrangement which I have myself seen in tracing these fibres. A small part of the right and posterior side of this vortex is formed by fibres from the posterior surface of the left ventricle, and from that part of the posterior surface of the right ventricle near the septum, and are attached above to the auricular tendinous rings, while the whole of the anterior and left side of the vortex is formed by fibres from the anterior surface and right margin of the ventricles. On tearing these last fibres, which form the principal part of the apex, from the anterior surface of the left ventricle, we find, as we proceed upwards, that a comparatively small part of them cross the anterior fissure upon the right ventricle to reach the right auricular tendinous ring. The greater number dip in at the anterior longitudinal fissure, and we shall afterwards find that they can be traced to the base of the septum of the ventricles. By tearing off these fibres downwards, we open into the apex of the left ventricle. A general notion of the manner in which these fibres, passing from the base of the septum, turn in at the apex, and proceed upwards on the inner surface of the left ventricle, may be obtained from *fig.* 273. To have been quite accurate the inner fibres should have been more scattered, and some of them represented as terminating in the columnæ carneæ. By unravelling the fibres which form the apex, we may open into the interior of the left ventricle without breaking a single muscular fibre. Having thus opened the apex of the heart, although the point is removed, the circular edge is left entire (*fig.* 274, *a*), and is formed of another series

Fig. 274.

of fibres, which, like those taken away, advance spirally from the base to the apex, and turning over the edge (*fig.* 274, *b*) ascend in the opposite direction, continuing their course after being reflected. "Proceeding in the same manner the whole apex of the left ventricle may be removed, and the same principle of arrangement is found throughout the whole heart even to the base. When we get down as far as the apex of the right ventricle, although the principle remains the same, its effects are more complicated, as it applies to two cavities instead of one." I have frequently satisfied myself of the correctness of the description contained in this passage, which I have quoted from the manuscript of Dr. Duncan. This is the same kind of arrangement which, we have already stated, has been insisted upon by Gerdy, but which we believe can be more satisfactorily seen by tracing the fibres in this manner. Gerdy lays it down as a general law, that all the fibres of the heart form loops, the apices of which look towards the apex of the heart (*fig.* 271). I find that Dr. Duncan states that while the apices of those loops which form the lower part of the heart point to the apex, as Gerdy has described, "yet he commits a great error when he asserts that the apices of all the fibres of the heart point in that direction, since the number of tops which point in the opposte direction is not less."* When the superficial fibres of the heart have been removed as represented in *fig.* 274, we will find that if we trace the great mass of fibres occupying the lower and middle part of the left ventricle, they will be seen to run spirally in strong bundles from above downwards and from right to left, to wind round and form the posterior as well as the anterior part of the point of the heart; that the greater mass pass in at the apex of the left ventricle to assist in forming the columnæ carneæ and internal surface, while others pass in at the apex of the right ventricle, and others again, after turning a little upwards, dip into the interior below some of the higher fibres. On tracing them upwards, on the other hand, they dip in at the anterior longitudinal fissure (*fig.* 274, *d*) where they are as it were dovetailed with other fibres from the anterior surface of the right ventricle passing in at the same fissure, and then mount almost vertically upwards to the base of the septum, forming part of the septum of the right ventricle, only separated from its lining membrane by a thin layer of fibres, and are inserted in a strong band in the ox into the bone of the heart, which is placed between the auriculo-ventricular openings and aorta, while in the human heart they are spread

* Mémoires de l'Acad. Roy. 1711. p. 197.

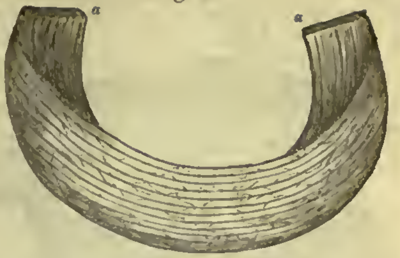
† De Motu Cordis: Opera omnia, tom. iv. p. 96. 1745.

* I could not discover in Dr. Duncan's manuscript any other description or allusion to the fibres here mentioned whose arrangement is opposed to the general law which Gerdy is anxious to establish. There is no doubt, however, that many of these loops at the base are principally directed to the periphery of the organ, and very little downwards, and that a few in the infundibulum are slightly directed upwards.

over a wider surface at this their upper insertion. I have been more particular in describing this part of the heart, as this arrangement of the fibres appears to me to be intimately connected with the production of the tilting motion of the heart. The fibres which occupy the upper part of the anterior surface of the left ventricle, as well as those occupying the upper part of the posterior surface (nearer the base than those bands already described as passing from the anterior surface), partly dip into the interior of the left ventricle as they wind round it, partly pass in at the posterior longitudinal groove to assist in forming the septum, while other strong bands, more particularly near the base, cross this groove and dip into the interior of the right ventricle. In the human heart I have stripped off pretty strong superficial bundles from the upper part of the posterior surface of the left ventricle over the posterior longitudinal groove, and over the surface of the right ventricle as far as the anterior longitudinal fissure, into which they dipped. In stripping off the fibres from the posterior and anterior surface of the right ventricle at this stage of the dissection, part of them disappear in their course around the ventricle, where they dip in to assist in forming the interior; others proceed as far as the anterior groove before they dip inwards; while part of the fibres which arise from the conus arteriosus cross the upper part of the anterior fissure upon the anterior surface of the left ventricle, where they pass into the interior of the left ventricle. These fibres, crossing the anterior surface of the right ventricle, and which dip in at the anterior fissure, form the inner surface of the septum of the right ventricle. On tracing those fibres which dip inwards at so many different points, they are observed to rise upwards to the tendinous rings either directly or indirectly through the medium of the chordæ tendineæ. In following the fibres in this manner we perceive the intimate connexion that exists between the two ventricles, and that their contraction must be simultaneous. We also see that comparatively few fibres cross the anterior longitudinal groove except near the base, while large bundles of fibres cross the posterior groove. When these fibres crossing the two grooves have been torn away, the two ventricles become detached from each other. By this time the apices of both ventricles have been opened.

On examining the deeper fibres (which occupy that part of the heart near the base), they are seen to form a series of curved bands, of one of which *fig.* 275 is a representation. These bands are imbricated, the lower disappearing by its internal extremity below the higher, so as to be inserted by that extremity into the tendinous rings at a point more internal than the corresponding extremity of the higher bands. Some of these bands are common to both ventricles, others belong exclusively to one. The fibres of the right ventricle become very complicated where they form the conus arteriosus and fleshy pons between the

Fig. 275.



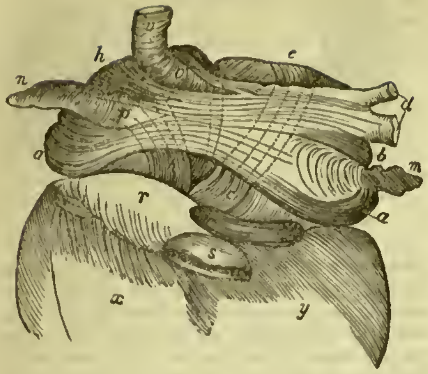
pulmonary artery and right auriculo-ventricular orifice. The fibres of the left ventricle are stronger and coarser than those of the right ventricle, while those of the conus arteriosus are still firmer than those on the lower part of the right ventricle.* "There do not occur in any part of the heart cellular sheaths or tendinous aponeuroses dividing bundles of fibres as separate muscular fasciculi. Although a complex it is not a compound muscle, and does not consist of a number of distinct bellies or heads. The only thing approaching to this structure are the columnæ and a strong muscular stay between the peripheral and septal wall of the pulmonic ventricle, and the reticulated texture on the inside of the ventricles, much more conspicuous in man than in oxen." "Many fibres are attached to each other by agglutination or in a manner not easily understood." "Many fibres bifurcate, and the divided fibres follow different directions: or two fibres from different parts approximate, and at last are united and proceed as one fibre. I am doubtful if this can be considered as a tendinous point of union of all three. These points of union are often arranged in one line so as to give some appearance of a pennated muscle, but the tendinous points, if they exist, do not adhere to form membranes or strings. This bifurcation is very evident in the connection of the septal with the peripheral walls of the heart."†

The auricles are formed by two sets of fibres, a superficial and a deep. The arrangement of these two sets of fibres does not follow the same laws as those of the ventricles. The superficial layer (*fig.* 276, *a a*, *fig.* 277, *a a*), surrounds the base of the auricles, and is of unequal height and thickness. It is broader on the anterior and narrow on the posterior surface, more particularly on the posterior and outer part of the right. It extends upwards towards their superior edge on the anterior surface, and on the posterior surface of the left as far as the inferior pulmonary veins. It is very thin, particularly on the outer and posterior part of the right auricle. In its course round the auricles the fibres diverge to enclose the appendices, and the orifices of the

* Dr. Duncan has given a very minute description of the fibres of this and other parts of the heart, which are much too long for insertion here. He has also given a very accurate and minute description of the bone in the heart of the ox.

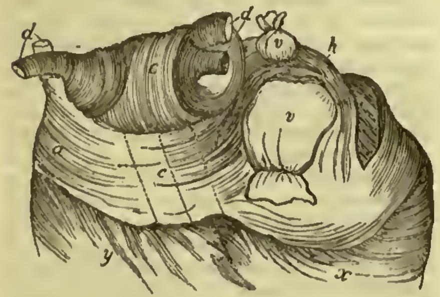
† Dr. Duncan.

Fig. 276.



large veins. These fibres cross transversely between the anterior surface of the two auricles and connect them together. These superficial fibres are also prolonged into the interauricular septum (*fig.* 277, *f*) to assist in forming the

Fig. 277.



circular band of fibres which surrounds the fossa ovalis. Gerdy figures a superficial band of fibres (*fig.* 276, *b*) as belonging exclusively to the left auricle.

The deep fibres belong exclusively to a single auricle. They are superficial at various parts, where the external or circular fibres are deficient. By their inner surface they are connected to the inner membrane of the auricles, and a thin layer of cellular tissue unites their outer surface to the inner surface of the superficial fibres. In the left auricle Gerdy describes, 1st, a left auricular loop (*fig.* 276, *c c*, *fig.* 277, *c c*), which embraces the auricle from its superior edge to its base, which runs a little obliquely to the left, before, above, and then behind the auricle, and is attached by its extremities to the auricular tendinous ring near the septum. It is contracted at that part where it passes between the pulmonary veins. 2d. The pulmonary veins are surrounded by circular fibres (*fig.* 276, *d d*, *fig.* 277, *d d*), which are continued along their course to a variable extent,—sometimes they merely surround the termination of one or more of these veins, at other times I have seen them prolonged outwards as far as the roots of the lungs. These fibres generally form a continuous layer, and of sufficient thickness to render them capable of constricting these vessels considerably. 3d. Some fibres proper to the appendix (*fig.* 276, *m m*), which, by passing between and uniting themselves to the other fibres of the appendix, form that reticulated appearance which it presents in its inner surface. Some of these fibres are circular, others form incomplete circles.

In the right auricle, Gerdy has described, 1st, a right auricular loop (*fig.* 276, *h h*, *fig.* 277, *h*), which is attached anteriorly to the tendinous structure at the base of the auricle; it extends upwards in the anterior edge of the septum auriculorum; it then curves round the fossa ovalis, of which it forms the projecting edge, and at the orifice of the vena cava superior it divides into a right and left band. The first proceeds downwards, becomes engaged with some of the superficial fibres around the cava superior, and forms the angle between them (*tuberculum Loweri*), from which it passes downward to the auricular tendinous ring along the right side of the cava inferior. The left division passes along the left side of the cava inferior, in the posterior edge of the auricular septum, where it intermixes with the fibres which embrace the entrance of the coronary vein. 2d, Some muscular fibres (*fig.* 276, *p*), which pass between the anterior part of the tendinous ring and the appendix. 3d, Some circular fibres, which surround the entrance of the cava superior (*fig.* 276, *o*): these do not extend upwards beyond the orifice of the vein. 4th, The bundles of fibres which arise from the right side of the auricular ring proceed upwards to the posterior part of the appendix, and form the musculi pectinati seen in the interior of the auricle. 5th, A few fibres proper to the auricle (*fig.* 276, *n*), which assume the circular form. The action of all these fibres superficial as well as deep must be to diminish the capacity of their cavities, and draw them towards the auriculo-ventricular openings, and thus favour the passage of their contents through these openings.

Inner membrane of the heart.—Each side of the heart has its own lining membrane, and both of these are closely allied to the serous membranes in structure and appearance. They are continuous with the inner coat of the vessels which open into their different cavities. These have been termed the endocarde by Bouillaud to distinguish them from the serous coat of the pericardium on the outer surface of the heart. If we commence to trace the inner membrane of the right side from the entrance of the two cavæ, we find that it is folded upon itself to form the Eustachian valve at the entrance of the inferior cava; it then passes upon the inner surface of the auricle, and at the opening of the coronary vein it is again folded upon itself to form the valve of the coronary vein. It passes through the auriculo-ventricular opening, adheres to the inner surface of the tendinous ring, and is there folded upon itself to assist in forming the tricuspid valve. It now proceeds upon the inner surface of the ventricle, and at the origin of the pulmonary artery it assists in forming the semilunar valves, and becomes continuous with its inner coat. If we trace the inner membrane of the left side of the heart from the entrance of the pulmonary veins, we find that, after lining the auricle, it is continued through the auriculo-ventricular opening, and is there folded upon itself to assist in forming the mitral valve. In the left ventricle it surrounds the chordæ tendineæ and unattached columnæ carneæ in the same manner as in the right ventricle; and at the origin of the aorta it assists in forming the semilunar valve, and becomes continuous with the inner coat of the artery. These membranes adhere intimately to the inner surface of the heart by close cellular tissue, and have their inner surface perfectly polished and smooth. That of the left auricle is thicker than that of the right. They are thicker in the auricles than in the ventricles. In the ventricles, except near the origin of the large arteries, they are exceedingly thin.

Nerves of the heart.—The heart is supplied with nerves from the sympathetic and par vagum. The sympathetic branches come from the superior, middle, and inferior cervical ganglia, and frequently also from the first dorsal ganglion. The branches from the par vagum come directly from the trunk of the nerve, and indirectly from the recurrent or inferior laryngeal. The course of these on the right side differs from those of the left in some respects, and requires a separate description. These nerves, like most of the other branches of the sympathetic, are very irregular in their size, number, and origin, so that it would be difficult to find two subjects in which they are exactly alike; they are also very irregular in their course before they reach the cardiac plexus, but become more regular when they gain the arteries of the heart, whose branches they accompany. These nerves, after forming different anastomoses and plexuses with each other of the same side, converge at the upper and back part of the arch of the aorta, where they form a free anastomosis with those of the opposite side, and then pass on to the heart. The left cardiac nerves are sometimes much smaller than those on the right side, so as to appear, as in the dissection described by Lobstein,* merely accessory to those on the right. On the other hand the size of those on the left side may preponderate considerably over those on the right. The proportional size of the different nerves of the same side is also very various. When the nerves of one side are small, the deficiency is made up by the greater size of those of the opposite side; and when any particular branch is either unusually small or entirely wanting, its place is supplied by the greater size of the other nerves of the same side, or of those of the opposite side. The branches from the par vagum, particularly those coming from the recurrent, vary also considerably in size. All the sympathetic branches of the cardiac plexuses are of a gray colour, and are generally not so soft as Scarpa has described them.

The right cardiac branches of the sympathetic are generally three in number: 1st, superior cardiac *(supremus et superficialis cordis)* arises from the lower and inner part of the superior cervical ganglion, or from the continuation of the sympathetic between the superior and middle ganglia, or from both these origins. It generally also receives a filament from the par vagum. In its course down the neck it lies behind the sheath of the carotid artery. It anastomoses with the external laryngeal nerve and descendens noni, and sends a twig along the inferior thyroid artery to the thyroid body; and at the lower part of the neck it sometimes divides into two branches as figured by Scarpa,* one of which unites itself to the middle cardiac, the other forms an anastomosis with the recurrent nerve of the same side. At other times it passes into the thorax either in front or behind the subclavian artery, takes the course of the arteria innominata, and reaches the posterior part of the arch of the aorta, where it anastomoses with branches of the middle and inferior cardiac nerves, or with branches of the recurrent. It more rarely appears to pass to the cardiac plexus without any anastomosis with the middle and inferior cardiac branches. It frequently presents a ganglion in its course down the neck.

Middle cardiac nerve.—This nerve arises by several short twigs from the middle cervical ganglion. This is generally the largest of the cardiac nerves, and is named by Scarpa the great or deep cardiac nerve *(n. cardiarus medius, s. profundus, s. magnus).* It proceeds downwards and inwards, crosses the subclavian artery, sometimes in front, at other times it divides into several branches, which surround the artery and again unite. It anastomoses with the branches of the recurrent, in the neighbourhood of which it runs, also with the par vagum, superior and inferior cardiac nerves; and following the course of the arteria innominata it passes behind the arch of the aorta to terminate in the cardiac plexus.

Inferior cardiac nerve (n. cardiacus minor of Scarpa).—This nerve generally arises by filaments from the inferior cervical ganglion, sometimes from the first dorsal ganglion, at other times from both. It proceeds behind the subclavian artery near to the recurrent nerve. It follows the course of the innominata close to the middle cardiac, with which it anastomoses, and proceeds to join the cardiac plexus.

Left cardiac nerves.—Perhaps the differences in the course of the right and left cardiac nerves are principally to be attributed to the known differences between the large arteries of the two sides. The left superficialis cordis is figured by Scarpa† as dividing a little above the arch of the aorta into four branches; two of these pass in front of the aorta to form an anastomosis with a branch of the par vagum and deep cardiac; a third also passes in front of the aorta to unite itself with the middle cardiac; and the remainder of the nerve proceeds behind the arch to unite itself with the cardiac plexus.

* De Nervi Sympathetici humani fabrica, &c. pp. 16 & 18.

* Tab. iii. Tabulæ Neurologicæ, &c.
† Tab. iv. op. cit.

The left middle cardiac nerve is generally smaller than the right, and is frequently partly formed by a branch from the inferior cervical ganglion. It passes behind the arch of the aorta, sometimes in the form of a single trunk, sometimes double, at other times triple, and generally throws itself into the upper and left part of the cardiac plexus.

Cardiac plexus (great cardiac plexus of Haller) is placed behind the arch of the aorta and in front of the lower part of the trachea, extending from the arteria innominata to the right branch of the pulmonary artery, and is formed by the convergence of nearly the whole of the cardiac nerves of both sides, but more particularly of the middle cardiac nerves. There is occasionally a distinct ganglion at the junction of these nerves; more generally there is only a plexiform arrangement. From this plexus a very few branches pass upon the anterior surface of the aorta *(cardiaci superficiales aortæ)*, and anastomose with the right coronary plexus: some twigs also pass backwards to anastomose with the bronchial plexuses. By far the greater part of the cardiac plexus proceeds to the heart in the form of two large divisions to form the right and left coronary plexuses which accompany the coronary arteries. Where the right branch leaves the lower part of the plexus there is a gangliform swelling (ganglion of Wrisberg), which is occasionally, however, very indistinct. This ganglion furnishes the greater part of the superficial plexus of the aorta which we have just described. This great right cardiac branch divides into two parts; the smaller passes between the aorta and pulmonary artery to reach the right side of the origin of the pulmonary artery, where it attaches itself to the right coronary artery to form the principal part of the right coronary plexus; the other and larger portion creeps under the pulmonary artery to the posterior part of the heart, to assist in forming the left coronary plexus. The great left cardiac branch, which principally comes from the upper part of the cardiac plexus, and at first passes from right to left posterior to the ductus arteriosus, after which it is joined by other smaller branches which pass in front of the ductus arteriosus. It also divides into two branches; the smaller passes between the aorta and pulmonary artery, and reaches the origin of the right coronary artery, and throws itself into the right coronary plexus; the larger bends round the posterior surface of the pulmonary artery to reach the left coronary artery, where it forms, with the larger branch of the right, the left coronary plexus. There is thus a free interchange of filaments between the nerves of both sides. The left coronary plexus is considerably larger than the right, in proportion as the left side of the heart is thicker than the right. These coronary plexuses consist of a number of minute filaments which accompany the ramifications of the coronary arteries everywhere, and are distributed upon the surface of the auricles as well as upon the ventricles. They anastomose with each other upon the anterior and posterior surface of the heart. All the nerves of the heart enter into its substance upon the surface of the arteries, and cannot be traced beyond the second or third division of the arteries. The nerves of the heart are generally considered to be small compared to the size of the organ.* Though the nerves of the heart are not equal in size to those of the tongue and eye, yet Scarpa is doubtful if they are not equal to the nerves of the other voluntary muscles, as, for example, the muscles of the arm. It must be remembered that the minute subdivision and diffusion of these nerves over a large extent of surface, by which many of them can only be seen after a minute examination, causes them to appear of less size than what they collectively really are. Soemmerring maintained that very few of the nerves of the heart were distributed to the muscular tissue of the heart, and that they more properly belonged to the arteries: "nervi cardiaci proprie ad arterias, ad aortam et arterias coronarias pertinent, eaque filia subtilia nervorum parum sibi (cordi) constant."† Behrends, the pupil of Soemmerring, affirmed that not a single twig went to the muscular tissue of the heart, but that they were entirely distributed on the coats of the arteries.‡ The announcement of these opinions, bearing so directly as they do upon the Hallerian doctrine of the nature of irritability, so keenly agitated immediately before throughout Europe, could not fail to create considerable sensation at the time, and it is probable that to this we owe the splendid work of Scarpa upon the nerves of the heart, which has entirely set the question concerning the distribution of these nerves at rest. Scarpa has shown that when followed to their minute distribution, the nerves of the other muscles accompany the arteries in the same manner as the nerves of the heart, and that the nerves of the heart only differ from those of voluntary motion in this, that the nerves accompanying the arteries of the voluntary muscles are firmer and thicker than those of the heart.

Bloodvessels of the heart.—The heart is supplied with blood by the two coronary arteries, for a description of which see Aorta. The blood is returned by the coronary veins. The branches of the coronary veins generally accompany those of the arteries. They are divided into the larger coronary vein and smaller coronary veins.

Great coronary vein (vena coronaria maxima cordis).—This vein is formed by several branches, three of which surpass the others considerably in size. One of these lies in the anterior longitudinal groove; another runs along the obtuse or left margin of the heart; and the third, which may be replaced by two or three

* Bichat in his Anatomie Générale says, "that the nervous mass intended for the muscles of organic life is much inferior to that of the voluntary muscles. The heart and deltoid muscle, on being compared together, display in this respect a very considerable difference."

† Corporis humani fabrica, tom. v.

‡ Dissertatio qua demonstratur cor nervis carere. After making this general statement, he admits, in one part of his treatise, that he has traced two twigs of the cardiac nerves into the substance of the heart.

smaller veins, runs along the posterior surface of the left ventricle, between the obtuse margin and posterior longitudinal groove. The first of these is frequently described as the trunk of the vein, and it commences at the apex of the heart, where it anastomoses with the smaller posterior and anterior veins. It runs upwards in the anterior longitudinal groove along with the left coronary artery, gradually increasing in size as it ascends, from the junction of the other veins. When it reaches the base of the ventricles it changes its direction, enters the groove between the left auricle and ventricle, leaves the coronary artery, passes from left to right in the posterior part of the same groove, when it becomes considerably dilated *(sinus of the coronary vein).* It then opens into the right auricle at its lower and back part close upon the posterior edge of the septum auriculorum.

Smaller posterior coronary vein (vena coronaria cordis minor).—It commences at the apex of the heart, runs up in the posterior longitudinal groove, or a little to its right side, and receives its blood principally from the right ventricle. It generally joins the sinus of the coronary vein; at other times it enters the auricle separately immediately by the side of the great coronary vein, so that its aperture is also covered by the coronary valve.

Smaller anterior coronary veins (venæ innominatæ of Vieussens).—These are very small and variable in number, and are placed on the anterior surface of the right ventricle. One of these, larger than the others, (generally the superior,) sometimes receives the name of anterior vein of Galen. They frequently unite to form a single trunk; more generally perhaps they continue separate, pass in front of the right coronary artery as it lies in the auriculo-ventricular groove, and enter the right auricle at its anterior and inferior part. One of the musculi pectinati overlaps their entrance, forming a kind of valve.

Venæ minimæ, or *veins of Thebesius,* are minute veins, which enter the auricle at various points. It was maintained by Vieussens, Thebesius, and Ruysch, that some of the coronary veins opened into the left side of the heart, thus producing a slight intermixture of the dark blood with the arterial. This has been more lately asserted by Abernethy,* and has been supposed to occur more frequently in phthisical cases; the difficulty of transmitting the blood through the lungs causes their enlargement. Such injections are liable to great fallacy, from the great facility with which fine injections, or even coarse injections when forcibly pushed into the vessels, escape into the cavities of organs. Especial care is, therefore, required in conducting them. Notwithstanding that we have the authority of some of the most accurate anatomists in favour of this opinion, it is very doubtful if any of these veins open into the left side of the heart.†

Sinus of the coronary vein.—This is always described as a dilatation of the large coronary vein, but I have found it decidedly muscular in man and in several of the Mammalia, as the dog, horse, ox, and sheep; and it presents the appearance of a muscular reservoir placed at the termination of this vein, similar to the auricles at the termination of the two cavæ. This sinus is placed in the posterior part of the groove between the left auricle and ventricle, adheres intimately to the outer surface of the auricle, and communicates by one extremity with the auricle, and by the other with the large coronary vein. The commencement of the dilatation is generally abrupt, and the first appearance of the muscular fibres well defined. I have seen it vary from two inches to only half an inch in length. These muscular fibres are generally circular; part of them, however, are oblique. Some of them belong exclusively to the vein; a great part appear to be connected with the muscular fibres of the auricle. This muscular sinus must serve to prevent regurgitation along the coronary veins. I have also generally found a distinct valve at the termination of the coronary vein in the sinus. This valve resembles the valves found in the veins of the extremities. It is generally single, sometimes it is double. I have also occasionally found one or more single valves in the course of the vein.* A distinct valve may also occasionally be seen at the termination of the posterior coronary vein in the sinus. Portal† mentions that he has seen the coronary valve situated in the interior of the vein a little from its mouth. Thebesius and Morgagni have observed valves placed in some of the smaller veins where they terminate in the larger. The valves of the coronary veins do not in general prevent the passage of injections contrary to the course of the blood along them.

Lymphatics of the heart.—The lymphatics of the heart are divided into two sets—superficial and deep; the superficial commencing below the external serous membrane, and the deep upon the internal membrane. They follow the course of the coronary vessels. Some of them pass directly into the thoracic duct, and, according to Meckel, sometimes directly into the subclavian or jugular veins. Others pass into the lymphatic glands situated in front of the arch of the aorta, while others pass into the glands situated around the bifurcation of the trachea, and a few also join the lymphatic vessels of the lungs.

Pericardium.—The pericardium is a fibrous

* Philos. Trans. 1798.

† Professor Jeffray (Observations on the Heart, &c. of the Fœtus, p. 2) mentions a case in which the large coronary vein opened into the left auricle. Lecat (Mém. de l'Acad. des Scien. 1738, p. 62) found the coronary veins in a young child unite themselves into a single trunk and enter the left subclavian. It is probable that Soemmerring had this case in view when he states, "Rarissime vena hæc in vena subclavia *dextra* finitur," (de corp. hum. fab. tom. v. p. 340. 1800.) particularly as Haller, (Element. Phys. tom. i. p. 375, 1757), in quoting the case, has inadvertently substituted the word *dextra* for *sinistra.*

* I have seen two or three pair of double valves in the course of the coronary vein in the horse and ass. These animals have no Thebesian valve.

† Anatomie Médicale, tom. iii.

bag surrounding the heart and origin of the large bloodvessels, but without any direct attachment to the heart itself, having its inner surface lined by a serous membrane. It is from this latter circumstance that it is generally termed a fibro-serous membrane. It is placed behind the cartilages of the second, third, fourth, and fifth ribs of the left side and middle part of the sternum. Posteriorly it rests upon the parts contained in the posterior mediastinum; anteriorly it corresponds to the anterior mediastinum, and may be reached by perforating the left side of the sternum, as has been proposed in some cases of hydrops pericardii. The pleuræ adhere to its lateral and part of its anterior surface by pretty close cellular tissue, when the interposed fat is small in quantity. The phrenic nerves with their small accompanying arteries pass down the thorax between the pleuræ and lateral surfaces of the pericardium. Below, the fibrous part of the pericardium adheres intimately to the upper surface of the cordiform tendon of the diaphragm, and is also connected by pretty dense cellular tissue to the upper surface of the muscular fibres running into the anterior part of the left lobe of the tendon. It adheres more firmly to the cordiform tendon at the edges, particularly anteriorly, than at the centre. It is broader below where it adheres to the upper surface of the diaphragm, narrower above where it is attached to the large vessels that pass in and out from the heart. Upon these large vessels the fibrous part of the pericardium is prolonged, forming a kind of sheath, which gradually becomes thinner until it is confounded with the cellular coat of the vessels. From the manner, however, in which the vena cava inferior enters the heart, it can have no fibrous sheath of this kind. At the different points where the fibrous coat becomes applied upon these vessels, and where the cava inferior passes through the cordiform tendon, the serous coat is reflected upon the outer surface of the vessels, and accompanies them back to the heart to cover the outer surface of that organ. In this manner the serous part of the pericardium is a shut sac, the outer surface of which adheres to the inner surface of the fibrous portion, and to the outer surface of the heart. The inner surface, like that of all the other serous membranes, is unadherent, smooth, and shining, and is everywhere in contact with itself, and only contains the small quantity of fluid which serves to lubricate its interior. The serous portion of the pericardium adheres intimately to the inner surface of the fibrous. At that part, however, where the serous leaves the fibrous to pass back upon the surface of the large vessels, there is a small triangular space left between them. The serous membrane is reflected upon and covers the outer surface of the aorta rather more than two inches above its origin; upon the pulmonary artery about the same distance and immediately before its bifurcation; upon the cava superior about an inch above its entrance into the right auricle; upon the cava inferior shortly before it reaches the heart; upon the two right pulmonary veins soon after they have emerged from the right lung; and upon the left pulmonary veins shortly before they enter the auricle. This serous membrane, in passing upon the aorta and pulmonary arteries, covers the anterior surfaces of both before it passes round upon their posterior; it then envelopes both arteries in the same sheath, so that their opposed surfaces are only separated from each other by a little cellular tissue. It leaves part of the posterior surface of the cavæ and pulmonary veins uncovered, occasionally, however, enveloping the whole or nearly the whole, of the left pulmonary veins. It adheres but loosely to the large bloodvessels, and firmly to the outer surface of the auricles and ventricles. The attachment of the fibrous part to the cordiform tendon is very firm at the edges and blended with the tendon, but becomes looser towards the centre. Cloquet* describes the serous membrane as lying in contact with the upper surface of the cordiform tendon; or, in other words, he appears to consider the fibrous part not to be prolonged over the upper surface of the tendon, but to stop at its attached margin. In most cases I have been able to trace the fibrous part of the pericardium over the upper surface of the cordiform tendon, but almost always more or less diminished in thickness. In some cases I was unable to detect anything like a fibrous layer at this part. The fibrous part of the pericardium is comparatively thin, and is composed of tendinous fibres interwoven together. It is not much larger than sufficient to contain the heart when its cavities are distended. This fact taken along with the physical properties of the membrane, not admitting of sudden dilatation, explains how the sudden escape of a small quantity of blood (8 oz. or sometimes less) into the interior of the pericardium is sufficient to arrest the heart's action.

The arteries of the pericardium are small and come from various sources, from the bronchial, œsophageal, phrenic, from the arteries of the thymus gland, internal mammary, coronary arteries, and the aorta itself. Its veins partly terminate in the azygos, and partly accompany the corresponding arteries to terminate in the veins of the same name. Its lymphatics pass to the glands placed around the cava superior. The nerves can be traced into its texture.

Uses of the pericardium.—The pericardium restrains within certain limits the irregular movements of the heart. The inner serous surface of the pericardium must also facilitate its ordinary and healthy movements.

Relative position of the vessels within the pericardium.—The pulmonary artery at its origin overlaps the anterior surface of the aorta as it springs from the left ventricle. (See *fig.* 276, *s*, for the relative position of these vessels at their

* Traité d'Anatomie Descriptive, p. 633, translated by Knox. Cloquet does not state distinctly that the fibrous part of the pericardium is not continued over the cordiform tendon, but this may be inferred from the statement that the serous membrane "is applied below, directly and in a very close manner upon the aponeuroses of the diaphragm."

origin.) It then proceeds into the concavity of the arch of the aorta, and as it is about to pass through the fibrous coat of the pericardium, it divides into its two branches, the right and left. The left branch passes in front of the descending portion of the arch of the aorta to reach the left lung; the right branch passes behind the ascending portion of the arch to reach the right lung. In the fœtus the pulmonary artery divides into three branches, the two we have just mentioned, and a third, the ductus arteriosus, which unites the pulmonary artery to the descending portion of the arch,—in other words, after the aorta has given off the large branches to the head and superior extremities. The descending cava, immediately before it perforates the fibrous coat of the pericardium, crosses the right branches close upon the bifurcation of the trachea; within the pericardium it lies on the right side of the ascending portion of the arch of the aorta. The inferior cava is seen perforating the cordiform tendon of the diaphragm, and almost immediately afterwards it enters the posterior and inferior angle of the right auricle. The pulmonary veins are placed inferior to the two branches of the pulmonary artery. The two right pulmonary veins pass behind the right auricle to reach the left, which they enter near the septum auriculorum.

Peculiarities of the fœtal heart.—(For an account of the developement of the heart and large bloodvessels see Ovum.) The heart of the fœtus before the fourth month is placed vertically, but towards that period the apex begins to turn towards the left side. The auricular part of the heart is considerably larger in proportion than the ventricular. The relative size of the heart to the body at birth differs considerably from that of the fœtus at an earlier period of its developement. According to Meckel the relative size of the heart to the body about the second or third month of uterine life is 1 to 50; at birth and for a few years afterwards as 1 to 120. The greater size of the heart of the fœtus seems to depend principally upon the greater thickness of the walls of its cavities. The great disparity between the thickness of the two sides so very apparent shortly after birth does not exist in the earlier periods of uterine life, though also generally sufficiently well-marked in the fœtus at the full time. This is explained by the circumstance that the two sides of the heart at this period have nearly equal obstacles to overcome in propelling the blood.* In the earlier stages of its developement the infundibuliform portion of the right ventricle is less prominent than at a later period. The left ventricle is at first a little larger than the right; at birth and for a short while after they are equal. The two auricles communicate with each other through the foramen ovale.* This foramen is at its maximum size about the sixth month.

Valve of the foramen ovale.—This valve, which, however, can scarcely be called a valve, as it is a provision for effecting the obliteration of the foramen ovale at the time the child assumes its independent existence, first makes its appearance at the lower part of the foramen about the third month, or, according to Senac and Portal, about the second month. It is formed by the inner membranes of the two sides of the heart, containing some muscular fibres between them, particularly at its lower part. It is of a semilunar form; its convex edge adheres to a greater or less portion of the margins of the valve as its growth is more or less advanced; its concave margin, which is free and loose, looks upwards and forwards. This valve may be said to belong almost exclusively to the left auricle, as it is attached to that margin of the foramen.† Though this valve is of sufficient size at birth to shut the foramen, yet its concave or upper margin is easily depressed so as to leave a considerable interval between it and the upper margin of the foramen. We will find, from the manner in which the valve is attached to the left margin of the foramen, that it is much more easily depressed by a current passing from the right auricle into the left than in the opposite direction. In fact any force of this kind applied in the opposite direction would rather tend to keep the valve applied to the upper edge of the opening; a circumstance which occurs after birth when the blood flows along the pulmonary veins into the left auricle, and which must materially assist in producing complete obliteration of the foramen. The manner in which the blood passes between the auricles through the foramen ovale in the fœtus was the subject of a violent controversy in France at the termination of the seventeenth and the commencement of the eighteenth centuries. It was first commenced between Meri on the one side, who had proposed a new theory of the fœtal circulation by which the blood was made to pass from the left auricle into the right, and by Duverry and Fauvery on the opposite side, who maintained the opinion of Harvey, and which is now universally adopted, that it passes from right to left. Many celebrated anatomists and mathematicians attached themselves to the opposite parties, and at last the controversy extended itself to the neighbouring kingdoms.‡

Eustachian valve.—This valve, the appearance and position of which have been already

* In two fœtuses, however, which I lately examined, and where I had positive evidence that they had not yet reached the sixth month of utero-gestation, the difference between the thickness of the two ventricles of the heart was distinctly marked.

* This opening is frequently termed *trou de Botal* by the French writers though described by Galen.

† This explains how the depression (fossa ovalis), marking in the adult the position of the valve, should be better seen from the right than the left auricle.

‡ Those who may be anxious to acquaint themselves more fully with the nature of this controversy and to examine the arguments adduced on both sides may consult the Mémoires de l'Academie for that period, and Senac's Traité de la Structure du Cœur, tom. i. p. 369, and the Supplement in tom. ii.

pointed out in describing the interior of the right auricle, is also intimately connected with the peculiarities of fœtal life. It was discovered by Eustachius about the middle of the sixteenth century, who contented himself by pointing out its position. Little attention was paid to it until the commencement of the eighteenth century, when it was more particularly brought into notice by Boerhaave and Lancisi, who published a new edition of the works and plates of Eustachius, which had then become very scarce. Lancisi supposed that this valve prevented the blood of the superior cava from falling with too much force upon the column ascending by the cava inferior. Winslow,* finding it only perfect in the fœtal state, and having cause to believe that its diminution kept pace with the increase of the valve of the foramen ovale, was led to adopt the opinion that its presence had a special reference to that state, and believed that it not only served to break the current of the superior cava as stated by Lancisi, but also opposed the regurgitation of the blood of the auricle into the inferior cava. In the absence of this valve he supposed there would arise two inconveniences in the fœtus—the imperfect intermixture of the contained blood, and the regurgitation of the blood of the umbilical vein into the placenta. Senac† believed that the Eustachian valve can have no effect in preventing the blood of the cava superior from falling upon the current ascending by the cava inferior, and that it must direct a part of the blood of the cava inferior through the foramen ovale. Sabatier‡ more particularly pointed out that from the position of this valve passing from the anterior and left part of the vena cava inferior to the left side of the foramen ovale, and from the situation of the foramen ovale at the inferior part of the auricle, the blood of the cava inferior must be directed through the foramen ovale; and further, from the difference in the direction of the two cavæ themselves—the superior looking downwards, forwards, and to the left side, while the inferior, though it is also slightly directed to the left, passes at the same time upwards and backwards, when combined with the upper thick margin of the foramen ovale—it would necessarily happen that the blood of the superior cava must fill the right auricle.

In three injections of the fœtal circulation which I performed, where arrangements were made to imitate, as far as possibly could be done, the manner in which the two currents flow into the heart during the life of the fœtus, results were obtained confirmatory of the opinion of Sabatier.§ This arrangement cannot of course exist in the early months of uterine life from the imperfect developement of the heart itself, and in all probability part only of the blood of the inferior cava is transmitted through the foramen ovale into the left side of the heart for a short time before birth. The pulmonary veins appear to bring very little blood to the left side of the heart until the time approaches that the fœtus must necessarily assume an independent existence. The circulatory apparatus becomes gradually prepared for this change;—the Eustachian valve begins to shrink, the foramen ovale to diminish in size, and a greater quantity of blood is transmitted through the lungs. Billard* has ascertained from the examination of the bodies of a great number of infants who died within a few days after birth, that the foramen ovale and the other circulatory passages peculiar to the fœtus are generally shut about the eighth day after birth. In nineteen infants who had lived only one day the foramen ovale was completely open in fourteen; in two it had commenced to become obliterated, in the remaining two it was completely shut. On the subsequent days the number of those with the foramen shut continued to increase; and in twenty examined, who had died on the eighth day, five only had the foramen open.

Physiology of the heart.

Mode of action of the valves of the heart.—While the blood is rushing through the auriculo-ventricular openings during the contraction of the auricles, the lips of the mitral and tricuspid valves are separated from each other and thrown outwards from the axis of the opening, and the larger lip of both is at this time carried towards the arterial orifices. It has generally been supposed that the mitral and tricuspid valves are, during the systole of the ventricles, passively floated up towards, and obstruct the auriculo-ventricular orifices so as to prevent the free regurgitation of the blood into the auricles; and that the use of the cordæ tendineæ is merely to limit the movements of the valves,—to permit them to be raised sufficiently to close the orifices, but at the same time to provide against the otherwise unavoidably fatal consequences that would result from these unresisting valves being carried through into the auricles by the current of blood. Mayo, Bouillaud, and others have, however, maintained that the lips of these valves are not approximated in the mechanical manner just stated, but by the contraction of the musculi papillares of which the cordæ tendineæ are the proper tendons. As the musculi papillares contract along with the other fibres of the ventricles, the lips of the valves are drawn towards the axis of the opening, and are closely applied to each other, forming a kind of cone, the apex of which projects downwards into the ventricles. It is from the adoption of these views that Bouillaud proposes to call these musculi papillares, the tensor, elevator, or adductor muscles of the valves. That the lips of the

§ Edinburgh Medical and Surgical Journal, 1835. These injections are also confirmatory of one made by Kilian, where the fluid thrown along the aorta passed to the head and superior extremities, and that along the pulmonary artery to the lower part of the body.

* Traité des Maladies des Enfans nouveau-nés, &c., p. 557, 1828.

valves are approximated in this manner appears to me to be the much more probable opinion; for when we examine the uniform position and course of the musculi papillares and chordæ tendineæ, more particularly those of the left ventricle; that the chordæ tendineæ pass from each musculus papillaris to both lips of the mitral valve, occasionally crossing each other; and that the posterior or smaller lip, though it may be drawn inwards so as to meet the larger and more moveable, is so bound down as to be scarcely capable in most cases of being floated up on a level with the orifice; and further, when we also remember that the musculi papillares contract at the same time with the other fibres of the heart, we can scarcely resist coming to this conclusion. Besides, if the lips of the valves were floated up to the orifice, a greater quantity of blood would regurgitate into the auricles during the systole of the ventricle than in all likelihood takes place; for as the lips of the valve must be widely separated from each other when the systole commences, it is evident that a less quantity of blood must have passed through the orifice before the lips are sufficiently approximated to obstruct its further passage when these are assisted by an active force, than when they are merely passively brought together by the current of blood passing in that direction. It has, however, been supposed that the musculi papillares do not contract with the other fibres of the ventricles. Haller states* that on laying open the heart he has seen the muscles of the valves contract during the systole of the heart. It may be objected to this experiment that the unusual stimulus applied to the heart in cutting its fibres across may have deranged the usual order of its contractions. I have repeatedly opened the heart in rabbits and waited until its contractions had ceased, and on renewing its movements by irritating the inner surface at a distance from the cut edges, I have observed that the columnæ carneæ acted simultaneously with the other muscular fibres of the heart.† I was also satisfied that the musculi papillares were proportionally more shortened during their contraction than the heart itself taken as a whole, which is nothing more than what we would expect when we remember that the fibres of the musculi papillares are so far free and run longitudinally, while by far the greater part of the other fibres run in a spiral manner.

Haller, in relating his observations on the contraction of the musculi papillares, makes another statement, which, however, is decidedly adverse to this opinion. The chordæ tendineæ appeared to him to be relaxed during the contraction of the musculi papillares.

It is difficult to make satisfactory observations upon the effects of the contractions of the musculi papillares upon the tension of the chordæ tendineæ. In several animals upon which we attempted to ascertain this, it was only when the heart was acting languidly that we could observe what was likely to be the effect of the contraction of the musculi papillares on the chordæ tendineæ when they were placed as far as possible in their natural relation to each other. We could never observe that they contracted sufficiently to move the valves, but they certainly rendered some of the chordæ tendineæ more tense. When, however, we take into account, that in an experiment of this kind, the valves are not thrown out widely from the orifices of the auriculo-ventricular orifices, the ventricle is not distended with blood, the chordæ tendineæ consequently not put so far on the stretch as occurs at the commencement of the systole, and that the contractions of the musculi papillares are languid, we can easily perceive how, in the natural systole of the heart, these contractions of the musculi papillares should be sufficient to move the valves inwards, though not to such an extent as to apply them closely to each other. The contraction of these musculi papillares apparently sets the valves in motion, and they are subsequently applied to each other by the currents of blood. It may be supposed that if the contraction of these musculi papillares can render the chordæ tendineæ sufficiently tense to move the valves, this would prevent the subsequent elevation of them to obstruct the auriculo-ventricular opening. We believe, however, that it is only at the commencement of the systole that they are sufficiently tense to move the valves, for as the contraction proceeds the capacity of the heart is so much diminished, both in its transverse and longitudinal dimensions, that they become relaxed. Besides, if we could suppose that these musculi papillares are capable of contracting through a sufficient space to draw the valves together, this would be all that is necessary to prevent the regurgitation of the blood through the auriculo-ventricular opening.*

So convinced, indeed, were the older anatomists and physiologists that the chordæ tendineæ are relaxed during the systole of the heart, and of the necessity of an accompanying diminution of the length of the ventricles themselves to effect this, that this argument adduced by Bassuel appears to have been principally instrumental in deciding the once keenly controverted question whether or not the heart was elongated during its contraction.†

* Elementa Physiolog. tom. i. p. 390. Sur le Mouvement du sang, p. 129. Mémoires sur la Nature sensible, tom. i. p. 379.

† [The observations of the London Committee appointed by the British Association to examine into the motions and sounds of the heart confirmed this view of the simultaneity of contraction of the columnæ carneæ and ventricular fibres.—Ed.]

* All these experiments upon the action of the columnæ carneæ were finished and the article forwarded to London about the middle of June, 1836.

† Mr. T. W. King in an elaborate essay (Guy's Hospital Reports, No. iv. April 1837,) has pointed out what he conceives to be a "safety-valve function in the right ventricle of the human heart." This view is founded upon the fact which he believes that he has ascertained, "that the tricuspid valve, naturally weak and imperfect, closes less and less accurately, according to the increasing degrees of the ventricular distention." From this he is "convinced that, in all cases in which the

It may be supposed that the relative size of the auriculo-ventricular orifices to the length of the lips of the valves would not admit of their apices being brought together in the form of a cone as described, but it must be remembered that from the course of the muscular fibres in the immediate neighbourhood of those openings, their areas must be diminished during the systole of the heart. There is at least one thing certain connected with the action of these valves, viz. that the contraction of the musculi papillares can never cause the valves to strike the inner surface of the ventricle and produce a sound as has been supposed.

The manner in which the semilunar valves at the origin of the aorta and pulmonary artery perform their office is entirely mechanical and easily understood. During the systole of the heart they are thrown outwards from the axes of these vessels; but during its diastole, when part of the blood driven into the artery would fall back into the ventricles, these valves are thrown inwards and obstruct completely the whole calibre of the arteries. In all probability the sinuses of Valsalva placed behind these valves contain a certain quantity of blood even during the systole of the heart, and this reacting upon the valves through the agency of the elasticity of the arteries brought into operation at the termination of the systole, materially assists in producing the more rapid and certain action of the valves.

Movements of the heart.—The heart is a muscle of involuntary motion, being, for the wisest of purposes, placed beyond the direct control of volition. The case of Colonel Townshend * is of too obscure a nature to entitle us to found upon it an opposite doctrine, more particularly as it is at direct variance with every other fact or observation.

The movements of the heart, when the body is at rest or in a state of health, proceed without our consciousness. In certain cases of disease they are attended by uneasy feelings, but they are never at any time or under any circumstances dependent upon sensation for their continuance.

It is not so easy a matter as may at first be imagined to ascertain the order of succession in which the different cavities of the heart contract and dilate, and the different circumstances which attend these movements, even by experiments on living animals, more particularly the warm-blooded animals; for if the heart when exposed is acting vigorously and rapidly, every one who has examined for himself must have felt the exceeding difficulty of following and analysing these movements by the eye. If, on the other hand, the animal has become debilitated and the movements of the heart languid, these are apt to deviate from their natural order, and to be performed in an irregular and unnatural manner.* It is in this way that we can account not only for the discrepant statements of the older observers, but also for the very frequent announcement of new views on this subject which appear in the medical periodicals of our own day. As we will find that many of these theories connected with the physiological actions of the heart even in the present day, have been founded upon false notions of the normal anatomy and natural movements of the organ, and only require a reference to these for their full and satisfactory refutation, it will be necessary that we attend particularly to the manner in which these different contractions and relaxations succeed each other, and the visible phenomena by which they are accompanied, as observed by the most accurate experimenters.

When the heart of a living animal is exposed and the organ is acting in a natural manner, the auricles are observed to become distended with blood, then to contract rapidly and simultaneously, and propel part of it into the ventricles; this is accompanied with a corresponding enlargement of the ventricles, which is immediately followed by their simultaneous contraction and the propulsion of their blood along the large arteries: then follows a pause, during which the auricles become gradually distended by the blood flowing along the veins. When the auricles are filled, they again contract, and the same train of phenomena just described occur in uniform succession.

Systole and diastole of the auricles.—The contraction or systole of the auricles is preceded by their relaxation or diastole. During the diastole the auricles become distended with the blood flowing along the veins. The commencement of the diastole occurs during the contraction of the ventricles; the latter part corresponds to the pause in the heart's action, and to the interval between the recurrence of the sounds of the heart, and is more or less long in proportion as the blood flows more or less rapidly along the veins.

The systole of the auricles is performed with great rapidity when the action of the heart is still vigorous, and appears to be effected by the simultaneous contraction of all its fibres. The terminations of the cavæ and pulmonary veins are seen to contract simultaneously with the fibres of the auricles, but sometimes they are seen to contract previous to the auricles, into which they expel their blood. In the cold-blooded animals this contraction of the terminations of the large veins extends over a greater surface, and is visible in the venæ he-

right ventricle is, in any material degree, temporarily distended or permanently dilated, the heart and lungs are relieved by a considerable reflux of the ventricle's contents into the auricle and systemic veins." In experiments upon the lower animals I have repeatedly seen the right ventricle, when gorged with blood and acting feebly, empty itself through an opening in the jugular vein. Edinb. Med. and Surg. Journ. 1836.

* Cheyne's English Malady, p. 307. 1734, London.

* The illustrious Harvey thus describes the difficulties which he experienced in his first attempts to analyse the movements of the heart: "ita ut modo hinc systolem, illinc diastolem, modo e contra, modo varios, modo confusos fieri motus me existimarem cernere."

paticæ.* Judging from the number of muscular fibres which surround the termination of the pulmonary veins in the human species, we would expect these contractions to occur to a greater extent in these veins than in the cavæ. These contractions in the veins must assist the *vis à tergo*, or the force with which the column of blood flows along the veins towards the heart, in limiting the regurgitation along these during the contraction of the auricles. This regurgitation along the veins appears to be to a small extent only when the circulation is proceeding in a natural manner, but becomes considerable where there is any impediment to the free passage of the blood into the ventricles, and when the blood becomes stagnated in the veins. When the actions of the heart are enfeebled, the contractions of the auricles are slower, and may become more or less vermicular, as I have myself occasionally observed. Two or more contractions of the auricle may also now be necessary before the languid ventricle can be excited to contraction. When the action of the heart is still more enfeebled, particular portions only of the auricles continue to contract. According to the observations of Harvey, Lower, Senac, Haller, and others, the contractions of the auricles are performed with considerable force.

Harvey states that he has observed that if the finger is applied to the ventricles in those cases where the action of the auricles continues after the contractions of the ventricles have ceased, a distinct beat is felt in the ventricle at each stroke of the auricle; and Senac, in quoting this, adds (evidently from his own observation) that it is similar to the pulse in the arteries. Senac also states that if an opening be made into the apex of the heart under those circumstances, a jet of blood rushes through it at each stroke of the auricle. He, however, admits that the contraction of the auricles in these cases is not sufficient to dilate sensibly the walls of the ventricles, but, of course, very considerable allowance ought to be made for the enfeebled state of the auricles at this stage of the experiment.† In the experiments of Dr. Hope, Mr. Carlisle, M. Bouillaud, and the Dublin Committee for investigating the cause of the sounds of the heart, the contraction of the auricles appeared to be comparatively trifling, and was most apparent in the appendices. From my own observations upon rabbits and dogs I am convinced that the auricles contract considerably more when the movements of the heart are proceeding in a natural manner, than some of these last experiments would lead us to believe, and that this contraction is not confined to the appendix, but extends over the whole auricle. When the circulation through the lungs becomes impeded, the right ventricle is then unable to empty itself, and the auricle of the same side (and this is the one that is most generally observed in such experiments) is consequently impeded in its movements. The auricles do not certainly exert the force or contract to the extent which some have stated, do not expel the whole of their contents, and their diastole is comparatively feeble; but that none of the muscular fibres of the auricles are passive, but exert a force proportionate to their strength, we have evidence both from experiment and the effects of disease. In some of those cases where an impediment to the passage of the blood from the auricle to the ventricle exists, all the muscular fibres of the auricles become much increased in thickness and in strength. As the left auricle has naturally greater difficulties to overcome in propelling its blood than the right, so we find that the left auricle is considerably more muscular than the right.* The appendix from its being loose, and supplied by a band of longitudinal fibres drawing it backwards, must enjoy a freer motion than the other parts of the auricle.

Systole and diastole of the ventricles.— When the heart is acting vigorously, the contraction of the ventricles succeeds immediately upon that of the auricles, so that they sometimes appear continuous; or, in other words, the sudden distention of the ventricles by the blood propelled into them during the systole of the auricles is rapidly followed by the contraction of the ventricles. The systole of the ventricles must occur during the diastole of the auricles. As we are only sensible of the systole of the ventricles from external examination during life, the expression *systole of the heart* is always employed as synonymous with the systole of the ventricles. When the action of the heart is a little less active, an apparent interval is observable between the completion of the contraction of the auricles and the commencement of the contraction of the ventricles, —the irritability of the ventricles being at this time somewhat impaired, their contraction does not so quickly follow their sudden distention. The ventricles during their systole are diminished in all their dimensions; the apex is drawn upwards to the base and tilted forwards so as to strike the parietes of the thorax between the cartilages of the fifth and sixth ribs.†

* The contractions of the different parts of the heart in cold-blooded animals have been observed to occur in the following order: first, the termination of the large veins, then the auricles, then the ventricles, and, lastly, the bulb of the aorta.

† I have convinced myself of the accuracy of these statements of Harvey and Senac in experiments upon dogs opened soon after they had been deprived of sensation.

* In the case mentioned by Allan Burns, where an ossific deposit covered the whole surface of the ventricles, so as to entirely, or nearly entirely, prevent their action, the auricles must have performed part of their functions for some time before death. In one of the experiments of Dr. Williams, of London, upon asses, he observed the circulation along the arteries continue although the ventricles were quiescent, and the auricles alone contracted.

† "Dr. C. J. B. Williams has, in a lecture lately published in the Medical Gazette (July 28, 1838, p. 692,) pointed out that, during a deep inspiration, the ribs are elevated without raising the heart in the same degree, and the impulse may be felt

The parietes of the ventricles at this time are firm and resisting, and present some rugæ on their outer surface. Haller* states that though the principal movement of the ventricles during their systole is from the apex upwards, yet he has sometimes observed a slight but distinct movement from the base downwards. The contraction of the ventricles is performed with great force, and, when vigorous, appears to be accomplished by the simultaneous action of all its fibres; but at other times, when it has become enfeebled, it has been observed to commence at the apex and extend itself upwards.

The diastole of the ventricles consists of two distinct stages. The first, which immediately follows its systole, is sudden, the apex being pushed downwards and apparently passing deeper into the chest, and is occasioned by the return of the heart to its state of rest. The second is also sudden, and attended by a rapid but not very extensive enlargement of the heart in all its dimensions. The parietes of the heart are soft and flaccid, and their external surface smooth during their diastole. The diastole of the heart is performed with considerable force, so that Pechlin, Perrault, Hamberger, and others long ago maintained that this equally with the systole is the result of a vital action. This opinion was again revived by Bichat, Dumas, and their followers, and is still introduced by some into the discussions upon the movements of the heart. Before we can admit an opinion of this kind, it would be necessary that very strong evidence be adduced in its favour, as it is at perfect variance with all that we know of the arrangement of the fibres of the heart, and of the laws of muscular contractility.†

Oesterreicher‡ has performed the following experiment, which appears nearly decisive on this point. When a body is placed on the heart of a frog heavy enough to press it flat, but sufficiently small to allow the heart to be observed, it will be seen that the body will be lifted during the contraction of the heart, but that during its extension it will remain flat. From this it appears that the extension of the heart after the contraction is not a muscular act. The diastole of the heart depends then upon two circumstances. 1st, Upon the natural elasticity of the organ, which it possesses in common with every other muscle, and by which it instantly resumes its state of rest as soon as its contraction has ceased. This, which is usually termed the relaxation of a muscle in whatever part of the body it occurs, must be expected to be more energetic in the heart than in the muscles of voluntary motion, as from the arrangement of its fibres a great part must be more strongly compressed. This occurs during the first of the two stages into which we divided the diastole. 2d, Upon its sudden distention during the contraction of the auricles, when we have every reason to believe that the ventricles are completely passive. This constitutes the second stage of the diastole. The blood must then pass from the auricles into the ventricles during each diastole at two distinct periods of time, corresponding to these two stages. During the first stage, or the relaxation of the ventricles, it flows from the auricles to fill up the vacuum produced in their interior; while, during the second stage, it is forcibly propelled by the auricles. It would be difficult to estimate the relative proportion of these two quantities of blood. Those who suppose that the contraction of the auricles is feeble must consequently believe that most of the blood passes from the auricles into the ventricles during the first stage.

It has been long disputed whether or not the ventricles empty themselves completely during each systole. It is very difficult to perceive anything like correct data upon this point in the warm-blooded animals with opaque hearts; but reasoning from analogy, from what we see in the cold-blooded animals whose hearts become quite pale during each systole, (not, as Harvey supposed, from the blood being pressed out of its parietes, but from the blood in its cavity, seen through its transparent sides, being almost entirely expelled during its systole,) we would be inclined to believe that little blood remained after each systole in the active state of the organ, while we can easily suppose that a greater or less quantity is left after each contraction when the organ is less vigorous.

It was the subject of a violent dispute at the commencement of the last century between the Montpellier and Parisian anatomists and physiologists, whether or not the heart became shortened or elongated during its contraction. In all the warm-blooded animals at least it undoubtedly becomes shortened.* We may at the same time state that the obliteration of the cavity of the ventricle depends much more upon the approximation of its sides than the drawing up of the apex.

Impulse of the heart.—It has been at various times, and still is by some late and modern experimenters,† maintained that the apex of the heart strikes the parietes of the thorax during

below the sixth rib. On the other hand, when the ribs are depressed, as during a deep expiration, the apex of the heart may be felt beating between the fourth and fifth ribs."

* El. Phys. tom. i. p. 400.

† Scharschmid supposed that certain pretended longitudinal fibres by shortening the heart enlarged its cavities, while the transverse fibres by contracting separately diminish its capacity.

‡ Müller's Handbuch der Physiologie des menschen, Erster Band, p. 163.

* The authority of Harvey has been quoted in favour of the opinion that the heart becomes elongated during its contraction, and certainly in one part of his work it is distinctly stated, that it is so to a certain extent: "Undique contrahi magis vero secundum latera; ita uti minores magnitudinis et *longiusculum*, et collectum appareat."

† Pigeaux, Stokes, Burdach, and Beau. Dr. Corrigan has, much to his credit, publicly renounced his previously published opinions on this question, after more accurate observations had convinced him of his error.

its diastole, and not during its systole. This is in reality what we would *à priori* expect, for it certainly does at first appear somewhat paradoxical that the heart should strike the parietes of the chest when the apex is approximated to the base. The concurrent testimony of the most accurate observers has, however, fully established the correctness of the fact. Harvey observed it in the human body when the heart had been exposed from the effects of disease.* One of the principal arguments adduced in support of this opinion by these authors was drawn from the fact that the pulse at the wrist is not synchronous with the impulse against the chest, an opinion which had been pretty generally maintained since the time of Aristotle. It is difficult to be convinced of this when the pulse is quick; but when it is slow, and in certain cases of disease of the heart, it can generally be satisfactorily ascertained. So far then they are right, but in the next and most important step of the argument they fall into a decided error; for they proceed upon the supposition that the pulse is synchronous in all the arteries of the body at the same time, and consequently the impulse of the heart at the chest cannot be synchronous with the flow of blood along the arteries, or, in other words, with the systole of the heart. In opposition to this opinion, Dr. Young† had previously shown upon the principles of hydraulics that the pulse along the arteries must be progressive, yet in general so rapid as to appear to arrive at the extremities of the body without the intervention of any perceptible interval of time. And when the attention of medical men was turned to this subject, various observers soon ascertained by repeated experiments that the pulse could be felt in favourable cases to pass along the arteries in a progressive manner, — that the pulse in the large arteries at the root of the neck and impulse at the chest are synchronous or nearly so, that both precede that at the wrist, and more distinctly still that of the dorsal artery of the foot.‡

Various attempts have been made to explain in what manner the apex of the heart is made to impinge against the parietes of the chest by those who maintain that it occurs during the systole of the ventricles. Senac supposed that this was principally effected by the curvature of the two large arteries, but principally of the aorta, which arise from the ventricles; for at each stroke of the ventricles when an additional quantity of blood is driven into the large arteries, as they are curved they make an attempt to straighten themselves; and as this takes place to a slight extent, the heart, which is attached to their extremities, ought to be displaced, and its apex, which describes the arc of a circle greater than the other parts of the heart, is thus made to impinge against the walls of the chest. He also believed that the distention of the left auricle with blood during its diastole has also, from its position between the spine and base of the heart, the effect of pushing the heart forwards; and this occurring at the same time with the attempt which the curved arteries make to straighten themselves, it thus acts as a second or subsidiary cause in tilting the heart forwards.* Though this supposed effect of the curvature of the large arteries has been a favourite explanation with many of the impulse of the heart against the chest, yet it really appears to have little, if any, influence in producing this. Shebeare,† and, more lately, Dr. Corrigan,‡ have shown that the direction of the curvature of the large arteries is such, that if any effect of this kind is produced, the heart would not be carried to the left side, but in the direction of the curve, which is exactly in the opposite direction. Besides the tilting forwards of the heart has been observed though no blood was passing along the large vessels at the time, and the same thing takes place after the large vessels have been cut through and the heart removed from the body.§ Haller and others have supposed that the secondary cause assigned by Senac,—viz. the sudden distention with blood of the left sinus venosus which lies impacted between the spine and left ventricle,—is the principal if not the sole cause by which the heart is pushed forwards against the ribs. In confirmation of this opinion Haller states ‖ that if we inflate the left auricle after having opened the chest, we see the point of the heart approach with vivacity the region of the mamma. As we cannot, however, under these circumstances distend the auricle without also distending the corresponding ventricle, this movement of the heart depends more upon the sudden inflation of the ventricle than upon any

* "Simul cordis ipsius motum observavimus, nempe illud in diastole introrsum subduci et retrahi; in systole vero emergere denuo et protrudi fierique in corde systolem quo tempore diastole in carpo percipiebatur: atque proprium cordis motum et functionem esse systolem: denique cor tunc pectus ferique et prominulum esse cum erigitur sursum." As quoted by Shebeare, Pract. of Physic, vol. i. p. 195.

† Phil. Trans. 1809.

‡ It is interesting and curious, as shewing the revolution of opinions, to compare the strict similarity of the arguments adduced by the modern supporters of this doctrine with those maintained by Shebeare in 1755. (Practice of Physic, vol. i. p. 193.) "This, however plausible it may appear, cannot be the true cause of it (impulse of the heart), because then this stroke must be during the systole of the ventricles, which would be synchronous with the diastole of the arteries; whereas the beating of the heart precedes the dilatation of the arteries, and thence this stroke must be made during the diastole of the ventricles: thus the diastole or distention of the heart is the cause of the beating against the ribs."

* Op. cit. tom. i. p. 356. The cause of the tilting motion of the heart was also, at a later period, attributed to the curvature of the aorta and to this exclusively by Dr. W. Hunter. Note in John Hunter's Treatise on Inflammation, p. 146, 1794.

† Op. cit. p. 195.

§ Dr. Carson (Inquiry into the Causes of the Motion of the Blood, p. 183.) maintains that no proof can be adduced that the curvature of the aorta is rendered more straight during the systole of the heart.

‖ Sur le Mouvement du Sang, p. 124.

distention of the auricle, as any one may easily satisfy himself by repeating the experiment. Besides, the distention of the auricles by the blood flowing along the veins is too gradual for this sudden and rapid impulse of the heart; nay more,—the impulse may be observed when no blood is flowing into the auricles. Sabatier* believed that this impulse depends upon two causes,—1st, principally upon the distention of the auricles, more particularly the left; and, 2dly, upon the curvature of the large arteries. Apparently, however, perceiving the necessity of there being a sudden distention of the auricles to produce this, he supposed that this was effected by the auriculo-ventricular valves. He argued that, as these valves during the diastole of the heart form a cone stretching from the base towards the point of the ventricle, which is full of blood when the systole commences, when the valves are carried upwards to obstruct the auriculo-ventricular orifices, this blood is pushed before them into the auricles, producing a reflux into the auricles, which, with the blood flowing along the cavæ and pulmonary veins, causes a sudden distention of the auricles, which pushes the ventricle forwards.† Meckel appears to have adopted the opinions of Sabatier. We need not repeat our objections to this explanation. Dr. Alison, perceiving the insufficiency of all these explanations, has for a considerable time past suggested in his lectures, that this might be explained by the arrangement of the fibres, "more particularly by the irregular cone which they form, being *flattened posteriorly*, and by the consequent greater mass of fibres on the anterior surface." More lately Mr. Carlisle ‡ has also attempted to explain this by the greater length of the anterior fibres of the heart than of the posterior. As the shape of the ventricles is an oblique cone, and as they have their longest sides in front, he argues, "that it is a law of muscular contraction that fibres are shortened during their contraction in proportion to their length when relaxed. For instance, if a fibre one inch long lose by contraction one-fourth of its length, or one quarter of an inch, a fibre two inches in length will lose one inch by contractions of equal intensity. The apex then does not approach the base in the line of the axis of the ventricles, but is drawn more to the side of the longer fibres, that is, towards the front, thus producing the tilting forwards." We believe that it may be proved on mechanical principles, that though the anterior and left surfaces of the ventricles are considerably longer than those on the posterior and right, yet during their contraction, when they are drawn towards their fixed attachments, if the fibres are of equal thickness, the apex will be drawn up nearly in the diagonal of the two forces, and that if any tilting upwards of the apex take place, this will be only to a small extent, and be quite insufficient to account for the impulse felt at the chest. We must therefore look to some other circumstances besides a mere difference in length of the two surfaces to account for this. Mr. Alderson* has ingeniously attempted to apply the law of action and reaction between bodies,—one of considerable importance in mechanical philosophy, and upon which Barker's centrifugal mill has been constructed. Unfortunately, however, for this explanation, the axes of the large arteries and the direction in which the apex is tilted do not by any means accord. Dr. Hope's supposition that "the retropulsion of the auricular valves" may assist in producing this impulse, "as these act on a column of blood which offers a greater resistance than the weight of the heart, the action is reflected on the organ itself and impels it forwards," is, on the other hand, completely opposed to the law that action and reaction are the same. As well may a man attempt to propel a boat by standing in the stern, and push with an oar against the prow. Dr. Filhos attributed the impulse to the spiral turns of the fibres at the apex of the heart attempting to straighten themselves during their contraction, and so raise themselves suddenly and throw themselves forwards. The objections to this explanation are so palpable that they must occur to every one. Since the tilting of the apex of the heart forwards is observed after the blood has ceased to flow through its cavities, it is obvious that we must look for the cause of this in the arrangement of the muscular fibres themselves, though it may be difficult to point out that particular arrangement. It appears to me that the distribution of some of the strong bands of fibres, the course of which I have already described when treating of the muscular tissue of the heart, may satisfactorily account for it. We there pointed out that several strong bands of fibres arise from the base of the septum between the ventricles, pass downwards and form part of the septum, then emerge from the anterior longitudinal groove (*fig.* 274, *d*), and wind round in a spiral manner to form both the anterior and posterior part of the lower portion of the heart. On entering the apices of the ventricles, (principally the left,) the fibres are scattered over their inner surfaces, and while a great number of them go directly to be inserted into the tendinous rings, others form part of the columnæ carneæ. We have thus strong bands of fibres attached by one extremity (their septal extremity) to the base of the ventricles at a point pretty far posterior, while at the other extremity many of the fibres are loose, or at least only attached to the tendinous rings through the media of the chordæ tendineæ and valves, which must admit of a certain degree of contraction of these fibres before they become tense. At each systole of the heart when these fibres act, it is evident that the tendinous rings must form the fixed points towards which all these fibres contract; and since they are by one extremity all closely and directly connected to a

* Traité complet d'Anatomie, tom. ii. p. 230.

† Dr. Bostock has failed of his usual accuracy in detailing the opinion of Sabatier on this question.

‡ Transactions of British Scientific Association, vol. iii. Dublin Journal of Medical Science, vol. iv.

* Quarterly Journal of Science, &c. vol. xviii. p. 223.

fixed attachment, viz. the tendinous rings, while by their other extremity part only are directly attached to the tendinous rings, the other part being loose, or at least only connected to the tendinous rings through the lax chordæ tendineæ and valves, it must follow that the force with which the contraction takes place towards the septal extremity must preponderate over the other. If these bands of fibres had been as closely connected to the tendinous rings at the one extremity as at the other, then the force of the contraction towards both would have been equal; but since this is not the case, the apex must be carried forwards at the same time that it is drawn upwards towards the base. This forward motion may also probably be assisted by another arrangement of the same fibres which we have been describing; for some of these muscular bands are attached by their inner extremity to the anterior part of the left auriculo-tendinous ring, so as to form loops, the greater part of which lie more in front than behind the axis of the heart, and may have a tendency, when in a state of contraction, to draw the apex forwards and upwards. Now when we remember that by this elevation of the apex forwards, the heart, before placed obliquely, now becomes more horizontal, and consequently more approximated to the walls of the chest,—the more particularly as the transverse diameter of the chest diminishes rapidly as we proceed from below upwards, we believe that we have here sufficient to account for this impulse against the chest. As the proximity of the apex of the heart to the chest is affected by the position of the body, as we have already pointed out, this circumstance ought to be attended to in judging of the strength of the impulse of the heart.

What parts of the heart most irritable.—The inner surface of the heart is considerably more irritable than the outer. In experiments, when the heart has become quiescent, and refuses to obey a stimulus applied to the outer surface, it frequently contracts readily for a short time after this when air is introduced into its cavities, or when any other stimulant is applied to its inner surface. After death the different cavities of the heart generally lose their contractility in the following order, the left ventricle, the right ventricle, the left auricle, and last of all the right auricle.* And as the heart is generally the part of the body which shews the latest evidences of contractility, the right auricle has long received the name of *ultimum moriens.* Haller supposed that the greater persistence of contractility in the right side of the heart over the left might depend on the circumstance that the right side of the heart generally contains a greater or less quantity of blood after death, while the left side is generally empty. In this manner the inner surface of the right side of the heart is subject after death to the presence of a stimulant from which the left side is comparatively free. He put this opinion to the test by performing repeatedly the following experiment.* He emptied the right side of the heart by the section of the pulmonary artery and venæ cavæ, having previously retained the blood of the left side by passing a ligature around the aorta. The experiment succeeded many times: the right auricle remained perfectly immoveable, and the only motion which the right side retained arose from the connexion of its fibres with those of the left ventricle. The left auricle retained its movements for a certain time, the ventricles during a longer period, sometimes even for two hours. He adds, we thus transfer from the right auricle to the left ventricle the property of being the last living part in the body, in preserving for it during a longer period the irritation produced by the contact of blood. These experiments of Haller certainly shew that the left side of the heart will continue to contract longer than the right where it is subjected to a stimulant of which the other is deprived; but they do not entitle us to conclude that the persistence of their contractility is the same when placed under similar circumstances. We have every reason for believing that the right auricle is the part of the heart which last loses its contractility. Indeed Haller himself confesses, that if any part of the heart remains longer contractile than another, it is the right auricle. Nysten,† who performed a number of experiments upon the comparative persistence of the irritability in the different contractile parts of the body in the human species, after decapitation by the guillotine, and when the heart was consequently emptied of its blood, obtained the following results upon the order in which the different parts of the heart lose their contractility:—1st, the left ventricle, the contractility of which is annihilated much more quickly than that of the other organs; 2d, the right ventricle, the movements of which generally continue more than an hour after death; 3d, the two auricles, the right being of all the parts of the heart that which preserves for the longest time its contractile power.

The stimulant used in these experiments was galvanism. The greater persistence of the contractility in the right auricle over the other parts of the heart has been observed by other experimenters, after it had been cut from the body, and consequently without any contained blood. The particular part of the auricle which last loses its contractility varies in different cases. Sometimes the appendix is found contracting when the rest of the auricle is quiescent; at other times, and perhaps more frequently, those parts of the auricle around the entrance of the venæ cavæ retain their contractility longest.

* There is occasionally considerable variety observed in the order in which the different cavities lose their contractility after death. The left ventricle has been seen to contract after the right auricle; and Haller has observed in experiments upon cats the irritability of the left auricle first cease. In experiments upon dogs I have seen the ventricles contract after the auricles had ceased to do so.

* Sur le mouvement du sang, p. 172. Similar experiments were performed by Walther with the same results: Experimenta de vivis animalibus, p. 11, as quoted by Burdach.

† Recherches de Physiologie, &c. p. 321.

Harvey and some of the older anatomists observed the movements of the venæ cavæ to continue in some of the lower animals after the auricles had ceased to move. The apex of the ventricles frequently remains longer contractile than the rest of the ventricle. Haller suggested that this might depend on the remaining blood gravitating to the apex, and there acting as a stimulant.

Duration of contractility after death.—In the cold-blooded animals the heart may be made to contract fourteen, twenty, thirty-four hours, or even longer after death. In warm-blooded animals the heart remains contractile for a much shorter period after death than in cold-blooded animals. Haller found the heart contractile in a warm-blooded animal in one case four hours after death, and in another seven hours. He sometimes observed it to cease before the vermicular motion of the intestines. Wepfer found it irritable in a dog six hours after death. Nysten, who attended particularly to this subject, found in one of his experiments on the human subject, that the ventricles refused to contract upon the application of galvanism one hour after decapitation, while the auricles continued contractile for seven hours five minutes after death.* In another case the right auricle was still contractile eight hours after death;† and in a subsequent case which he relates, it remained contractile in the neighbourhood of the entrance of the superior cava sixteen hours and a half after death.‡ In the Mammifera, Nysten found that the left ventricle often refused to contract thirty minutes after death; that the right ventricle retained its contractility two hours, and sometimes longer, while the right auricle was not quiescent upon the application of the galvanism until eight hours after death.

He found it to vary in birds according to the degree of muscular activity which they enjoyed during life. In those of high flight, and which exercise great muscular contractility during life, and have a rapid circulation, as the sparrow-hawk, the irritability of the heart and other muscles becomes much more speedily exhausted than in those the movements of which are comparatively slow and feeble, as in most domestic fowls.§ Nysten supposes that the explanation of the greater persistence of contractility of the right ventricle over the left lies in the circumstance that the left acts with greater vigour during life, thus referring it to the important general law which he has established by his experiments upon the comparative excitability of the muscular tissue in the various classes of animals, that the duration of the contractility after death is in the inverse ratio of the muscular energy developed during life.|| Before we could admit this explanation, it would be necessary to show, what we believe it will be found impossible to do, that the left ventricle, apart from its greater quantity of muscular fibre, exerts greater strength or exhibits more energetic contractions during life than the right ventricle. In young animals, immediately after birth, the contractility of the heart continues longer after death than in the adult animal. We would expect this to be most apparent in those which are born with their eyes shut, as puppies and kittens, and in those birds which are hatched without feathers, since these animals at that period of life approach in their physiological conditions to the cold-blooded animals. There is a curious circumstance stated by Mangili, and confirmed by Dr. Marshall Hall, connected with the hybernation of animals, that if those mammalia which hybernate are killed while under a state of lethargy, the heart and other muscles remain contractile for a longer period than when they are killed in a state of activity, thus resembling, when under the influence of this lethargy, in this as in many other respects, the physiological condition of the cold-blooded animals. The contractions of the heart may frequently be renewed by the application of warmth after they have apparently ceased. I have repeatedly observed the fact which has been stated by Haller and Nysten, that when any of the cavities of the heart become congested with blood, their contractility becomes arrested, and, in their opinion, extinguished.* I have also found that unloading the right side of the heart soon after the congestion has taken place, which can be done in many cases by opening the external jugular vein, acts as a valuable adjuvant under certain circumstances in renewing the heart's action. These it would be out of place to discuss here; but I may state that it appears to me to be principally useful in certain cases of poisoning, in asphyxia, and after the accidental entrance of air into the veins. Since the introduction of a considerable quantity of air into the veins produces death by mechanically arresting the movements of the right side of the heart, we believe that circumstances may occur in which the surgeon may be justified in introducing a tube into one of the large veins passing into the upper part of the chest, and suck-

* Op. cit. p. 316.

† Page 318.

‡ In these experiments all the other parts of the body lost their contractility before the right auricle.

§ Op. cit. p. 349.

|| Dr. Marshall Hall (Phil. Trans. 1832) has more lately laid it down as a general law that the irritability of the heart and other muscles is in the inverse ratio of the oxygen consumed in respiration. Various experimenters distinctly show that as we descend in the scale of animals the quantity of oxygen consumed diminishes, and that Birds consume more than Mammalia. Dr. Edwards has also shown that the young of the Mammalia deteriorate the atmospheric air less rapidly than the adult animals; and the experiments of Mangili and Prinella prove that hybernating animals, when in a state of lethargy, consume exceedingly little oxygen, so that there is evidently some relation between irritability and the quantity of oxygen consumed in respiration; but for the proof that the irritability is exactly in the inverse ratio of the respiration, we must wait for Dr. Marshall Hall's promised experiments.

* Haller supposed that this was effected, as must be if allowed to continue for any length of time, by the too great distension of the muscular fibres, in the same manner as distension of the bladder produces paralysis of its fibres.

ing the frothy blood from the right side of the heart. It is also necessary to remember this circumstance in experimenting upon the length of time during which the heart remains contractile after death, as the division or non-division of the large veins at the root of the neck in laying open the thorax may considerably modify the results.*

For the probable force exerted by the heart, the share which the heart has in carrying on the circulation, and the probable quantity of blood expelled at each contraction, see the article CIRCULATION.

Frequency of the heart's action.—The frequency of the heart's action is considerably modified by age, condition of the other functions of the body at the time, by mental emotions, and by the original constitution of the individual. Its movements are influenced by very slight muscular exertion, and the extent of this appears to vary at different times of the day. In the fœtus its movements are rapid, being about 140 in the minute. At birth it is from 130 to 140; at one year 115 to 130; second year 100 to 115; third 90 to 100; seventh 85 to 90; fourteenth 80 to 85; middle age 70 to 75; in very old age 50 to 65. The heart's action generally sympathises powerfully with the other organs of the body, and this has always been regarded as a most important and necessary guide in the detection and cure of diseases.

It becomes strong and rapid in some cases of inflammation, while in others it becomes rapid and feeble. It becomes quicker after eating and slower during sleep. It is much increased in frequency during bodily exertion. In cases of great general debility it becomes very quick and feeble. It becomes more rapid and weaker during inspiration, slower and stronger during expiration.

It is an important fact that when the contractility of the heart is much enfeebled by extensive injuries of the central organs of the nervous system or of the other parts of the body, (as when a limb is extensively crushed,) its contractions are not only much weaker, but are also greatly increased in frequency. It is also worthy of remark that such injuries do not produce convulsive movements in this organ. The effect which severe injuries and certain inflammatory affections have in greatly debilitating or even destroying the contractility of the heart is a fact of great practical importance, as it not only explains the cause of the most alarming symptoms in such cases, but also points out the most appropriate remedies to avoid the chief tendency to death. To this cause, for example, we are to attribute the rapid and feeble pulse, in concussion of the brain, in extensive mechanical injuries, the shock after operations, extensive burns, peritonitis, &c. It is very fortunate that the contractions of the heart become more frequent when its contractility becomes enfeebled. If the heart under these circumstances had required, as we would *à priori* expect, the presence of a greater quantity of blood to stimulate it to contraction, instead of a smaller quantity, as is actually the case, what would have been the consequence? It is evident that since the resistance, under ordinary circumstances, which the heart has to overcome in contracting, is, according to a well-known hydrostatic law, in proportion to the extent of the area of the inner surface of the cavities of the heart at the commencement of their contraction, (each square inch of surface, according to the experiments of Hales, having a pressure upon it nearly equal to four pounds,) the more frequent contractions, where there is a smaller quantity of blood present in the heart at the commencement of each contraction, will not demand the same degree of muscular force for their performance, as if these had been less frequent. If, when the contractility of the heart became debilitated, the presence of a greater quantity of blood than usual in its interior had been necessary to stimulate it to contraction, and if the area of the inner surface of the cavities of the heart be in proportion to the quantity of blood contained there, it is apparent that the movements of the heart would have been much more rapidly and frequently arrested when its contractility became enfeebled, than they are under the actual arrangement.

The influence of mental emotions upon the movements of the heart requires no illustration, for this is so universally experienced that in common language the heart is considered to be the seat of the affections and passions, and this has had a powerful influence upon the phraseology of all languages.

In sanguine temperaments the heart generally contracts more frequently than in phlegmatic temperaments. In women it is also generally a little quicker than in men.

It varies very much in different classes of animals.

Burdach* has given the following table collected from numerous sources, as an approximative valuation of the frequency of the heart's action in various animals.

Number of pulsations in a minute.†

In the Shark	7
Mussel	15
Carp	20
Eel	24
Snake	34
Horse	36
Caterpillar	36
Bullock	38

* Edinburgh Medical and Surgical Journal, 1836. When I performed these experiments, I was not aware that I had been anticipated to a certain extent by Mr. Coleman. (Wilson on the Blood, &c. p. 131.) It is very possible that the sinuses upon the inferior cava and hepatic veins in the seal may, besides answering other purposes, have the effect of preventing this mechanical distension of the right side of the heart.

* Physiologie, vol. iv. p. 251.

† We cannot consider the number of pulsations of the heart in a minute given in the above table as by any means quite satisfactory. The number of pulsations in the ox and horse is given on the authority of Vetel in Froriep, Notizen, t. xxiv. p. 112. Other observers state the number of pulsations in a minute at from 38 to 52 in the horse, and from 64 to 70 in the ox.

For the effects of the respiration upon the contractions of the heart, and the influence of the circulation of dark blood upon its irritability, see ASPHYXIA.

The cause of the motion of the heart.—The motion of the heart, and the constancy and regularity of its movements, are circumstances so remarkable that they could not fail early to excite a deep interest among medical philosophers when they had once turned their attention to the explanation of vital phenomena. When we contemplate the heart commencing its movements at an early period of fœtal existence, and never resting from its apparently unceasing toil until the latest moments of life, and when we remember the uniform and regular manner in which all its actions are accomplished—all conspiring for the proper performance of the deeply important functions assigned to it, we are at first impressed with the idea that it is regulated by laws different from similar textures of the body, and altogether peculiar to itself. It must have been under the influence of similar impressions that the older medical philosophers approached this subject, and it is in this manner only that we can account for many of the strange speculations on the heart's action which they have left recorded.

We find one sect attempting to explain it by a peculiar innate fire. Sylvius, the head of the chemical sect, had recourse for its explanation to an effervescence excited by the intermixture of the old and alkaline blood with the acid chyle and acid pancreatic lymph.* Descartes supposed that a constant succession of explosions occurred in the heart from steam generated there, which propelled the blood through the body. Stahl got at once out of the difficulty by affirming that the heart was more particularly under the guidance of the anima or soul. But we cannot here dwell longer on these obsolete and to us in the present time almost incredible opinions, and the only use to which they are now applicable is to serve as beacons to keep us, in all our inquiries into the phenomena of living bodies, within the strict path of facts and observation, and to forcibly impress upon us into what strange and fatal errors even the brightest intellects may fall, when they leave the inductive method of investigation, and wander into the alluring but dangerous regions of hypothesis. And the effects of these errors are only the more to be dreaded as they are often clothed in the most seductive ingenuity. It ought also still more forcibly to inculcate upon us the important truth, which, though generally in our mouths, is not unfrequently forgotten in practice,—that as the material world and all which it contains have been placed by the Author of Nature under arbitrary and fixed laws, it is impossible to extend our knowledge of these by theorizing in the closet, and that this can only be effected by the patient interrogation of Nature herself.

It was not until the time of Senac and Haller that accurate notions began to be entertained on the nature of the heart's action.

The cause of the movements of the heart is distinctly referable to the same laws which regulate muscular contractility in other parts of the body, only modified to adapt it for the performance of its appropriate functions. Like all the other muscles it is endowed with irritability, which enables it to contract upon the application of a stimulus. The ordinary and natural stimulus of the heart is the blood, which is constantly flowing into its cavities. The greater irritability of the inner surface over the outer is evidently connected with the manner in which the stimulus is habitually applied. When the blood is forced on more rapidly towards the heart, as in exercise, its contractions become proportionally more frequent; and when the current moves on more slowly, as in a state of rest, its frequency becomes proportionally diminished. If the contractions of the heart were not dependent upon the blood, and their number regulated by the quantity flowing into its cavities, very serious and inevitably fatal disturbances in the circulation would soon take place.

As the heart continues to contract often for a very considerable time after the venæ cavæ have been tied, and after the blood has ceased to pass through its cavities, or after it has been removed from the body, this has been supposed by some to indicate that there is something in the heart's structure or in its vital properties which enables its movements to proceed independent of all other circumstances. But in all these cases a stimulus has been applied in some form or other to the heart. If the heart has been allowed to remain in its place, though the circulation of the blood may have come to a stand, part of it may yet remain in the different cavities of the organ; or if the pericardium has been opened, the impression of the external atmosphere may act as a stimulus. The experiments of Walther and Haller formerly mentioned upon the comparative irritability of the

* In the same manner Borelli says, "Constat ex dictis immediatam causam motivam cordis esse ebullitionem fermativam tartarei succi sanguinei excitatam à commistione succi spirituosi à nervis instillati." De Mutu Animalium, p. 97.

two sides of the heart, and the different results obtained when the one side of the heart was emptied of blood, and when it was retained in the other, are sufficient to shew the effect which the presence of blood in the cavities of this organ has upon the continuance of its action after the circulation has ceased. If the heart has been removed from the body and emptied of its blood, it must naturally follow that its different cavities will be filled with atmospheric air; and it has been well ascertained that this acts as a very powerful stimulant upon the inner surface of the heart.* Every circumstance connected with these experiments is in exact conformity with the opinion that the movements of the heart are only called into action by the application of a stimulant. Thus, when the irritability of the heart becomes more languid, and when the blood or the atmospheric air in its cavities becomes insufficient to raise it to contraction, strong and energetic movements may still generally be excited by having recourse to a more powerful stimulant, such as the prick of a scalpel or the application of galvanism. Since the heart is highly endowed with irritability, various other mild fluids besides the blood are capable of exciting it to contraction. As every organ, however, has its irritability adapted for the function which it is destined to perform, so we find that the heart, the central organ of the circulation, is most fitly called into action by the blood, its appropriate and natural stimulant.

In examining the nature of the irritability of the heart, and contrasting it with that of the voluntary muscles, we must not compare its contractions with those excited by volition in the muscles of voluntary motion, for these last are evidently modified by the nervous influence for an obvious purpose; but let us observe both when placed under similar circumstances, and irritated by the application of the same stimulant applied to the muscles themselves, and we will find that they only differ in this,—that in the voluntary muscles each successive application of the stimulant is generally followed by a single contraction, while in the heart it is followed, except when the contractility is much impaired, by several consecutive contractions alternated with relaxations. This tendency to successive contractions is also observed, though not to the same extent, in the muscular coat of the intestines.

We must admit, however, that the contractions of the heart proceed under circumstances where it is difficult to point out the presence of any sufficient stimulus, and where, to account for their continuance, we are almost obliged to have recourse to the supposition, that there is some innate moving power in the heart itself. It has been stated, for example, that the movements of the heart will proceed under the exhausted receiver of an air-pump. I have repeatedly placed under the bell-glass of an air-pump the heart of a frog when removed from the body and emptied of its blood, and I could never satisfy myself that the frequency or strength of its contractions was at all affected by the withdrawal or renewal of the air; and though it might be urged that the air is only rarefied, not entirely removed, in the best exhausted receiver of an air-pump, and that consequently in such experiments a stimulant still existed in the presence of the rarefied air, yet I would not consider this explanation of the continuance of its contractions by any means satisfactory. In these experiments there is another source of stimulation present which ought to be taken into account, for, as I shall afterwards shew, the slightest movement of the heart, such as that caused by its contraction, upon the surface upon which it is placed when removed from the body, is sufficient, from the great irritability of the organ, to act as a stimulant upon it. If these external stimuli appear to be insufficient to account for the persistence of the contractions of the heart under the circumstances we have mentioned, we may have recourse to another explanation drawn from the mechanical structure of the organ; for it is possible, as has been suggested by Dr. Alison, that from the peculiarly convoluted arrangement of the fibres, the outer may, during the contraction of the organ, pinch or stimulate the inner, and so cause this tendency to repeated contractions from one application of a stimulant. We do not, however, consider that we have succeeded perfectly in accounting for the continuance of the contractions of the heart under all circumstances, but we are unwilling to admit the existence of any peculiar innate and unknown agency in the production of any phenomenon, until it is satisfactorily established that it cannot be accounted for on the known laws which regulate similar phenomena in the same texture in other parts of the body. And it must also be remembered that these movements of the heart have only been observed when its contractility was still comparatively vigorous, and where sources of stimulation were still present. We ought, besides, to be the more cautious in admitting the existence of this innate moving power, since it is in opposition to a well-known law in the animal economy,—that though the various tissues of an organized body are endowed with certain vital properties, yet the application of certain external and internal stimuli is necessary to produce their manifestations of activity. In fact it is from the action and reaction of these tissues and excitants upon each other, that the phenomena of life result.*

* Peyer, Brunner, and Haller have seen the contractions of the heart renewed by blowing air into the cava ascendens. Wepfer and Steno produced the same effect by inflation of the thoracic duct. Enman states that he once observed the renewal of the heart's action in the human subject by blowing air into the thoracic duct. Vide Senac, tom. i. p. 326.

* The remarks which we have made above, illustrating the great length of time which the heart will continue to contract after being removed from the body, and when all communication between the nerves ramified in its substance and the sympathetic ganglia and the central organs of the nervous system have been cut off, when taken along with the equally well ascertained fact, that its contractions

Upon what does this irritability of the heart depend?—This has been one of the most keenly agitated questions in physiology, as a great part of the experiments, and much of the reasoning upon the nature of *muscular irritability*, have been furnished by this organ. As, however, the general doctrines entertained on this subject have already been fully discussed under the article CONTRACTILITY, we shall here confine ourselves to a few of the leading facts connected with it which have a special reference to the heart. The two principal questions on this point since the time of Haller have been, whether does it depend upon nervous influence? or is it a property of the muscular fibre itself independent of the nerves?

We have seen that the nerves distributed upon the heart are the par vagum and sympathetic. Numerous experimenters have removed portions of the par vagum on both sides of the neck without the slightest diminution of the strength of the contractions of the heart. These experiments we have frequently performed with the same results. There can now be no doubt that the sudden death which occasionally follows this operation is not to be attributed to the cessation of the heart's action, as some of the older experimenters believed, but, as Legallois has shewn, it depends upon an arrestment of the movements of the muscles attached to the arytenoid cartilages. Portions of the sympathetic have also been destroyed in the middle of the neck without any effect upon the contraction of the heart, except what could be sufficiently accounted for by the pain of the incisions and the terror of the animal. A portion of both of the sympathetic and pneumogastric nerves may be removed in the neck with the same results; in fact we cannot, in the dog and most quadrupeds, cut the par vagum in the middle of the neck without also dividing the sympathetic. Magendie affirms that all the sympathetic ganglia of the neck, along with the first dorsal, may be removed without any sensible derangement of the parts to which their nerves are distributed. Brachet* supposes that the reason why the excision of the sympathetic ganglia in the neck does not always arrest the heart's action, is because there is another source of nervous influence for the cardiac nerves placed below this in the cardiac plexus or ganglion. He accordingly put this opinion to the test of experiment, and he assures us that the total destruction of the cardiac plexus was followed by the sudden and permanent arrestment of the heart's action. Now when we consider the nature of such an experiment as this, with the chest of the animal laid open, the respiration arrested, and the heart exposed during the time the experimenter is searching and tearing for the plexus placed deep behind the aorta and pulmonary artery, and which would require a considerable time to display even in the dead body when unembarrassed by the movements of the heart, we must be more astonished that the action of the heart had not completely ceased before the experiment was finished, than that it should have continued so long. Besides, even allowing that this experiment could be relied upon, we have sufficient evidence, from the facts stated above, to entitle us to conclude that the heart is not dependent for its movement upon any influence constantly transmitted along its nerves from the central organs of the nervous system,—the brain and spinal marrow. Brachet is himself obliged to admit, from other experiments which he performed, that the division of the sympathetic at the lower part of the neck is not sufficient to arrest the heart's action, so that this experiment is intended to shew that its irritability depends upon the ganglia of the sympathetic itself. The independence of the irritability of the heart upon the brain and spinal marrow can be very satisfactorily proved in another manner. The occurrence of acephalous monsters,* and the experiments of Wilson Philip,† Clift,‡ and Brachet§ demonstrate that the brain or spinal marrow may be naturally wanting; that one or both of them may be removed entirely, or destroyed in small portions at a time, without arresting the heart's action. We may here observe that the experiments of Legallois,‖ Wilson Philip, Wedemeyer,¶ Brachet, and many others, in which the action of the heart was arrested by crushing large portions of the brain or spinal marrow, though they do not prove the dependence of the irritability of the heart upon the brain and spinal cord, at least shew, what the effects of mental emotions upon the movements of the heart had already pointed out, that it can be influenced to a great and most important extent through these organs. The advocates for the dependence of the irritability of the heart upon the nerves appear to have pretty generally abandoned the opinion that this is derived from the central organs of the nervous system, and now maintain the doctrine, which was more prominently developed by Bichat, that this is derived from the sympathetic, the ganglia of which, according to him, are independent sources of nervous influence. From the manner in which the sympathetic is distributed upon the heart, it is

may be readily increased or renewed under those circumstances, by mild excitants applied to its inner surface, are completely opposed to the supposition that the heart is called into contraction in a manner similar to those sympathetic movements more lately described under the term excito-motary. Though this mode of explanation may be considered quite legitimate when applied to those sympathetic movements which do not require the intervention of the brain for their performance, such as deglutition, respiration, &c., it is certainly pushing the doctrine far beyond its proper limits to apply it to the explanation of the movements of the heart.

* Du système nerveux ganglionaire, p. 120.

* The heart is generally though not always absent in acephalous monsters.

† Experimental Inquiry into the vital functions.

§ Système nerveux ganglionaire.

‖ Legallois performed these experiments on the spinal cord alone, and supposed he had proved that the movements of the heart were dependent upon that portion of the nervous system.

¶ Physiol. Untersuchungen über das Nervensystem, &c. p. 235.

perfectly impossible to insulate that organ from the nerve and experiment upon it; but we think we are justified in concluding from observations and experiments derived from other sources, that in all probability the contractility of the heart depends upon a property possessed by the muscular fibre itself without any necessary intervention of its nerves. The possibility of exciting or increasing the action of the heart by stimuli applied to its nerves has been mixed up with this question. Though it must be admitted that mechanical and chemical stimulants applied to a considerable surface of the central organs of the nervous system quicken the heart's action, yet experimenters have generally acknowledged that these stimulants applied to the nerves of the heart produce no effect upon its movements. Burdach,* however, maintains that he has quickened the heart of a rabbit deprived of sensation by applying caustic potass to the trunk of the sympathetic, or its inferior cervical ganglion. That the heart can be excited to contraction by the application of galvanism has had many supporters, and many celebrated names are arranged both on the affirmative and negative sides of the question. That the movements of the heart may be increased or renewed by the application of galvanism as the experiment is usually performed, there can be no reasonable doubt; for if one wire is placed upon the nerve and the other upon the heart, the moist nerve will act as a conductor to the electricity, and the effect produced will be the same as if the stimulant had been applied to the substance of the heart itself. Nysten admits that movements of the heart were excited by the galvanism when one of the wires was applied to one of the large arteries from which all the visible filaments of the nerves had been dissected off. Dr. C. Holland,† in a number of experiments, satisfied himself that the tissues of the body conduct galvanism with so much facility, that the heart's action could readily be excited, when one wire was placed upon the heart and the other in the nose, mouth, and even among the moist food in the stomach. I have performed similar experiments with the same results. Humboldt and Brachet assert that they have quickened the movements of the heart by applying both wires to one of the cardiac nerves. If these and the experiments of Burdach could be relied upon, they would be sufficient to prove that the heart could be occasionally stimulated through the cardiac nerves, but the negative experiments on the other side are so numerous, and the sources of fallacy in judging in this manner of the relative quickness of the heart's action between one time and another so obvious, that we must be allowed to distrust them unless they should be confirmed by other accurate observers.

Constancy of the heart's action.—The constancy of the heart's action is more apparent than real. After each contraction a state of relaxation follows. The relative duration of the contraction of the auricles and ventricles, according to Laennec, appears to be as follows:—a third at most, or a fourth or a little less by the systole of the auricles; a fourth or a little less by the state of quiescence; and the half or nearly so by the systole of the ventricles. From this he calculates that the ventricles, when the heart is acting with its usual frequency, rest twelve hours out of the twenty-four, and that in those individuals in whom the pulse is naturally below 50, it must be in a state of relaxation sixteen hours out of the twenty-four.* Now this is a degree of contraction of which many muscles of the body are probably susceptible, such as the muscles which support the trunk when we sit or walk, and which some, as the diaphragm and intercostals, generally perform.

Regularity of the heart's movements.—The regularity of the heart's movements, so essential to the welfare of the animal, has appeared, even to many modern physiologists, to be intimately connected with some peculiarity in its structure. We are inclined, however, to agree with Haller, that this is perfectly explicable on the known laws of muscular contractility in other parts of the body. The regularity of the heart's action was another fertile subject of hypothesis to the older physiologists; and even in the present day we find the term "*organic instinct*" employed to designate it.

The contractions of the heart take place in the order in which the blood flows into its different cavities; and if the blood be the habitual stimulant upon which its movements depend, this is exactly what we would expect.† The blood forced in greater quantity into the auricles by the contraction of the termination of the cavæ and pulmonary veins, stimulates the auricles to contract and propel an additional quantity into the ventricles; and this, acting as a stimulant upon the ventricles, excites them to contract and drive the blood into the arteries, when the same series of phenomena is renewed and repeated in the same succession.

The continuance of the heart's action after the circulation has ceased, we have already attempted to explain; and if these contractions depend upon the presence of a stimulus, they must evidently be in the same order as in the natural state of the organ, as these have not been interrupted. The continuance of the regular order of the contractions of the heart after its removal from the body can in general, we think, be satisfactorily accounted for by the substitution of a new stimulant for that of the blood; the cavities are then occupied with air instead of blood, and each

* Traité de Physiologie, tom. vii. p. 74, traduit par Jourdan.

† Experimental Inquiry, &c. p. 275.

* We have not here given Laennec's calculations of the relative duration of the contraction and relaxation of the auricles, as they must be founded on false data—on the supposition that the second sound of the heart marked the duration of the contraction of the auricles.

† This was also the doctrine maintained by Senac, op. cit. tom. i. p. 325. Senac, however, was opposed to the doctrine of Haller, that the contractility of the heart was a property inherent in the muscular fibre, and independent of the nerves, Tom. i. p. 451.

contraction of the auricle must force an additional quantity into the ventricle, and this, though small in quantity, may be quite sufficient to excite the ventricles to contraction, when the irritability is not too much impaired.* It is only in this manner, taken along with the greater irritability of the internal surface over the external, that we can explain the observation made by Dr. Knox in the course of his experiments upon the irritability of the heart in fishes, where, when the irritability was nearly exhausted, contractions excited in the auricle were sometimes followed by contractions of the ventricle, when irritation of the outer surface of the ventricle itself produced no effect.† Certainly, under ordinary circumstances, this regularity of the heart, so necessary for the proper performance of its functions, is a marked feature in its action; but that it is not either necessarily connected with its structure or vital properties, but depends solely on the manner in which its stimulant, the blood, is applied, is proved by various facts. 1st. The movements of the auricles and ventricles generally cease at different times after death; and though the auricles much more frequently continue to contract after the ventricles, yet several accurate experimenters have observed the left auricle become quiescent before its corresponding ventricle.‡ 2dly. When the movements of the ventricle have ceased, while the auricles continue to contract, the ventricle may generally be excited to vigorous contractions by the application of a powerful stimulus. 3dly. When the irritability of the heart becomes somewhat languid, two, three, or sometimes six or seven contractions of the auricle may take place before the ventricles are roused to contraction; the evident deduction from which is, that the contractions of the ventricles do not necessarily follow those of the auricles, unless the contractions of the auricles occasion the application of a stimulant to the inner surface of the ventricles sufficient to excite them to contraction. 4thly. The movements of the ventricles and auricles will go on in the same manner, though detached from each other by the knife. 5thly. If we were allowed to argue from final causes in negative cases, we could easily shew that a peculiar endowment, such as we are contending against, would not be of the slightest advantage in securing the regularity and constancy of the heart's movements. It appears, then, quite unphilosophical to call in the agency of some unknown and indefinite principle for the production of these periodic movements, as they have been called, of the different chambers of the heart, when they can be satisfactorily referred to the laws which regulate muscular contractility in other parts of the body. We have here a beautiful example of the manner in which nature produces adaptation of means to an end, not by the creation of new properties, which we, in our ignorance, sometimes erroneously attribute to her, but by the employment of those already in use in the performance of other functions, only modified to accommodate them to the circumstances under which they are placed.

Sounds of the heart.—On applying the ear over the region of the heart, two distinct sounds are heard accompanying its contraction. Though the existence of such sounds seems to have been known to Harvey,* who compares them to the noise made by the passage of fluids along the œsophagus of a horse when drinking, yet, as is well known, it is to Laennec that we owe the first accurate description of the character of these sounds, the order of their succession, and the manner in which they may hereafter be made available for the important purposes of the diagnosis of the diseases of the heart.

The first of these sounds is dull and prolonged; the second, which follows closely upon the first, is sharp and quick, and is likened by Laennec to the flapping of a valve, or the lapping of a dog. After the second sound a pause ensues, at the end of which the sounds are again heard. These three—the first sound, the second sound, and the pause—occur in the same uniform order, and when included along with the movements of the heart, to which they owe their origin, have received the term *rhythm of the heart*. As the dull prolonged sound is synchronous with the impulse of the heart, and consequently with the contraction of its ventricles, Laennec attributed this sound to the contraction of the ventricles. The second sound, which is synchronous with the diastole of the ventricles, he supposed must depend upon the systole of the auricles; and to this he was naturally led by the supposition that their contraction must also produce some sound. From the weight of Laennec's authority, this opinion

* When the heart has ceased to contract, it may frequently be called into pretty vigorous action by opening one of the large veins, and blowing some air into its cavities.

† I have repeatedly attempted to ascertain if the circumstances here described as sometimes occurring in the cold-blooded animals could be observed in the warm-blooded animals, but without success. In one experiment upon the heart of a rabbit, after all the movements of the ventricles had ceased, but *where they could still be readily excited by the application of a stimulant*, we were convinced that contraction of the auricle, when excited by stimulation applied to itself alone, was sometimes followed by contaction of the ventricle even after the ventricle had been *slit open*. But in subsequent experiments upon dogs, we ascertained a source of fallacy which we had overlooked in the other experiment, for we found that a slight movement of the heart on the surface upon which it rests, such as that caused by a very gentle pull at the large arteries, and not exceeding the effects produced by the contraction of the auricle, was, in some of these cases, sufficient to excite contractions of the ventricles.

‡ In one experiment upon a cat, I distinctly observed the right ventricle occasionally pulsate twice for each pulsation of the auricle. In another experiment, I distinctly observed the contractions of the ventricles precede those of the auricles, when the contractility of the heart had become enfeebled. In this case, the pause in the heart's action occurred after the contraction of the auricles.

* Op. cit. cap. v.

seems to have been almost implicitly adopted until the appearance of a paper by the late Professor Turner, in 1829. Professor Turner there recalled to the attention of medical men the observations of Harvey, Lancisi, Senac, and Haller, upon the order of succession in which the cavities of the heart contract, which appear to have been forgotten amidst admiration at the brilliancy of Laennec's progress. He also pointed out from their experiments that if the second sound was dependent upon the contraction of the auricles, it ought to precede instead of following the first sound, and that the pause ought to occur after the first sound, and not after the second. He also adduced, in farther proof of Laennec's error, observations drawn from the effects of disease, when, from some impediment to the passage of the blood from the right auricle into the ventricle, a distinct regurgitation takes place into the large veins at the root of the neck, and showed that in these cases the regurgitation marking the contraction of the auricles occurs without any accompanying sound; that immediately afterwards the impulse is felt attended by the first sound, and that the second sound takes place during the diastole of the ventricles and the passive condition of the auricles. He suggested that the second sound might be accounted for by the falling back of the heart into the pericardium during its diastole, to which "the elasticity of the ventricles at the commencement of the diastole, attracting the fluid by suction from their corresponding auricles, may perhaps contribute." Soon after the appearance of Mr. Turner's paper, Laennec's explanation of the cause of the second sound appears to have been pretty generally abandoned; and numerous attempts, both in this country and in France, have since that time been made to solve this difficulty. Some of these explanations appear to be mere guesses, occasionally at total variance with the anatomical structure of the organ, and at times presenting even as wide a departure from its normal action as that given by Laennec himself. Others, again, have entered upon an experimental investigation of the subject with enlightened views of its anatomy and physiology, have furnished us with much additional information, and lead us to indulge in the pleasing prospect that in a short time the matter will be completely set at rest.

The result of the experiments of Hope and Williams, attested as they have been by various gentlemen well qualified to judge of their accuracy,—also those of Mr. Carlisle, Magendie, Bouillaud, and the Dublin Committee, have satisfactorily determined that the account of the order of the contractions of the heart, and their isochronism to the sounds as stated by Mr. Turner, are perfectly correct. As, however, so many different circumstances attend each movement of the heart, any one of which may be capable of producing these sounds, it became a much more difficult matter, and one requiring great perseverance and accuracy of investigation, to determine upon what particular one or more of these, each sound depends. For accompanying, and synchronous with the first sound, we have the contraction of the ventricles, the collision of the different currents of blood contained there thus set in motion, the approximating of the auriculo-ventricular valves, the impulse of the heart against the chest, and the propulsion of the blood along the large arteries; while attending the second sound, we have the diastole of the ventricles, and the rush of a certain quantity of blood from the auricles into the ventricles, the sudden separation of the auriculo-ventricular valves towards the walls of the ventricles, and the regurgitation of part of the blood in the arteries upon the semilunar valves, throwing them inwards towards the axes of the vessels; so we will find that each of these in its turn has been thought capable of producing the sound which it accompanies, and still has, or until lately had, its advocates and supporters. As the subject is one surrounded with numerous and unusual difficulties, and is of comparatively recent investigation, it has followed, as was to be anticipated, that as new facts and observations are collected, many of the opinions first promulgated on this question have required to be modified or changed; and the scientific candour displayed by several of these authors in renouncing former published opinions is deserving of the highest praise.

Several of the explanations of the cause of the sounds of the heart proceed, however, upon the supposition that the relation of these sounds to the movements of the organ is different from what has been here represented. We shall merely state these without alluding to the arguments adduced in support of them, as we believe that they are founded upon inaccurate observation. Sir D. Barry believed that the first sound was synchronous with the diastole of the auricles, and the second sound with the diastole of the ventricles. Mr. Pigeaux, Dr. Corrigan also until lately, Dr. Stokes, Mr. Hart, and Mr. Beau, have maintained that the first sound is synchronous with the diastole, and not with the systole of the ventricles. According to Mr. Pigeaux, when the auricles contract they project the blood against the walls of the ventricle, and a dull sound (first sound) is produced; on the other hand, whilst the ventricles contract, they project the blood against the thin walls of the great vessels which spring from them, and a clear sound (second sound) is the result. Dr. Corrigan supposed that the first sound was produced by the rush of blood from the auricles into the dilating ventricles, and that the second sound owed its origin to the striking together of the internal surfaces of the ventricles during their contraction, after they had expelled all their blood. Mr. Beau believes with M. Magendie that the first sound arises from the impulse of the heart against the inner surface of the chest, but differs from him in maintaining that this occurs during its diastole, and not during its systole. The second sound he believes to depend upon the dilatation of the auricles. M. Piorry has revived the obsolete and perfectly untenable opinion of Nicholl, that the two ventricles contract at different times, and attributes the dull sound to the contraction of the left ventricle, and the clear sound to the contraction of the right ventricle. Dr. David Williams, while he believes that the first sound depends upon the rush of blood into the large arteries during the systole of the ventricles, attributes the second sound to the musculi papillares, which he considers as forming part of the valvular apparatus, causing the valves to strike against the walls of the ventricles. These musculi papillares do not, in his opinion, contract during the systole of the ventricles, but immediately afterwards, for the purpose of throwing open the auriculo-ventricular valves. In a former part of this article several circumstances are stated adverse to this opinion.

We shall now proceed to the explanation of the cause of these sounds given by those who maintain the views of the rhythm of the heart which we have here adopted, as resting upon the concurrent testimony of numerous accurate observers. These may be divided into those who attribute both sounds *to causes intrinsic to the organ*, or, in other words, to circumstances occurring within the organ itself, and into those who place them *external to the organ*, and depending upon extraneous objects. The only supporters of the latter opinion are Magendie and his followers. Magendie maintains that "in contracting, and for causes long since known, the ventricles throw the apex of the heart against the left lateral part of the thorax, and thus produce the first sound, *i. e.*, the dull sound. In dilating, in a great measure under the influence of the rapid influx of the blood, the heart gives a shock to the anterior paries on the right of the thorax, and thus produces the second sound, the clear sound." In proof of this, he states that on removing the sternum of a swan (an animal selected expressly for the experiment, as it interfered less with the natural action of the heart than in the Mammalia), he found that the movements of the heart produced no sound, while, on replacing the sternum, and allowing the heart to impinge upon its posterior surface as in the natural state, both sounds were again distinctly heard. He adduces several arguments drawn from the action of the heart both in its healthy and diseased state in favour of his opinion; and he ingeniously attempts to get rid of the objection which must instantly suggest itself, that in many cases, such as frequently occur in hypertrophy of the organ, the loudness of the sounds is diminished, while the force of the impulse is increased, by arguing that in these cases this increased impulse depends rather upon a heaving of the chest produced by the heart, which from its increased size is brought close to its inner surface, than upon a distinct impingement upon it, such as takes place in the healthy state. Dr. Hope, M. Bouillaud, Dr. C. J. B. Williams, and the Dublin and London Heart Committees have, however, distinctly heard both sounds of the heart, after that portion of the chest against which it impinges had been removed. It may, nevertheless, be objected to these experiments, that as the stethoscope was used in many of them, the impulse of the heart against the extremity may have produced an effect similar to its impulse against the parietes of the thorax. M. Bouillaud, having apparently this objection in view, states that the rubbing of the heart during its movements against the extremity of the stethoscope, is easily distinguished from the sounds of the heart; and that he has distinctly heard both sounds, though feebler than through a stethoscope, as was to be expected when nothing but a cloth was interposed between his naked ear and the surface of the heart. Dr. C. J. B. Williams, in his experiments, heard both sounds when the stethoscope was placed over the origin of the large arteries, and where no external impulse could take place; and this observation was repeated by the Dublin Committee. The Dublin Committee heard both sounds through the stethoscope, though feebler after the pericardium had been injected with tepid water; and in another experiment they were also heard when the ear was simply approximated to the organ. From all these experiments, I think there can be little doubt that the movements of the heart, independent of all extraneous circumstances, are attended by a double sound. As the impulse of the heart against the chest must produce some sound, as any one may convince himself by making the experiment in the dead body, and as this occurs during the systole of the heart, or, in other words, during the first sound, it may increase the intensity of that sound. Dr. R. Spittal,* after relating several experiments in which a sound similar to that of the first sound of the heart was heard by tapping gently with the apex of the heart or the point of the finger against the chest, both when empty and when filled with water, and after pointing out several sources of fallacy which he supposes were not sufficiently guarded against in the experiments which we have adduced above as subversive of this view, and which deserve the attention of future experimenters, comes to the conclusion that "it is highly probable that the percussion of the heart against the thoracic parietes during the contraction of the ventricles assists materially in the production of the first sound." He is also inclined to believe "that the act of the separation of the heart from the thorax after its approach, which was found in his experiment to produce a sharp, short sound, somewhat resembling the ordinary sound, may in certain circumstances be an assistant cause to the second sound."† Magendie's explanation of the second sound is completely untenable.

Among those who maintain that these sounds depend upon causes intrinsic to the heart, *the first sound* is referred by Rouanet, Billing, Bryan, and Bouillaud to the rapid approximation of the auriculo-ventricular valves during the systole of the ventricles, to which Bouillaud

* Edin. Med. and Surg. Journal, July 1836.

† Though Dr. Spittal is inclined to believe that the impulse of the heart against the chest has considerable share in the production of the first sound, he does not concur with Majendie in the explanation of the second sound.

adds the sudden separation of the semilunar valves when the blood is forced into the large arteries; by Mr. Carlisle to the rushing of the blood along the inner surface of the large arteries during the systole of the ventricles.* Dr. Hope, in the appendix to the second edition of his work, describes it as consisting, 1st, possibly of a degree of valvular sound; 2d, of a loud smart sound produced by the abstract act of a sudden jerking extension of the muscular walls, in the same manner that such a sound is produced by similar extension of the leather of a pair of bellows; to avoid circumlocution, he calls it the *sound of extension*; 3d, a prolongation and possibly an augmentation of this sound by the sonorous vibrations peculiar to muscular fibre." Dr. C. J. B. Williams has very justly objected to the correctness of the second cause here adduced as aiding in the production of the first sound, as the phrase "sound of extension" is obviously contradictory when applied to a contracting muscle.† Dr. C. J. B. Williams maintains "that the first sound is produced by the muscular contraction itself," the clearness of which is increased by the quantity of blood in the heart "affording an object around which the fibres effectually tighten, whilst the auricular valve, by preventing the reflux of the blood, increases its resistance, and thus adds to the tension necessary for its expulsion." He was first led to the adoption of this opinion by the observations of Erman and Wollaston upon the existence of a sound accompanying every rapid muscular contraction. This opinion he afterwards put to the test of experiment, the results of which we give in his own words. "Experiment 1st, observation 8th; I pushed my finger through the mitral orifice into the left ventricle and pressed on the right so as to prevent the influx of blood into either ventricle; the ventricles continued to contract strongly (especially when irritated by the nail of the finger on the left), and the first sound was still distinct, but not so clear as when the ventricles contracted on their blood. Observation 9th. The same phenomena were observed when both the arteries were severed from the heart." He also found in other observations that the first sound was louder over the surface of the ventricles than over the origin of the large arteries, which is in direct opposition to the opinion of those who believe that this is produced by the rush of blood along the great arteries. That the first sound is not dependent upon the closing of the auriculo-ventricular valves, he also ascertained from observations, in which the closure of these valves was partially or completely prevented, and yet the first sound was still heard. Besides, this sound continues during the whole of the ventricular systole, while the shutting of the valves must take place and be completed at the commencement of the systole." That the collision of the particles of fluid in the ventricles does not produce this sound he was convinced from observations, in which it continued although there was no blood in the ventricles.

Though we must admit that these experiments of Dr Williams prove that part at least of the first sound is caused by the muscular contraction of the ventricles, yet we must consider it still problematical, until we obtain further observations, whether it produces the whole of that sound, for it is very possible that some of the other circumstances attending the systole of the heart may increase its intensity. M. Marc d'Espine has maintained that both sounds depend on muscular movements; the first sound upon the systole, and the second upon the diastole of the ventricles. The Dublin Committee have in the meantime concluded that the first sound is produced either by the rapid passage of the blood over the irregular internal surface of the ventricles on its way towards the mouths of the arteries, or by the *bruit musculaire* of the ventricles, or probably by both these causes. We must wait for further experiments before this question can be fairly settled.*

Second sound.—Later experimenters appear to be more nearly agreed about the cause of the second sound than that of the first sound. M. Rouanet appears to have been the first who publicly maintained the opinion that the second sound was dependent upon the shock of blood against the semilunar valves at the origin of the aorta and pulmonary artery. M. Rouanet himself acknowledges that he owed the suggestion to Dr. Carswell, at that time studying in Paris, who came to that conclusion by a beautiful process of reasoning upon the phenomena which presented themselves in a case of aneurism of the aorta. The same opinion has been supported by Billing, Bryan, Carlisle, and Bouillaud.† It is, however, to Dr. C. J. B.

* As Mr. Carlisle is a member of the Dublin Heart Committee, we must now consider him as concurring with the report of that Committee.

† Medical Gazette, Sept. 1835.

* The London Committee, in their report given in at the meeting of the British Scientific Association for 1836, have adduced some additional experiments in favour of the opinion that the first sound of the heart depends upon muscular contraction. It appeared to them that the sound produced by the contraction of the abdominal muscles as heard through a flexible tube resembles the systolic sound. They, however, admit that though "the impulse is not the principal cause of the first sound, it is an auxiliary and occasional cause, nearly null in quietude and in the supine posture, but increasing very considerably the sound of the systole in opposite circumstances." From the great care with which these experiments appear to have been performed, we believe that we are now fully justified in adopting this explanation of the cause of the first sound. The Dublin Committee, in their report given in at the same time, also detail some experiments which they believe to be confirmatory of their former conclusions. See Sixth Report of British Scientific Association.

† In justice to Dr. Elliott, of Carlisle, I must state that I find, on consulting his Thesis De Corde Humano, published in Edinburgh in 1831, that he states (p. 51) that he believes that the second sound of the heart is dependent upon the rush of blood from the auricles into the ventricles during their diastole, and also upon the sudden flapping inward of the sigmoid valves at the origin of the large arteries by the refluent blood.

Williams that we owe the first direct experiments in support of it. In one experiment he ascertained that the second sound was louder over the origin of the large arteries than over the surface of the ventricles, while it was the reverse with the first sound; that pressure upon the origin of the aorta and pulmonary artery suspended the second sound; and that the second sound disappeared after the auricles had been laid open, although the first continued. In a second experiment* we find the following observations stated:—"Observation 6. A common dissecting hook was passed into the pulmonary artery, and was made to draw back and thus prevent the closure of the semilunar valves; the second sound was evidently weakened and a hissing murmur accompanied it. A shoemaker's curved awl was then passed into the aorta so as to act in the same way on the aortic valves. The *second sound now entirely ceased and was replaced by a hissing.* Observation 7. The hook and the awl were withdrawn; *the second sound returned and the hissing ceased.* Observation 8. The experiment 6th was repeated with the same result, and whilst Dr. Hope listened I withdrew the awl from the aorta. He immediately said, 'Now I hear the second sound.' I then removed the hook from the pulmonary artery; Dr. Hope said, 'Now the second sound is stronger and the murmur has ceased.'" The Dublin Committee have repeated and confirmed these experiments of Dr. Williams. In their experiments one of the valves in each artery was transfixed and confined to the side of the vessel by a needle, and the second sound disappeared; on withdrawing the needles they re-appeared.

As the second sound thus appears to be produced by the *shock of the blood upon the semilunar valves*, its intensity must, in a great measure, depend upon the diastole of the ventricle drawing part of the blood back upon them, but perhaps more particularly upon the elasticity of the large arteries returning suddenly upon their contents during the diastole of the ventricles, when the distending force of the ventricles has been withdrawn. We would therefore expect that the second sound should be louder in those whose aorta retains its elasticity, than in those (a circumstance sufficiently common in old age) in whom, from a morbid alteration of the structure of its coats, the elasticity is either lost or greatly diminished. This is an observation which, as far as I know, has not yet been verified; but my friend Dr. W. Henderson informs me that he is positive from numerous observations that the second sound is louder in young than in older persons; but whether this is in the exact ratio of the change upon the elasticity of the coats of the large vessels he is not at present prepared to say.

* These experiments were performed upon asses, in which the sensation was first suspended by a dose of wourara poison and then maintaining artificial respiration. In this manner the heart continued to act upwards of an hour after the commencement of the artificial respiration.

BIBLIOGRAPHY.—As a complete bibliography of the Anatomy and Physiology of the Heart would include all the systematic works on Anatomy and Physiology, we shall here confine ourselves to the enumeration of those works and memoirs which treat exclusively or in a prominent manner of the normal anatomy or functions of that organ.

(John Reid.)

ON THE ARRANGEMENT OF THE FIBRES OF THE HEART.—[The Editor hopes that the following detailed account of the researches of Mr. Searle on this difficult point of minute anatomy will not be deemed unacceptable. Any reference to the labours of other anatomists has been rendered unnecessary in consequence of that part of the preceding article which bears upon this subject.]

Preliminary remarks.—In order to unravel the fibres composing the ventricles of the heart, considerable preparation is necessary. The auricles, fat, coronary vessels, and external proper membrane should be cleanly dissected off; the heart should then be boiled thoroughly, but not too much, so as to give its fibres the requisite degree of firmness without rendering them fragile. For example: sheep's hearts should be boiled ten or fifteen minutes; calves' twenty or thirty, and bullocks' forty or fifty minutes; immediately afterwards they should be immersed in cold water; for if they be exposed to the air while hot, their superficial fibres become dark, dry, and brittle. As the process of unravelling occupies many hours, and as the heart requires to be preserved in a good condition, it should be immersed during the intervals in weak spirit and water. The heart of the calf is preferable to that of any other animal, it being on a scale which affords distinct views, while the fibres of young are more easily separated than those of older animals. The conformation is the same in all quadrupeds, and bears a complete resemblance to that of the human heart. When the coronary vessels are dissected off, a depressed line or track is left on the anterior and posterior surfaces of the heart. Since this line corresponds externally to the entire edge of the septum, and to the boundary of the right ventricle, it may be usefully employed in reference to these parts. It is therefore denominated the anterior or posterior coronary track, accordingly as it pertains to the anterior or posterior surface of the heart.

The fibres of the heart are not connected together by cellular tissue as are those of other muscles, but by an interlacement which in some parts is very intricate, and in others scarcely perceptible. At the entire boundary of the right ventricle they decussate, and become greatly intermixed; at the apex and base of the left ventricle they twist sharply round each other, and so become strongly embraced; but in general the interlacement is so slight that they appear to run in parallel lines. Whether a mere fasciculus or a considerable mass of this last description of fibres be split in the direction of the fibres, a number of delicate parallel fibres will present themselves, some being stretched across the bottom of the fissure perfectly clean and free from any connecting medium whatever; and although some must necessarily be broken, yet these are so few that they do not attract attention unless sought for. In this process of separation very little resistance is offered; and none that is appreciable when a single fibril is taken hold of by the forceps, and stripped off, and which could not be done if bound down by cellular membrane.

If a piece of common muscle be afterwards split, it will be found to offer great resistance, and to be attended with so much laceration of the fibres, that instead of a beautiful series of fine muscular threads arranged in parallel lines, a ragged mass of mutilated fibres appears; and during the process of separation, the cellular substance is seen not only to connect the fibres, but to afford the resistance which is experienced.

This comparison obtains in the undressed state of the specimens; but when cooked, other distinctions are met with. For example: in whatever direction a roasted heart be sliced, its cut surface is uniformly smooth, not grained like other muscles when dressed; and it eats short, not offering that elastic resistance which other muscles do during mastication.

The absence of cellular substance as a con-

Fig. 278.

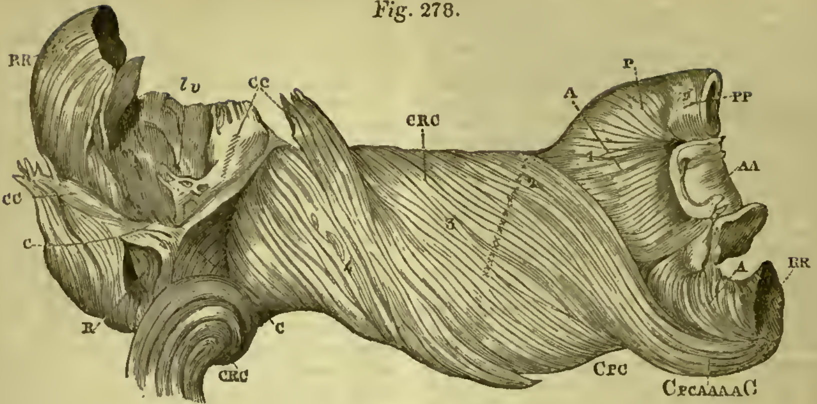

Fig. 279.

Fig. 280.

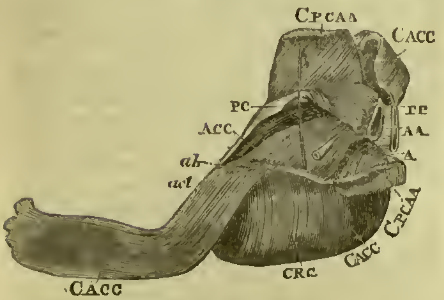

Fig. 282.

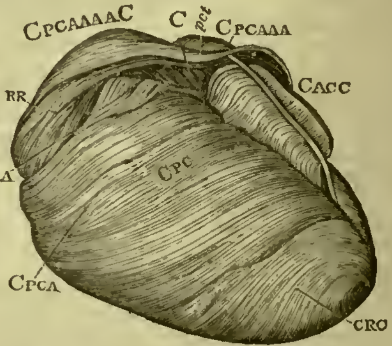


necting medium among the fibres in question is not only proved by the absence of its physical characters, but by its not being discovered through the medium of the microscope. Neither Mr. Kiernan nor Mr. Goadby, who examined the fibres with me, could detect its existence.

Since the chief utility of cellular membrane in investing and connecting together the fibres of a muscle is, most probably, that of retaining them within their proper spheres of action, and since the fibres of the heart are devoid of this agent, the question arises as to what other retaining power these possess. On this head no difficulty presents itself; for the fibres, in winding round and round the cavity of the left ventricle, become arranged in concentric layers; and in taking a larger sweep, in surrounding the right ventricle, the same arrangement is preserved, so that during the systole of the heart the whole mass of the fibres firmly compress each other, which necessarily retains them all within their proper spheres of action, excepting the superficial fibres, of which those towards the base, and especially those upon the right ventricle, where there is great latitude of motion, do not preserve a parallelism with their subjacent fibres, but lie nearly at right angles with them. It is on this account, most probably, that the superficial fibres have attracted notice, and have been viewed as a distinct layer.

The disposition of the fibres varies in different parts of the heart, forming parallel lines, angles, decussations, flat and spiral twists. The fibres are arranged in fasciculi, bands, layers, and a rope, which are so entwined together as to form the two chambers called the right and left ventricles. These are lined with their internal proper membrane.

The fasciculi are connected with the aorta, pulmonary artery, and carneæ columnæ, and contribute to the formation of the bands.

The bands.—By tracing the fibres in bands, we are enabled to develop the formation of the ventricles in a progressive and systematic manner. The bands spring from a mass of fibres which forms the apicial part of the left ventricle, and which, in winding round just above the apex of the heart, separates into two bands to form the right ventricle.

It will render the demonstration more intelligible if a preliminary and cursory view be taken of the general course of these bands (*fig.* 283, *p.* 626,) by referring to the diagram. The bands, as there given, form a mere skeleton of the heart, merely indicating the several courses they take. The average width of the bands is not less than a third of the extent between the apex and base of the left ventricle. In the diagram, CRC indicates the winding of a considerable mass of fibres just above the apex; at the septum, S, it splits into two bands. The shorter, CACC, encircles spirally both ventricles, one half round the right, the other round the left ventricle. The longer band describes two circles: it first passes through the septum, round the left ventricle marked CPCA; it secondly passes round the base, and includes both ventricles in its circuit, marked progressively CPCAA, CPCAAA, CPCAAAAC, and RR.

After employing so many letters, it is requisite to explain that as the bands are frequently receiving fresh accessions of fibres, it is desirable to characterise those increments individually by the initials of the names of the respective sources from which they are derived; and in order to make a distinction between the indications of the fibres and of their respective origins, the latter are characterised by double, and the former by single initials. Accordingly, the aorta, the pulmonary artery, the rope, and the carneæ columnæ are designated AA, PP, RR, and CC, while their fibres are marked A, P, R, and C. This plan is modified in one instance only, viz., the fibres of the main bulk of the heart, being derived from the rope and the two carneæ columnæ of the left ventricle, are designated in the first instance by their proper initials CRC; but as numerous increments of fibres are being made, in succession, to these three original sets, it is convenient to make an abbreviation in the lettering; thus, CRC is indicated by C large, when combined with other initials; accordingly, CRCA is contracted to CA, and CRCPCA to CPCA, and so with the rest.

The layers.—Although the heart admits of being split into a number of layers, yet there being no material division formed by fasciæ or condensed cellular membrane, such separations are strictly arbitrary. It is, however, found convenient to separate the fibres into certain layers, in order to give a methodical demonstration of the formation of this organ. The same remarks obtain regarding the bands.

It is generally supposed that the superficial fibres properly constitute a distinct layer, forming a common sac, which encloses the two ventricles. This is not strictly the case, for it has the same origins and terminations as have the fibres immediately subjacent to it. Nevertheless, the superficial fibres are, in the following description, considered as a separate layer, to show the peculiar construction of the apex.

The rope.—It has already been stated that the longer of the two bands terminates at the base in the rope. The fibres of this band, in forming the brim of the left ventricle, make a sharp twist like those of a rope, by which means they become the inner fibres of this chamber, and expand into a layer which enters largely into the formation of the mass which divides into the two bands. So the principal band, although it receives several increments of fibres, has no complete beginning nor ending, a considerable portion of it originating and terminating in itself, which circumstance renders it necessary to fix upon the most convenient part of its course for the commencement of the demonstration.

Although the system here adopted of unravelling the fibres of the heart be strictly arbitrary, as every other must be, yet it will, most probably, be found the only method by which all the various courses, and several connexions made by the fibres in forming the heart, could be displayed.

The demonstration.—It is requisite to pursue two methods of demonstration;—one, describing the *dissection*, or unfolding, which consists in unravelling and separating the fibres, and tracing, from the circumference to the centre of the heart, their various courses, in the form of bands, by which they become in order unwound, and by which a general view of the formation of the two ventricles is at the same time presented. The other, describing the *formation*, or winding up of the fibres, comprehends the retracing of the fibres from the centre to the circumference, showing their respective origins, associations, courses, connexions, and terminations, also the manner in which they are wound up to form the two ventricles into one compact conical body.

The dissection.—The first stage consists in separating the superficial fibres from the two ventricles, which, perhaps, cannot be accomplished in a more simple manner than by raising them in the forms of two wings and a tail, as represented in *fig.* 279, which is to be done by commencing at the anterior coronary track, cutting through the superficial fibres and detaching them by means of a blunt scalpel in their natural direction, so far as their insertions at the base; this will be found to divest the right ventricle, and, from their obliquity, a part of the left. (See the left wing, Cacc.) Then recommencing at the anterior coronary track, the fibres should be separated in the contrary direction, over the left ventricle towards the apex. These fibres take a very spiral course, and as they approach the apex converge, but on reaching it they twist sharply round upon themselves, like the fibres of a thick cord, and entering at the apex become the internal fibres of this chamber. The remaining part of the superficial fibres, extending from the apex to the base, pertains exclusively to the left ventricle; these should be divided an inch or two above the apex, and the apicial portion detached, which will complete the tail, Crc. Its fibres are represented, as they appear after separation, untwisted. The basial portion of these fibres should now be detached so far as the annulus arteriosus, and reflected like the right wing, Crc. These, as do most other fibres which approach the base, take a more longitudinal course, and in general they become so separated as they diverge to encompass the basial part of the heart, that they cannot be raised in an entire layer unless some of the subjacent fibres be taken with them.

The second stage of the dissection comprises the disconnecting the bands which compose the outer or proper wall of the *right ventricle.* The superficial layer of fibres having been removed, there remain two other layers pertaining to this wall of the ventricle, viz. the middle and the internal. The *middle* is separable into two bands, the upper or basial, and the lower or apicial. It is better to detach the *apicial* band first, which makes one spiral circle round the heart. Its outer extremity being attached to the root of the aorta at its anterior face, and sometimes to the pulmonary artery also, an incision should be made extending from the upper part of the anterior coronary track obliquely towards the annulus arteriosus, which incision should, in a calf's heart, be a little more than an inch in length and a tenth of an inch in depth. The band should then be detached agreeably to its spiral course from the base and middle third of the left, and from the lower half of the right ventricle, as far as the anterior coronary track, the line from which the separation commenced. It here receives on its posterior surface a considerable accession of fibres from the right surface of the septum, by the junction of which this part of the boundary of the ventricle is formed, but the further separation of the band prevented. In *fig.* 281, in the first or basial part of its course it is indistinctly seen, marked Cacc. In *fig.* 282 its middle course may be traced, although the half circle of the band which wound round the left ventricle has been cut off. In the preparation exhibited in this figure the separation of this band could not be effected under the posterior coronary track, on account of the separation having been conducted too deeply, where the fibres decussate to form the posterior boundary of the right ventricle. In *fig.* 281, which exhibits a dissection of the right ventricle of a bullock's heart, the whole of the band, Cacc, is separated as far as the anterior boundary of this cavity, and lies extended; and the accession of fibres it receives from the right surface of the septum are seen prolonged into it.

The *basial* band crosses the upper half of this ventricle. It cannot be raised from its situation on account of the numerous lateral connexions it forms in its progress with the margins of the orifices of the aorta, pulmonary artery, and annulus venosus. In order to detach it as far as it will admit, an incision about half an inch on the right side of and parallel with the anterior coronary track, should be made, extending from its lower edge to the base, and an eighth of an inch in depth, or as deep as will expose the fibres from the pulmonary artery, which in general pass at an angle with those of the band. Although this band cannot be disconnected from the base, it can in general be detached from the fibres of the subjacent layer, so far as the posterior coronary track; sometimes, however, they are too interwoven to admit of any separation. The first part of this band is represented in *fig.* 281, marked Cpcaa; it was divided more than half an inch from the anterior coronary track. Its continuation may be seen in *fig.* 282, lettered Cpcaaa, where it is evidently not disconnected from, but merely raised towards the base, and if replaced would overlap the fibres taking the middle course round the heart. The depression at the line of the posterior coronary track, *pct*, is occasioned by the band being bound down at the base and at its under surface also, by which means the upper half of the posterior boundary of this ventricle is formed. As the further pursuit of this band pertains to the third stage, it will be made hereafter.

The *internal* layer. By the separation of the two former bands the internal layer is exposed. It is composed of fibres from the pulmonary artery and from one of the carneæ columnæ. In *fig.* 281 the fibres, pc, are seen arising from the root of the pulmonary artery at its entire circumference, first forming a channel and then expanding into a layer, which, in proceeding obliquely across the cavity, obtains an accession of fibres from one of the carneæ columnæ, which is not brought into view, and which, on reaching the line of the posterior coronary track, joins a band emerging from the septum, and thus forms the apicial half of the posterior boundary of this ventricle. It is raised from its situation, but when replaced its edge, which is everted by the probe, applies itself to the anterior boundary of this cavity. This layer cannot often be so extensively disconnected from its superjacent bands as this figure represents.

The third stage of the dissection.—Having separated the layers composing the right or proper wall of the right ventricle, the next proceeding consists in detaching and unwinding the band and layers composing the left ventricle. First, the detachment of the basial band. As this band has already been detached over the right ventricle in the second stage of the dissection, it is necessary to resume its separation at the posterior coronary track. But as the further separation is somewhat difficult, it will be rendered less so if the remaining portion of this band be first examined in *fig.* 282, wherein it is represented detached. When in its natural situation it forms the uppermost third of this, the left ventricle, and its lower fibres overlap a part of those which occupy the middle third. The fibres which overlap the others in taking an oblique course towards the base reach the brim of the ventricle and pass over it, while the under fibres of this band are appearing in succession, and taking a similar spiral course until the whole bundle of fibres is twisted in the form of a rope. In order, therefore, to trace out and detach this band as it becomes transformed into a rope, it is requisite to commence near the posterior coronary track *(pct)*, in a continuous line with the lower edge of its former portion, introducing the handle of a scalpel obliquely upwards so as to detach the fibres which overlap those of the middle third, and to carry the separation so far up as will reach those marked A, coming obliquely down from the aorta. In conducting this separation from left to right it is soon found that the fibres of this bundle, instead of overlapping others, become themselves by twisting overlapped, rendering it necessary, therefore, to turn gradually the handle of the scalpel obliquely downwards, tracing the rope according to its windings. Two scalpels will be required in conducting the further separation.

The next step should be preceded by viewing the fibres of the rope in *fig.* 280, descending and radiating into a layer which sweeps round the cavity of this ventricle. The heart should now be placed in a small cup or jar of a size that will support it with its base upwards, and then, with the scalpels employed vertically, the separation should be proceeded with, and in passing through the septum a vertical section should be made through the aorta in the line of separation, which should be pursued round and round, and progressively deeper until the handles of the scalpels perforate the external fibres, which, if they have been rightly inclined, they will do a little above the apex of the left ventricle, just after they have completed the division through the layers of the septum. The band of fibres occupying the middle third of the heart, and which now pass over the scalpels, should be divided; the incision being made along the side of the posterior edge of the septum. A section should be made through the rope also, which allows the right ventricle to be raised from the left, and the heart to be unwound as far as the separation has been carried. There yet remains a mass of fibres around the cavity of the left ventricle to be detached. This last process of separation should be conducted in a contrary direction to that which has hitherto been adopted, viz. from right to left, until the internal membranous lining is exposed, and which should be torn in order to lay open this chamber.

The heart can now be unwound and extended as in *fig.* 278, placing the left ventricle, *lv*, at one end and the right at the other, removing that section of the aorta, AA, connected to the right ventricle from its counterpart which exclusively pertains to the left, and which is hidden by the rope, RR; removing also the two portions of the bisected rope to the two most distant diagonal points in this view. The niche, CPC, indicates the part occupied by the divided band which passed along the middle third of the heart.

The second method of demonstration.—The formation, or winding up of the fibres, of the heart. This description comprehends the retracing of the fibres from the centre to the circumference, showing their respective origins, associations, courses, connexions, and terminations, also the manner in which they are wound up to form the two ventricles into one compact conical body.

The first stage consists in retracing the superficial layer from its origins to its terminations. It is necessary to commence at the very centre of the heart—the interior of the left ventricle, whence spring the fibres composing its main bulk. *Fig.* 278, at its right extremity, exhibits the left ventricle, *lv*, laid open, exposing the two carneæ columnæ, CC and CC, one of which is placed out of its situation, in order to show the interior of the chamber. The fibres of the two carneæ columnæ, CC and CC, expand in a fan-like manner; those of the rope, RR, expand in a similar manner; the radiated fibres of each of these three bodies wind round the axis of this ventricle forming its parietes; and as they wind so as to form an inverted cone, it is clear that the inmost fibres alone can reach the apex. Accordingly, a fasciculus of the inmost fibres from each of these three bodies, marked C, R, and C *respectively*, pass down to the apex associated together, and in their course make a gentle twist from left to right, gradually contracting the cavity to a point and closing it; they then twist sharply round upon each other and complete the apex marked CRC *conjointly*, so that by means of this twisting the internal fibres are rendered external. These excluded fibres now enter into the formation of the superficial layer, and form the tail of *fig.* 279. They take a very spiral course near the apicial part, and over the anterior surface of the left ventricle as far as the anterior coronary track; but as they approach the base, pass more longitudinally. It is evident that these few fibres would be inadequate to form a complete layer, unless in their prolongation they pursued an uniformly spiral course. They are more than enough to cover the apicial part as they twist over each other; but in consequence of the conical form of the heart they soon become singly arranged, and as they diverge, separate and leave interspaces, some of which are occupied by fibres which apparently arise abruptly at the surface. The fibres which pass longitudinally to the base of the left ventricle are inserted into the tendinous margin of the annulus arteriosus, and into the posterior part of the root of the aorta, forming the right wing, CRC. The spiral fibres have been stated to arrive at the anterior coronary track along its whole length. The majority of them terminate at the coronary vessels; others are merely intersected by them, while others pass under these vessels and become superficial again: those which maintain their course over the right ventricle vary in different hearts from a small to a considerable number. Along the whole length of this track accessory fibres from the interior of the right ventricle are emerging to associate with these in their way over this ventricle. They take a longitudinal course to the base, and therefore start at an angle with the spiral fibres which are on the left side of the coronary track. In *fig.* 281 these accessory fibres from the aorta, AA, and from two of the carneæ columnæ, are seen passing together obliquely down the right surface of the septum, marked ACC, to enter into the formation of the extended band. These accessory fibres perforate it along the anterior boundary, *ab*, and become superficial. This layer is, accordingly, in *fig.* 279, marked CACC; its fibres pass at nearly right angles with the subjacent fibres, and when raised form the left wing; its insertions are the anterior part of the root of the aorta, the tendinous margin of the annulus venosus, and again the right part of the root of the aorta. Sometimes festoons are formed at the base by communications of fibres between the pulmonary artery and the aorta, at its right and posterior aspects.

It occasionally happens that the accessory fibres which arise from the interior of the right ventricle are not very numerous; in such cases a greater number of fibres arise abruptly from its surface.

The superficial layer has three sets of origins: one, primitive, from the interior of the left ventricle; the others, accessory, from the interior of the right ventricle, and from the outer surface of both. It cannot with propriety be considered as one common investment, since each ventricle for the most part gives birth to its own superficial fibres. It is necessary to raise it as a distinct layer for two reasons: first, that the superficial fibres of the right ventricle in general pass nearly at right angles with their subjacent fibres, and therefore require to be removed in order to proceed with the next stage of separation: secondly, that it developes the peculiar mode of closing the left ventricle, and of forming the apex; and probably no other method than that of the twisting of the fibres could have been so secure, especially as the parietes at the apex of the ventricle do not generally, even in a bullock's heart, exceed a tenth of an inch in thickness.

The second stage —The external layer having been traced from its origins to its insertions, we may now trace the deep-seated layers; and as these have, for the most part, the same origins, courses, and insertions as the superficial layer, we may commence the description at the same points.

It has been already stated that the fibres of the rope and of the two carneæ columnæ expand in a fan-like manner, that their inmost fibres pass through the apex and become external, but that the chief of them wind round the axis of the left ventricle above the apex, as exemplified in *fig.* 279, CRC. The respective sets of fibres pertaining to these three bodies continue separate during their radiation only, after which they become plaited together by folding one over the others. Their mode of association is shown in the extended portion of the split layer, CRC in *fig.* 280, also in its counterpart, CRC, winding round the apicial part of the ventricle. Again, in *fig.* 278, it may be seen that the fibres at the bases of these columns turn under and pass up in conjunction with those of the rope forming the middle mass, CRC, at the upper of which they fold over making flat twists upon themselves, which have, however, become exaggerated in appearance by the unwinding of the heart, as in rolling it up again some of the angles are converted into spires, preserving a considerable degree of parallelism.

Having shown the origins, and the method adopted in the association, of the fibres forming the middle mass in *fig.* 278, we proceed by tracing the divisions and prolongations of its fibres, and the plan of building up the two chambers of the heart. First, the formation of the *left ventricle*. If the right carnea columna, CC, be replaced in contact with its fellow, and if the rope, RR, be brought round the upper part of this cavity so as to embrace them, and if portion 4 be split from the middle mass, CRC, and be wound, in association with the apicial fibres, CRC, round the lower part of this cavity, that division of the heart, comprising the left ventricle and the middle mass, will bear a near resemblance to that represented in *fig.* 280; in which figure the rope, RR, in embracing the heads of the carneæ columnæ, CC, brings into view its fan-like fibres, R, sweeping round the upper part of the axis of this ventricle; in which the fibres of portion 4, in winding round the lower half of the axis, embrace the bodies of the carneæ columnæ, CC, and associate with the apicial fibres, CRC, and in which the extended layer, CRC, represents the middle mass minus the portion 4, which is split from it. Thus much pertains exclusively to the description of the formation of the left ventricle. That of the right is more complicated, and constitutes—

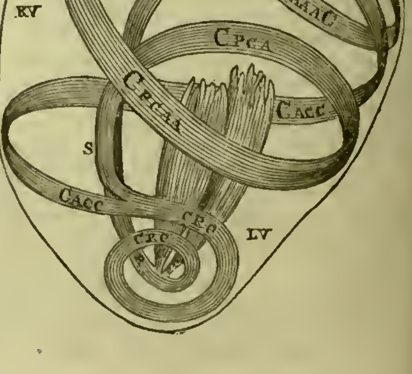
The third stage. In pursuing the mass of blended fibres, CRC, occupying the middle of *fig.* 278, it is found that, after having formed the left, it splits under the line marked by stars into two bands, which embrace and contribute to form the right ventricle. These separated bands were stated in the preliminary remarks to be of unequal lengths, the longer making two and the shorter making but one spiral circle round the heart. The longer, in the first place, assumes the character of a layer and forms the middle layer of the septum. It requires to be described in three portions. Portion 1, being attached to the valve of the other section of the aorta, was stripped off in unwinding the heart; in the wound-up state it passes over the pulmonary channel of fibres, P, along the part marked 1, in its way to the aorta, AA; its absence, however, opens to view the fibres coming from the base and forming the right layer of the septum. Portion 2 proceeds from the starred line across to enter into the formation of the rope, RR, and will be noticed hereafter. Portion 3 is the longer band; it is not entirely seen, being overlapped by some of the fibres of portion 4; it passes across to the niche, CPC, where it was divided in unwinding the heart, in order to liberate the two ventricles which were encircled together by this band. Previously to pursuing this band further, it is better to trace it as the middle layer of the septum in its natural situation—the wound-up state of the heart. In *fig.* 280 it forms the extended layer, CRC, in association with portion 2, and split from portion 4, which does not belong to the septum; on being replaced, its cut edge, *a*, applies to the cut edge, *b*, in passing as the middle layer between the right and left layers of the septum. The middle layer is seen in *fig.* 282 emerging at the posterior edge of the septum, where portion 2 disconnects itself to join at the under surface the band above, but in this figure is marked C large, indicating that it is derived from this layer, which has hitherto been lettered CRC. This layer, being now deprived of all its other portions, will hereafter be considered as a band, and it has already been explained why it should be denominated the longer band. This band in emerging at the posterior edge of the septum is joined by another band of fibres, which is seen in *fig.* 281, forming part of the internal layer of the proper wall of the right ventricle; its fibres, PC, arise from the pulmonary artery, PP, and from one of the carneæ columnæ not in sight; they cross obliquely over this cavity to the posterior edge of the septum to join the band in question. By the intimate blending of the fibres of these two bands the apicial half of the posterior boundary of this ventricle is constructed. The longer band, now augmented, is lettered accordingly in *fig.* 282, CPC, and in proceeding soon receives at its inner surface an accession of fibres, A, coming down from the aorta. This band, CPCA, in winding spirally from left to right round the left ventricle along its middle third, gradually approaches both the base and the surface: for when it arrives at the anterior edge of the septum it becomes the basial band, and having been traced round the left *under* the right ventricle, in making its second circle it passes *over* that cavity. In *fig.* 281 the commencement of its second course is exhibited. It is bisected, one portion, CPCAA, being held up by a probe; the other, at the anterior coronary track, *a c t*, receives at its inner surface a fasciculus of fibres, A, from the aorta, AA, and is also lettered CPCAA. This fasciculus and portion of the band form together a groove, by winding over the pulmonary channel when brought down into its place, and which together form the basial part of the anterior boundary of this cavity. This band in its progress round this ventricle constitutes the basial band of the middle layer of its proper wall, and forms so many connexions with the base, that to trace them all would be found a very complicated piece of dissection; it is, therefore, deemed better to give a general description of them. For instance, the aorta presents three different aspects under which this band is connected to it: the first, at the termination of the anterior coronary track; the second, between the pulmonary artery and the annulus venosus; and the third, between the annulus venosus and the annulus arteriosus, or at the extremity of the posterior coronary track. The aorta receives at each of these parts an insertion of fibres from the outer surface of the band; and the band receives on its inner surface a fasciculus from the aorta. These reciprocal communications occasion the band to be very firmly bound down to the base, and to be arranged, to a certain extent, into festoons. For each of these accessions from the aorta, an additional A is added to the lettering of the band, which is, accordingly, designated CPCAAAA. As the band passes the annulus venosus, its outer fibres by a gentle obliquity in their course successively arrive at its tendinous margin, into which they become inserted immediately below those of the superficial layer, and some proceeding still more deeply pass under the tendinous margin into the ventricle, and form the musculi pectinati. In order to avoid repetition it may be here remarked, that this part of the description applies to the annulus arteriosus also. The last two accessions of fibres this band receives should be traced, since they assist in the construction of the posterior boundary of the right ventricle. In *fig.* 282 this band is seen in the latter part of its course round the right ventricle, marked CPCAAA; on reaching the posterior coronary track, *pct*, it is joined on its inner surface by two fasciculi which bind it down to the base, but on each side of this track it is separated and raised. One of these fasciculi, the last derived from the aorta, is not seen in this figure; the other appears emerging from under this ventricle, being portion 2 of the middle layer of the septum, which disconnected itself from this band, CPC, in its first circle round the left ventricle; it is marked C large, being derived from the middle mass of fibres, CRC, in *fig.* 278, in which portion 2 is seen crossing over to join the band CPCAAAAC, just before it becomes the rope; the fasciculus of fibres A from the aorta A A is also seen joining this band at its inner surface nearer the base. By the union of these two fasciculi with the band in question, the basial half of the posterior boundary of the right ventricle is formed. By pursuing, in *fig.* 282, this band or combination of fibres, lettered CPCAAAAC, it is seen to form, while it is gradually twisting upon itself, the brim of the left ventricle, and then to make a sharp twist of its fibres into the rope R R, by which means they are rendered the internal fibres of the left ventricle; in *fig.* 280 they may be traced expanding again into a layer, pursuing the same spiral sweep from left to right, but from the base towards the apex, and inwardly instead of outwardly. Thus the demonstration brings us back to our starting-point.

We have yet to trace the shorter of the two bands which originate in the splitting of the middle mass of fibres, CRC, in *fig.* 278, to embrace the right ventricle. This view exhibits only the inner fibres of this mass as they are prolonged into the inner or longer of the two bands; but *fig.* 281 affords an outer view of this mass of fibres as they are prolonged into the outer or shorter band. They are seen winding spirally up from the apex marked CRC, and at the anterior coronary track, *act*, they split, in the form of a band, from the general mass to pass over the lower half of the cavity of the right ventricle. In this figure this band is separated and left extended, in order that the accessions of fibres it receives from the right surface of the septum may be seen, which are the fibres A from the aorta AA, and the fibres C and C form two of the carneæ columnæ (not in view) passing obliquely down from right to left to the anterior edge of the septum, from which they extend into the band which is lettered CACC, and unite intimately with its fibres. When the band is replaced in its course over the ventricle, its accessory fibres are made to reflect at an acute angle upon themselves, and thus form the apicial part of its anterior boundary. This band describes one spiral circle round the heart, arriving again at the anterior coronary track at its basial extremity; it is inserted into the aorta, and if the fibres make a very oblique approach to the base, they will be also inserted into the tendinous margin of the annulus arteriosus. The continuation of this band round the posterior side of the heart can be traced in *fig.* 279. Its width is equal to about a third of the heart's axis; it is seen marked CACC in its spiral ascent from left to right, passing, first, a little below the middle third of the heart; at the posterior coronary track, *pct*, becoming the middle third, and afterwards approaching gradually the base in its way to its points of insertion before-mentioned.

As the tracing the fibres from the circumference to the centre, and from the centre to the circumference, is a matter of much difficulty, and as the description has been attended with much detail, it is desirable that a more general and concise view by means of a diagram should be afforded of the courses which the fibres take in constructing this organ.

RECAPITULATION. (Vid. the diagram *fig.* 283.) We commence tracing the fibres of the heart from its very centre. The fibres, CC, from the two carneæ columnæ of the left ventricle, LV, are joined by the fibres, R, from the rope RR, after those fibres of the rope have expanded and formed the internal layer of the septum S; in winding round the axis of this cavity they blend together as the initial letters CRC indicate. The inmost of these fibres descend as far as the apex, where they twist sharply round and close the cavity, by which means they construct the apex, and become the superficial fibres of the heart. But the chief bulk of this mass of blended fibres makes a spiral sweep from left to right round the axis above the apex; and when it has described two circles, CRC, it splits at the anterior edge of the septum into two bands, one being considerably longer than the other. The longer first makes one circle round the left ventricle, then another, enclosing both ventricles. In making the first circle it passes through the septum forming its middle layer, and on reaching its posterior edge it receives from the pulmonary artery accessory fibres, which have crossed over the cavity of the right ventricle, forming the inmost layer of its right or proper wall, and fibres from one of the carneæ columnæ of this ventricle, and from the aorta, being marked CPCA. The accessory fibres are not represented, as they would have rendered the diagram complicated and unintelligible; but they are indicated by their initials being added in the lettering of the bands. This band in question may now be traced round the middle third of the left ventricle advancing towards both the base and the outer surface of the heart; on completing its first

Fig. 283.



circle it arrives again at the anterior edge of the septum, receives another fasciculus of fibres from the aorta, and is marked Cpcaa. It is then seen to take its course round the base and in front of the right ventricle. As it passes by the right aspect of the aorta, it again receives from it a fasciculus of fibres, and is lettered Cpcaaa; on reaching the posterior edge of the septum, it is further augmented by two accessions of fibres, one from the aorta at its posterior aspect, and the other from the middle layer of the septum. This combination of fibres from various sources is indicated by the combination of their initial letters, CpcaaaaC. It should be borne in mind that C large is the synalepha of crc—the initials of the primitive mass of blended fibres. This band, in passing along the base of the left ventricle, makes at first a gentle twist of its fibres forming the brim of this chamber; it afterwards makes a sharp twist and assumes the form of a rope, by which means its fibres are transferred to the interior of the ventricle. In descending this chamber, they expand again into a layer, and wind spirally round its cavity, first forming the internal layer, a, of the septum, and then associating with the expanded fibres of the two carneæ columnæ, and thus arrive at the points from which we commenced tracing them. We now return to the anterior edge of the septum, S, in order to trace the shorter band. At this part the primitive mass of blended fibres splits into two bands: the longer passes behind the right ventricle through the septum as already described; the shorter passes in front. The shorter first receives a considerable accession of fibres from the right surface of the septum, which pass down from the aorta, and from the two carneæ columnæ springing from this surface: it is lettered Cacc; it describes one spiral circle round both ventricles. It first passes over the lower half of the right ventricle, forming the apicial band of the middle layer of its proper wall, and then round the left ventricle in an oblique direction to the base, and terminates at the aorta near the anterior coronary track, having completed its spiral circle round the heart.

As the demonstration has, in reference to the construction of the septum and of the right ventricle, been unavoidably disconnected, it is requisite to give a more systematic and comprehensive description of their particular formation.

The *septum* is composed of three layers: a left, a middle, and a right layer. The two former properly belong to the left ventricle; and the last or right layer exclusively pertains to the right ventricle. The two former are composed of the primitive mass of fibres derived from the rope and the carneæ columnæ of the left ventricle; the left layer being formed of the expanded fibres, a, of the rope, rr, *fig.* 280, in their first sweep round the cavity; and the middle layer of the continued fibres of the rope in its second sweep, blended with the expanded fibres of the two carneæ columnæ. These blended fibres form the extended layer cac; its cut edge *a* applies itself to the cut edge *b*, evidently forming the middle layer of the septum. The last or right layer of the septum has not the same origins as the two former have. Its fibres arise from the root and lower margin of the valve of that section of the aorta which pertains to the right ventricle, from that part of the root of the pulmonary artery contiguous to the aorta, and from the carneæ columnæ of the right surface of the septum. The fibres attached to the aorta and pulmonary artery may be seen in *fig.* 278, lettered a and a respectively, and in *fig.* 280 the fibres from the aorta blended with those of the carneæ columnæ are exhibited marked acc, forming the right layer of the septum.

The right ventricle.—Although the right layer of the septum belongs anatomically to the right ventricle, yet when functionally considered it pertains, as well as the other layers, entirely to the left. For the concavity of this layer is, like that of the other layers of the septum, towards the cavity of the left ventricle, and therefore during the systole approaches the axis of this cavity, while it recedes from that of the right ventricle; thereby assisting in the propulsion of the blood from the former, and to a limited extent counteracting the propulsive effort of the latter ventricle.

The right ventricle has, therefore, but one proper wall, which is connected to the left ventricle in a manner to be described hereafter. The right chamber should be divided into three channels: the *auricular*, the *pulmonary or ventricular*, and the *apicial*. The auricular is that which receives the blood directly from the right auricle; the pulmonary is that formed by the fibres which arise from the root of the pulmonary artery at its entire circumference: in *fig.* 278, the pulmonary artery, pp, and the fibres, p, are seen turned a little upon their axis, by which means the fibres are rendered oblique, and the channel the more complete; and the apicial channel is that which forms the channel of communication between the other two, and which extends to the apex. The proper wall is considered as having three layers, the superficial, middle, and internal, although they cannot always be detached from each other. The *superficial* is composed of the mere superficial fibres of this wall, having the same origins and terminations as have its subjacent fibres; it forms the left wing Cacc of *fig.* 279, and may be seen in *fig.* 281, raised from the right ventricle and reflected over the base marked Cacc. The *middle* layer is composed of two bands, the apicial and the basial. The apicial is formed of the first semicircular portion of the shorter band of the heart, and passes over the lower half or apicial channel of this chamber; it lies separated and extended over the apex of *fig.* 281, marked Cacc. The basial band of this layer is formed of the first semicircular portion of the longer band as it makes its second circle round the heart. It is bisected and separated as seen at Cpcaa, of *fig.* 281; in its natural situation it passes over the pulmonary and auricular channels of this ventricle, and is closely connected to the base. The *internal* layer arises chiefly from the pulmonary artery, PP; it first forms the pulmonary channel, P, and then expands into a layer which crosses obliquely over the apicial channel, associated with fibres derived from one of the carneæ columnæ. The basial portion of this layer which crosses over the auricular channel, cannot often be separated from the fibres of its superjacent band, the fibres of the musculi pectinati being intricately interwoven with them. When this layer is replaced, its lower loose edge applies itself to the anterior boundary, *a b*, of this cavity, and is lined with its internal proper membrane. Of the three layers composing the proper wall of this ventricle, two, the middle and inner layers, are confined at the edge of the septum, forming thereby the lateral boundary of this cavity.

The boundary of the right ventricle.—It is true that every part of the internal surface of this chamber contributes in forming its boundary. But, as this cavity is formed chiefly by the splitting of the mass of fibres into layers and by their re-union, it is clear that unless the layers so separated were well secured at their points of junction, their separation would progressively increase, and the cavity enlarge to a fatal extent by the repeated dilatations to which it is subjected. The mode of union which secures this lateral boundary merits therefore particular notice. As the lateral boundary corresponds to the edge of the septum, it admits of the same division into *anterior* and *posterior*. The *anterior* boundary being formed by the splitting of the layers, and the posterior by their re-union, their respective modes of construction are not precisely similar. The anterior boundary is principally formed by a certain set of fibres winding and reflecting upon themselves, as shewn in *fig.* 281. The basial part of this boundary, *a b*, is formed of fibres A, from the aorta A A, winding over the pulmonary channel of fibres P, in contributing to form the band CPCAA. The fibres of this channel also contribute to form this part of the boundary, as is represented in *fig.* 278. The apicial part of this boundary is obviously constructed by the fibres ACC which form the right layer of the septum being prolonged into the extended band, which on being replaced occasions them to be doubled upon themselves in passing over the apicial channel in association with the fibres of this band.

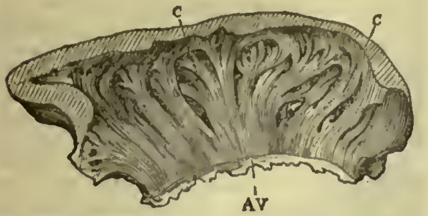
The *posterior* boundary is constructed by the re-union of the fibres which pass in front of the cavity with others which pass behind it, and by the attachment of some of the fibres at the base to the aorta. The basial half of this boundary being formed by the conjunction of the under fibres of the basial band CPCAAA, *fig.* 282, with a fasciculus of fibres, c, emerging from the middle layer of the septum, and with another fasciculus of fibres, A, *fig.* 278, arising from the aorta, AA. That part of the boundary contiguous to the base is greatly strengthened by the outer fibres of the basial band being attached to the aorta at its posterior aspect. And the apicial half of the posterior boundary being formed by the conjunction of the principal part of the internal layers of fibres which cross obliquely the cavity of the right ventricle with the chief part of the fibres of the middle layer of the septum as they emerge at its posterior edge, where they freely decussate. In *fig.* 281 the internal layer of fibres, PC, is seen crossing the cavity obliquely towards the apicial part of the posterior boundary, and in *fig.* 282 their conjunction with the fibres which emerge from the septum is seen forming a firm union. But the lateral boundary is rendered doubly secure by the curious circumstance of the coronary vessels, deeply penetrating the substance of the heart along the entire edge of the septum, stitching down, as it were, just on the outside of the boundary, all the fibres which form it.

The conical form of the heart.—The only point now remaining for consideration is the conical form of the heart. This form admits of the following explanation. Along the central cavity of the left ventricle are placed the two carneæ columnæ, the length of which is equal to the lower three-fourths of the length of the axis of this cavity. The fibres of these two bodies radiate, as represented in *fig.* 278; and the radiated fibres wind round the axis closely upon them, as is seen in *fig.* 280. By this radiation, instead of all the fibres passing longitudinally, which would have preserved these bodies in a state of equal thickness throughout their length, they are progressively parting with their fibres, retaining but a few, which, by their longitudinal course, reach the apex; consequently these columns gradually diminish, becoming pyramidal, and forming together an inverted cone; and as the fibres in well-formed hearts wind closely round these columns, the entire ventricle gently assumes the form of a cone. And although the right ventricle is, as it were, appended to the left, yet it is not so connected to it as to destroy the conical form, but, on the contrary, in such a manner as to form a concave parabolic section of a cone which adapts itself to the gentle cone of the left ventricle. The two ventricles thus united assume the form of the more rapid cone of the heart.

Construction of the auricles.—For the purpose of ascertaining the mode in which the fibres form the auricles, large hearts, as those of bullocks and horses, should be selected. Notwithstanding the muscularity of the auricles is very much greater in large than in small hearts, yet the plan is the same in both, although less developed in the latter.

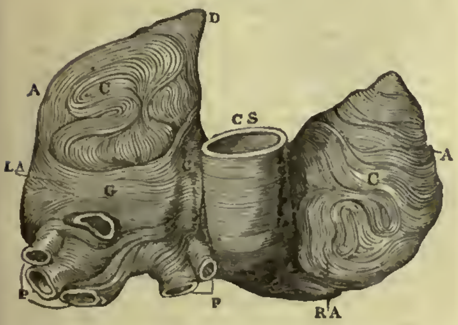
The fibres of the auricles arise chiefly from the tendinous margins of the annulus venosus and annulus arteriosus; they ascend interiorly, and arrange themselves into several columns, which give off branches. Some of the branches form a simple communication between two of the trunk-columns, but most of them subramify, by which means the interstices are filled in. In small hearts the columns are not only more slender, but more numerous and interlaced; in these, the interstices in many places are not filled in, the internal and external proper membranes being in contact, and thus completing the wall. *Fig.* 284 affords an interior view of a section of the right auricle, in which,

Fig. 284.



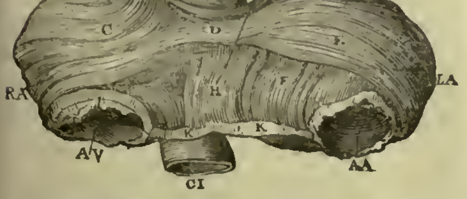
the lining membrane being removed, the fibres are seen arising from the tendinous margin of the annulus venosus AV, forming the internal part of the wall of this auricle, and in their progress up arranged into columns, C, the branches of which are entwined together so as to construct the appendix. These convoluted columns at the posterior aspect of the appendices are flattened, as shown in *fig.* 285, C, where their fibres are associating together, and

Fig. 285.



in passing round the edges to the anterior surface become evenly arranged again, as seen in the appendix A of the right auricle, RA, of *fig.* 286. Thus far the construction of the two auricles

Fig. 286.



agrees, the fibres of each arising from its respective annulus, forming first the inner part of the wall of the auricle, and then being arranged into columns which entwine together, forming the whole of the appendix. The fibres of the right auricle, after having formed the wall of this cavity, are prolonged to form the outer part of the wall of the left auricle. As may be seen in *fig.* 286, the fibres which extend from the convoluted fibres of the posterior surface of the right auricle, RA, wind evenly arranged, some over the apex, and others round the auricle, marked C, completing the outer part of the wall of the entire auricle: they then meet at the septum S, across which they pass associated together, marked D, and on reaching the left auricle divide into an upper portion and an anterior and posterior band. The *upper portion* is composed of the continued fibres D, which proceed up the appendix and encircle its apex. The *anterior band* E winds round the left auricle LA, and on reaching the root of the aorta K, its fibres become more or less attached to it in different hearts; in its course upwards, marked F, when it has completed a circle it passes behind the fibres which form the first part of the circle to enter into the formation of the fleshy columns of the appendix. The *posterior band* passes over the left auricle between the appendix A and the vena cava superior CS; and in *fig.* 285 it can be traced, coming over, marked G, and passing along the posterior surface of this auricle LA, including in its course the posterior edge of the appendix A; the fibres which pass along the posterior edge of the appendix, on arriving at the anterior edge, separate from the band G to pursue their course round the edge of the appendix,—now along the anterior edge,—and join the fibres D, which cap the apex. This division of the band which encircles the appendix is constant, and evidently affords particular strength to its edge. The band itself G winds down towards the base, expanding and surrounding the orifices of the pulmonary veins P; some of its fibres become lost on the surface of the auricle, and the others may be traced to the root of the aorta.

This band cannot be completely detached in consequence of some of its fibres being interwoven with its subjacent fibres.

The left auricle, without the addition of these bands, would nearly balance in substance and strength the right; their addition gives, therefore, to the left a considerable preponderance in these respects over the right auricle.

The septum S is, in *fig.* 286, shown to be composed, superiorly, of the transverse band of fibres D, which passes from the right to the left auricle; in its middle part, of the ascending fibres H, which arise from the root of the aorta K, and pass up behind the band D, some joining this band, the others proceeding to the vena cava superior CS; and lastly, at the inferior and posterior part, of a slender fasciculus of fibres which crosses the septum transversely between the root of the aorta K and the vena cava inferior CI, extending from the annulus venosus to the left auricle, but which cannot be seen in this figure.

In concluding these remarks on the construction of the auricles, it may be mentioned that in the hearts of large animals a great difference exists in the structure of the two venæ cavæ, the superior being particularly fleshy, and the inferior apparently devoid of muscularity.

(H. Searle.)

HEART, ABNORMAL CONDITIONS OF.—There is no organ in the body in which the various deviations from the normal state have been more diligently or more carefully explored than the heart; nor ought it to be otherwise, when we take into account the important part which the heart performs in the organism, and the serious nature of the derangements which its diseases in general produce,—how many organs and how many functions are involved in the break-up which too often follows the occurrence of morbid alterations of the heart. The great frequency* of diseases of this organ, and the manifest and tangible shape which these diseases assume, as well as the little liability of its component structures to those appearances which have been denominated pseudo-morbid, these circumstances render it comparatively easy to detect and observe its abnormal conditions. To one who has made the natural condition of the whole organ, as well as of its several parts, the subject of careful study, there is no field of investigation in morbid anatomy which presents fewer difficulties.

The records of anatomy are not without instances of total absence of the central organ of circulation *(acardia)*; and it may well be supposed that such cases would also afford examples of the defective development of other not less important organs. In short, it is in acephalous and anencephalous fœtuses that the heart is most frequently wanting, although its absence is not, as some observers suppose, a constant characteristic of these forms of monstrosity; nor on the other hand does acardia necessarily imply acephalia or anencephalia. Thus in the case recorded by Marrigues†, and quoted at length in Breschet's Memoir *Sur l'Ectopie du Cœur*,‡ the brain was present, while all the usual contents of the thorax were wanting, their place having been supplied by a large bladder full of clear water which occupied the whole thoracic cavity. The details of another case were communicated many years ago to the Royal Society by Sir Benjamin Brodie, and are published in the volume of their Transactions for 1809. The fœtus was one of twins, as is most frequently the case when the heart is absent. The brain was "nearly the natural size, and nothing unusual was observed in it." The heart, thymus gland, and pleura were absent, and the lungs most imperfectly developed. The aorta, however, was tolerably perfectly developed, but as a continuation of the umbilical artery extending from the left groin upwards on the fore-part of the spine to the upper part of the thorax, where it gave off the two subclavian, and afterwards divided into the two carotid arteries without forming an arch. The external and internal iliac arteries of the left side came from this artery in the left groin immediately after it left the umbilicus, and the common iliac of the right was given off from it in the lumbar region after it had gained the situation of the aorta.

We shall first examine the congenital deviations from the normal state in this organ, and secondly its morbid alterations.

I. *Congenital abnormal conditions.*—These are observed under three heads. 1. Congenital aberrations of position, or ectopiæ of the heart. 2. Malformations by defect in developement. 3. Malformations by excess of developement.

1. *Congenital aberrations of position.*—The simplest form of malposition is that in which the heart retains the vertical position which it occupies during the early periods of intra-uterine life; but of this the authentic instances are rare.* Better known is that deviation in which the heart is directed downwards, forwards, and to the right side. This malposition generally occurs as a part of a universal transposition of the abdominal and thoracic viscera, of which many well-marked examples are now on record; however, it sometimes, although more rarely, exists alone without ectopia of any other organ. Breschet† records four cases of this latter kind. Otto‡ has met with three instances, and many other examples are scattered among the records of anatomists.§ In this form of transposition of the heart, the aorta sometimes passes down along the right side of the spine, and at other times down its left side. In the latter case the transposition is not so complete, the ventricles retaining their natural position with reference to the anterior and posterior aspects of the body. Again the heart may be pushed too much to the left side, as a mechanical result of congenital diaphragmatic hernia of the right side; and it has been found laid across in the chest from one side to the other, the apex being at one time directed to the right side, and at another to the left, or turned upside down, the base toward the abdomen, or in that cavity, the apex upwards still remaining in the thorax.

In such cases as have been just detailed, the heart still retains its title to be considered as a thoracic viscus; but other and more remarkable malpositions of it have been found, where it is excluded from that cavity. These are, in fact, congenital thoracic herniæ in various directions, of which Breschet, whose memoir already referred to contains the most complete account of this subject, enumerates three principal varieties, according to the situation in which the heart is found, viz. the superior or cervical displacement, the abdominal or inferior, and the thoracic or anterior.

Thus Breschet details a case in which the heart, lungs, and thymus gland were all contained in the anterior part of the neck, forming a large tumour under the lower jaw. The point of the heart was attached to the base of the tongue, and placed between two branches of the lower jaw. The thorax was occupied

* Out of 520 post-mortem inspections recorded by Dr. Clendinning, 170 were cases of diseased heart, or about 33 per cent.—Vide his Croonian Lectures for 1838, Med. Gazette, vol. xvi. p. 657.

§ Reuss' Repertorium, vol. x. p. 90-91.

by the abdominal viscera, which had passed up through a fissure in the diaphragm. In a second instance of this high displacement the apex of the heart adhered to the palate; but in this case the malposition appears to have been owing to a morbid adhesion of the umbilical cord to the head, by which all the viscera were drawn out of their natural positions. A less degree of cervical displacement is where the heart is found immediately above the thorax, in the front of the neck, which, however, is very rare.

When the malposited heart is found in the abdomen, the diaphragm is generally deficient to a greater or less extent.

In a case narrated by Mr. Wilson,* the heart was in a fissure on the convex surface of the liver—the infant lived seven days! Ramel also gives an instance of the heart being placed in the region of the stomach, and the individual in whom he observed it was ten years of age. And in the extraordinary case related by Deschamps, the heart occupied the place of the left kidney! Not the least marvellous circumstance about this case is, that the individual was an old soldier, who had served several campaigns, and enjoyed excellent health, with the exception of nephritic pains, which ultimately procured him his discharge from the service. The right kidney alone existed, and was found in a state of suppuration.† The vessels emanating from the heart passed through an opening in the diaphragm into the thorax.

Dr. Paget mentions some instances of varieties of position which parts of the heart may assume with respect to each other. In a case recorded in the first volume of the Edinburgh Medico-Chirurgical Transactions by Dr. Holmes of Canada, the right auricle, enlarged to the capacity of a pint, was found to open into the left ventricle in place of the right, into which, however, the blood afterwards found its way through a small perforation in the septum of the ventricles.

The aorta and pulmonary artery may arise from one ventricle alone, either right or left, and instances of each præternatural origin are preserved in the museum of the Edinburgh College of Surgeons.

When the anterior wall of the thorax is deficient, the heart may be found protruding through the opening, as in fissure of the sternum, or a defect in its inferior portion as well as in some of the ribs; nor does this malposition necessarily destroy life. Where the deficiency is not confined to the wall of the thorax, but also extends to the abdomen, the stomach, liver, and spleen, with the heart, are found occupying a large hernial sac in front of the opening, which is sometimes contained in the sheath of the umbilical cord, or covered by an extension of the common integument. In the case of simple fissure of the sternum, it has occurred that the heart had not protruded, but occupied its natural position, being simply exposed to view by the abnormal opening in the chest.*

* Phil. Trans. 1798.

† Quoted by Breschet from the Journ. Gén. de Méd. t. xxvi.

2. *Malformations by defect in developement.*—Our limits compel us to restrict the present account to little more than an enumeration of the congenital malformations which may be placed in this class. In these malformations we find a diminution in the normal number of the heart's cavities, either from a very early arrest in the developement of the whole organ, or from a total non-developement of the septum, or from its imperfect developement. A few rare instances, many of which have occurred in the lower quadrupeds, of an extremely imperfect state of the heart, are quoted by Otto, in which that organ seemed to consist of nothing but a fleshy enlargement at the commencement of the aorta, described as "a mere fleshy mass without any cavity," or "a longish solid mass from which the vessels arise," "or a mere expanded vascular trunk."

The *dicœlious* heart of Hunter, or that with two cavities, exists at a very early period of the developement of the Mammiferous embryo: it is described and figured by Baer in the embryo of a dog, of three weeks, only four lines in length, as consisting of a single auricle and a single ventricle.† The permanence of this state of the heart, similar to the natural condition of that organ in fishes, constitutes one of the simplest but rarest malformations in the human subject. From the ventricle a single vessel arises which subdivides into the aorta and pulmonary artery. A very perfect example of this malformation is described by Mr. Wilson in the Philosophical Transactions for 1798; it is the same case which has been already alluded to as affording an instance of malposition. In this case the blood was returned from the lungs by two veins which joined the superior vena cava, and entered the auricle along with it, the inferior cava being formed in the usual way. Other examples are recorded by Mr. Standert,‡ Dr. Farre,§ Professor Mayer,‖ and Dr. Ramsbotham.¶

The heart with three cavities (tricoilia of Hunter), that is, containing two auricles and one ventricle, or that form of the heart which belongs to the Batrachian reptiles, must be very rare, if indeed it ever occurs.

A case is related by Breschet,** in which a

** Rép. Gén. d'Anat. tom. ii.

single ventricle and two auricles existed, but along with an imperfect inter-auricular septum. The two auricles, therefore, virtually formed one cavity. A similar case is recorded by Wolff,* and is remarkable from the fact that the individual in whom it was observed lived to the age of twenty-two. These hearts then do not exactly correspond to the tripartite heart of Batrachia, inasmuch as the two auricles communicate. A similar case, shewn by Mr. Lawrence to Dr. Farre,† explains more particularly the true nature of the malformation. It was a deficiency of the septa, both auricular and ventricular, the latter having been altogether wanting; the former consisting only of a small muscular band, which left a large foramen ovale without a valve, but the venæ cavæ and pulmonary veins opened into their respective auricles, which externally appeared to be quite separate. The ventricle communicated with the two auricles by a single ostium ventriculi, and the aorta and pulmonary artery, the entrance of the latter being somewhat contracted, arose side by side from the left part of the ventricle.

Most of the other defective malformations of the heart consist in præternatural communication between the right and left cavities, resulting from various causes. 1. The communication is direct, either from an open foramen ovale, or from an imperfection in the septum of the auricles or of the ventricles, or from the co-existence of all three or any two of them. 2. The communication is indirect, the septa being perfect, but the ductus arteriosus remaining pervious.

The open foramen ovale is by far the most common of all the malformations of the heart; numerous examples of it are now on record, as found in persons of all ages. The opening of communication varies considerably as to size, apparently according to the period of developement at which the arrest took place; the diameter of the opening ranges between two and twelve lines. We know that the size of this orifice is inversely as the size of the fœtus during intra-uterine life, whence we may infer that the larger the opening is, the earlier must have been the period at which further developement ceased. In many instances the valve-like portions which bound this opening have acquired their full developement, and the only defect seems to be the non-adhesion of their margins, so as to close the cavity; this non-adhesion again may involve the whole extent of the margins of the valves, or only a very small portion, thus leaving a large or small opening of communication between the two auricles. Such a condition of the inter-auricular septum does not necessarily occasion that intermixture of the blood which so commonly accompanies the communication between the right and left cavities; and where the opening is small, of course this intermixture is the less likely to occur. Thus every anatomist must be aware that it is not an unfrequent occurrence to find an opening large enough to introduce a goose-quill in the hearts of adults who during life exhibited no derangement of the circulation, and who died of diseases totally unconnected with the heart. On the other hand we are often surprised at the amazing size of the opening in the hearts of persons who have lived many years, and have shewn less disturbance of functions than the freedom of the communications between the auricles would warrant us to expect. In many of these cases the absence or mildness of symptoms may be accounted for by the obliquity of the passage of communication, and the overlapping of the margins of the valves, so that at times they completely oppose the flow of the blood from one side of the heart to the other, whilst at other times the passage is left more or less free. In a heart which I lately saw in the Museum of Guy's Hospital, the circumference of the open foramen ovale was equal to that of a halfpenny, (i. e. about an inch in diameter,) and yet the patient had lived to the adult period; and in a case quoted by Dr. Farre from Corvisart, the foramen ovale was "more than one inch in diameter." Such cases strongly favour the opinion that the foramen undergoes considerable enlargement when once all impediment to the passage of the current of blood from one side to the other has been removed.* More rarely we find the fossa ovalis cribriform, and thus several small openings of communication exist between the auricles, and sometimes in addition to the unclosed foramen ovale, we have a true imperfection in the septum, as in the case related by Walter,† and another by Otto.‡

Imperfection in the septum ventriculorum is a much less frequent cause of the communication between the right and left hearts than the open foramen ovale. The opening, varying in diameter from two lines to about an inch, is situated towards the base of the septum, so that the ventricles communicate at their bases; a fact which evidently indicates that the opening results from the progress of the developement of the septum being arrested near its completion, since the base of the septum is the last portion formed. The orifice of communication generally opens upwards towards the orifices of both arteries, and is bounded inferiorly by the rounded smooth edge of the ventricular septum. In these cases the aorta opens into both ventricles and appears to arise from both; and frequently the orifice of the pulmonary artery is contracted and more rarely obliterated, either from non-developement or from previous morbid action; moreover, ap-

* In Kreysig's die Krankeit, Herz. B. iii.

† Loc. cit. p. 30.

* It is not, perhaps, correct to suppose every case of open foramen ovale congenital; at least it is certain that many patients date their symptoms from a fall or blow; and even without any evidence of the occurrence of such violence many cases have been observed which can be explained only by supposing that the foramen ovale had been morbidly re-opened. See Abernethy in Phil. Trans. 1798; Otto, Selt. Beobachtungen; and Pasqualini, Memorie sulla frequente apertura del foramine ovale rinvenuta nei cadaveri dei tisici. Rom. 1827.

† Observat. Anatom.

‡ Pathol. Anat. by South.

parently as a consequence of this contracted state of the arterial outlet of the right ventricle the ductus arteriosus often remains open, which, by its communication with the aorta, conveys some blood into the pulmonary arteries from that vessel; and, as a further complication, the right ventricle is very small and appears merely as an appendage to the left; sometimes also the left auricle is very small, while the right is much dilated.

Where so much complication exists, as that just detailed, one is only surprised that vitality can be at all supported after extra-uterine life has commenced; yet we find that children with hearts so malformed live three, four, or five days, and even as many weeks or months; but where the perforation of the septum is not accompanied with the contracted state of the pulmonary artery, life may be prolonged to a considerable period. Thus, Louis quotes one case of a general officer (age not stated), whose death was occasioned by the active part he took in the American war. Along with ossified valves of the right auriculo-ventricular orifice, there existed a perforation of the septum ventriculorum large enough to admit the extremity of the little finger. In another case, quoted from Richerand, the patient aged 40, the perforation of the septum was half an inch in diameter.

We say that the two sides of the heart communicate indirectly when the ductus arteriosus continues, as in its fœtal state, to convey the blood of the right heart into the aorta descendens, where it becomes intermixed with the blood of the left heart. But it is very rare to find this condition existing alone, and when it does so exist, the canal of communication is generally very narrow. More frequently it is complicated with a contracted state of the pulmonary artery, the place of which it seems to supply. In a case related by Mr. Howship,* this vessel constituted, in fact, the trunk of the pulmonary artery. The pulmonary artery proper arose in its usual situation, but was quite impervious at its root, though far beyond, and terminated in a cul-de-sac beside the heart. Similar cases are recorded by Dr. Farre. At other times the ductus arteriosus is employed to supply the place of the aorta descendens; the aorta is perfect only as far as the termination of its arch, where it contracts, and its continuation is formed by the ductus arteriosus, through which the descending aorta receives its whole supply of blood.†

A very perfect case of this kind is quoted by Dr. Paget‡ from Steidele. The aorta and pulmonary artery arose as usual; the aorta was entirely distributed to the head and upper extremities, while the pulmonary artery, after giving off two branches to the lungs, continued as the *aorta descendens* without any communication with the *aorta ascendens*.

Malformations of the valves.—A not unimportant class of defective malformations in the heart consists of imperfections in the number or structure of the valves. The aorta may have two valves only, one of which may retain its natural form and size, while the other presents the appearance of having been formed by the fusion of two valves; it may therefore present one or more openings in it, so as to appear somewhat cribriform. A similar condition is met with in the pulmonary artery, when sometimes the three valves seem as it were united to form one membrane, which like a diaphragm stretches across the mouth of the artery, and is perforated in the centre by an opening through which the blood finds its way into the artery. This narrowing of the orifice of the pulmonary artery is the most frequent of the congenital malformations of the valves: we have already described it as a frequent concomitant of imperfect septum of the ventricles. Congenital imperfections of the mitral and tricuspid valves are of very rare occurrence. The perforated or cribriform condition which is frequently seen affecting these valves, the Eustachian and Thebesian valves, and more rarely the semilunar valves, is probably the result of a morbid atrophy.

Congenital absence of the pericardium.—Connected with the malformations by defect of developement we may mention the congenital absence of the pericardium, which, although very rare, rests on too strong evidence to admit any further doubt of the possibility of its occurrence. Most of the cases related by the older authors were in connexion with displacement of the heart, and from the liability of mistaking universal adhesion of the pericardium for this congenital absence, many anatomists, among whom was Haller, denied that such a defect had ever existed.

Dr. Baillie* was the first of modern anatomists who accurately described a case of this kind. "Upon opening," he says, "into the cavity of the chest, in a man about forty years of age, in order to explain at lecture the situation of the thoracic viscera, I was exceedingly surprised to see the naked heart lying on the left side of the chest, and could scarcely at first believe what I saw, but the circumstances were too strong to keep me long in doubt. The heart was as bare and distinct as it commonly appears in opening into the cavity of the pericardium, and every collateral circumstance confirmed the fact. . . . . The heart lay loose in the left cavity of the chest, unconnected in any way except by its vessels; was of a large size, elongated in its shape, and had its apex opposite to the eighth rib. The right auricle was obviously in view in the same manner as when the pericardium has been opened, and the vena cava superior and inferior were clearly observed entering into it. The appendage of the left auricle was as clearly in view; and when the heart was inverted, so as to have its apex turned upwards, the extent of its cavity was seen with the two pulmonary

* Edin. Med. and Surg. Journ. vol. ix.

† See Sir A. Cooper's cases in Farre, loc. cit.

‡ Loc. cit.

* On the want of a pericardium in the human body, in Transactions of a Society for the Improvement of Med. and Chir. Knowledge, vol. i. p. 91, with a plate of the appearances.

veins of the left side entering behind the appendage. The right and left ventricles were distinct, with the coronary vessels running upon them; and the aorta and pulmonary artery were seen clearly emerging from them." There is nothing in Dr. Baillie's description to indicate positively whether the visceral layer of the serous pericardium was absent or not, although we may infer its absence; what he says bearing upon this subject is as follows: "The heart was involved in the reflection of the pleura, belonging to the left side of the chest, which became its immediate covering, and upon making the slightest incision into the substance of the heart, its muscular structure was laid bare, as in any common heart deprived of its pericardium."

Breschet* has put on record a case in which the pericardium was absent, not altogether, but in greatest part. The subject of it was a young man of twenty-eight years of age, who died in the Hôtel Dieu of an inflammatory affection of the intestines. The heart lay free under the left lung without any external fibro-serous envelope. The mediastinum was formed only by a simple serous lamina belonging to the right pleura, and upon the left of this lay a rudimentary fibrous capsule, attached above to the origin of the great vessels. The serous membrane was altogether absent, but the heart was immediately inverted by a serous lamella, which was prolonged from the left pleura. In both this case and that of Baillie, the left phrenic nerve was displaced and brought towards the mesial line of the body, and not covered by the serous membrane,—an anatomical character, which, as Breschet suggests, may serve to distinguish congenital absence of the pericardium from the simple adhesion of that membrane to the heart.†

II. *Malformations of the heart by excess of developement.*— Plurality of the heart itself may be obviously regarded as coming under this head; but I am not aware of any instance in which a double heart has been found in a perfect single fœtus, nor can the possibility of such an occurrence be deemed admissible. It is in monsters formed by the junction of two that this double form of the heart has been met with. Thus, in one case referred to in Bouillaud's work, all the upper parts of the fœtus were double, while the inferior were simple. There were two heads, two necks, quite separate and of the ordinary size. The necks terminated in a single very wide thorax, to the upper part of which and between the insertion of the two necks an arm was attached in the vertical direction, one perfectly formed arm being placed on each side of the thorax. There were four lungs, each having a distinct pleura, but only one diaphragm: there were also two hearts and two pericardia, each of which had two venæ cavæ and a pulmonary artery, four pulmonary veins and an aorta. The two aortæ united at the lower part of the dorsal region of the spine, and formed the artery by which the abdominal viscera and lower extremities were supplied.

The evidence respecting the occurrence of an increase in the number of the parts of the heart is very unsatisfactory. The often quoted case of Kerkring,* with a double right ventricle; one by Vetter,† with four auricles and four ventricles, quoted by Otto; a third by Chemineau,‡ with three ventricles, are, if genuine, the most remarkable instances on record, besides various instances in the lower animals, especially birds. Andral states that he has seen a heart with three auricles, and another with four ventricles: it is much to be regretted that he has given no description of these singular malformations.§

Supernumerary cavities, or septa dividing the primitive cavities of the heart, are the most common instances of excessive developement. Adopting the arrangement of Andral,|| we find—1, a supernumerary cavity forming a sort of accidental appendage to one of the auricles or ventricles, and communicating with the cavity of the part to which it is attached: 2, a supernumerary septum, forming an imperfect division of one of the natural cavities; 3, a second cavity, completely partitioned off by one of these septa, and giving off supernumerary vessels, which communicate with the regular vessels of the heart. It appears to me, however, to be very questionable that all cases of supernumerary cavities are the result of excessive development, but that, on the contrary, they are sometimes mechanically consequent upon defective formation in other parts. At least it is in this way that I account for the condition of the heart of a boy, aged ten years, which I examined several years ago, and which has been described by my respected friend, Dr. John Crampton, in the Transactions of the Dublin College of Physicians for 1830. In this heart there were three instances of defective developement—absence of the valves of the pulmonary artery, an open foramen, and an imperfect septum ventriculorum. Attached to the right ventricle there was a supernumerary cavity with which the pulmonary artery communicated. This cavity communicated also with the right ventricle, by an opening large enough to admit the little finger, and formed under the columnæ carneæ of the ventricle. The pulmonary artery was not only destitute of valves, but at the usual situation of the valves its lining membrane was puckered, by which its orifice was manifestly contracted. The supernumerary cavity, in this instance, was in all probability occasioned by a partial dilatation of the infundibular portion of the right ventricle, in consequence of the obstruction at the pulmonary orifice.

Increase in the number of the valves of the large arteries may be counted among the ab-

|| Loc. cit.

normal formations by excess. Thus, four or even five valves are occasionally found in the pulmonary artery more frequently than in the aorta. The supernumerary valves are always small, and sometimes appear to have been formed at the expense of the next normal one.

Anomalous connexion of the vessels of the heart. — Our space will only permit us to enumerate the principal observed varieties. 1. The aorta or pulmonary artery, or both, appear to arise equally from both ventricles, the septum of the ventricles being more or less deficient. 2. The aorta may arise from the right ventricle, and the pulmonary artery from the left, the veins preserving their natural position. 3. The vena azygos opens into the right auricle. 4. The hepatic veins open into the right auricle. 5. The ductus arteriosus opens into the right ventricle. 6. Two superior venæ cavæ open into the right auricle. 7. Very rarely the right auricle gives insertion to one or more pulmonary veins, and on the other hand the left auricle receives sometimes the superior vena cava, and at other times the inferior. 8. Meckel states that he has seen the great coronary vein of the heart to open into the left ventricle.* Professor Jeffray, of Glasgow, relates a case in which the inferior cava opened into the upper part of the right auricle, taking the course as well as the place of the vena azygos.

On displacement or ectopia of the heart as a consequence of disease.—The most common cause of *morbid* displacement of the heart is an effusion of air or liquid into one of the pleural cavities. The displacement is most manifest when it follows effusion into the left side, by which the heart is pushed over to the right, the degree of displacement depending on the amount of effusion, and thus alteration of the heart's position becomes one of the diagnostics of empyema, hydrothorax, pneumothorax. In general, the more rapid the effusion the more certainly will the displacement be effected, and the greater will be its extent. In nine cases out of ten, as my friend Dr. Townsend remarks,† when the heart is removed out of its natural situation, the displacement will be found to have arisen from empyema or pneumothorax; and of twenty-seven cases observed by him, the heart was perceptibly displaced *in every instance.* On the other hand, when the effusion is slow and gradual, the extensibility of the neighbouring textures is more completely brought into play, and the displacement of the heart is thus counteracted, whence it happens that in cases of chronic dropsical effusions into the chest, displacement of the heart is not of frequent occurrence, nor is it extensive when it does take place. When the effusion occurs on the right side, the heart may be pushed more to the left, and upwards, than is natural, but to effect this a considerable effusion is necessary. The first notice of this fact is due to my able friend, Dr. Townsend, to whose article I have already referred. In a case of pneumothorax to which he refers, and which I also witnessed, the effusion was on the right side, and the heart was distinctly seen and felt pulsating between the fourth and fifth ribs, near the left axilla. After paracentesis, which was performed by the late Dr. M'Dowel, the heart gradually returned to its normal position, as the displacing force was removed by drawing off the air and fluid contained in the opposite pleura. Moreover, as has recently been ascertained by Dr. Stokes, the absorption of an effusion of the right side will cause the heart to be displaced to that side, the pleural cavity being obliterated by lymph, while the lung of the left side is enlarged so as to aid in occupying the vacant space and pushing the heart over.

It is scarcely necessary to observe that tumours forming in the right or left sac of the pleura may occasion displacement; thus aneurismal tumours may push the heart to the right, to the left and upwards, or even forwards and outwards against the wall of the thorax, or downwards, so that its apex will pulsate in the epigastrium. Of this last displacement, Dr. Townsend* relates an example. I have myself observed, some years ago, a case where the heart was pushed forwards and outwards, and as it were compressed against the ribs by an enormous aneurism of the thoracic aorta; the sounds of the heart were so modified by this compression as to lead to the erroneous diagnosis of concentric hypertrophy. In the case recorded by Drs. Graves and Stokes,† the heart was pushed upwards and to the right side by an abdominal aneurism, so as to pulsate in the intercostal space of the third and fourth ribs. Dr. Hope mentions the displacement to the left by an aneurism of the ascending aorta. Any cause which pushes the diaphragm upwards and prevents its descent, such as distension of the abdomen by an enlarged viscus, a tumour, or an effusion, will change the position of the heart, so that its axis will be directed horizontally; and Dr. Hope has remarked that the same position may be produced by an adhesion of the pericardium to the heart, by which its enlargement downwards is prevented. A diaphragmatic hernia will displace the heart to an extent proportionate to that of the visceral protrusion. In a case recorded by Drs. Graves and Stokes, the stomach and a large portion of the transverse arch of the colon were lodged in the left cavity of the thorax, and pushed the heart and mediastinum towards the right side. When the lung is enlarged from dilated air-cells, the heart may be displaced: it may be drawn considerably downwards by the diaphragm, which yields before the enlarged lung, thus increasing the vertical diameter of the chest; or it may suffer a slight degree of lateral displacement, the mediastinum being pushed to the right side by the lung.‡

Dr. Stokes has related the remarkable, and so far as I know unique case of displacement, or as he terms it "dislocation," of the heart

* This enumeration is taken from Bouillaud, Traité des Maladies du Cœur, t. ii. p. 588.

† Cyclop. Pract. Med. vol. ii. p. 390.

from external violence. The patient was crushed between a water-wheel and the embankment on which the axle was supported. Several ribs were broken, as well as the right clavicle and humerus. The heart, which, according to the statement of the patient, had always occupied its natural situation, was now found beating at the right side.*

MORBID ALTERATIONS OF THE MUSCULAR SUBSTANCE OF THE HEART.

1. *Inflammation of the muscular structure of the heart, or carditis* (the carditis *proper* of some pathologists).—The same anatomical characters which would lead us to pronounce any muscular tissue in a state of acute inflammation, would justify a similar conclusion respecting the heart. But from the sparing deposition of cellular tissue around this organ and between its fibres, the anatomical phenomena which denote the previous existence of inflammation are not so marked in it as in the muscles of animal life; and judging from the rarity of these organic signs, as well as from the unfrequent occurrence of those symptoms which so great a morbid process could scarcely fail to produce, we may reasonably conclude that active inflammation deeply implicating the carneous fibres of the heart, and originating in them, is very seldom met with.

The anatomical characters indicative of carditis are a dark, almost black, colour of the muscular substance, the fibres of which have lost in a great measure their cohesive power; they are very compressible and readily torn, and consequently cannot be easily isolated to any great extent, although easily separable *en masse*. When the muscular wall of either ventricle is pressed, the blood oozes out from the divided vessels on the cut surface in much greater quantity than usual. In Mr. Stanley's case, as in all cases, the dark colour of the fibres " evidently depended on the nutrient vessels being loaded with venous blood." When in addition to these signs we find purulent deposits in various parts of the muscular structure, and moreover, when it is manifest that the internal and external membranes are implicated, from the effusion of coagulable lymph on them to a greater or less extent, no doubt can be entertained respecting the exact nature of the lesion. In Mr. Stanley's case, " upon looking to the cut surface exposed in the section of either ventricle, numerous small collections of dark-coloured pus were visible in distinct situations among the muscular fasciculi."† A similar case has been recorded by Dr. P. M. Latham, the anatomical characters of which accorded with those above mentioned. " The whole heart was found deeply tinged with dark-coloured blood, and its substance softened; and here and there, upon the section of both ventricles, innumerable small points of pus oozed from among the muscular fibres."‡

Every anatomist must have noticed how variable is the colour and the consistence of the muscular structure of the heart, even independent of disease of the lining tissues. The pale, soft, compressible, flexible, and, to use a common word, *flabby* heart, strongly contrasts with the firm, plump, fresh-looking elastic one; in the former, the flaccid parietes fall together immediately the cavities are emptied; in the latter, the surfaces retain their convexity, although the contents of the cavities have been completely removed. Between these two extremes there are various grades of colour and consistence, of which Bouillaud particularises three as being the result of inflammation, the *red softening*, the *white* or *grey*, and the *yellow*. The first is probably that which may be said unequivocally to follow primary inflammation of the muscular texture; the other two, however, as Bouillaud admits, occur most frequently in connection with pericarditis: they occur, too, as Dr. Copland observes, where no sign of inflammation is manifest, and where during life there had been no evidence of cardiac disease; in cases of general cachexia and of constitutional disease, attended by discoloration of the surface of the body, arising, in fact, as Dr. Williams explains, from an altered state of the nutrition of the organ, owing perhaps to partial obstructions in the coronary vessels rather than to the immediate influence of inflammation. This last excellent observer makes the following judicious remarks in reference to this matter.* " To judge that the tissue of the heart is especially diseased, we must see that it differs much in appearance from the other muscles of the same subject. You will find, on comparing the same muscles in different subjects, a remarkable variety of colour; and in some there is no freshness in any of the muscles, but all are pale, and verging on a pinkish drab or dingy brick colour." Perhaps the most correct arrangement of the various circumstances under which softening of the heart may take place is that given by Andral. 1st, Softening connected with active hyperæmia of the heart; 2d, softening connected with anæmia of the heart; 3d, softening connected with atrophy of the heart; 4th, softening connected with an acute alteration in the general nutritive process (as in typhus); 5th, softening connected with a chronic alteration in the general nutritive process (as in a variety of chronic diseases); 6th, softening which we are not yet enabled to refer to any morbid condition of the heart itself or of the rest of the system.†

Suppuration.—The occurrence of an abscess uncomplicated with any other lesion in the walls of the heart, does not unequivocally denote the previous existence of carditis, although it may afford strong presumptive evidence of the fact: when, however, we find abscess, with lymph or adhesions of recent date, we may reasonably infer its inflammatory nature. Dr. Copland has introduced in a note to his invaluable and profoundly learned article on Dis-

† Otto says that violent exertion appears as in other muscles to render the heart easily broken down; thus, for instance, it is found very weak in hunted deer.

eases of the Heart,* an abstract of several cases in which pus was found in the substance of the heart. Those quoted from Corvisart, Raikem, and Simonet, and probably that from Dr. Graves,† may be regarded as examples of purulent formation following carditis, general or partial. So likewise is Laennec's case, in which, however, the carditis was consequent upon pericarditis. There is no anatomical character which will enable us to distinguish whether a simple purulent deposit, surrounded by natural muscular texture, be inflammatory or not, for there is no reason why the heart should be exempt from that which we know often occurs in other muscles, namely, non-inflammatory deposits.

Ulceration.—As true carditis seems to be generally admitted to be rare, so we may conclude that ulceration is equally so. It is by the ulcerative process that some of the perforations or ruptures of the parietes of the heart take place; it is probable, however, that the great majority of the ulcerations we meet with commence from the surface, and result from membranous inflammation rather than from that of the muscular substance; the ulcer commences on the surfaces, either in or immediately subjacent to the internal or external membrane; and as it burrows deeply, it may perforate the muscular wall, and so destroy the membrane on the side opposite to that on which the ulceration had commenced. Sometimes an ulceration of this kind gives rise to aneurismal tumours or sacs, very variable in size, projecting from that part of the cavity which corresponds to the artery. It seems evident that these tumours are produced by the pressure of the contained blood distending the thinned and yielding wall of the heart. We shall return to this subject further on in treating of aneurisms of the heart.

Induration.—This condition of the muscular structure of the heart seems most probably to be a result of inflammation, especially of the chronic kind. It is generally found in small circumscribed portions; it may occur in any part of the heart, and may even co-exist with softening: the hardened portion has become particularly firm, is cut with difficulty, and when struck with the scalpel sounds, as Laennec says, like a leather dice-box. It is harder, denser, less elastic, and as regards colour is paler than the hypertrophied muscular tissue.

Cartilaginous and osseous transformations.—Induration of the subserous cellular tissue of the heart is in general the precursor of many of these transformations. This indurated portion increasing in thickness gradually assumes the appearance of cartilage—in this cartilage the calcareous particles are deposited. I have not been able to ascertain whether this so-called ossification exhibits, on examination by the microscope, the lamellar arrangement of true bone, as osseous transformations of certain permanent cartilages do, those of the thyroid cartilage for example. These calcareous or osseous patches or tumours compress the subjacent muscular tissue, and produce atrophy of them, and according to Andral, sometimes are connected by prolongations of the same material with other calcareous deposits formed round the orifices. Many pathologists believe that these transformations are the result of inflammation. I suppose there can be no doubt that they follow an increased afflux of blood, and so they may be considered, although not an immediate, at least a remote effect of inflammation, or rather of the altered nutrition and secretion to which inflammation gave rise.

In a case recorded by my friend Mr. Robert Smith, of Dublin, the apex of the left ventricle was converted into a dense, white, firm, cartilaginous structure, the division of which with a scissors required the employment of considerable force; the alteration of structure had extended to some of the carneæ columnæ.*

Tubercles.—These productions are very rarely if ever met with in the heart. No reliance can be placed on most of the instances recorded, in consequence of the imperfect and unsatisfactory descriptions accompanying them; what appears to one person to be tubercular may present a totally different aspect to another. Laennec says vaguely, "only three or four times have I met with *tubercles* in the muscular substance of the heart." And Andral states, that they are never met with in the heart, except when they likewise occur in other muscles. Otto says, "although I have dissected a great number of scrofulous men and animals, I have never found a tubercle on the heart, and therefore consider them very rare." Dr. Elliotson† mentions a case in which there were scrofulous deposits in the walls of the left ventricle, surrounded by white and almost cartilaginous induration. In a case which came under my own observation, in a woman between 50 and 60 years of age, there were several white tumours in the parietes of the right ventricle, each about a quarter of an inch in diameter, of uniform consistence throughout, nor showing any disposition to softening in the centre.

Scirrhus.—Equally unsatisfactory are the reports of anatomists respecting this alteration. Rullier and Billard relate cases in which scirrhus had developed itself on the heart. Rullier's‡ case was an instance of degeneration of the whole substance of the heart into a scirrhous mass, which formed irregular knobs on the external and internal surfaces of the heart. Billard found three scirrhous tumours embedded in the heart of an infant only three days old.§

Medullary fungus, or encephaloid tumours.—Of these, several instances are quoted by Andral from others, and he describes two which he saw himself.‖ In the first of Andral's cases the whole of the walls of the right auricle and ventricle were converted into a hard, dirty white substance, traversed by a number of

‡ Bull. de la Faculté, 1813.
§ Malad. des Enfans.
‖ Loc. cit. vol. ii. p. 346.

reddish lines, and possessing all the characters of encephaloid. In the second case, the external wall of the right ventricle was occupied by a tumour extending from its apex to its base, which projected so far externally as to lead him to mistake it for a supernumerary heart, and likewise protruded internally into the cavity of the ventricle. In a case which I saw myself, the tumour resembled the well-known encephaloid or cancerous tumour of the liver, being, like it, raised above the surrounding muscular structure, and irregular on its surface.

Melanosis.—This deposit is also found very distinctly in the heart. It appears in the form of small spots under the pericardium or endocardium, or as tumours in the substance of the ventricle. In a specimen in the Museum of King's College, London, the melanotic deposits are situated, some beneath the pericardium covering the right ventricle, and others on the carneæ columnæ of the same cavity, immediately subjacent to the endocardium. Neither Andral nor Bouillaud notices the occurrence of melanosis in the heart.

Hypertrophy of the heart.—When the walls of any of the heart's cavities experience an increase of thickness, owing to the developement of the muscular substance, they are said to be in a state of hypertrophy; and there is no morbid state of this organ which is more frequently brought under the notice of the physician than this, as affecting the parietes of one or more of its cavities. There is no alteration in the muscular texture apparent to the naked eye, except, perhaps, a slight increase of the red colour—the heart is firm, dense, and elastic; in short, it presents all those characters which we so often see manifested in the external voluntary muscles, the developement of which is increased by frequent use.* Hypertrophy may affect all the cavities simultaneously, but in general it is limited to one or at most two cavities. The left ventricle is that in which it most frequently occurs, next the right, and lastly and rarely the auricles. Nor does the hypertrophy affect necessarily the whole parietes of the cavity, but sometimes it is limited to a small portion, or to the septum, or to one or more of the carneæ columnæ. In some cases, as Andral remarks, the thickening may be at its maximum at the base of the heart, and diminish gradually towards its apex, which sometimes retains its natural thinness, when all the rest of the parietes are three or even four times as thick as natural; or at other times, as Cruveilhier observes, becomes so thin that one is astonished that perforation or dilatation of the heart at its apex is not more common. In other individuals again the thickening is equal and uniform from the base to the apex, which then loses its pointed form and acquires a rounded shape. Lastly, it sometimes happens that the hypertrophy is greatest about midway between the apex and base of the heart, or is even exclusively confined to that part. When the septum is principally affected, the capacity of the right ventricle is so diminished that it sometimes looks like a small appendix attached to the left ventricle.* When the hypertrophy affects chiefly or exclusively the right ventricle, the apex of the heart seems to be formed by it, whereas in the normal state the apex belongs to the left ventricle.

An hypertrophous state of the parietes of all the cavities not only affects the form of the heart by changing it from the oblong to the spherical, but, as was first noticed by Dr. Hope,† its position is altered; "as the diaphragm does not retire sufficiently to yield space downwards for the enlarged organ, it assumes an unnaturally horizontal position, encroaching so far upon the left cavity of the chest as sometimes to force the lung upwards as high as the level of the fourth rib or even higher."

Bertin‡ distinguishes three varieties of hypertrophy of the heart. 1. That in which the hypertrophy is not accompanied with any alteration in the capacity of the cavities of the heart—*simple hypertrophy.* 2. That in which there is dilatation of the cavity along with the increased substance of its walls—*excentric hypertrophy* or *active aneurism* of Corvisart. 3. Where the capacity of the ventricle is diminished as if the walls had encroached by their increase of thickness upon the cavity, or as Bouillaud expresses it, as if the internal muscular layers and the carneæ columnæ were principally the seat of hypertrophy—*concentric hypertrophy.*§ Of these the most frequent is that which is accompanied by dilatation, the dilata-

* Dr. Williams mentions that in leucophlegmatic subjects the muscular texture is soft and flabby and of a duller colour. This is obviously a condition resulting from other causes, and not a character of the hypertrophous heart as such. And the threads or laminæ of dirty white tissue intermingled with the muscular tissue, described by him, seem clearly the result of the inflammation which caused the concomitant adhesion of the pericardium. In the same light I would regard the dense fibrous tissue described and delineated by Carswell.—See *Med. Gaz.* vol. xvi. p. 915.

* Cruveilhier doubts the occurrence of partial hypertrophy affecting the septum or one or more carneæ columnæ.

† Cyclop. of Pract. Med. art. Hypertrophy of the Heart.

‡ Maladies du Cœur.

§ A certain standard of health is absolutely necessary to enable us to determine as to the existence of disease. With this view we transcribe here the table of weight and dimensions drawn up by Bouillaud as the average of health.

In an adult of ordinary size and good constitution the mean weight = 8 to 9 oz.; mean circumference = 8 to 9 inches; mean of the longitudinal and transverse diameters = 3½ inches (the latter generally predominates slightly over the former); the mean of the antero-posterior diameter = 2 inches.

Mean thickness of the walls of left ventricle at the base =	6 to 7 lines.
Ditto, right ventricle at the base =	2½ lines.
Ditto, left auricle =	1½ lines.
Ditto, right auricle =	1 line.

The average capacity of the ventricles is sufficient to contain a hen's egg (that of the right ventricle slightly exceeding the left).

For some useful observations on this subject, and on the normal weight, bulk, &c. of the heart in relation to other viscera, see Dr. Clendinning's Lectures in Med. Gazette, vol. xvi.

tion in all probability preceding and giving rise to the hypertrophy by rendering an increased force of contraction necessary. Simple hypertrophy is the least common, according to Bouillaud; concentric hypertrophy, according to this physician, is not rare. Considerable doubt, however, has been excited recently by the high authority of M. Cruveilhier as to the real existence during life of such a condition as this. This anatomist believes the diminished cavity to be merely the result of a tonic contraction of the muscular wall of the ventricle in death. "The concentrically hypertrophied hearts of Bertin and Bouillaud appear to me," he says, "to be hearts more or less hypertrophied, which death surprised in all their energy of contractility."* The hearts of all those examined by Cruveilhier, who died by the executioner, presented to his observation to a great degree the double phenomenon of increased thickness of walls and diminished cavity, and he has observed the same with persons who died a violent death.† On one occasion I was particularly struck with a similar condition of the heart of a donkey which had been accidentally transfixed by a large trocar, whereby the death of the animal was caused in a few minutes. The muscular structure of the heart was singularly dense. It had contracted at its apex quite to a sharp point, and on cutting into it the cavity of the left ventricle appeared almost obliterated, and the muscular wall much increased in thickness. I have many times, too, observed the fact noticed by Cruveilhier, that the cavity may be easily enlarged or restored to its natural dimensions by introducing the finger and dilating it, or still more easily, if the heart have been macerated in water for a short time previously. This fact is further confirmed by Dr. Budd, who supports the views of Cruveilhier in an interesting paper in the last volume of the Medico-Chirurgical Transactions. In one of Dr. Budd's cases the thickness of the parietes of the left ventricle eighteen hours after death varied from an inch to an inch and a half, on a transverse section made at a distance from the apex of one-third of its length, and the cavity was not large enough to hold the second phalanx of the thumb, and was almost filled by the carneæ columnæ. This heart, in its open state, was put to macerate; *no force was applied to extend it*. At the end of some days, on being folded up, it was found to have dilated very considerably, so that the left ventricle could not then be said to be smaller than natural. Dr. Budd argues against the existence of the diminished cavity from the fact that of eight cases collected by him, no one afforded signs, either during life or after death, of any obstacle to the circulation through the heart. There were no irregularity of pulse, no dropsy during life, no dilatation of the right cavities after death, phenomena which, it may be said, must of necessity be present if there be an obstacle to the circulation in the heart. It is impossible, as he states, to conceive that a left ventricle, which could scarcely hold an almond, should offer no obstacle to the circulation through the heart. Yet Laennec has recorded a case in which the parietes of the left ventricle had acquired the thickness of from an inch to an inch and a half, and the cavity seemed capable at most of containing an almond stripped of its shell. Yet the day before the patient's death his pulse was natural, the breathing perfectly free, "and nothing," says Laennec, "led me to suppose that this man had a disease of his heart."

Hypertrophy with dilatation.—It is in this morbid condition that the heart acquires the greatest increase of size as well as the most striking alteration of form. The *cor bovinum* of some authors, so called from its enormous size, affords an instance of an extreme developement of this form of disease. The extent to which the heart may become enlarged in this way is quite extraordinary. Of certain cases recorded by Bouillaud, in one the right ventricle was large enough to contain a goose's egg, and the left, still larger, the closed hand of a female; in another, the left ventricle was similarly increased in capacity. In a third, the right auricle of a child, aged seven years, was so dilated as to contain a coagulum as large as the closed hand of an adult. The thickness of the left ventricle in Bouillaud's cases varied from 7 to 14 lines, that of the right 3 to 5 lines; but in some instances it was as considerable as from 8 to 10 lines or 11 to 16 lines. The weight of the heart, in some instances, trebled the natural; thus in one case of general hypertrophy the weight was 22 ounces, and others weighed from 13 to 20 ounces. The circumference of the heart was often increased to twelve inches, the longitudinal diameter five inches, and the transverse eight inches. In a patient who died at the Hôtel Dieu in 1834, the heart measured fifteen inches and a half at its base. Hypertrophy seldom occurs in the auricles, except when accompanied by dilatation: the musculi pectinati are generally the seat of the increased muscular developement, and as the number and developement of these muscular columns is greater in the right auricle than in the left in the normal state, (in the left they are only found in the auricular appendage,) the remark of Dr. Hope follows almost as a matter of course, namely, that in the right auricle hypertrophy proceeds to the greatest extent, its walls being sometimes rendered nearly equal in thickness to those of the right ventricle in the normal state.

In the vast majority of cases of this kind the products of inflammatory states of the pericardium or endocardium, or its appendages, are present; in short, a diseased state of the valves constantly co-exists with hypertrophy and dilatation. These conditions of the cavities are very frequently traceable to some obstacle to the circulation through the heart, and sometimes it would seem that the valvular disease preceded and gave rise to the hypertrophous and dilated cavity; but it is not impossible nor unlikely that the valvular disease may follow the hyper-

* Dict. de Méd. et Chir. Prat. art. Hypertrophie.

† Mr. Jackson and Dr. Budd have observed this state of the heart in persons who died of cholera.

trophy, and may result from the violence of contraction of the enlarged ventricle. Dilatation of the aorta at its commencement and its arch is frequently the consequence of this disease in the left ventricle, and dilatation of the pulmonary artery ensues upon it in the right ventricle.

Dilatation of the cavities of the heart.—"When the heart is incapable of sufficiently expelling its contents, whether in consequence of obstruction in the vessels from it, of regurgitation into it through imperfect valves, of want of power, of irritability, or of both, it becomes distended, and in time permanently dilated."* We have already described that kind of dilatation which is the most common, namely, that accompanied by hypertrophy; dilatation also occurs in connexion with an opposite condition of the parietes, namely, attenuation of them. The muscular tissue has lost its tone, and yields, as it were, without resistance to the distending force. It is laid down by authors that a third variety of dilatation may exist, what they call *simple dilatation*, or that in which, while the cavity is dilated, the parietes are of their natural size. It seems to me impossible that any cavity of the heart can, in a dilated state, continue of the natural thickness without hypertrophy, in the absence of which dilatation implies necessarily a diminution in thickness; during diastole the parietes of the heart's cavities are thinner than during systole; what a contracted muscle gains in one dimension it loses in another; and the same may be said of a relaxed or distended muscle. Again, if we contrast a contracted with a dilated bladder, it seems evident that we cannot inflate the former, however incompletely, without producing a manifest diminution in the thickness of its walls. Hence I infer, that if the parietes of any cavity be perfectly natural, they must become thinned under the influence of the force which produces the dilatation; and, on the other hand, if we find that the parietes of a dilated cavity possess the normal thickness, we may be assured that it is slightly hypertrophous. It appears then to be most correct to limit the varieties of dilatation to two, that with hypertrophy and that with attenuation, or the *passive aneurism* of Corvisart.

In this latter form of dilatation, then, we see a manifest alteration of the muscular tissue; it is paler, softer, less resisting, less elastic than natural. When the heart is emptied of its contents, the walls do not at all return upon themselves, but remain flaccid; nor when cut do they show any disposition to retract; and it is this state of the muscular substance which will serve best to enable the anatomist to distinguish morbid dilatations from those which result from mechanical distension of the cavity by a coagulum formed at the time of death. An obviously diseased state of both the internal and external membranous coverings of the heart is constantly present along with this form of dilatation. These membranes lose their transparency in several parts, apparently from some abnormal deposit subjacent to them: the white spot so often seen upon the external surface of the right ventricle is an almost invariable attendant upon the dilated heart. Dilatation may affect any or all of the heart's cavities; but it is met with by far the most frequently in the right ventricle, and very commonly both ventricles are dilated, in which case the right cavity is generally more capacious than the left.

An extreme case of dilatation is afforded in an example quoted by Bouillaud: "the right cavities were so dilated and their walls so attenuated, that the auricle was converted into a kind of transparent membrane, and the ventricle was reduced only to the ordinary thickness of the auricle."

In determining as to the degree of attenuation of the walls which may accompany any particular case of dilatation of the auricles, the anatomist must bear in mind that even in the natural state the interval between the musculi pectinati of the right auricle is only composed of the endocardium and pericardium, separated by a very fine and transparent cellular tissue, and by a few muscular fibres crossing obliquely from one pectinate muscle to the next one. I have twice seen a perfectly natural right auricle carefully put up as a museum specimen of morbid attenuation of the parietes, owing to ignorance or forgetfulness of this fact.

Dilatation of the orifices of the heart.—As a natural result of dilated cavities we meet with dilated orifices of the heart, and the enlargement of which again produces in many cases insufficiency of the valves. Bouillaud gives the measurement of the auriculo-ventricular orifice (which is the most liable to dilatation) in three hearts; in one it measured five inches in circumference, and in another four inches three lines, while in a third the dilatation was stated to be so great that the tricuspid valve could not be closed.

Aneurism of the heart.—A diseased state of the heart occurs not unfrequently, strongly analogous to that which under the same name is so well known as occurring in the arterial system. Most of the varieties too of arterial aneurism find their analogues in the heart: thus we have, 1. the aneurism by simple dilatation, or true aneurism, resulting from partial dilatation of one of the heart's cavities; 2. the false aneurism or that resulting from rupture of one or more of the textures entering into the formation of the heart's parietes; 3. we find the *dissecting* aneurism analogous to that remarkable form of arterial aneurism first described by the late Mr. Shakelton; 4. not improbably, we also meet with what is analogous to the varicose aneurism, and may be designated *spontaneous varicose aneurism of the heart*. To the zeal and acuteness of Mr. Thurnam * morbid anatomists are much indebted for his having arranged, compared, and classified a considerable number of cases of aneurismal dilatations connected with the heart, either observed by himself, or preserved and

* Dr. Williams, loc. cit.

* Vide his valuable monograph on Aneurisms of the Heart in Med. Chir. Trans. vol. xxi. An appendix containing references to cases is added.

recorded by others, whence he has been able distinctly to prove the analogies above-mentioned, and by which much light has been thrown upon those forms of disease.

The partial dilatation of one of the cavities, or true aneurism, is by far the most common of the varieties above-mentioned. In its early stage this disease consists in little more than a bulging of the wall of the ventricle or auricle in a certain direction; as this increases a pouch or sac is formed, which communicates with the heart's cavity by a more or less narrow opening. In some cases this sac does not extend beyond the external surface of the heart, nor would it be detected, were the anatomist to content himself with merely examining the exterior, it is as it were lodged in the fleshy substance of the ventricular paries; but in other instances a tumour is formed projecting considerably beyond the exterior. As in arterial aneurisms, the sacs frequently contain laminated coagula, and, as might be expected *a priori*, the larger the cavity and the narrower its orifice of communication, the more abundant is this lamellar deposit. One or more aneurismal sacs may belong to the same cavity: thus, in fifty-two out of fifty-eight cases collected by Mr. Thurnam, only one aneurism existed in each; but in four cases two were met with in each; in one there were three, and in another four incipient aneurisms. In two instances, Mr. Thurnam states, it is not improbable that two sacs which were originally distinct had coalesced, so as to form a single aneurism, and in another case three sacs appear to have united in this way. We find the aneurismal pouches of all sizes: in nine of the cases referred to in Mr. Thurnam's memoir, the size might be compared to that of nuts; in twenty, to that of walnuts; in seven, to fowl's eggs; in fourteen, to oranges; and in nine cases, it almost or quite equalled that of the healthy heart itself. We cannot always satisfactorily ascertain what textures enter into the formation of these sacs; however, in the majority of cases, the three structures of which the heart's parietes are composed are found in the walls of these sacs; in others the muscular tissue has disappeared, atrophied probably by the pressure, and the wall is composed only of the endocardium and pericardium, and in others again the endocardium is wanting, and the muscular fibres and the pericardium are the only component elements.* In some cases the wall of the sac is strengthened by an adhesion formed with the loose layer of the pericardium.

These aneurisms are always in connection with the left ventricle or left auricle; very rarely however with the latter, and never with the right cavities. In the paper already quoted from, Mr. Thurnam has collected references to fifty-eight cases of aneurism of the left ventricle, and eleven of the left auricle. All parts of the ventricle are liable to aneurismal dilatation, but it occurs most frequently at the apex: next in frequency it is found at different points of the base; less frequently still it occurs in the lateral walls at situations intermediate to the two last-named, and very rarely it is met with in the interventricular septum.

I will give the description of auricular aneurism in Mr. Thurnam's words: "The disease would appear, from the preparations I have inspected, and the cases which have been recorded, to have been nearly uniformly of the diffused kind, and to have generally involved the entire sinus of the auricle. The dilated walls of the cavity are often thickened and the seat of fibro-cellular degeneration. The lining membrane is opaque, rough, and otherwise diseased, and in some cases even ossified, and is lined with fibrinous layers, very similar to those met with in arterial aneurisms. In all these cases, the lining membrane appears to have been continued into the interior of the dilated portion, which consequently merits the name true aneurism. Occasionally the dilatation is confined to the auricular appendage, which becomes extensively distended with lamellated concretions."*

The false aneurism, or that resulting from rupture, must be spoken of merely as a possible and probable occurrence. I know of no unequivocal example of it; but inasmuch as we must admit that partial rupture of the heart's wall may take place, we cannot deny the possibility of the production of cardiac aneurism in a manner similar to that in which arterial false aneurism is produced.

Dr. Hope describes cases, which Mr. Thurnam very aptly compares to "the dissecting aneurism." In those cases, Dr. Hope says, "steatomatous degeneration had caused the formation of a canal from the aorta underneath one of the sigmoid valves and the internal membrane of the left ventricle." But Mr. Thurnam's explanation seems to me much more likely to be the true one. He supposes that the aneurisms had been originally formed in the ventricle, and had subsequently communicated with the aorta, as a consequence of the co-existent disease of the valves of that vessel.

The possibility of the formation of an aneurism resembling the *varicose aneurism*, has been likewise suggested by Mr. Thurnam, from the occurrence of aneurismal pouches in the septum ventriculorum. If such an aneurism were to burst, it would establish a communication with the right ventricle, a portion of the venous system—thus producing "a lesion altogether analogous to that which results from the wound of an artery and its accompanying vein, and to which the name of *spontaneous varicose aneurism of the heart* is perfectly applicable."

Mr. Thurnam mentions a fourth form of aneurism which is not without its analogue in the arterial system, namely, that in which the aneurismal sac is formed by the endocardium and pericardium. This may be compared with a variety of external aneurism in which the lining membrane of the vessel protrudes through a rupture in the middle tunic, constituting a

* Vide Thurnam, loc. cit. p. 219.

* Loc. cit. p. 245.

lesion which has been sometimes designated "aneurisma herniosum," and sometimes "internal mixed aneurism." This form of arterial aneurism has been described by Haller, Dubois, Dupuytren, and Breschet.

In a large number of these cases of aneurism of the heart, the pericardium has been at some period or other of the disease more or less extensively inflamed, and adhesions are consequently found: the endocardium likewise frequently exhibits marks of inflammatory action, opacities, white spots, &c. and this sometimes extends to the valves. In some the muscular substance in the neighbourhood of the sac is degenerated, and assumes the cellulo-fibrous form.*

Atrophy of the heart.—The heart, or a portion of it, may be said to be in the state of atrophy, when its muscular fibres are pale, soft, easily torn, inelastic, attenuated, so that the thickness of the parietes is greatly diminished, and the pericardium covering the heart or the atrophied part of it, is shrivelled and wrinkled. When atrophy affects the whole heart, that organ becomes much diminished in size, the capacity of its several cavities being proportionally diminished; and in some instances the diminution of the general size appears to be more at the expense of the dimensions of the cavities than of the thickness of the walls.

Morbid deposit of fat on the heart (fatty degeneration of some authors). There is an alteration met with not uncommonly in the muscles of animal life, which is very often described as the fatty degeneration of muscle, but which is in truth an atrophy of the muscular tissue, and not at all a transformation into fat. This condition, which resembles fat only in its yellow colour, and may be easily distinguished from it by its fibrous form, has never, I believe, been met with in the heart; a perfect cessation from active contraction must be essential to its production; and as such a state of quiescence cannot occur in the heart during life, this form of degenerate muscular tissue is not found in that organ. We do, however, meet with cases frequently, in which fat seems to take the place of the muscular fibres of the heart: in proportion as they appear to waste away the fat is deposited under the serous membrane, until the muscular parietes of the heart are reduced to a very thin lamina, of a pale colour and easily torn, between which and the pericardium a thick stratum of fat is deposited, so that a superficial examination might lead one to suppose that the walls of the heart were wholly converted into this tissue. The ventricles are generally, if not uniformly, the seat of this deposit, which must be regarded as an increase in the deposit which is found naturally along the course of the coronary arteries. It occurs chiefly in old persons, and it is difficult to say whether the muscular atrophy which is always present is a consequence of the fatty deposit, or precedes it. So enfeebled has the muscular tissue become that persons labouring under this disease very commonly die of a rupture, or rather a giving way, of the wall of one of the ventricles. It occurs in persons of debilitated habits, who either are incapable of active exertion or from circumstances never attempt it, and, what is remarkable, the subjects of this disease are frequently very emaciated: thus M. Bizot* found this condition in fourteen out of twenty-nine emaciated females. The disease is likewise more common in women than in men; and sometimes free oil is present in the blood in inordinate quantity.

Such I believe to be the correct history of this state of the heart, of which most erroneous notions have been formed, owing in a great measure to the name under which the disease has been so often described. The description which I venture to offer has been drawn up from several cases of the disease in various grades of the deposit, which have come under my observation, and on comparing this description with some of the best detailed cases on record, it seems perfectly to consist with the appearances described in them. In Mr. Adams' case,† for instance, "the right ventricle seemed composed of fat, of a deep yellow colour through most of its substance. The reticulated lining of the ventricle, which here and there allowed the fat to appear between its fibres, alone presented any appearance of muscular structure. The left ventricle was very thin, and its whole surface was covered with a layer of fat. Beneath this the muscular structure was not a line in thickness, and was soft, easily torn, and like liver." Two cases, recorded by Mr. R. Smith,‡ presented the remarkable concomitant of an oily condition of the blood; in one "numerous globules of oil were found floating on the surface of the blood which escaped from the divided vessels;" and in the other "the surface of the blood was thickly covered with globules of limpid oil." In this last case the condition of the heart's substance is described as follows: "the heart was remarkably soft, pale, and flaccid, its substance most easily broken, and its surface covered with a layer of fat a quarter of an inch in depth; the parietes of the ventricles were thin." The anatomical condition of the former case is not so precisely described as to admit of comparison. The subjects of both these cases were old women, one aged ninety, the other seventy; and the former died of rupture of the left ventricle.

I am quite unable to account for the following description of a case by Dr. Elliotson. He says, "I once saw the muscular substance of the heart completely changed, *except at the*

‡ Dublin Journal, vol. ix. p. 412.

surface, to fat. A mere layer of red muscular structure covered the internal and external parts of the heart and the columnæ carneæ: within every spot was fatty matter."*

Rupture of the heart.—A degenerate condition of the muscular tissue is the most common cause of rupture of the heart: the states last described are those in which it most frequently occurs; they correspond to the *senile softening* of Blaud:† the wall literally gives way at a certain point, and a laceration frequently to a very trifling extent is found in that situation on examination after death: in some cases, moreover, several ruptures are found in the wall of the same cavity, and sometimes the rupture is very extensive, or it is large internally and small externally, or vice versa. Any of the cavities may afford examples of this form of rupture, but the left ventricle is by far the most frequent seat of it, as may be understood from the following numerical statement by Ollivier: "out of forty-nine cases the rupture was seated in the left ventricle in thirty-four, in the right ventricle in eight, in the left auricle in three, and in two cases the ventricles presented several ruptures. In these cases the apex was the situation of the rupture in nine; in the rest the rupture took place near the base. Rupture, however, may occur in a healthy state of the organ, from violent bodily exertion; of this a remarkable example was afforded in the case of one of Whitbread's draymen, who in attempting to raise a butt of porter, fell dead, from a large laceration of the left ventricle, the structure of which was perfectly healthy. I had lately an opportunity of examining the preparation of this heart in the Museum of Guy's Hospital.

Rupture is also found to ensue upon abscess in the heart, or upon ulceration and consequent perforation; it is sometimes caused by dilatation of it, and sometimes by contraction of one or more of the orifices.

Partial rupture may occur, i. e. the external fibres may be ruptured to a certain depth, without penetrating the cavity, or the internal ones may be similarly torn, the exterior being unaffected. A more remarkable kind of partial rupture is that in which the carneæ columnæ or chordæ tendineæ are engaged. Cases of this form of rupture seem to have been detailed first by Corvisart, who attributed the rupture to violent efforts. Other cases have been subsequently recorded by Cheyne, Adams, and Townsend. In Dr. Cheyne's case, "the internal surface of the left ventricle was much inflamed, several irregular excrescences were attached to the mitral and semilunar valves. The chordæ tendineæ, which connected the larger portion of the mitral valve to the wall of the left ventricle, were torn off just at the point of their insertion into the edge of the valve; four of these ruptured tendons hung loose into the ventricle."‡

MORBID STATES OF THE MEMBRANES OF THE HEART.

I. *Morbid states of the pericardium.*—1. *Pericarditis.* The morbid changes of the serous pericardium which most frequently come under the notice of the anatomist, are those which are consequent upon inflammation. What the alterations are which indicate the first onset of inflammatory action it is not easy to determine precisely, as the opportunities of inspecting the parts in this early stage of pericarditis are extremely rare. The following, however, may be stated as indicative of the earliest period of pericarditis. The natural exhalation becomes diminished or totally suppressed, and consequently the surfaces of the membrane do not present their usual moist appearance; the visceral layer of the pericardium is not so transparent as in the natural state, and several red points, which to the naked eye appear like extravasations of blood, are manifested on a considerable portion of the membrane. These spots, however, are not extravasations, but when examined with a lens, they are seen to be produced by a close network of extremely minute capillary vessels; as inflammation advances these spots increase in number, neighbouring ones coalesce, a more or less diffused redness is produced, as well from vessels subjacent to, as in the membrane, the membrane becomes less and less transparent, and now an exudation is distinctly formed on its surface of a very soft semifluid material (coagulable lymph), which, on looking carefully along the inflamed surface, is seen to be developed in minute granules. The further progress of the disease is characterised by the increased deposition of this plastic material, and the effusion of a straw-coloured serous fluid into the bag of the pericardium. These morbid changes, of course, vary in extent; but it is not uncommon to find them extending over the greatest part or even the whole heart, so that in some cases a second complete envelope is formed for the heart between the visceral and parietal layers of the serous pericardium; on the other hand a very circumscribed spot may be occupied by these changes, not exceeding a half-crown or a crown piece in circumference; but we seldom or never have opportunities of seeing the disease on this limited scale in so early a stage, and judge of its occurrence only from the existence of alterations which may justly be regarded as its sequelæ.

Certain varieties are observed as regards the form assumed by the lymph, and the quantity of the fluid effused in this disease. The lymph varies in its characters; almost always deposited in a membranous form, it is sometimes quite smooth and uniform on its free surface; at other times it is rough, and hangs in flocculi into the fluid contained in the sac of the pericardium; again it presents a reticulate appearance, compared by Corvisart, Laennec, and Bertin, to the inner surface of the second stomach of the calf, or, as Laennec suggested, to the appearance produced by quickly separating two slabs of marble which have been applied together, with a small quantity of butter or some similar substance between them. The depth of the depressions in this false membrane varies with the thickness of the membrane itself. Shortly after its deposition the lymph is very tender and easily torn, but when it has been some time deposited, it acquires a considerable power of resistance. The effused fluid in pericarditis varies likewise in quality and quantity. In some cases it is whey-coloured, with flocculi of lymph floating in it; in others it is of a yellowish colour, approaching that of pus, and in some degree of the same consistence: sometimes it is of a brownish colour. When it is in very small quantity it is less turbid; when in large quantity it resembles whey. In some cases the quantity is very considerable. It may be said to vary from a few ounces to more than a pint; but in some extreme cases it goes even far beyond this; thus Corvisart mentions a case in which the effused fluid amounted to eight pounds, and in one described by Bertin the distended pericardium formed a bag seven or eight inches broad, five deep, and ten or eleven in height. Sometimes the effusion cannot be distinguished from pus.

The coagulable lymph is effused not only on the free surface of the visceral layer of the pericardium, but likewise on that of the parietal layer. That which is effused upon this latter layer is, however, often much thinner and more delicate. These two deposits of lymph are continuous with each other at the reflection of the serous pericardium from the great vessels on to the muscular fibres. When the effused fluid has been removed by absorption, the two pseudomembranes being brought into apposition with each other, are as it were glued together; they become organised by new vessels shooting into them from the cardiac vessels, and at length they assume the form of cellular tissue. The cavity of the pericardium thus becomes obliterated by the development of this new cellular tissue. The adhesions thus formed are more or less extensive according to the extent of the primitive inflammation, so that in some cases the pericardium is universally adherent to the heart; in others the adhesion is circumscribed within very narrow limits; in this latter case the new cellular membrane is often of considerable length, inasmuch as the spots to which it adheres on the opposed layers of serous membrane do not at all correspond; but when the adhesion is extensive, the connecting cellular membrane is generally short and close, so much so in some cases that the pericardium and heart appear to be completely identified. The muscular substance subjacent to the inflamed pericardium sometimes appears to participate in the inflammatory process, acquires a greater hue of redness than is natural, and becomes softer, and loses to a greater or less degree its cohesive power.

Such is the ordinary course and termination of pericarditis. Every museum contains many specimens illustrative of the different stages of this disease. The cellular adhesion which fills up the pericardial cavity occasionally exhibits further alterations. Sometimes we find it infiltrated with serum, and quite anasarcous; at other times a sero-purulent or purulent fluid is effused into it. It becomes condensed, fibrous in its character; or cartilaginous or fibro-cartilaginous or even osseous plates are formed in it, which sometimes are of so large a size that the heart appears as if enveloped in an osseous case. This cartilaginous or osseous deposit, however, sometimes takes place in the fibrous pericardium. Dr. Hodgkin mentions a case of osseous transformation so extensive that the osseous plate occupied a large portion of the base of the heart, where it formed a complete bony ring, the apex of the heart, however, being left at liberty. A somewhat similar case is recorded by my friend Mr. Smith. "The pericardium was united to the surface of the heart by close and old adhesions, and around the base of the organ bony matter was deposited in considerable quantity, apparently between the two serous layers of the pericardium; it formed an osseous belt surrounding nearly the entire of the base of the heart; its surface flat and rough, its margin irregular and waving, and its average breadth about one inch. This bony girdle penetrated into the substance of the ventricles, and reached in some parts almost to the lining membrane of the latter."* In Mr. Burns' case the whole extent of the pericardium covering the ventricles, and the ventricles themselves, except about a cubic inch at the apex of the heart, were ossified and firm as the skull.

White spot on the heart.—There is no appearance with which anatomists are more familiar than the white spots on the heart. A single portion of white opaque, or nearly opaque membrane, situated on the anterior part of the right ventricle nearer its apex than its base, and varying in circumference from that of a shilling to that of a half-crown, as thick as the pericardium itself and sometimes considerably thicker, constitutes what I have most frequently seen. They may be found, however, occasionally on the posterior surface as well as the anterior, on the left side as well as the right, on the auricles as well as the ventricles. On careful examination, it is evident that the opacity is occasioned by an adventitious deposit. This deposit, in a great number of the cases in which I have examined it, consisted of a thin lamina of condensed cellular membrane adherent to the free surface of the visceral layer of the pericardium, which could easily be dissected off, and which I have often peeled off with my fingers, leaving the pericardium apparently as if no deposit had been found there. Dr. Baillie, and more recently Laennec and Louis, testify to the facility with which it may be dissected off. Others, however, affirm that the deposit is most frequently under the serous covering of the heart, and consequently in the subserous cellular tissue by which that layer is connected to the heart. Corvisart

* Dub. Journ, vol. ix. p. 419.

maintains this opinion exclusively, and Dr. Hodgkin states his belief that in by far the greater number of cases these patches depend on a deposit on the attached surface. This writer adds—"From the circumstance of their being often found immediately under the sternum, and from their being occasionally met with on other parts of the heart, to which a firm and resisting body has been unusually opposed; as for example, when a bony deposit has taken place beneath the reflected pericardium, or when an uneven and remarkably indurated liver has, even through the diaphragm, presented an unequal pressure against a particular part of the heart, I have thought it probable that such pressure, aided by the movements of the heart itself, may have led to the production of these spots. These formations may certainly take place at a very early period of life. I have met with one rather loose and thick, but in other respects perfectly resembling those found in the adult, on the right ventricle of a child only ten weeks old. Similar thickening of the close pericardium sometimes marks the course of the coronary arteries and their branches; and this circumstance amongst others tends to confirm the idea which I entertain as to its mode of formation."*

Mr. T. W. King, in an Essay on this subject in the sixth number of Guy's Hospital Reports, records a very remarkable example of the opacity. The patch, "a uniform whitish thickening of the close pericardium," nearly equalled in extent the anterior surface of the right ventricle, and was extended over the anterior surface of the pulmonary artery as far as its bifurcation. Two similar patches were found on the under surface of the ventricle. Mr. King inclines to the opinion that this deposit is seated in the proper tissue of the serous membrane, and considers it always inflammatory and pretty constantly the effect of friction and irritation. "The situation of these patches," observes Mr. King, "whenever they occur, implies to my mind a egree of attrition at the part more than belongs to the pericardium generally. They are found on the surface of the right auricle almost as frequently as on the ventricle, but not in so morbid a form; and much more divided, even minute, and often clustered like the rippling of the sand at ebb-tide. One is not unfrequently seen along the anterior face of the great pulmonary artery. All these relate to the right side of the heart, which all pathologists are aware is often, and more than the left, the subject of distensions. The patches may occasionally, perhaps, be seen on any part of the close pericardium. I have seen them behind the left pulmonary veins; but, omitting this instance, the next most common appearance of the kind is that of lengthened, narrow, winding, and even branching lines immediately over the great vessels of the ventricles whenever they are the subject of considerable dilatation. Here, also, we have evidence of a disproportionate space of attrition, resulting from undue prominence."

*Lect. on Morb. Anat. of serous membranes, p. 98.

I am not aware of any well-authenticated instance of ulceration or gangrene of the pericardium. In cases of ulcerative perforation of the heart, it may be said, however, that the pericardium ulcerates as the other parts do.

Tubercular formations.—Tubercles, whether cancerous, melanotic, or scrofulous, are formed subjacent to either serous layer of the pericardium; sometimes, and most frequently they are deposited between the visceral layer and the heart, or they may be found between the fibrous pericardium and the parietal aspect of the serous layer.

Cysts.—The serous cysts which are described as occurring in the heart are sometimes formed immediately subjacent to the serous membrane, and project into the pericardial sac. According to Andral they occur most frequently in this situation. Similar cysts have been found between the fibrous pericardium and its serous lining.

Hydrops pericardii or *hydropericardium.*—This disease consists in an undue accumulation of fluid in the sac of the pericardium. The fluid is either simply serous, of yellowish character, or it may be of a brownish or reddish hue. In quantity it rarely exceeds two pints. The effusion is not generally attended with any evident morbid change either of the heart or its membranes, excepting that in cases of some standing, the heart seems somewhat atrophied, and the pericardium has lost its perfect transparency.

Pneumopericardium.—The presence of air in the pericardium, as the effect of morbid action during life, must be very rare. Laennec, however, speaks very confidently of its existence. "Sometimes," he says, "the air is combined with a liquid, and this is by much the most frequent case; at other times the pericardium is distended by air alone." Could the cases of dry pericardium related by Baillie have been produced by the developement of air in its cavity?

Morbid states of the endocardium.—1. *Endocarditis.* The lining membrane of the heart is so similar in its structure and properties to the pericardium, that their morbid states are very similar likewise. The constant contact of the blood with the former membrane serves, however, to modify considerably the anatomical characters of disease in it. We want, I think, satisfactory proofs of the changes induced by endocarditis in its earliest stage; these changes are described to be, redness of the membrane, with a more or less thickened or swollen condition of it; but the redness is not the result of capillary injection, but seems to be a stain on the membrane, the result of contact with the blood. The stain is not merely superficial, but has sunk into the substance of the tissue, and it cannot consequently be washed off.

The lining membrane of the heart is often found stained of a red colour as a post-mortem result; and this is invariably the case in hearts examined after putrefaction has commenced. The blood contained in the heart has begun to alter, various gases are given out, and the internal membrane more readily imbibes the colouring matter that is brought in contact with it.

Can this redness be distinguished from that which is consequent upon inflammation? It seems to me that there is no *anatomical* character by which the true nature of the discoloration can be proved. The anatomist must be guided in coming to a conclusion upon the question by concomitant circumstances, of which the time which has elapsed after death, the quantity and quality of the blood in the heart, and the state of the other organs or textures of the body, are the most important. If the examination has been made soon after death, that is, within twenty-four hours, if the blood in the heart presents no undue predominance of colouring matter, nor has undergone any decomposition, and if the other tissues retain their natural state, and show no unusual tendency to putrefaction, the redness may be inferred to be morbid and inflammatory; but this inference is confirmed with the utmost degree of certainty, if the redness is accompanied by an effusion of coagulable lymph or of pus, and by an unequivocal thickening or swelling of the endocardium itself; sometimes, also, as Bouillaud remarks, the adhesion of clots, resembling the buffy coat of blood, are among the anatomical signs of inflamed endocardium. The inflamed endocardium is, according to Bouillaud, more easily detached from the internal surface of the heart, owing in all probability to the subjacent cellular tissue having lost its force of cohesion, and become fragile.

Lymph effused on the endocardium does not generally take the laminated form as in pericarditis, nor do we find it covering an extensive surface, as in that disease. Small patches of membranous lymph are sometimes met with here and there, either on the surface of the valves or over some part of one of the cavities; at other times it assumes a granular or warty form, or it projects in papilliform or conical or globular masses from the surface of the valve. Thus are formed the vegetations which are among the most frequent valvular diseases, and which offer the greatest impediments to the adequate action of the valves. When examined recently after their formation, they present all the characters of the albumino-fibrinous exudations of serous membranes, their form being determined by the frequent changes of relation which the inflamed surface undergoes in the heart's action, as well as by the current of blood from the heart continually flowing over it.

The further progress of inflammation of the endocardium induces thickening of the membrane or of the valves, organization of the effused lymph, which thus becomes more firmly adherent to the surface on which it had arisen, and induration of the membrane from cartilaginous or calcareous deposits, which however are generally met with within the fold of membrane constituting the valves, and more intimately connected with the interposed fibrous than with the serous membrane.

When inflammation of the folds of endocardium forming the valves runs its course with great rapidity, it may induce destruction of them to a greater or less extent. Softening, ulceration, and rupture of the affected valve are very speedily produced. "The ruptured and ulcerated portions," to borrow Dr. C. J. Williams's description, "are found loaded with ragged, soft, fragile vegetations, more or less tinged with blood, and these are also sometimes seen adhering to adjacent parts where the endocardium is entire. The remaining parts of the valves are much thickened and opaque yellowish white, with a pink hue; and pink patches are often seen in the aorta with atheromatous thickening." Sometimes a valve is perforated in its centre by ulceration, and the circumference of the perforation is surrounded by warty vegetations.

It is well known that the endocardium of the left side is much more liable to disease than that of the right, whether as regards the valvular portion of it or that which lines the interior of the heart. But the views of Bichat and others, who denied the occurrence of disease on the right side, have been abundantly refuted by modern observations.

Chronic valvular diseases.—Chronic endocarditis affects the valves of the heart in such a manner as in all cases to occasion more or less obstacle to the flow of the blood from the ventricle or auricle. Sometimes, however, the disease is not of a kind to interfere with the valvular action and to permit regurgitation; but at other times the disease has gone so far in one or more of the valves as to prevent its contributing to the perfect closure of the orifice, and consequently to destroy the power of the valves to oppose regurgitation. Hence the subdivision proposed by Dr. Williams, for valvular diseases, into those which more or less obstruct the current of the blood in its proper channel, or the *obstructive*, and those which permit it to pass in the reversed direction, or the *regurgitant*. Thickening of a valve, so as to prevent its complete apposition to the internal surface of the artery or of the ventricle, will occasion obstruction, the degree of which will depend on the degree of perfection of apposition with which the valve may be applied to the neighbouring surface; on the other hand, the degree to which regurgitation is permitted will depend upon the degree of induration of the valve, and the want of extensibility which it manifests.

Thickening of the edges of the valves is among their most common diseased states; the attached margin or base of the valve is also very frequently the seat of thickening, and in both these situations the fibrous tissue seems to be engaged principally in the disease. The intervening portion is generally affected as a consequence of the extension of the disease from these margins. In such cases the thickening arises from a deposit between the layers of the fold forming the valve; in other cases the thickening is produced by a deposit upon the surface of the valve. On the aortic valves this deposit, when on the ventricular surface, is apt to assume the form of two crescents corresponding in position as well as form to the two crescentic portions of fibrous tissue within the fold of membrane by which the valve is formed. This fact was, I believe, first pointed out by Dr. Watson.

Ossification most commonly manifests itself in the fibrous zones which surround the heart's orifices, and therefore it is chiefly to be found at the bases of the valves; but it likewise extends towards their free margin; and it too is apt to be developed in the double crescentic form in the aortic valves. Sometimes the ossification appears to involve principally the margin of the valve in whole or in part, and this occurs much more frequently in the semilunar than in the auriculo-ventricular valves. Osseous deposits in the valves are either in the form of thin calcareous laminæ or spiculæ, small rounded points, or large masses more or less rounded, and often projecting to a considerable extent beyond the surface of the valve.

The effect which the developement of these new deposits on or in the valves has upon their size and form, as well as upon the size and form of the openings which the valves surround, is very various and very interesting to the pathologist. The almost invariable alteration which they produce in the size of the valve is to shorten it or diminish it in depth; the valve becomes corrugated, its free margin thickened, or folded in the direction of the current, or in an opposite direction, the whole valve presenting a curled appearance. The orifices are always more or less diminished in size when one or more valves have acquired this rigid, inelastic, and contracted form; the diminution is produced by the valve or valves always projecting more or less into the orifice; but the greatest degree of narrowing of the aperture is occasioned by the adhesion of two or more valves at their free margins; and in this way, as may be readily conceived, an orifice becomes sometimes almost completely obliterated. The same causes change the shape of the orifices, and consequently we find altered size and shape constantly going together. It is in the left auriculo-ventricular opening that these changes are most commonly seen; they rarely occur to so great an extent in the aortic orifice, and seldom at all in the apertures of the right heart. My friend, Mr. Adams, has made some most valuable remarks upon the contracted auriculo-ventricular orifice of the left side, in his very valuable paper on diseases of the heart in the Dublin Hospital Reports. His description of the anatomical characters of the disease corresponds so exactly with what I have many times witnessed, that I cannot refrain from quoting it. "When the dilated (left) auricle is cut into and cleared of the blood it contains, at its lowest part, instead of the mitral valve, a concave membranous septum of a yellow colour is seen, which is perforated by an oblong fissure, about half an inch in length, and one or two lines broad; this fissure I have observed to be always obliquely situated, and to run parallel to the septum of the ventricles; it generally is of a semilunar form, the concavity of the curve looking towards the root of the aorta, the convexity backwards; the first formed by the larger portion of the mitral valve, the latter by the smaller; the edges of this oblong fissure are generally studded with long depositions; viewed from the left ventricle, the membranous septum is convex, and the angles of the fissure are connected by shortened chordæ tendineæ, with two very thick fleshy columns, the one in front, the other behind."

Dilatation of the valves.—We sometimes find the valves of the heart in a dilated or aneurismal state. Laennec has placed on record an example of this affecting the mitral valve:* "A little pouch, half an inch long and more than four lines in diameter, projected on the superior surface of this valve," i. e. into the left auricle. Mr. Thurnam has appended the detail of several cases to his memoir already quoted on Aneurisms of the Heart.† He describes a specimen, preserved in the Hunterian Museum, affording an example of four aneurismal pouches of the tricuspid valve. The same writer likewise records a case in which there was congenital absence of one aortic valve; the two, which were present, were thick and fleshy, and rough on their ventricular surfaces. The edge of the one was smooth, that of the other rugged; there was a deposit of ossific matter at their points of attachment. From the ventricular surface of the valve with the smooth border, there projected a little bag that would hold a swan-shot, and which opened by a little round mouth on the aortic surface of the valve. It had two little slits in its most depending portion, and was evidently formed by a dilatation of the valve itself."

Atrophy of the valves.—We have a familiar instance of atrophy of valves in the case of the Eustachian valve, which undergoes as it were a sort of natural atrophy from the commencement of extra-uterine life. The valve becomes cribriform, and the holes by which it is pierced gradually enlarge and coalesce, and in this way the valve is worn away. We often find one or more of the semilunar valves perforated by openings of a similar kind, without the co-existence of any other disease; the margin of the opening is always smooth, and the valve itself thinner and more flaccid than is natural. According to Dr. Williams, the wasting affects the posterior portion of the mitral valve, "the membrane of which is often annihilated by it, the cords being inserted directly into the auricular ring." The anterior lamina is also occasionally found much shortened, and without those fine thin expansions of membrane which commonly unite the cords to each other, below their insertion into the thicker part of the valve.

Entozoa in the heart.—The occurrence of entozoa in the human heart must be considered to be extremely rare, at least the cases on record which may be depended on are very few. Andral states that he found the cysticercus once in the human heart, but has seen it frequently in the hearts of measly pigs. Many examples are mentioned by various authors of ascarides, filariæ, cercariæ, and other entozoa in the hearts of dogs and many other of the in-

† Loc. cit.

ferior animals, Mammalia, as well as birds, reptiles, and fishes.*

States of the blood in the heart after death.—What appears to be the natural state of the contents of the heart after death is as follows. The right auricle contains a coagulum of dark blood, and the right ventricle contains a similar one, of less size; a very small quantity of coagulum or of fluid blood is found in the left cavities, and it is not uncommon to find a coagulum extending into the aorta; white coagula are often found in these cavities. Sometimes these coagula, especially at the right side, adhere closely to the wall of the cavity in which they are situated, and appear as it were moulded upon it, sinking into the interstices between the fleshy columns, so as to render it difficult to remove them. The modification which we most frequently meet with in this state of the heart's contents, is that in cases of asphyxia; affording, however, merely an instance of aggravation, if I may so speak, of the natural state; the right cavities and the vessels leading to and from them are gorged with dark blood, liquid or coagulated, while the left cavities are nearly empty. Such states of the heart's cavities, it is obvious, are formed in articulo mortis. Fibrinous masses, either mixed with or deprived of the colouring matter of the blood, have been many times found, which it cannot be doubted were formed in the heart some time prior to death, and probably gave rise to symptoms of a serious nature; these are the *true polypous concretions* of the heart. The manner in which Mr. Allan Burns, one of our earliest British writers on the heart, explains the formation of some of these concretions, is deserving of attention. "If," he says, "we strictly scrutinize all the reputed cases of polypus in the heart, we shall reduce the real examples of this affection to a very limited number indeed. Still we shall leave a few, where there is reason to believe that the concretion had been formed a very considerable time before death: but it must be understood, that these concretions are seldom found except in hearts otherwise diseased. In health, the blood does not tarry for any length of time in either the heart or vessels; it is incessantly in motion, circulating with greater or less rapidity, according to the state of the heart and arteries. The blood never in health remains so long in contact with the surfaces of the heart, as to allow of its being changed by their action. In some diseases of this organ, irregular actions are excited by very trifling causes; the blood stagnates longer in the heart than it usually does or ought to do, while here it undergoes changes by the reciprocal action of the blood on the heart and the heart on the blood; new organized matter is deposited, and adheres to the parietes of the cavity in which it is lodged. This concretion slowly increases, the first particle acting as the exciting cause for the deposition of the second, and so on."

The strongest evidence of the formation of such coagula some time before death consists in their being organised: in a case recorded by the writer from whom the preceding passage was quoted, a large and fully organised polypus was found in the right auricle; its attachment was by a rough surface to the musculi pectinati, and its body hung down into the right ventricle. It very much resembled a nasal polypus, and it was so firmly fixed to the heart, that it allowed the whole mass of the heart and a considerable portion of the lungs to be suspended by it, without showing any tendency to separate. It was pendulous and tapered from below upward; its structure was dense and lamellated, and not a single red globule entered into its composition." In this case, as in other similar ones quoted by Andral, the adhesion of the polypus seemed due to an inflammation of the endocardium, either excited by the contact, or before the formation of the coagulum. That such coagula may be permeated by bloodvessels is proved by the cases of Bouillaud and Rigacci, quoted by Andral: in the latter cases, these reddish filaments passed from the columnæ carneæ and entered the substance of the polypous mass: they had all the appearance of bloodvessels, and when injected with mercury were found to divide into a number of small branches that ramified through the substance of the polypus. By careful dissection it was ascertained that the tumour was formed altogether of a mass of fibrine, such as is found in the sac of arterial aneurisms Pus is occasionally found in the centre of these fibrinous concretions, but whether carried to the heart in the blood, and accidentally enclosed in the coagulum during its solidification, or formed in the coagulum by some action within it, it is impossible to decide. Osseous and cartilaginous deposits too have been found in them, as in the case from Burns, in which one of these polypi was ossified in several points, and so perfectly organized that on inflating the coronary vein, a number of minute vessels on the surface and in the substance of the tumour became distended with air.

(R. B. Todd.)

HEAT, ANIMAL.—Judging merely by our sensations, we should infallibly conclude that our bodies undergo very considerable changes of temperature. This belief was indeed necessarily entertained previously to the time when natural philosophy had discovered a means of ascertaining the true state of the matter. The application of the thermometer has dissipated the error. But then error of an opposite kind was run into, and the results of a very limited number of observations led men to conclude that the temperature of the human body was invariable or nearly so. Still the measures of temperature given by different observers did not perfectly accord, though each presented his conclusions as the temperature of the race. It was but reasonable to imagine that these discrepancies arose not from any want of accuracy in observation, but from diversities inherent in the subjects observed. This is now known to be the case. But though proofs of this truth have been greatly multiplied, the

* For a list of the references to such cases, see South's edit. of Otto, Path. Anat. p. 293.

whole subject has never been presented in a connected and systematic manner.

Since it is proved that the temperature of the human body varies, we can only obtain an approximation to its actual amount by taking the mean of all the good observations that have ever been made, being particularly careful to include the extremes; for a mean gives but a very imperfect idea of a term that ought to represent a variable number, if the limits are not at the same time assigned and taken into the account. The best observations of this kind, provided they be sufficiently numerous, will be those that have been made by the same individual, inasmuch as there is great likelihood that he will always have made use of the same procedure and of the same instruments, by which the results become more readily comparable one with another.

Temperature of the human body.—In the following observations we shall make use of the measures of temperature given by Dr. John Davy. These amount to one hundred and fourteen in number, and were made on individuals of both sexes and of different ages in three quarters of the world, in Europe, Asia, and Africa, in different latitudes, under various temperatures, and among individuals of different races. But, as the knowledge of the mean and extreme temperatures of the body of man would have little value apart from the statement of the circumstances and conditions under which they were ascertained, we shall at the same time give the ages of the subjects and the temperature of the air at the time of the observations.

The mean age of the subjects of Dr. Davy's observations was twenty-seven years. The mean temperature of the air was 23°, 3 c. (74° F.*) between the limits of 15°, 5 (60° F.) and 27°, 8 (82° F.). In these circumstances the mean temperature of the body, which was always taken in the mouth, was 37°, 7 (100° F.) between the extremes 35°, 8 (96°, 5 F.) and 38°, 9 (102° F.). The greatest difference in one hundred and fourteen observations, therefore, scarcely exceeded three degrees. The temperature of the human body thus obtained might be considered as exact if the conditions of age and external atmospheric temperature approached pretty closely to their respective means. This, in fact, was the case as regards the first term, but not as concerns the second; for some of the observations were made under very intense degrees of heat, such as 27°, 8 (82° F.), but none at the opposite extreme, or at a temperature which could be reputed cold, a temperature of 15° (59° F.) being already sufficiently agreeable. So that if the temperature of the air influences that of the body, a question which we shall examine by-and-by, the mean which we have stated as the temperature of the species would be too high.

It is of some consequence to pursue these inquiries among the lower members of creation, among animals; and the writer to whom we are indebted for the observations quoted upon man has also made a great number upon the lower animals. We shall therefore continue to make use of this series of experiments, as we have already made use of that which bore upon man individually.

Temperature of the Mammalia.—The observations here were made on thirty-one different species taken from among the principal divisions of this class, and under a mean temperature of the external air equal to 25° (77° F.), between the limits of 15° (59° F.) and 30° (86° F.).

The mean temperature of the body of the Mammalia was 38°, 4 (101°, 10 F.), the maximum being 40°, 5 (105° F.), the minimum 37°, 2 (99° F.). The extent of variation consequently presented by the Mammalia, 3°, 3 of the centigrade scale (6° F.), is nearly equal to that exhibited by man. But there is this difference between the two scales, that the extremes and the mean in the case of man are inferior to the corresponding terms in the case of the Mammalia.

Temperature of Birds.—The observations here were made on fifteen species in different orders. The mean temperature of the air was 26°, 1 (79° F.), between the extremes 15° (59° F.) and 31°, 5 (88°, 75 F.). The temperature of the subjects of the experiments offered a mean of 42°, 1 (107°, 86 F.), the superior limit being 43°, 9 (111° F.), the inferior 37°, 2 (99° F.). The temperature of birds, therefore, presents a scale much more extensive than that of man and the Mammalia, amounting to as many as 6°, 7 degrees centigrade (12° F.). It also stands above both of the others in the point of its mean, which is higher by 3°, 7 (6° F. nearly) in its upper limit, and 5° centigrade (about 9° F.) higher in its lower limit. The lower limit, in fact, corresponds very nearly with the mean term of the heat of the Mammalia as exhibited in the preceding scale. But in neither scale can we say much in regard to the inferior limit, inasmuch as no observation was taken at a temperature lower than that of fifteen degrees centigrade (59° F.).

When we compare the preceding statements of the temperature of animals, it is apparent that it varies but little between one species and another of the same class. In passing to different classes, however, the difference becomes very considerable, and though the observations are here much fewer in number, they are perfectly satisfactory as regards the general result.

Temperature of Reptiles.—From nine observations made on members of the four orders of Reptiles, Dr. Davy found, the external air having a mean temperature of 26°, 5 (79°, 75 F.) between the extremes 32° and 16° (89°, 5 and 60°, 75 F.), that the temperature of Reptiles was not higher than 28° (82°, 5 F.).

Temperature of Fishes.—If from Reptiles we pass to Fishes, corresponding and even more remarkable differences are perceived. Dr. Davy, indeed, gives the temperature of

* [The valuations according to Fahrenheit's scale the editor desires may be regarded as mere though close approximations to the indications according to the centigrade scale.]—Ed.

no more than five species, but they belonged to very different orders. The mean external temperature being 22°, 3 (72°, F.), that of fishes was found to be but 23°, 2 (74° F.), which is very little more than one degree centigrade higher. This difference becomes even more striking, if possible, as we descend in the scale of animals.

TEMPERATURE OF INSECTS.—From eight observations on Insects of very dissimilar species, the mean temperature of the air being 24° (75°, 5 F.), that of the insects was 24°, 2 (75°, 75 F.)

TEMPERATURE OF THE CRUSTACEA.—Two species of Crustaceans, the cray-fish and crab, presented a still more interesting phenomenon. The mean temperature of the air was 24°, 4 (76° F.) at the time of experimenting, that of the Crustacea 24°, 1, or somewhat lower than the ambient medium. This we do not presume to present as the rule, but we would say that the temperature of the Crustacea is nearly equal to that of the medium in which they are plunged.

TEMPERATURE OF THE MOLLUSCA.—In observing the temperature of a single Mollusc, the common oyster, the temperature of the sea being 27°, 8, (82° F.) that of the animal was 27°, 8 also.

It is obvious, therefore, that the differences in the temperature of animals from reptiles inclusively downwards is very inconsiderable. All these animals, indeed, may be united under a single category, and regarded as constituting a single group characterised by the state or degree of their temperature. The same may also be done with reference to the animals of the two higher classes, Mammalia and Birds, which in point of temperature are so nearly akin to each other.

There are consequently two grand divisions of animals as regards temperature; the one comprising the Mammalia and Birds; the other including Reptiles, Fishes, Insects, Crustaceans, and Molluscs. The first is known under the name of *warm-blooded animals*, the second under that of *cold-blooded animals.*

To characterize the first under the view of temperature, the mean of the temperatures of the respective classes which compose it must first be taken. From the experiments of Dr. Davy the mean temperature of Mammalia appears to be .... 38°, 4 (101° F.)
that of birds .... 42°, 1 (108° F.)

Mean of both classes 40°, 25 (104°, 5 F.)

We may therefore say that the mean temperature of warm-blooded animals, including man, surrounded by a moderate external temperature is in round numbers 40° (104 F.) between the limits of 36° and 44° (97° and 111°, 5 F.), by which we have a scale of difference amounting to 8° (about 14° F.).

The other class, that, namely, including the *cold-blooded animals*, having no peculiar temperature proper to them, may be characterized in the following manner:—their temperature differs little or not at all from that of the surrounding media in which they live, when this is at a degree which may be called moderate; so that the differences are either inappreciable, or do not exceed the limits of + 4 (39°, 50 F.). We shall return by-and-by upon this character, which requires development.

General conditions of organization in relation with the production of a greater or less degree of heat.

So wide a difference in the heat of the two categories of animals might lead to the presumption that there is also a very great difference in point of structure. If, indeed, this relation exists and is easily detected, we may be led to discover the general conditions of organization upon which the production of heat depends. Is there an organization common to Mammalia and Birds, distinct and different from that belonging to the other classes of animals? This question can be answered in the affirmative: there is a well-marked diversity of organization which distinguishes Mammalia and Birds from all other animals.

I. The most prominent feature of diversity exists in the sanguiferous system, which is divided through its entire extent into two distinct parts without direct communication between them, the heart presenting a complete median septum, the bloodvessels in like manner forming two systems of canals, which have also no immediate communication in their trunks.

II. This peculiarity of structure, which is only met with among animals having warm blood, is regularly associated with an organ adapted for aerial respiration. The character which distinguishes this respiratory organ from the one met with among cold-blooded animals, reptiles especially, is this,—that either in itself or its appendices (the air-sacs of birds) it presents a much larger extent of surface in relation with the air.

III. Warm-blooded animals are farther distinguished from the cold-blooded by important modifications of the digestive canal. 1. The first portion of the apparatus from the mouth to the stomach is much more complex in them; for instance, it presents either a much more perfectly developed dental system, fitted to divide the food, or a sac, as among birds, fitted to macerate the aliment, and cause it to undergo a kind of preparatory digestion before it is passed to the stomach. 2. The stomach is more distinct; either the entrance to and exit from this pouch are better marked, being often provided with a valve, as in the Mammalia, or its structure and form are more special, as we observe it among Birds. 3. The intestinal canal is much longer in the warm than in the cold-blooded tribes.

IV. The nervous system presents diversities still more important and well-marked. The most striking character exists in the proportion of the principal trunk of this system, and especially of its encephalic extremity, which is much larger in the warm than in the cold-blooded animals.

The most remarkable structural conditions of warm-blooded animals, then, are four in number, three of which are referable to the organs of nutrition, the fourth to the nervous system, which may be briefly related in the following order:—1. higher complication and greater extent of the digestive apparatus; 2. entire separation of the circulating apparatus into two systems, the venous and arterial, without direct communication between them; 3. organs of aerial respiration presenting a much larger surface to the contact of the atmospherical air; 4. a nervous system of which the axis, and especially the encephalic extremity, bears a very high ratio to the whole.

These structural characters determine the following modifications of function. 1st, The complexness and greater extent of the digestive apparatus in warm-blooded animals produces a more perfect elaboration of the matters which serve for the formation of blood. 2nd, The arrangement of the parts of the circulating system maintains the arterial blood quite distinct from the venous, and in a state of complete purity. 3rd, The respiratory apparatus, by the great extent of its surfaces in contact with the air, secures that its distinguishing qualities be imparted in the highest possible degree to the arterial blood, which moreover is elaborated in larger quantity. The predominance of their nervous system, and especially of its encephalic extremity, renders all the parts of the body much more excitable, and gives the greatest energy to the nutritive functions. The whole of these organic conditions are mutually dependent, and may be reduced to the expression of these two general conditions:—1st, *the formation and distribution of the arterial blood, the particularly exciting and nutritive blood of the body*; 2nd, *the most powerful influence of the nervous system.*

As these characters of primary significance in the animal economy coincide in Mammalia and Birds with the greater production of heat, and thus distinguish them from all other animals, it is probable that between these organic conditions and caloricity or the power of evolving caloric, there is a relation of the nature of cause and effect. It is even almost impossible that this should be otherwise than as it has been stated; for the characters of organization and the peculiarities of function, coincident with the greater evolution of caloric, are almost the sole points of any importance that distinguish warm from cold-blooded animals.

It is therefore nearly certain that the conditions requisite to the production of heat must exist within the circle of the functions which we have described. And if this relation do actually exist—as these functions are in a state of mutual dependence,—it follows that one of them cannot be modified, the others remaining, so to speak, in the same condition, without modification resulting in the calorific capacity likewise. It is of great consequence to verify this assumption, because if it be well-founded, the probability already elicited of the power of engendering heat being dependent on the state of the functions in the relations which have been indicated, becomes matter of certainty. So that it is of the highest import to follow the modifications of these functions presented by animals and man in order to compare them with the respective varieties of calorific power presented by each. And if we find that they coincide, and accord with the principle established, we shall have discovered the conditions of organization and of function upon which the production of caloric depends.

Conditions of organization and of functions may be entitled the physiological causes of the production of animal heat. If we succeed in determining these, we ought to rest satisfied. If, indeed, to this knowledge we could add that of the immediate cause of this phenomenon among animals, or what is the physical cause, it would be a great gain for science. This, accordingly, was the object of the labours of the majority of physiologists who have given their attention to the subject of animal heat. But they could not possibly succeed in their researches, for the simple reason that natural philosophers themselves have not yet discovered how heat is produced in the inorganic world; although indeed they have presumed that they were acquainted with it. It is not to be wondered at, then, that attempts have been made to detect this presumed cause amidst the complicated phenomena of life. But natural philosophers have lost confidence in the theory which they had formed, and are searching for a new one. Meantime they are doing what ought always to be done under such circumstances; they are studying with care the various conditions and circumstances in which it is produced; determining these with precision, and measuring with rigour the quantity of heat produced. Of late, therefore, many distinguished physiologists have entered on the same path, and by experiment have endeavoured to ascertain the physiological conditions of the production of heat. But if their predecessors have not attained the object they had in view, they have nevertheless rendered very essential services to science; for in searching after the physical cause of heat, they have determined with precision the physiological conditions of the production of animal heat, which are of very great importance. Independently of the simple observation of the actual temperature of animals, the labours of physiologists on this subject consist almost entirely of experimental facts, that is to say, facts created by science.

But there is one source of inquiry into the laws of animal heat which has been little dipped into, although it is beyond all comparison the most abundant. I allude to that presented to us by nature in the all but infinite variety of modifications of organization and phenomena exhibited in the vast chain of animated things, not only in the diversities of species, but also in the varieties of age and constitution, and the changes induced by the states of health and disease. In making this an object of peculiar study, we become acquainted with the greatest possible number of phenomena connected with animal heat; and in determining the physiological conditions of its production, we shall lay up a store of theoretical knowledge peculiarly applicable to practice, the end and object of all physiological investigation.

The means of comparing these modifications, however, and of judging of their importance are not always easy. We shall do as much as the actual state of our knowledge permits if we inquire first, by what means we can appreciate the modifications relative to the arterial blood.

1. As regards the *quantity* of the arterial blood, we shall view this point of the inquiry less with reference to the whole amount of blood circulating in the body, than to the quantity which is formed at a time, as it were, in the lungs; because it is evident that if the arterial blood influences the phenomenon of heat, the more that is formed at any given time the greater ought to be the direct or indirect influence upon the production of heat. *a*. As it is not always possible to have a direct and precise measure of the relative quantity of blood in the organs, we must be content with an approximative mode of estimating this, which consists in ascertaining in what degree the lungs are loaded with blood. *b*. An aid to the judgment may also be derived from the relative size of the lungs, the tissue being presumed to be nearly alike throughout their entire mass. *c*. With an equal volume of lungs, the greater or less compactness of the tissue must be taken into the account. The closer the tissue is, the more are the surfaces in contact with the air multiplied. *d*. The extent and rapidity of the respiratory motions form another element in the calculation; for to increase the amount of relation with the air is analogous to the formation of a larger quantity of arterial blood within a given time.

All the foregoing data refer to the absolute or relative quantity of arterial blood. But there are other particulars connected with its constitution which it is necessary to mention. The blood, for instance, is composed of a fluid and solid part, the latter existing under the form of globules. It is obvious that the fluid is not the characteristic part of the blood, inasmuch as this is met with elsewhere, whilst the globules of the blood are only known as constituents of this fluid. *The arterial blood consequently ought to have qualities by so much the more distinctive and energetic as it contains a larger proportion of globules.* Now this is a character that may be appreciated with exactness, and measures of it have been given. But the globules of the blood are not invariably of the same nature, a fact which may be judged of by outward and very obvious and appreciable characters, namely, size and form. The smallness and more or less perfectly spherical or rounded form of the blood-globules distinguishing animals with warm blood, coincide in the Vertebrata with a higher capacity to produce heat. For we do not institute this comparison here save in reference to animals included in this division, inasmuch as the characters of the blood have only been studied under these relations among them. We shall, therefore, hold the energy of the calorific power to be connected with the smallness and rounded form of the globules of the blood in vertebrate animals.

2. The materials of the blood being supplied by the digestive apparatus, we might judge, all things else being equal, of the perfection of the blood by the perfection of this apparatus. But there is likewise a necessary co-relation between the result of the function, and the aliment; for instance, when the apparatus shall be found nearly alike in any two cases, the difference of food necessarily influencing the qualities of the blood, the comparison must be established, every other circumstance being equal, according to the higher or lower nutritive qualities of the food.

As the use of the arterial blood is to excite and nourish the different parts of the body, there will be a necessary correspondence between the blood and the result of the nutrition which may become manifest in the nature and quality of the tissues. And in this case it would be fair to make use of these characters of tissues to form an estimate of the nature of the blood in reference to its aptitude to produce heat; and this we shall accordingly do. But even in the event of all these characters failing us, there is another source whence we can derive comparative measurements, which are susceptible of very rigorous application.

Since it is necessary that the venous blood should pass through the lungs in order to become arterial from contact with the air of the atmosphere, it is obvious that it cannot undergo any change in its constitution without the air at the same time suffering a change. That the air is altered by the respiratory act is well known to all, and as there is a necessary co-relation between the blood aerated during respiration and the air which it alters, the amount of alteration undergone by the one may be estimated from the change suffered by the other. The quantity of air altered by respiration, all other things being equal, ought to be found in relation with the production of heat.

The different characters which we have mentioned all refer directly or indirectly to the blood. There still remains one of another order which may also serve us as a guide in making comparisons in reference to the production of heat. The allusion here made is to the nervous system, the superior value of which in warm-blooded animals has already been commented on. It is thus, then, that we may assume the predominance of the nervous axis, and particularly of its encephalic extremity, as a condition favourable to the production of heat, and which, in circumstances of parity among the other conditions, must tend to the production of a greater quantity of heat. Such are the modes of proceeding which we shall follow in investigating the modifications of the organic conditions and of the functions which coincide with the greater evolution of heat. To ascertain whether this coincidence is to be viewed as being in the mutual relation of cause and effect, it imports to know whether or not their variations are in relation with those of the heat produced. If they coincide whenever we compare them, provided these comparisons are but sufficiently numerous, we shall be safe in admitting a necessary connexion between them. We were led to the relation which engages our attention in the course of our comparisons of warm-blooded animals with those having cold blood considered in general. Let us now enter upon a comparison of the same kind, but more particular, whilst we take account of the most important subdivisions of these two great groups in order to verify our first inductions.

We shall first compare Mammalia and Birds to determine which of the two classes, in conformity with the principle to which we have been led, has its organization most favourable to the production of heat.

The lungs of Birds, although smaller, are more loaded with blood than those of the Mammalia, and are in communication with extensive air-cells, spreading all through the body and even penetrating into the cavities of the bones, so that the air may be said to penetrate the body generally, and to be in contact with the ramifications of the aorta as well as with those of the pulmonary artery; the blood of these animals is therefore in the most extensive relation imaginable with the air of the atmosphere. Again, if the nature of the blood of Birds be considered, independently of this extensive relation with the air, the organic condition here will not appear less favourable to them. The globules of this fluid, indeed, are a little larger and less spherical than in Mammalia, which is a disadvantage; but the proportion they bear to the fluid part is so favourable to Birds that this circumstance must give them immensely the advantage in reference to the character which engages us. With regard to the nervous system, if the encephalic extremity is developed in a minor degree in Birds, their circulating and respiratory systems act with greater quickness. Lastly, and as an effect of the whole of these conditions, the consumption of air is much greater among Birds than among Mammalia.

From all that precedes, it follows, if the principles already laid down be correct, that Birds ought to produce the greatest quantity of heat; and this is actually the case, as we have seen when we were speaking of the actual temperatures of the different classes of animals—the mean temperature of the Mammalia is 38°, 4 (101° F.), that of Birds 42° 1 (108 F.). Here, then, is a powerful confirmation of the relation which we have recognized between the conditions of the organization and the production of heat; it is of so much the more value as the relation being based on the comparison of two classes so numerous, the verification is made on a scale of proportionate extent. We shall extend it still farther by contrasting in the same manner the two other classes of the Vertebrata, Reptiles and Fishes.

1. The organs which prepare the materials of the blood—the digestive apparatus is more complete among Reptiles than among Fishes; 1st, in the dental apparatus when it exists; 2d, in the more distinct stomach; 3d, in the greater length of the intestines.

II. The blood of Reptiles is superior to that of Fishes both as regards the nature of the globules and their relative proportion, their size being smaller, and their numbers greater, than among Fishes.

If the whole of the blood in the Reptile is not transmitted through the organ of respiration, whilst in the Fish it is, a larger quantity of this fluid is brought into contact with the air in the same space of time in consequence of the greater extent of surface of the organ in the Reptile, and then the Reptile has the farther immense advantage of a pulmonary or aerial respiration, whilst that of the Fish is branchial or aquatic. To conclude, the nervous system of Reptiles is much more developed in the cerebro-spinal axis, and especially in the encephalic extremity, than in Fishes.

From this comparison it follows that the organic and functional conditions, judging of these in conformity with the principles which we have taken as our guide, are much more favourable to the development of heat in Reptiles than in Fishes. This theoretical deduction is fully confirmed by direct observation, as we have seen above, and this verification becomes a new confirmation of the accuracy of the principle.

We continue to pursue this parallel by a summary comparison of the organization in its relations with the production of heat in the cold-blooded Vertebrata and the Invertebrata generally. A glance suffices to shew the vast inferiority of the Invertebrata in this as in every other respect. In the first place their blood is so little of the same nature as that which has been recognized most favourable to the production of heat, that it wants the characters whether of arterial or of venous blood. The blood of the Invertebrata, with the exception of a very small group (the worms with red blood), is colourless. In the structure and number of its globules it is also greatly inferior. The globules, indeed, may be smaller, but then they are of a much more simple structure, aod consequently lower in the scale, in other words more imperfect. In the relation to the fluid part of the blood too, they are in much smaller proportion than among the Vertebrata. An analogous character is manifest in the tissues generally, the proportion of water in them being incomparably larger in the Invertebrate than in the Vertebrate series of animals. Finally, there is an immeasurable inferiority in the nervous systems of the Invertebrate compared with even the lowest of the Vertebrate series of animals.

From all this it results, agreeably to the principle of which we are now showing the application, that the Invertebrate ought to have a much smaller capacity of producing caloric than even the cold-blooded Vertebrate animals; and this is exactly as we found matters to be by direct experiment in regard to the temperature of the different classes, the results of which have been already stated. The comparison might be carried out in regard to Insects and the Mollusca, which present some appreciable differences. If attention were confined solely to the structure of the greater number of the organs of nutrition, which are much more largely developed in Molluscs, it might be inferred that they had a higher calorific power than Insects; but when we take into the account, 1st, the final result of the nutritive functions, the quality of the tissues, which in the Mollusc are much more loaded with watery fluid, by which they acquire a greater degree of softness and flaccidity, (whence the class has its name,) whilst in the Insect they are, on the contrary, as remarkably dry and firm;—2d, when the most general mode of respiration is compared in the two divisions, it being in the Insect aerial, in the Mollusc aquatic; 3d and lastly, when we glance on the one hand and on the other at the state of the nervous system, and observe how much less perfectly this is developed in most of the Molluscs than in the Insect, it is impossible not to perceive that according to the principles influencing the production of heat, the Mollusca must be inferior in this respect to Insects. This is indeed the result of observations of all kinds, however imperfect or limited these may have been, as we have seen above.

It is impossible to carry the comparison further; the phenomena connected with heat in the lower grades of the animal creation become inappreciable; and this even in virtue of the same principle that has been announced; for the tissues are found to become more and more watery as we descend in the scale, till at length the solid constituent is almost inappreciable. Of course the circulating fluid must be watery in a still greater ratio; it contains but few globules; and then the nervous system falls off in a still greater proportion; it becomes more and more imperfect, till at length no trace of it is to be discovered. We thus arrive at the last links of the chain, after having run over the whole animal kingdom, and we have found one uniform principle of correspondence between organic modification and calorific power. It were difficult to imagine any more satisfactory proof of a principle than has been afforded; indeed as this has on no one occasion been found belied, we are fully authorized to regard it as established.

We have as yet examined but two points in reference to animal heat; 1st, the temperature of man and of the different classes of animals; 2d, the general relations of organization with the production of heat. In mentioning the temperature in any case, we have spoken of it as determinate; and farther, to have data that should be always comparable, the temperatures have been taken regularly in the same places,—viz. the mouth in man, and the other extremity of the intestinal canal in animals. We have still to ascertain whether the temperature varies or is identical in different parts of the body.

Temperature of different parts of the body.—There is no need of the thermometer to tell us that all parts of the body do not at all times preserve the same temperature. We are often certain that the extremities are colder than the trunk for example; and a law of decrease of temperature in the ratio of the distance of parts from the heart had even been deduced from this observation. But when exact measurements came to be taken, this law was soon found to be at fault, as will be seen by-and-by in the course of these observations. Dr. Davy, in taking the temperature of the different parts of the body of a lamb, found that of the right ventricle of the heart 40°, 5 (105° F.), that of the left ventricle 41°, 1 (106° F.). The left ventricle was therefore higher in temperature than the right to the extent of a degree of the scale of Fahrenheit's thermometer. The temperature of the rectum corresponded with that of the right ventricle.

In my inquiries along with M. Gentil into the relations in point of temperature of certain external parts, we found in a strong man, perfectly at rest in mind and body, in the month of July, the external air being at 21°, 25 c. (71° F.), the temperature of the mouth 38°, 75 (102° F.); that of the rectum corresponded. The hands presented the next highest degree, marking nearly 37°, 5 (99°, 5 F.). What is remarkable is that the axillæ and groins, which corresponded with one another, were very sensibly lower in temperature than the hands; they did not raise the thermometer higher than 36°, 96 c. (99° F.). The cheeks marked 35°, 93 (96°, 5 F.), the temperature being ascertained by enveloping the bulb of the thermometer in the skin of these parts. The feet were a little lower, 35° 62 (about 96° F.); their temperature being determined by placing the thermometer between the two, so that the bulb was surrounded on every side. The temperature of the feet was, therefore, notably lower than that of the hands, differing to the extent of 1°, 88 of the centigrade scale (above 3° of Fahrenheit's thermometer). Placed on the skin between the thorax and abdomen the thermometer was at its minimum, not rising higher there than 35° (95° F.); but here a part of the bulb being in contact with the air, there must have been considerable cooling.

As the question here is not of absolute but merely of relative temperatures, we can make great use of the results come to by the different writers quoted. We shall present a summary of these under the following head.

Relations between the temperature of internal parts.—1st. The warmest part of the body, according to John Hunter, is in the abdomen close to the diaphragm. 2d. The next part in point of temperature is the left ventricle of the heart. 3d. The right ventricle of the heart is the next in succession. The rectum and the mouth shut are of the same temperature. The greatest difference consequently between the temperature of these internal parts does not amount to more than 1° centigrade, or at the utmost 2° Fahrenheit.

Supposing the relations in temperature of the internal parts to be pretty constant in the normal state, the temperature of the right ventricle of the heart and of the rectum may be determined by taking the temperature of the closed mouth; that of the left ventricle will be found by adding 0,44 c., or 1° F., to the degree indicated.

Relations in point of temperature between external parts.—We have only data for instituting comparisons in regard to the hand, the axilla, the groin, and the feet among the external parts of the body. In a moderate summer-heat the hand appears to be the part which is most susceptible of showing a high, the feet the parts most susceptible of exhibiting a low temperature. The axilla and groin generally exhibit nearly the same degree of temperature; and the amount in which they differ in this particular from the mouth may be stated at about 1°, 75.

When we direct our inquiries with a view to ascertaining any general relation in the temperatures of different parts of the body, whether external or internal, we soon discover, as has been already stated, that this has no connexion of an inverse kind with their distance from the heart. At the same time there is a general condition discovered influencing the temperature of the different parts. This is their situation in reference to the surface or inside of the body. The temperature is higher, for instance, within the trunk than on its outside. Whatever other reason may be assigned for this, there is one which is purely physical, that must influence it powerfully. It is obvious that the surface of the body and limbs must cool much more rapidly than the interior of the body. So that, supposing the temperature at first to be every where uniform, the difference in the rate of cooling would very soon suffice to cause a notable reduction on the exterior beyond that which took place in the interior of the body. This cause, however, can only be charged with its own share of influence; there are others which must act with considerable effect, and among these especially the one upon which the production of heat depends. We have seen that the condition of the functions of nutrition most closely in relation with animal heat was connected with the arterial blood. Now inasmuch as the arterial blood is that which is most intimately connected with the production of caloric among animals, we might fairly expect that the temperature generally would be rather above that of the venous blood. And we have seen that there was actually a difference between the temperatures of the two ventricles, that of the left being the higher. Experiment has also shown that there was a corresponding difference in the temperatures of the two kinds of blood circulating in the arteries and veins; arterial blood is actually higher in temperature than venous blood to the extent of a degree of Fahrenheit's scale. We shall add here, and in conformity with the same principle, that it is to this difference of temperature of the two kinds of blood that the difference in the temperature of the right and left ventricle of the heart is owing. We need not be hindered in adopting this conclusion from the circumstance of the blood of either ventricle being found in a slight degree inferior in temperature to the ventricle itself, inasmuch as the blood abstracted from the canals that contain it, and exposed to the air, begins to evaporate, and loses heat rapidly. Nevertheless it is not demonstrated that the difference in temperature of the blood out of and of the blood in the ventricles of the heart depends on this cause. There may be another at work; the influence of muscular contraction for instance, a point which we shall examine generally by-and-bye. New means of estimating variations of temperature have been lately discovered, by which changes that entirely escaped us as judged of by the thermometer are made abundantly obvious; by which, indeed, the temperature of parts inaccessible in their natural and normal condition to the thermometer are now investigated without difficulty. In using the thermometer as the means of estimating temperature, it is evident that this instrument could not be introduced into the external parts without injuring the tissues, without incisions, &c., which would necessarily alter them materially, and produce so much disturbance in their functions, that an increase or diminution of temperature must almost necessarily have been the consequence. The thermometer, besides, however small its dimensions, has the inconvenience of always either absorbing or giving out a considerable quantity of heat according to circumstances, before it gets into equilibrium with the parts with which it is brought into contact. A necessary fall or rise in the absolute temperature of these parts is the natural consequence of this. Further, the thermometer is incapable of showing sudden variations in temperature; several minutes must always elapse before it gets into a state of equilibrium in regard to temperature with the parts or medium surrounding it. If a thermometer, for instance, be placed in the mouth, three or four minutes must elapse before it will cease to show any increase of temperature. Now if any calorific phenomena of short duration were developed in that time, it is evident that all idea of their occurrence would escape us.

These considerations led to the adoption of thermo-electrical means by Messrs. Becquerel and Breschet. The processes they employed in procuring indications of temperature were the following. The only means we have of penetrating into the interior of organs without injury is to make use of a needle similar to that employed in acupuncture. Now it is easy to arrange this needle so as to obtain thermo-electric indications, which proclaim immediately and with the greatest precision the temperature of the part or medium with which the point happens to be in contact. It is enough to compose this needle of two others in metal, two of the extremities of which are soldered together in a few points only, whilst the other two are placed in communication with one of the extremities of the wire of an excellent thermo-electric multiplier. The slightest changes of temperature at the points of junction give origin to an electrical current, which, in reacting on the magnetic needle, causes it to deviate by a certain number of degrees, which consequently become indices of the temperature of the point of the needle, and therefore of the medium in which it is placed. The multiplier ought to be so sensitive as to show a deviation of one degree of the magnetic needle for each one-tenth of a degree of temperature as measured by the centigrade scale, an amount of temperature made sensible by the union of the two ends of the wire which forms its circuit with an iron wire soldered by its ends.

So much for the general principle upon which and by which the inquiries of Messrs. Becquerel and Breschet were conducted. As to all the precautions necessary to render researches of the kind fruitful, as these are numerous, we beg to refer for an account of them to the memoir of the authors themselves.

Difference of temperature according to the depth.—By the means contrived by Becquerel and Breschet the temperature of the calf of the leg at the depth of four centimetres from the surface was found to be 36°,75 (about 98° F.), and at one centimetre 34°,50 (about 94° F.), a difference of 2°,25 (4° F.). In the chest the temperature at the depth of the pectoralis major, compared with that of the superficial cellular tissue at the depth of one centimetre, showed a corresponding difference; the deeper parts were 2°,25 (about 4° F.) higher than the more superficial. In seven experiments made on the arm the mean difference of temperature between the deeper strata of the biceps and the superficial cellular tissue over the same muscle amounted to 1°,59 c. in favour of the deeper parts.

The next point of inquiry was to know whether it was enough to penetrate to the depth of three or four centimetres into the trunk and limbs to attain the points of highest temperature in these parts. With this view we have compared the observations made by the authors mentioned, in the same individual, with regard to the temperature of the mouth and of the biceps muscle, and we find that the mean temperature of the mouth was 36°,89, that of the biceps 36°,88, (about 98° F.),—a result which may be called identical with the former. The mean of seven other experiments, however, shows the relation of 36°,89 c. for the mouth, of 36°,75 c. for the biceps; the difference here is evidently in favour of the mouth. It were to be wished that inquiries in this direction were multiplied in order that absolute certainty may yet be attained.

In the preceding experiments, in penetrating to different depths, the nature of the tissues attained also differs, a circumstance which must tend to complicate the results; for it is possible that the nature of the tissue may have some influence on the evolution of heat. This is even an inference which we should deduce from the principles already established, were it merely in consideration of the different quantities of blood they contain. And this conclusion is even confirmed by the experiments of the parties mentioned; for on compressing the humeral artery strongly, the motion of the needle immediately announced a fall of temperature to the extent of several tenths of a degree. This experiment is interesting from the rapidity and precision of the effect. There are other cases well known by which we are led to a corresponding conclusion; but nowhere else is the fact seen in so simple a guise, or in so manifest a relation of cause and effect. In operations for aneurism, indeed, and other cases requiring the ligature of a large artery, the temperature of the parts supplied by the vessel tied falls so low as to require to be supported by artificial warmth; but then a severe and bloody operation has been performed by which the conditions are complicated. In the experiment mentioned, on the contrary, nothing occurs to disturb the state of the economy; the effect instantly follows the cause, and its amount is even at the same moment ascertained.

Seeing, then, that in the same tissue the freer or more interrupted access of arterial blood causes the temperature to vary, it is fair to infer that the relative freedom of access or quantity of this fluid which circulates through other tissues should have an influence upon their temperature; in other words, that tissues differ in their power of producing heat according to the quantity of blood which circulates through them. We can scarcely doubt, therefore, but that the differences of temperature observed between the deeper and more superficial parts are complicated by the mere fact of difference of distance from the surface, and also by the circumstance of difference of tissue. The superficial layer in the preceding experiments was cellular membrane; the deeper layer was muscular. But the muscles receive a much larger quantity of blood than the cellular membrane, and their temperature, from this circumstance alone, ought to be higher.*

* [Messrs. Becquerel and Breschet, in a memoir lately read before the Royal Academy of Sciences, (Ann. des Sciences Nat. Mai 1838,) entitled, "Further Observations on the Temperature of the Tissues of the body of Man and the lower Animals, as ascertained by means of thermo-electric effects," have made a few additional observations which deserve quotation in this place. The temperature of the mouth being used as the standard of comparison, the temperature of the biceps muscle was found to be but 36°, 20 c., instead of 36°, 60, which was the term derived from previous experiments, and to fall short of the temperature of the mouth by as many as 4° c. (above 7° F.)

In making experiments upon the influence of the temperature of surrounding media upon that of the tissues, Messrs. Becquerel and Breschet introduced the needles of their thermo-electrical apparatus into the biceps muscles of two young and healthy individuals, the air at the time marking 16° c. (61°F.). The magnetic needle did not deviate in the least; so that the two muscles possessed precisely the same temperature. One of the arms was now immersed for a quarter of an hour in water of the temperature successively of 10°, 8°, 6°, and 0° c. (50°, 47°, 43°, and 32° F.). The deviation of the needle did not amount to more than two degrees of its scale in favour of the muscle of the arm which was not plunged into the water. The partial cold bath, consequently, bad only caused a depression of temperature to the extent of about one-fifth of a degree c. The arm being now plunged into water

We might even deduce from this a fact of great importance in the animal economy, viz. that muscular contraction is a cause of heat, inasmuch as it determines the afflux of blood towards the muscles themselves as well as towards all the surrounding parts. It is very difficult to conceive an occasion of verifying this position in its simplicity; for bodily efforts, in which the skin becomes red and injected, are always accompanied with some disturbance of the respiration and motion of the blood. We have, however, had an opportunity of seeing one individual of athletic powers, who, by merely throwing the muscles of the fore-arm into strong contraction, could cause the integuments of the forearm to become red. During the act of muscular contraction consequently, the temperature must have a tendency to rise.

at the temperature of 42° c. (108° F.) for fifteen minutes, the temperature of the muscle as compared with that of the other was found to have increased onefifth of a degree. When the whole body was plunged in a hot bath at the temperature of 49° c. (120° F.), the deviation of the needle varied from 12° to 13° and 14° of its scale, which indicated a rise in temperature of from one-fifth to two-fifths of a degree c. The pulse was increased to 112 beats per minute, the body being immersed in this bath. The temperature of the body before immersion was 36°, 70 c. (98° F.), a degree to which it immediately returned after coming out of the bath. In trying experiments of the same kind subsequently, but with baths at a somewhat lower temperature, namely, 42°, 50 (109° F.), no rise of temperature was indicated. The immersion in these cases was not continued for more than twenty minutes. Had it been protracted for a longer time, the result might have been different. When a dog, whose muscles indicated a temperature of 38°, 50 (102° F.), was plunged into a hot bath at 49° c. (120° F.), the temperature rose rapidly by half a degree, a degree, and finally two degrees c.; but the animal had become so much enraged that it was found necessary to take him out of the water. The needle of the apparatus being passed into the chest, a like rise in temperature was indicated; but the rise in temperature was found to happen principally when the animal became angry; and it is doubtful how far the state of exasperation influenced the results.

In one experiment the one needle being passed into the biceps muscle of a young man, the other into the long radial supinator of a man aged forty-five, no sensible deviation of the magnetic indicator ensued. A vein was then opened in one of the arms, as near as possible to the point at which the needle had been introduced, but no change of temperature took place either during or after the flow of the blood. The common iliac artery of a dog was now isolated and a ligature thrown loosely round it, so that it could be compressed or left free at pleasure, and one of the needles of the apparatus plunged into the fleshy part of the thigh. The current of blood having been interrupted, the temperature of the limb began to fall, but not until after the lapse of an interval of twenty minutes, when it still amounted to no more than about half a degree c. The free access of blood having been restored, the temperature soon rose again to the normal point. The effect, though trifling in this case,—and the same experiment was repeated several times always with the same result,—is still sufficient to show that the arterial blood exerts a direct influence upon the temperature of the animal tissues. The effect, however, it is obvious from the time which elapses before it becomes apparent, is to be attributed, not to the blood which is circulating in the trunks and branches of the vessels, but to that which is contained in the vascular rete.—Ed.]

This fact is demonstrated in the most satisfactory manner by the delicate experiments of Messrs. Becquerel and Breschet as follows. When one of the joinings *(soudures)* is kept uniformly at a temperature of 36° c. (97° F.). and the other is inserted into the biceps muscle with the arm extended, the magnetic needle was found to deviate about .10 of a degree. On the arm being bent, however, the amount of deviation was observed to increase suddenly to the extent of from one to two degrees. Waiting till the oscillation of the needle and its return are completed, if the arm be bent anew so as to give a fresh impulse to the needle for several times in succession, a deviation of fifteen degrees is obtained at length, equivalent to a difference of five degrees in comparison with the original deviation, and corresponding to an increase of about half a degree of temperature as measured by the centigrade scale. If the needle be inserted into the biceps, and the arm be used in the action of sawing for about five minutes, the temperature is observed to rise considerably, sometimes to the amount of a degree centigrade.

In these researches, then, we have evidence of facts of which we could not have acquired any precise information by our ordinary means of investigation. Every one, indeed, knows that exercise warms the body; but every one also sees that in producing this effect, besides the contraction of the voluntary muscles, exercise is accompanied by an acceleration in the motions of the heart and organs of respiration. In this simultaneous concurrence of a variety of phenomena, it was impossible to distinguish the share which each had in the general result. Such an analysis could only be made by an experiment of the delicate and ingenious description of that which has been detailed.

It would appear that it is by the repetition of the muscular contraction after each relaxation that the highest evolution of heat is obtained, each contraction producing a slight increase of temperature, which, with the addition of that which follows, mounts to a certain limited point which it cannot pass. Let us remark, however, that the mere persistence of a primary contraction ought to have the effect of causing or maintaining a temperature higher than that which is evolved by a contraction followed immediately by relaxation; indeed it is now known that a permanent muscular contraction is but a series and succession of smaller and imperceptible contractions, following each other with extreme rapidity.

It were well to observe here, that neighbouring parts must increase in temperature at the same time much less in consequence of the direct communication of heat in virtue of contiguity than by the afflux of blood, which, transmitted to the muscles in larger quantity, must also be more copiously than usual distributed to adjacent tissues. The relaxation of the muscles ought, on the other hand, to have a tendency to reduce the temperature, and this by so much the more as the relaxation is more complete. From all this it follows that the attitude and state of the body will be favourable to cooling in the ratio of the general relaxation of the muscles, and of the degree in which each of them in particular is in a state of quiescence. This is what happens in sleep, of which we shall speak by-and-bye.

In the rise of temperature observed along with muscular contraction, we have in the first place only considered the action of the blood; but neither contraction of the muscles nor the afflux of a larger quantity of blood could take place without the nervous influence; for it is the will which determines the muscular contraction, and the will only acts through the medium of the nerves which are distributed to the muscles. From this consideration it follows equally as from general relations previously exposed, that whatever lessens the nervous influence will likewise tend to reduce the temperature. Here we are, then, reverting to the two general conditions which we had already found to be the most influential in calorification, namely, the arterial blood and the nervous system.

This examination of the relative temperatures of the different parts of the body has led us, by the immediate comparison of the superficial and deeper layers, to the consideration of the

Influence of external temperature.—An inert or inanimate body of higher temperature than the surrounding medium will of necessity cool faster at its surface than in its internal parts. A living body, likewise, having within itself a permanent source of heat, which we shall suppose equally distributed through it, will lose more caloric from its surface than from its interior. This loss will become apparent by the cooling of the surface, so long as the source of heat remains everywhere equal. If, on the contrary, it be unequally distributed, if it be greater towards the surface, so as to compensate the greater loss which takes place there, the surface will have the same temperature as the interior. Without such a supposition it were necessary that the surface of the body should be lower in temperature than the interior. This, indeed, is the actual state of the case. The external parts of living bodies are colder than the internal parts, because on the one hand the focus of heat is less, by reason of the nature of the component tissues, and on the other because the loss of heat there is greater. When the external temperature falls, then the outer layers will tend to sink in temperature also, and will, in fact, sink so long as the internal source of heat remains the same. This partial refrigeration will be propagated internally, and the general temperature will be lessened unless the economy provides against such an occurrence by an increase of activity in its calorific powers.

The same reasoning is applicable to movements of the temperature of bodies under the influence of that of the air. Heat will be propagated from without inwards, and will raise the general temperature of the body, unless it lessens in the same proportion as it receives external temperature, that which it produces of itself.

The consideration of the changes in the intensity of the internal focus, in other words, in the faculty of producing heat, and of the conditions which determine these, is the most important point of all in the study of animal heat, on account of the multitude of practical applications which result from it.

It is obvious from what has already been said that there is an essential difference between inert or inanimate and animate bodies subjected to the influence of external temperature. The temperature of the former depends solely on the general laws which regulate the propagation of heat, whilst the temperature of the others is subjected to the influence of another element, namely, the heat which they themselves produce. Did this element continue fixed and invariable, it would be possible to determine, by the application of the known data of physics, what must be the temperature of a living body under the influence of a given external temperature. But if this element varies, and the laws according to which it varies are unknown, it becomes impossible to predict in what manner the temperature of an animal will be affected by that of the medium in which it lives. It is only very lately, therefore, that the temperature of man and warm-blooded animals, with the exception of those that hybernate, has been believed to continue unaffected in the midst of extensive variations in the temperature of the surrounding atmosphere.

Variations in the temperature of animal bodies in a state of health, independently of external temperature.—Duly to appreciate the inquiries that have been instituted in this direction, the first question to be asked is, whether or not the temperature of the body presents variations, although external conditions continue the same, or nearly the same? The answer here must be in the affirmative: the body varies in temperature at different times, external circumstances as to temperature continuing nearly the same. This is apparent in the observations of Dr. John Davy instituted with another view, but quite available here. We perceive that the individual designated No. 1, having a temperature of 37° 8 (100° F.), when the air was at 26°, 4 (79° F.), had a temperature of only 37°, 5 (99°, 75 F.) when the air was at 26°, 7 (80° F.), that is to say, the same person showed a third of a degree c. less of temperature, when the air, instead of becoming colder, had actually become warmer in the same proportion. The temperature of No. 3 was 37°, 2 (99° F.), when the air marked 25°, 5 (78° F.), and on another occasion it was only 36°, 9 (98° F.), when the air was 26° (79° F.); in other words, the temperature of the body, instead of rising, had actually fallen by 0°, 7 cent., when that of the external air had risen 0°, 9 cent.

Influence of the natural temperature of the air on that of the body.—It must be obvious from the facts of the last paragraph that the influence of external temperature cannot be appreciated without having recourse to means of observation calculated to make variations dependent on foreign causes to disappear.

To render the comparison of the mean sums obtained more certain, we shall confine ourselves to the observations of the inquirer just quoted, made upon the same individuals at different temperatures. The following series is after the data supplied by Dr. Davy :—

Temperature of the air.	*Mean temperature of five men.*
15°, 5 (60° F.).....	36°, 85 (98° F.)
25°, 5 (78° F.).......	37°, 16 (99° F.)
26°, 4 (79° F.).......	37°, 32 (99° 5, F.)
26°, 7 (80° F.).......	37°, 58 (100° F.)
27°, 8 (82° F.).......	37°, 70 (100° 5, F.)

It is apparent that these differences, even the extremes, do not surpass the limits of the variations which the same individual exhibits, or may experience spontaneously under the same temperature of the air. But when it is considered that these differences are mean results, forming a series increasing with the rise of the external temperature, it is impossible to doubt of their standing in the relation to one another of cause and effect. If this dependence and connection actually exists, we must allow that it is very little obvious at the temperatures within the limits of which these observations were made; for whilst the temperature of the air varied to the extent of 12°, 3 c., the changes in the mean temperature of the body did not exceed 0°, 9. Such slight differences being apt to leave uncertainty in the mind as to the cause producing them, we shall confirm the impression they are nevertheless calculated to make by citing others, for which we are indebted to Dr. Reynaud, surgeon of the corvette La Chevrette, in a voyage of discovery in the Asiatic seas undertaken in the year 1827. The instruments used were furnished by the best makers of Paris, and were compared by M. Arago with those of the Observatory; and the observations were made conjointly with M. Blosville, lieutenant of the vessel, charged by the Academy of Sciences of Paris with various researches in natural philosophy.

Mean temperature of the body deduced from observations four times repeated upon each of eight men, under the torrid zone, the external temperature varying from 26° to 30° c. (79°, 86° F.)	37°, 58 (100 F.)
Mean temperature of the same eight men observed three times in the temperate zone, the external temperature varying from 12° to 17° (53° to 62° F.)	37°, 11 (99° F.)

These results confirm those of Dr. Davy by so much the more as they were made within the same limits of external temperature. The mean rise of the temperature of the body under the influence of that of the air is also equally confirmed; but the amount is still less than as given by the English observer.

It seems impossible, then, to doubt that the natural variations in the temperature of the air affect that of the body of man; but this is only in a very trifling degree, at least within the limits of temperature in which any extant observations have been made. It is greatly to be regretted that neither of the observers quoted had opportunities of ascertaining the effects of much lower temperatures than those they have given. There are, it is true, many isolated observations made by voyagers in the Arctic regions, both upon animals and man, and although conducted in no regular series, or as points of comparison with one another, they still lead to the same general result, namely, that great differences in the temperature of the air cause slight differences in the temperature of the body of animals. Thus, in the voyage of Captain Parry it was observed that the temperature of the Mammalia was very high. With the external thermometer at — 29°, 4 (— 21°, F.), the temperature of the white hare was + 38°, 3 (101° F.). With the thermometer at — 32°, 8 (27° F.), the temperature of a wolf was + 40°, 5 (105 F.); the temperature of the Arctic fox, under nearly the same circumstances, namely, when the thermometer was standing at — 35° (—31° F.), was as high as + 41° 5 (107° F.). Similar observations have since been made in the same high latitudes upon man.

The variations in the temperature of warm-blooded animals according to that of the seasons has been studied by the present writer, who confirms the results just stated. The experiments of the writer were made upon a great number of sparrows recently taken at different seasons of the year, which is preferable to keeping these creatures in captivity for any length of time. The mean temperature of these birds rose progressively from the depth of winter to the height of summer, within the limits of from two to three degrees centigrade. The observations made on sparrows exhibited the greatest differences. In the month of February the mean temperature of these birds was found to be 40°, 8 (105° F.); in April 42° (108° F.), in July 43°, 77 (111° F.). The temperature from this time began to decline, and followed, in the same ratio in which it had increased, the sinking temperature of the year.

Influence of media upon temperature.—The media in which animals live do not act solely in the ratio of their temperature, but also by virtue of the intensity of their cooling or heating power. Thus air and water at the same degree of heat will have a very different influence on the temperature of the bodies plunged in them. The power of air in heating or cooling is commonly known to be very inferior to that of water. Bodies acquire or lose temperature much more slowly in air than in water. A water-bath according to its temperature communicates sensations of heat or cold far more rapidly and powerfully than an air-bath. The writer and M. Gentil made the following experiment:—A young man seventeen years of age, of strong constitution and in good health, after remaining for twenty minutes in a bath the water of which marked 13° R. (61°, 5 F.), whilst the air was 14°, R. (63° F.), half an hour afterwards was found to have lost half a degree of his original heat in the mouth and hands, and a degree and a half in the feet. This temperature of the air may be regarded as a mean, or intermediate between heat and cold, and may be termed temperate (61° to 62° F.). It was superior to that of the water by a degree R., and yet the water of the bath, after immersion in it for no longer a time than twenty minutes, had reduced the temperature of the body according to its parts from half a degree to a degree and a half R.

Effects of external temperature upon an isolated part of the body.—Under this head let us examine, 1st, the extent of the effect, and 2nd, its influence on other parts. The facts we shall borrow from the researches just quoted, those namely of myself and M. Gentil. The hand, at 29° R. (98° F.) having been kept immersed in a tub of water cooled down to + 4° R. (41°F.), in all during twenty minutes, five minutes after it had been taken out of the water, marked no higher a temperature than 10° R. (55° F.) This experiment shows how rapid and extensive, and how much beyond what could have been anticipated, may be the refrigerating effects of cold water applied to an extremity. Another not less remarkable result is the singular slowness with which the temperature of an extremity is regained, although exposed to the gentle warmth of the air. The hand in the above experiment, after the lapse of twenty-five minutes from the time it was removed from the water, was still no higher than 16¼° R. (69° F.), and after the expiration of an hour and a half it was only 24½° R. (87° F.). The foot, in the same circumstances, gave nearly analogous results.

In a number of experiments of the same nature as the last, where one hand was plunged in water cooled down by ice, the other hand, which was not subjected to the action of the cold bath, lost nearly 5° R. in temperature.

It is therefore apparent, 1st, that partial chills, or the exposure of individual parts to low temperatures, may be and are felt very extensively even when the cold is not very severe; 2nd, that the chilling of a single part, such as the hand or the foot, may cause a loss of temperature in all the other parts of the body, even far beyond what could have been presumed as likely or possible. These facts give a key to the right understanding of the immense influence which partial chills are capable of exercising on the state of the general health

Of the effects of partial heating.—The hand being immersed in water heated to the temperature of 34° R. (109° F.), rose one degree of the same scale, and the temperature of other remote parts not immediately exposed to the influence of heat were found to have risen in a corresponding degree. Whence follows this axiom,—*that we cannot either raise or lower the temperature of any one part of the body without all the other parts of the frame being affected, and suffering a corresponding rise or fall in temperature, more or less according to circumstances.* We may further presume from the comparison of these facts, that the body and its parts are liable to variations of temperature towards either extremity of the scale from the mean, much more considerable than are generally imagined. This latter fact will appear very evidently from the other inquiries which are now to engage our attention.

Effects of an excessively high or excessively low external temperature upon the temperature of the body.—Hitherto we have only considered the changes in the temperature of the body produced by moderate degrees of external heat and cold. We now pass on to the examination of the effects caused by extreme external temperatures, and first of those that follow from excessive heat; designating by excessive heat any temperature that surpasses that of the human body. On a summer's day, the temperature of the air being 37°, 77 c. (100° F.), Franklin observed that the temperature of his own body was nearly 35°, 55 c. (96° F.). This fact, which is perhaps the first of the kind noted, is highly deserving of attention. It proves that man, and by analogy other animals, have a power of keeping their temperature inferior to that of the air. As in the observation quoted there is no means of knowing what effect the excessive external temperature had produced upon the temperature of the observer, recourse must be had to other facts. In numerous experiments made in England by Dr. Fordyce and his friends, and subsequently by Dr. Dobson, in which these experimenters exposed themselves to very high temperatures, which on some occasions exceeded that of boiling water, the heat of the body was never observed to rise more than one, two, three, or four degrees of Fahrenheit's scale at the utmost. As in these experiments the object especially proposed was to determine the degree of external temperature which the body could bear, all the attention which would have been desirable was not given to determine the temperature of the body before, during, and after the experiments. This is an omission which is common to the experiments of Fordyce and Dobson. The highest temperature of the body noted by Dr. Dobson is 102° F., but he does not mention the heat before the experiment, nor does he notice the rate of cooling subsequent to its termination. The highest temperatures of the human body exposed to excessive heats ever observed, were remarked by Messrs. Delaroche and Berger in their own persons. The temperature of M. Delaroche being 56° 56 c. (98° F.) increased 5° of the centigrade scale, by remaining exposed in a chamber the temperature of which was 80° c. (176° F.). M. Berger, whose temperature was the same as that of M. Delaroche, gained 4° c. by remaining for sixteen minutes in the hot chamber at 87° c. (188°, 5 F.). These experiments are liable to this objection,—that the temperature was taken in the mouth in an atmosphere of much higher temperature, which might have some influence in raising the thermometer. To arrive at conclusions against which no kind of objection could be raised, Messrs. Delaroche and Berger exposed themselves in succession in a box, out of which they could pass their head; the hot air or vapour of the interior being prevented from escaping by means of a circular pad of soft napkins placed between the edge of the outlet and the neck. The temperature of the mouth, in this way, if it was increased, must be increased in consequence of a rise of temperature in the parts of the body included in the bath. After a stay of seventeen minutes in the bath, heated from 37°, 5 to 48°, 75 c. (99° to 120° F.), the temperature of M. Delaroche's mouth rose 3°, 12 c. Under similar circumstances, the temperature of the bath being from 40° to 41°, 25 c. (104° to 106° F.), the temperature of M. Berger's mouth increased 1°, 7 c. in the course of fifteen minutes.

It is pretty obvious that experiments upon the human subject cannot be pushed far enough to ascertain the highest amount of temperature that can be acquired under the influence of exposure to air of excessively high temperature. To judge of this analogically, recourse must be had to warm-blooded animals of the two classes, Mammalia and Birds. Messrs. Delaroche and Berger consequently exposed different species of Mammalia and Birds to dry hot air of different temperatures, from 50° to 93°, 75 c. (122° to 201° F.), leaving them immersed till they died. The whole of the animals that were made subjects of experiment, in spite of diversity of class and species, and of the varieties of temperature to which they were exposed, had gained an increase of temperature nearly equal at the moment of their death. The limits of the variations being between the terms 6°, 25 and 7°, 18 c., the amount of difference did not exceed 0°, 93 c. which is a very trifling quantity. It may therefore be inferred that man and the warm-blooded animals cannot, under the influence of exposure to dry air of excessively high temperature, have the heat of their body raised during life to a greater extent than from 7° to 8° c. The temperature of the body being increased to this extent becomes fatal. It is in fact only attained at the moment of dissolution; perhaps death has virtually taken place before it is attained.

We have seen that Franklin observed the temperature of his body to be lower than that of the air on a very hot day. Such a circumstance is rare in what may be called natural conditions as regards man and the warm-blooded animals; inasmuch as it rarely happens that the temperature of the air surpasses that of their bodies generally. The case is different, however, as regards the cold-blooded tribes. It is not at all necessary that the temperature of the air be very high to afford opportunities of observing the phenomenon in question among cold-blooded animals. This was observed for the first time by Sir Charles Blagden in a frog, which on a summer's day, when the heat was by no means excessive, he observed to be lower in temperature than the surrounding air. A fact of this kind could not remain isolated and unconnected with others. Accordingly we observe among the experiments of Dr. Davy such facts as the following:—The temperature of the atmosphere being 32° c. (90° F.), that of a tortoise was only 29°, 4 (85° F.). The air marking 26°, 7 (80° F.), a frog indicated 25° (77° F.). The air being at 28°, 3 (83° F.), the blatta orientalis was at 23°, 9 (75° F.). The air at 26°, 19 c., (79°, 5 F.), a scorpion was at 25°, 3 (78° F.). It is therefore apparent that the phenomenon is general among animals with cold blood; that during the highest heats of summer, the temperature still falling short of excessive, the heat of their bodies is below that of the air. There is thus a limit of summer temperature which separates two orders of phenomena relative to the temperature of cold-blooded animals. Starting from a mean temperature of the air, that of cold-blooded animals, the vertebrate as well as the invertebrate tribes, is superior to this mean, only varying in this respect within the narrow limits of from a few fractional parts of a degree to about four degrees centigrade, until the air attains the summer heat. Towards this limit the differences decrease, and the term 25° or 26° c. (77° to 79° F.) attained, they become *nil*. The inverse phenomenon is also observed: the temperature of the greater number is inferior to that of the air, and the differences go on increasing with the rise in temperature of the external air.

These phenomena are of great interest in themselves, but of still greater from the light they cast on questions of a similar kind relative to man and the warm-blooded tribes of creation. The slight evolution of heat by the cold-blooded animals rendering their condition more simple, allows us to appreciate distinctly the influence of external causes.

We now proceed to treat of a third condition influencing temperature, namely,

Evaporation.—The fluids so far surpass the solids in the bodies of animals that they certainly constitute the larger portion of their masses; and, further, the exterior surface of animal bodies generally is extremely porous. Animals are consequently subjected to the ordinary physical laws of evaporation. It is very long since, in addition to the sweat or visible perspiration, the existence of an invisible perspiration has been recognized. The latter is owing in great part to the effects of evaporation. Now evaporation cannot take place without the occurrence of cooling or loss of temperature in the ratio of the quantity of vapour formed. Without keeping this cause of refrigeration in view, we should fall into serious mistakes in estimating the heat of animals. If, for example, we would compare the heat of two animals, which, unwittingly to the observer, should be under different conditions of evaporation, we should deceive ourselves greatly in regard to their respective temperatures.

It is even so with reference to another fact bearing upon temperature, which is often forced on the attention, and which has almost always led inquirers into error. There are many animals among the inferior classes of the Invertebrata, which tried by the thermometer exhibit no difference in temperature from that of the surrounding air. These creatures do not, consequently, appear to have any faculty of producing heat. But in the mere fact of their maintaining the temperature of the air about them, an inherent capacity to produce heat is apparent. Did they evolve no caloric, they would fall below the temperature of the air, in consequence of the evaporation which goes on from the surface of their bodies. They must of necessity produce as much as is necessary to repair the loss which takes place from this cause.

What we have said of animals is equally applicable to vegetables. To explain the progression of the temperature of cold-blooded animals, which we have exposed above, regard must be had to the relation which connects the quantity of vapour formed with the degree of external temperature. Within moderate limits, which may be styled *temperate*, the vapour formed will be nearly as the degrees of temperature of the air. But under higher temperatures, evaporation will go on in a greater ratio than that of the external temperature. Thus when the air is cool or moderately warm, evaporation is trifling, and among the superior classes of cold-blooded animals heat enough is produced to maintain their temperature above that of the air. But when the air becomes warmer, as in the height of summer, evaporation and the cold which results from it increase in a far greater ratio than the temperature of the body, so that the body remains at a temperature inferior to that of the air, and this by so much the more as the external temperature rises higher. Twenty-five degrees is the limit at which this change commences in regard to cold-blooded animals. But it is obvious that a higher degree must be necessary to observe such phenomena in man and the warm-blooded tribes, inasmuch as the heat from without is for a long time added to that produced internally, and which among the warm-blooded tribes is so much greater in amount than it is among the cold-blooded.

Relations of the bulk of the body with animal heat.—If the temperature of the larger animals be compared with that of the smaller, it will be found that the former do not mark so high a degree as the latter. In the elephant and horse, for instance, no higher a temperature than 37°, 5 c. (100° F.) has been observed, whilst in the rat and squirrel temperatures of 38°, 8, and of 39°, 4 (102° and 103° F.) have been noted. To prove that the difference is less owing to the order or species than to the simple size, we shall contrast several animals belonging to the same order, selecting the ruminants. The temperature of the air being the same, namely, 26° c. (79° F.), the temperature of the ox was found to be 38°, 9 (102° F.), whilst that of a castrated he-goat was 39° 5 (103° F.), and that of the she-goat and sheep 40° (104° F.).*

It is evident that smallness of size must in itself be one of the conditions unfavourable to height of temperature among animals, when this is merely viewed in relation with the ambient medium. As the external temperature is almost always lower than that of the bodies of animals, the ambient medium tends to lower their temperature; and small bodies having a more extensive surface in reference to their mass than large bodies, small animals must have a greater tendency to lose heat than larger animals. But, on the other hand, the circulation and respiratory motions generally increase in rapidity in proportion to the smallness of size; and we have seen that acceleration of these motions had an influence in keeping up the temperature. With a small size of the body, consequently, we find associated a higher activity of function which tends to compensate the disadvantage resulting from inferior size in reference to temperature. In fact it constantly happens that this higher activity more than compensates the cooling disposition from inferiority of size, and causes the balance to incline towards the side of higher temperature. It must be apparent, however, that there is no occasion for such a preponderance always existing in the case of small animals. And then we know that the motions of circulation and of respiration cannot be greatly accelerated without causing inconvenience and even danger to health and life. It follows that the external temperature being liable to fall disproportionately low, small animals have not, under like disadvantageous circumstances, the same power as larger animals of supporting their temperature. The relations of size naturally lead us to consider those that depend on age.

Relations of age with animal heat.—The size of the body changes with the age. The same relations between bulk of body and development of heat ought therefore to be exhibited in youth as compared with adult age. In early life the greater rapidity of the motions of circulation and respiration, all things else being equal, ought to increase the heat. At the same time the constitution differs in other respects, and if these were unfavourable to the evolution of heat, it would be impossible to foresee the result of these two opposite tendencies. Nevertheless it is probable, from what we have seen to happen in warm-blooded animals of different sizes, that there might occur a period in early life when the heat would be higher than in adult age. A confirmation of this inference may be found in comparing the different observations of Dr. Davy, who has given a table of the temperatures of fifteen children from four to fourteen years, the mean age of the whole being nine years and nine months. The mean temperature of the bodies of these children was 38°, 31 (101° F.). But the mean temperature of twenty-one adults was no higher than 37°, 82 (100° F.); a difference that seems the more worthy of being confided in from the temperature of the air having, at the time of the observations, been more favourable for the adults than for the children, this having, in reference to the former, been 26° and 26°, 7 (79° and 80° F.), whilst when the latter were made the subjects of investigation, it was but 24° and 26° (75°, 5 and 79° F.).

It seems impossible, therefore, to doubt from what precedes, that size is not an element which has much influence in the particular

* Vide Observ. of Dr. Davy.

direction we are considering. We have seen that with a decrease in the size of adult Mammalia the circulatory and respiratory motions were progressively accelerated, and that by this means the disadvantages as regards cooling in consequence of a smaller relative size of the body, are in some measure compensated, sometimes, indeed, we have seen the balance inclined the other way, and the greater rapidity of the motions more than compensate for the diminished size of the body. Great rapidity of the respiratory and circulatory motions may co-exist with other organic conditions having an opposite tendency as regards temperature; and, according to the relations of these, and as the one or the other predominates, we may have two different states of temperature in early life. This proposition is even made apparent when we compare the constitution in early youth and in adult age. In early life the celerity of the motions has led to the belief that all the functions of nutrition were peculiarly active. But strength or energy is not always an accompaniment of simple celerity; on the contrary rapidity is generally indicative of absence of power. It is quite true that in early life not only are circulation and respiration, but digestion, assimilation, and growth likewise, much more rapid than in the adult state. But does it follow from this that the materials of the blood are elaborated in the same degree of perfection, or that the products of the action and contact of this fluid, the various tissues, &c. of the body, are all as completely formed? Everything conduces to make us believe that the reverse is the case. If on the one hand rapidity of movement be a character of early life, weakness is a feature still more manifest. If the nervous system therefore, although acting rapidly, is less energetic, in the same proportion there may be an age at which the influence of this weakness on the production of heat may be manifest. And, as the weakness is greater as the being is younger, it is in the very earliest periods of independent existence that this relation must be investigated. Now such a relationship does actually exist, although an opinion to the contrary had always been entertained until direct experiments settled the question definitively. These experiments were performed by the writer, and a summary of them is here given. If the temperature of new-born puppies lying beside their mother be taken, it will be found from one to three degrees inferior to that of the parent. The same thing obtains in regard to the young of the rat, the rabbit, the guinea-pig, &c. and is probably universal among the Mammalia. Among Birds the same circumstance presents itself in a still more marked degree. If they be taken out of the nest in the first week or even fortnight of their existence, the difference of temperature extends to from 2° to 5° c. between the young and the parents. The fact has been ascertained in regard to the sparrow, the swallow, the martin, the sparrow-hawk, the magpie, the thrush, the starling, &c. &c., and is probably, as among Mammalia, universal. Whence we may conclude that the phenomenon is general as regards warm-blooded animals. We might have taken it for granted that man was comprised within the category, but it is just as well to have the assurance that he forms no exception to the law, that he has no peculiar privilege in this respect. To have a precise term of comparison, the temperature of twenty adults was taken at the same time, the thermometer being applied in the axilla. The temperature of these twenty persons varied between 35°, 5 and 37° c. (96° and 99° F.); the mean term was therefore 36°, 12 (97° F.). The temperature of ten infants varying from a few hours to two days in age, ascertained in the same manner, varied between 34° and 35° 5 c. (93°, 5 and 96° F.). The mean was therefore 34°, 75 c. (about 94°, 5 F.). There was consequently a difference of nearly two degrees between the temperature of the adult and of the newly born babes. Man is therefore proved to be subjected to the same law here as animals having warm blood in general, the young of which, so far as they have been examined, and we may presume universally, are inferior in temperature to their parents.

There are, therefore, two periods in youth at which the bodily temperature differs from that of the adult age. These may be distinguished as the first and second periods of infancy or youth. The first extends from birth to an indefinite period, but which is nearer or more remote from the period of birth in different cases. The second is included between the fourth and the fourteenth year; the limits cannot be more accurately determined. In the first the temperature is lower than in adult age, in the second it is higher. The differences of temperature in the first age of infancy, and the adult age, although very sensible and important as regards the economy, are indices of a difference incomparably greater than their numerical indication might be taken to imply. In fact, if the manner of observing be altered, results of so extraordinary a character are come to as to surpass all expectation. To develope these the temperature of the newly born being must not be taken only when it is in contact with its mother. If, after having ascertained the temperature of a puppy in this position, it be removed from the mother and kept isolated, the temperature will be found to fall rapidly; and this phenomenon takes place not only when the air is cold, but when it is mild. The phenomenon does not commence after a term; it is apparent from the moment the separation takes place, and is very sensible after the lapse of a few minutes. The following is the rate of cooling of a puppy twenty-four hours old, the external temperature being 13° c. (about 55°, 5 F.), taken at intervals of ten minutes; the series of course represents the successive losses of temperature in the course of the small intervals of time indicated: —temperature in commencing the observations 36°, 87 c.; the declensions in temperature at intervals of ten minutes successively, 0°, 63, 1°, 12, 1°, 38, 1°, 25, 1°, 29, 0°, 87, 1°, 63, 0°, 25, 1°, 0; in thirty-five minutes the temperature declined farther 1°, 25; in thirty-five minutes more it fell 3°, 12; in thirty minutes more 2°, 50; in twenty-five minutes more 1°, 25; in thirty minutes more 1°, 25; so that in the course of four hours in all the temperature declined by the amount of 18°, 12 of the centigrade scale (about 33° F.)! Not only had the temperature of the animal sunk by so large a quantity in so short a period of time, the external temperature being pleasant, but it actually could maintain its temperature at no higher a grade than 6°, 75 c. (44°, 5, F.) above that of the atmosphere. Experiments of the same kind performed on three other puppies of the same litter presented results in all respects analogous. The cooling may even go much further by protracting the period during which the young animals are kept apart from their parent. For instance, four puppies, twenty-four hours old and of much smaller size than the subjects of the former experiments, after having sunk 16° c. in four hours and thirty minutes, lost six degrees more of temperature in the succeeding eight hours and thirty minutes, the air remaining all the while at 13° c. (55°, 5 F.). They consequently lost twenty-two degrees centigrade in thirteen hours; and, what is very remarkable, their final temperature was but one degree above that of the surrounding air. Kittens and rabbits of the same age exhibited similar phenomena, if possible in a more striking degree. Some kittens were observed to cool twenty degrees centigrade within the short interval of three hours and a half, and some young rabbits suffered the same depression of temperature in two hours and ten minutes, the air being at the time at 14° c. (57°, 5 F.). These phenomena are unquestionably among the most remarkable we witness in warm-blooded animals. For here we have species of different genera of the Carnivora and Rodentia, which at two periods of their existence present the extremes in the production of heat. They may be said to be, to all intents and purposes, cold-blooded animals, with reference to temperature, during the earliest period of life; they are only truly warm-blooded animals in a later stage of their existence. The same phenomena undoubtedly present themselves in many other species; but it would not be reasonable to suppose that they were exhibited by all.

The phenomena being connected with the state of constitution, it may be expected to vary in different genera and families; and this, in fact, is what actually happens. A young guinea-pig, for instance, having a temperature of 38° c. (101°, 5 F.), will maintain this temperature when the atmosphere is mild, although separated from its mother. It is the same with the goat. These instances are enough to give us a key to the external characters in relation with the different capacities to produce heat inherent in the young Mammalia. In the first place we observe a manifest relation with the state of energy of the nervous system: on the one hand we have the puppy, the kitten, the rabbit, which are born extremely weak; on the other we have those animals that come into the world in a condition to walk, to eat, and, as it were, furnished forth to a certain extent with the means of providing for their wants. The question, however, is to discover some zoological character in relation with these differences. If this were to be derived from the state of the organs of locomotion, of the faculty of walking, we should sometimes be led into error; for man, at the period of his birth and long afterwards, is not in a condition to hold himself erect, and yet his temperature is maintained to within one or two degrees of that of his mother, if the external temperature be but mild. There is, however, one character that appears general; this is the state of the eyes. *Those species of Mammalia which in the earlier period of their existence do not maintain their temperature, that of the external atmosphere being mild or warm, but cool down to the standard of the cold-blooded animals, are born with their eyes closed; whilst those which maintain their temperature, that of the external atmosphere being mild, are born with their eyes open*; and this, whether they can walk about like the guinea-pig, the kid, &c., or cannot do so, as is the case with the human infant in particular.

This general view of the state of energy of the nervous system in relation with the production of heat in early life, comes in aid, in a very remarkable manner, of the general principles which have been already deduced in regard to the calorific power. In going more deeply into the subject, the confirmation becomes more manifest and more complete. The state of the eyes affords a mere external and zoological indication. It is but an indication of other deep modifications of the economy, which it is essential to determine more closely. Now in examining the state of the organs generally of puppies at the period of their birth, we observe a remarkable disposition of the sanguiferous system. The ductus arteriosus continues pervious and of large size. The consequence of this structure is that a free communication is established between the arterial and venous blood, by which they are mingled in large proportion one with another. And here we have precisely the physiological character derived from the nature or quality of the blood which distinguishes the cold-blooded from the warm-blooded Vertebrata (in the adult age understood). This character is exactly the same in the other species of Mammalia which we have mentioned as losing temperature and attaining the standard of the cold-blooded tribes. On the other hand, in the guinea-pig, to take an individual instance, which from the first day of its extra-uterine existence maintains its temperature nearly on a level with that of its parent when the air is temperate, the ductus arteriosus is closed immediately after birth. The arterial remaining distinct from the venous blood, this creature is therefore born with the organization characteristic of warm-blooded animals, and presents phenomena having reference to calorification of the same kind as adult warm-blooded animals.

This relation is preserved in the young Mammalia in every modification in a peculiarly interesting manner. The young Mammalia which are born with the eyes closed, at first present the phenomena of refrigeration nearly in the same degree during the two or three first days of their life; though they afterwards exhibit differences of great extent in this respect. Thus a young rabbit two days old had cooled down to 14° from 23° c. (to 58° from 74° F.) in the course of three hours fifty minutes, the air being at the time temperate; another three days old took seven hours twenty-five minutes to cool through a range of 18° c., when the process of refrigeration ceased. A third, of the age of five days only, lost 5° c. in temperature in the course of one hour fifty-five minutes, and maintained itself afterwards at this temperature. During the following days, smaller and smaller depressions of temperature were observed, till the eleventh day after birth, when the power of sustaining the temperature a little below that of the adult female parent seemed to be acquired permanently. When the modifications of internal structure are examined during this interval of time, we find that the ductus arteriosus has been contracting in the same proportion as the faculty of maintaining the temperature has been increasing, and that it is entirely closed at the epoch when the temperature becomes stationary, the external temperature being understood all the while as mild or pleasant. At the same period precisely too, the eyes are unsealed, a circumstance which confirms the exactness of the character derived from the state of this latter organ, as distinctive of the young of those Mammalia which are born as it were cold-blooded animals, from those that come into the world with the distinguishing attribute of warm-blooded animals.

Among the young of Birds we observe as marked differences in the calorific function as we have just acknowledged among Mammalia. Some lose heat rapidly when separated from the mother; others maintain their temperature to within a little of that of their species. Sparrows, for instance, which have been hatched but a short while, present a temperature from 4° to 5° c. lower than that of their parents when still contained in the nest, where they contribute to each other's warmth. But taken out of the nest and isolated, although the temperature be that of summer they begin to cool with extreme rapidity. A young sparrow a few days old lost as many as 12° c. in the short space of one hour seven minutes, the air at the time marking 22° c. (72° F.). The same thing happens with swallows, sparrow-hawks, &c. But the law is not universal; it does not hold in reference to all the genera. There are several that have the power of sustaining their temperature in spring and summer at a degree but little below that of their parents. Birds, therefore, form two groups as regards the production of temperature, just as the Mammalia do. The first cool down to the standard of cold-blooded animals; the second preserve their warmth, when the air is mild or agreeable as it is in the spring and summer. But the zoological characters that distinguish them are not the same as among mammiferous animals. All birds are hatched or born with their eyes open. But there are other characters which coincide with the difference of temperature; and this consists in the absence or presence of feathers. The covering of those that are hatched so provided, consists in a kind of down, very close and very warm, so that we might imagine the differences observed in the liability to lose heat or in the capacity to engender it, belonged to the coat. This has undoubtedly some influence, but analogy even will not suffer us to ascribe the chief effect to this cause. In the Mammalia which are born with their eyes closed, the refrigeration takes place to the same extent whether they are born with a fur-coat, as the kitten, the puppy, &c., or come into the world naked like the rabbit; the cooling is only more rapid in the latter than in the former. What further proves, and directly proves, that the refrigeration is not entirely due to the difference in the external condition as regards covering, although this of course must go for something, is that when the want of natural covering is artificially supplied, the cooling does not go on the less certainly on this account, and to the same ultimate extent; it only takes place somewhat more slowly. The counter-proof is attended with the same result. An adult sparrow which has had all its feathers clipped off does not at first suffer loss of temperature to the extent of more than a degree, and by-and-by recovers even this; whilst a young bird of the same species, though furnished with some feathers, cools rapidly and to a great extent, as we have already seen. *Birds are therefore divided into two groups as regards the production of heat. The one comprises those that are hatched with the skin naked, and which cool in a temperate air in the same manner as cold-blooded animals; the other embraces those that are produced with a downy covering, and maintain their temperature at a considerable elevation in the ordinary heat of spring and summer.*

There is not a less remarkable contrast between these two groups of birds in point of calorific power, than between the two groups of Mammalia already mentioned; but the zoological or external characters which distinguish them in the present instance are not of the same kind. The state of the eyes does not apply here, for all Birds are disclosed with their eyes unsealed. They also all come into the world with the ductus arteriosus closed or nearly so,—a circumstance which might have been predicated, or inferred from analogy. Yet the young of Birds in the power of producing heat present diversities no less remarkable than are observed among the young of the Mammalia. The separation of the two kinds of blood consequently is not the only condition which influences the production of heat; but all that modifies the blood on the one hand, and the nervous system on the other, as we have had occasion to observe in a previous part of this paper. Now it happens that we have an opportunity of applying this principle in a very particular manner in the instance of the two groups of Birds that engage us, and that differ so essentially in their powers of engendering caloric. In the one and in the other we observe the same difference in the state of the general strength which we have observed in the corresponding groups of the Mammalia. In the one which cools rapidly, there is the same state of weakness, of general impotency; in the other the young are in a condition to walk, and in a certain sense to shift for themselves as soon as they have escaped from the shell.

We perceive then in the first place, that the nervous system is much less energetic in the former than in the latter group; and in the second place, that the digestive powers are in an equal degree inferior in strength; for they are not only unable to take food of themselves from muscular incapacity, but also from the lack of the requisite instinct, and, farther, from their digestive organs not being in a condition to elaborate food to any extent. It is on this last account that the parents supply their young with food which has suffered maceration in their own crops, or has even in their stomachs undergone a kind of incipient or partial solution; or otherwise the parents have the instinct to select such articles as are easiest of digestion, and best fitted for the weakly state of the digestive organs of their progeny. We have already observed that a defect in the powers of digestion implies a corresponding imperfection in the blood. Whence we must conclude by analogy that the blood in the birds of the first group is inferior in quality to that of the birds of the second group. We consequently still find the two general conditions which regulate the production of heat throughout the animal kingdom—the state of the blood, the state of the nervous system.

The same principles are applicable to the first period in the existence of all animals, without distinction of groups, as compared with adults. On the one hand we have ascertained that all without exception have a temperature lower than that of their parents; on the other, nothing can be more manifest than their inferiority with reference to the energy of the nervous system. And more attentive and extensive examination shows that this extends in like manner to the digestive functions, and consequently to those of nutrition generally.

Let us first turn our eyes to the Mammalia. All of these are evidently inferior in this respect to the adult. This is proclaimed in the distinguishing character of the class: the females are provided with glands for the purpose of preparing a food appropriate to the state of weakness of their young. The state of the mouth of the young is a sufficient index of the defective power of the digestive organs; the jaws are either wholly or partially without teeth. The softness, delicacy, paleness of colour, and insipidity of the tissues of young Mammalia, complete the evidence of the imperfect elaboration of the nutrient juices. If, therefore, the first and last products of the nutritive functions are in an inferior condition, can we suppose that the intermediate product, the blood, will not participate in this inferiority? We have already shown in what this consists among the Birds of the first group. With regard to the second, the general considerations relative to the difference of the tissues is equally applicable to them, and these considerations possess a high value. When very young warm-blooded animals, without any exception, are compared in this respect to the cold-blooded Vertebrata, we perceive a great analogy in their component tissues, which are softer and less savoury than among the adults of warm-blooded animals. It is thus that we can account for a striking anomaly in the nervous system of young warm-blooded animals, especially Mammalia. Their nervous system, particularly the encephalon, bears a higher proportionate ratio to the whole body than it does in the adult; but the softness and the other characters of the tissue of this organ in early life cause it to approximate in a remarkable manner in appearance and character to the same tissue in the cold-blooded Vertebrata. If, therefore, the relative volume predominate in early life, one of the conditions favourable to calorification, the inferiority in respect of tissue counterbalances this advantage, and is only compatible with very inferior manifestations of energy.

It is obvious then that there is a universally pervading analogy between warm-blooded animals in the first stages of their existence and adult cold-blooded Vertebrata, and that the parallel holds good, not merely with reference to their inferior power of producing heat, but also with regard to the functions of nutrition generally and the functions of the nervous system. There is one point upon which it is highly necessary to insist, inasmuch as it is of the greatest importance, both theoretically and practically; it is this: that the analogy in the direction indicated is by so much the more remarkable as the warm-blooded animal is born with characters which distinguish it more strikingly from those it possesses when arrived at maturity. If it is born with the eyes closed, or without fur or feathers, instead of with the eyes open and the body covered with a fur coat or a thick down, it is because the creature comes into the world less perfectly developed in every respect, and the whole economy is more closely allied to that of inferior orders. This, in other words, is as much as to say that the creature is born at a period relatively precocious, or in a more imperfect condition. Whence it may be inferred that those warm-blooded animals which are born at a period short of the ordinary term of utero-gestation among the more perfect species, will present a more marked analogy with the cold-blooded tribes. Man himself will form no exception to this rule, which must be quite general. The verification of this law has been completed by the physiological experiments of the writer. A child born at the seventh month, perfectly healthy, and which had come into the world with so little difficulty that the accoucheur could not be fetched in time to receive it, had been well clothed near a good fire when the temperature was taken at the axilla. This was found no higher than 32° c. (under 90° F.). Now we have seen that the mean of the temperature of ten children born at the full time was 34°,75 c. (94°,5 F.); the temperature in no case descending lower than 34° (94° F.), and ranging between this and 35°,5 c. (96° F.). Let it be observed that at the seventh month the membrana pupillaris no longer exists; the infant has, therefore, at this epoch of its development, the essential characters of warm-blooded animals capable of supporting a high temperature when that of the surrounding atmosphere is mild. But if it were entering the world some considerable time before the disappearance of the pupillary membrane, it would be in a condition analogous to the Mammalia which are born with their eyes shut; it would no longer be in a condition to maintain an elevated temperature, and without doubt would lose heat precisely as they do without precautions to the contrary.

When we take a general view of the first and second periods in the early life of warm-blooded animals, we find that they are under the influence of two general conditions relative to calorification; conditions which, acting inversely, tend to compensate each other mutually; on the one hand, the celerity of the motions; on the other, the imperfection of the nutrient and nervous functions. The celerity of the motions of circulation and respiration diminishes, whilst the development of the nutritive and nervous functions increases with age. These two conditions influencing the production of heat are, therefore, in an inverse ratio to one another. And according to the nature of these relations will the temperature vary. Were the opposite effects equal, there would be exact compensation in the whole phases of the evolution, from the moment of birth to that of perfect adolescence, and the temperature of the body would be the same at every period of life. But the progression in the celerity of the movements on the one hand and of corporeal development on the other, is unequal; and there is but a single epoch in the whole course of childhood when such an equality or balance exists, and at which consequently the temperature of the child is the same as that of the adult. Previous to this epoch, the nutritive and nervous functions are so imperfectly developed, that their influence, inimical to the production of heat, surpasses the favourable tendency to this end, which we have in the celerity of the motions of circulation and respiration. It follows that the temperature of the body is inferior at the preceding limit or to that of the adult state; with the progress of time, however, the child attains this limit, and then we have a new relation established. The evolution of the nutritive and nervous functions continues, and although it have not yet attained its ultimate term, the defect of heat which results from this is all but compensated by the celerity of the motions, which is still sufficiently great, to surpass in a marked degree the celerity of the motions in the adult. The temperature at this period will, therefore, be above that of the adult. This period lasts for several years in childhood or youth; but then comes a gradual retardation in the motions both of respiration and circulation, and with this a reduction of the temperature to the standard of the adult.

There are consequently four states of the temperature from birth up to adolescence inclusive. In the first period the temperature is at the minimum; in the second, it attains the adult degree; this might be entitled the period of the mean temperature; in the third, the temperature exceeds that of the adult; finally, in the fourth, it sinks to the mean, that is, the temperature of the adult.

There are, therefore, *constitutions* in the same class of animals which are more or less favourable to the production of heat; for it is so among individuals that differ in age in the limits between the moment of birth and that at which adolescence is completed; and this leads us to new considerations.

Differences of constitution in relation with the production of heat among animals.

Since the body and the functions are progressively developed, and without interruption between the two grand periods named, there is in the course of this long interval as much difference in the state of the constitution as there are sensible degrees of development; a circumstance that implies a long series of varieties. But these intimate differences are not manifested externally by corresponding states of temperature of body. For we have seen that this undergoes but four sensible variations in this respect, and that, of these four modifications, two were of like import. It is every way worthy of attention to observe that, at the point which separates the first from the second period of infancy, the temperature should be equal to that of the adult.

It is difficult to imagine that this equality can exist under every variety of external circumstance, when we see that the elements upon which it depends are so different. And this leads us to consider the production of heat under a new point of view. Under what circumstances has this equality of temperature between the infant and the adult been observed? It was when the external temperature was mild or even warm. Would the same thing have been observed had this been cold or severe? It is evident that if the faculty to produce heat is the same at this period of infancy as it is in adult age, the heat of the body will always remain the same, making abstraction of the differences that depend on those of simple corporeal bulk. Thus, all things else being equal, a young animal at this epoch ought to cool to the same degree as an adult under the influence of external cold, if it have the same power of producing heat. If, however, it be inferior in its calorific powers, it will not be competent to maintain its temperature to the same degree as the adult, and it will fall under this limit in a proportion determined by the difference which exists in the faculty of producing heat. On making application of the principles which have been already announced, let us try if we cannot predict the effects. By reason of the inferiority in energy of the nervous system in early life, it is difficult to suppose that a young animal will resist the action of intense cold in the same manner as an adult. This inference is fully borne out by the following experiment. A young guinea-pig a month old, the temperature of whose body was high and steady, the temperature of the external air being mild, was exposed along with an adult to the same degree of diminished temperature—the air was at 0° c. (32° F.). In the course of an hour the young creature had lost 9° c. in temperature, whilst the adult had only lost 2°,5 c. This experiment, repeated several times with the same species of animal, always gave the same result. Young and adult birds of the same species, treated in a similar manner, showed the same diversity in their powers of resisting the effects of external cold, from which we may infer that the law is quite general. Several young magpies, for instance, whose temperature was stationary in a mild spring atmosphere, were placed with an adult in air cooled to + 4° c. After the lapse of twenty minutes, one of the young ones was found to have lost 14° of temperature. The others, examined at intervals, none of which exceeded one hour and ten minutes in length, had cooled from 14° to 16° c. The adult bird, on the contrary, similarly circumstanced, did not suffer a greater depression of temperature than 3° c. The loss of heat sustained by the young birds was so great as to be incompatible with life, if continued; that endured by the old one was trifling in amount, and not inconsistent with health. It is quite true that the difference in point of size and quantity of plumage has an influence upon this inequality of cooling; but at the period of development, when the experiment was tried, the difference was not remarkable in regard to either point; nevertheless it is only proper to take notice of it. By prolonging the period during which the adults were exposed to the cooling process, the advantages they derive from their greater size and closer plumage may be counterbalanced or compensated. It is essential to observe that in the course of the first hour the adult bird had only lost temperature in the proportion of one-fifth of that lost by the young birds, which obviously bears no ratio to the difference in point of size, plumage, &c. And then, the operation of the cold being continued, the adult suffered no further depression of temperature: it fell three degrees centigrade, and then became stationary. We cannot, therefore, ascribe the entire difference in the cooling to that of the physical conditions of size and plumage; a difference of constitution must go for a great deal; there are inherent diversities of constitution, favourable or the reverse, to the production of heat. The truth of this conclusion appears much more clearly if we continue to subject young birds to the same kind of experiment at successive epochs not so close to one another. The rapid progress they make in the power of evolving heat is, indeed, a very remarkable fact. A few days later, and they lose temperature in a much less considerable degree when exposed to cold under the same circumstances, although there was little or no apparent difference in the external appearance of the birds. And this is a new and convincing proof that the inequality in the disposition to lose heat obvious at different periods of life under exposure to a low external temperature, is principally owing to inherent inequality in the faculty of producing caloric.

It is of great importance that a precise idea be formed of this expression. Up to a very recent period in the investigation of animal heat, no one thought of comparing animals save with reference to the temperature of their bodies only: and when it was found that this was the same or different by so much, the account was closed, the comparison was pushed no farther, under the impression that every thing was included under this single ostensible character. Undoubtedly, it must be granted that, all else being alike, equality of temperature is an indication of equality in the capacity to produce heat. But animals in one set of circumstances may actually produce the same quantity of caloric, and not continue to do this the circumstances being changed. It is of consequence to distinguish the actual production, from the power to produce under different conditions. The one is *an act*, the other a *faculty*, a distinction of the highest importance in philosophical language in general, and especially in that of physiology. But animals of the same size, subjected to the same variations of external conditions, if they continue to exhibit corresponding degrees of temperature, whether these are higher or lower, have evidently the same faculty of producing heat. If, on the contrary, they present different degrees under the influence of precisely similar external variations of circumstance, it is obvious that they must possess the faculty of producing heat in different degrees. Unless we be actually persuaded of the value of this expression, so simple in other respects, and so constantly held in view in all analogous circumstances, the study of the phenomena of animal heat would remain as it were barren, whilst the investigation of the diversities of constitution in relation with this faculty is fertile in interesting and useful applications.

We have seen how constitutions differed in this respect according to age in the earlier period of life and in the adult state. It is probable that there are other varieties dependent on other causes; for example, differences of season, climate, &c. This point it will be our next business to examine.

INFLUENCE OF SEASONS IN THE PRODUCTION OF ANIMAL HEAT.

The temperature of an animal is the result, 1st, of the heat which it produces; 2d, of that which it receives; 3d, of that which it loses. The proportion of heat which is lost depends on two principal conditions, the relatively colder temperature of the atmosphere, and the amount of evaporation that takes place from the surface of the animal. In cold and temperate climates these two conditions of cooling are in inverse relations to one another in the opposite seasons of winter and summer. In winter the temperature of the air is lower; in summer the amount of evaporation greater. These two conditions of refrigeration, therefore, tend to compensate one another, and consequently to maintain the equilibrium of temperature as regards the body in the two opposite seasons. They have unquestionably a considerable share in this business; and it was long believed that the simple difference indicated in the external conditions sufficed to preserve the temperature of the body alike during the two periods. But in reflecting on the phenomena presented by cold-blooded animals with the changes of the seasons, which have already been spoken of at length, we find such an opinion or view to be inadmissible. For in examining those species of cold-blooded animals which from their structure are liable to lose more by evaporation than any other animal, we see that no such compensation takes place. Frogs, for example, the skin of which is so soft and permeable, and whose bodies besides are so succulent that they must be presumed in the most favourable circumstances to sustain loss by evaporation, ought to preserve the same temperature in winter and in summer if the low temperature in winter were compensated by the excess of evaporation in proportion as the heat of the season augments. But we know that the temperature of these creatures follows, to a very great extent, that of the atmosphere, between 0° and 25° c. (32° and 77° F.), differing at no time from it by more than a degree or two. The phenomenon here is simple, by reason of the slight evolution of caloric by the frog, and leaves no doubt upon the mind. We must, therefore, have recourse to other conditions, in order to explain the slight difference that is observed in the summer and winter temperature of man and other warm-blooded animals. Since external conditions do not appear to explain the phenomena, it must undoubtedly mainly depend on certain changes effected in the animal itself. Now, since the internal conditions which influence the temperature of the body are those also that regulate the production of heat, it is here that the change must be effected.

It is obvious that the cause of refrigeration in winter being more active, to meet the greater expenditure there must be the means provided for furnishing a larger supply—the calorific faculty must be more active in winter than in summer. The inverse of this takes place in summer; so that the temperature of the body in the two seasons is determined in the following manner:—in winter there is a *more active production* with a *greater loss*; in summer a *less production*, with a *smaller loss* of heat. In this way is there compensation, and a perfect equilibrium maintained at all seasons. To render this relation more evident, it may be expressed in another manner; as, for example, in summer the body receives more heat from without, and produces less; in winter it receives less and produces more.

These considerations carry us farther. As this difference in the production of heat lasts as long as the various seasons, and takes place progressively, it is to be presumed that it belongs to an intimate and more or less enduring change effected in the state of the body. In other words, the constitution alters, and the faculty of producing heat changes in the same degree. The fact thus expressed is immediately susceptible of an interesting application. If the faculty of producing heat is less in summer, the temperature of the body will not be maintained to the same point in the two seasons under sudden exposure to the same degree of cold. By subjecting animals to the test of experiment in the two seasons, it is easy to judge of the justice of the preceding deductions, as well as of the principles which led to them. To have the mode of refrigeration precisely the same, attention must be had not merely to the thermometric temperature of the air, but also to its humidity, which ought to be the same in both instances. A difference in the hygrometric state of the air will certainly produce a difference in the effects of refrigeration. The apparatus employed consisted of earthen vessels plunged amidst a quantity of melting ice. Air thus cooled soon reaches the point of extreme humidity. The air being at zero c. (32° F.), the animal is introduced, placed upon a stage of gauze to prevent its coming in contact with the moist and rapidly conducting surface of the vessel. A cover, also piled over with ice, is then placed over the apparatus, but so arranged as still to permit the ready renovation of the air contained in the interior. Still farther to secure the purity of the included air, a solution of potash, which of course absorbed the carbonic acid produced with avidity, occupied the bottom of the vessel. In winter, in the month of February, the experiment was made at the same time upon five adult sparrows, which were all included in the apparatus. At the end of an hour they were found one with another to have lost no more than 0°, 4 c., or less than half a degree; some of them having suffered no depression of temperature whatsoever, others having lost as much as, but none more than, 1° c. The temperature of the whole then remained stationary to the end of the experiment, which was continued for three hours. In the month of July the same experiment was performed upon four full-grown or adult sparrows. The temperature of these birds at the end of an hour had undergone a depression, the mean term of which was 3°, 62, and the extremes 6°, 5 and 2° c. At the end of the third hour the mean term of the refrigeration suffered was 6°, the extremes being 12° and 3°, 5 c. It ought to have been stated that in the experiment in the winter month, the birds had been for some time kept in a warm room, so that the sudden transition was the same in both instances, in the winter as well as the summer experiment. The diversity in the constitution of these birds, consequently, with reference to the powers of producing heat, was an effect of the difference of the seasons. Each month the temperature of which differs in any degree from that of the month before or after it, has an obvious tendency to modify the temperament or constitution in the manner which has been indicated. In summer we may presume, nay we may be certain, that the differences obtain in degree according to the mean intensity of the heat proper to each. This is even to be proved by direct experiment. The month of August, as commonly happens, was not so hot as the month of July, and six sparrows treated in the same manner as those that were the subject of the July experiment already detailed, were found not to suffer refrigeration to the same extent. After the lapse of an hour the mean temperature of the six had sunk 1°, 62, and after three hours 4°, 87 c., from which it is obvious that with the successive declensions of the external temperature the faculty of engendering heat increases. This is demonstrated by the experiments quoted. The animals that were the subjects employed suffered a relatively less degree of refrigeration in the cooler month than they had done in the hotter, when exposed to the same measure of cold. In the first set of experiments performed in one of the coldest months of the year, the power of resisting cold was made particularly manifest. The sparrows, kept for three hours in an atmosphere at the temperature at which ice melts, scarcely suffered any loss of heat at all. The results of the three series of experiments detailed confirm, in every particular, the conclusions which had been come to analogically and *à priori*. They do more than this. They bear out equally the principles which had been deduced with reference to the constitutions more or less favourable to the production of heat. It is apparent, in the first place, that the influence of the summer and that of the winter act on the constitution in the same manner as the two opposed periods of early youth and adult age. Let us therefore inquire in what manner these different conditions tend to produce analogous effects. We have seen that the constitution of early life differed from that of adult age, especially in the inferior energy of the functions of innervation and nutrition. Now this is that which constitutes or causes the principal difference between the winter and summer constitution of man. We generally feel ourselves weaker in summer than in winter, and our digestive powers are then also decidedly less vigorous. What completes the analogy is that the motions of circulation and respiration are accelerated in summer; and as a complement of the whole of these data, the temperature is somewhat higher in summer; just as we have seen that there is an epoch in youth when the temperature exceeds that which is proper to complete manhood. Thus, the parity between the constitution of youth (in the second period of childhood,) and that of the body in summer, contrasted with the constitution of the adult age and that of the body in winter, exists in the three following relations:—1st, a lessened faculty of producing heat; 2d, greater activity in the motions of circulation and respiration; 3d, a higher temperature of the body.

But this faculty of adaptation to the different seasons inherent in the body is only observed in the better constitutions. That it may be manifested, it is necessary there be present a certain energy of the nervous system; without this even the moderate colds of winter will not be resisted. Without this the adult will have a constitution that will present analogies with that of early infancy. At present we merely mention the kind of constitution; we shall return to the subject by-and-by.

Differences according to the nature of the climate.—The preceding facts render direct experiments to ascertain the influence of the temperature of different climates on the calorific power altogether unnecessary. This is so far fortunate; for it were no easy matter to institute them to the extent and with the precautions necessary to security and satisfaction. The knowledge of these effects is a necessary consequence of the researches that precede. The temperature of warm climates is represented by the summer temperature of temperate climates, with this difference, that it is higher, and that with slight variations it continues through the whole year. Whence it follows that warm climates taken generally must produce effects upon the constitution analogous to those produced by summer with us, only of greater intensity by reason of the higher thermometric range and longer continuance of the heat. The inhabitants of hot climates ought consequently to have an inferior degree of calorific power than those of temperate or cold countries, whatever be the season. And we find, in fact, that the natives of the warmer latitudes of the earth present the characters in general that distinguish the constitution of the body in the summers of temperate countries, and characterizes the second period of youth—more rapid motions of the circulatory and respiratory systems, and a higher temperature, conjoined with an inferior degree of energy in the functions of innervation and nutrition.

We shall not here enter upon the examination of the effects upon the natives of these warmer latitudes from change of climate. We shall speak of this elsewhere. After the periodical changes depending on the seasons we shall pass to others of shorter duration, but which revert much more frequently, and are under the influence of other causes.

INFLUENCE OF SLEEP ON THE PRODUCTION OF HEAT.

In the course of the twenty-four hours the body is in two very different and in some sort opposite states — the states of *sleeping* and *watching*. These two states are principally contrasted in the energy and weakness of the nervous system: from a perfect consciousness of all that is passing, we suddenly observe a complete suspension of this office in the whole circle of the functions of relation. At the same time the motions of the circulatory and respiratory system become slower. No more is needed to lead to the conclusion that in this state the temperature must be lower; this is an inference we draw without risk of error. But the degree in which these motions are retarded is extremely limited; and the depression of temperature must be expected to be in the same proportion: it is in fact very slight, although appreciable. What would happen were the retardation in the important motions mentioned more considerable? The temperature would suffer a corresponding and great depression, and various consequences might be conceived as calculated to ensue. If the degree of cold did no injury to the economy, the sleep would last the time required to repair by rest the energy which the nervous system had dissipated or lost by its activity during the period of watching. If, on the contrary, the refrigeration attained a considerable degree, it would by the consequent pain stimulate the nervous system so much as to cause it to wake up to general consciousness; but in case the nervous system were not in a condition to feel this excitement, in other words to re-act and produce waking, it would sink into the state of lethargy.

These divers states which we deduce as possibilities, as what might be expected to occur in sleep according to the relations of the functions, do in fact present themselves frequently in nature. It commonly enough happens that we are aroused from our sleep by a feeling of cold, although the external temperature has not changed. With regard to the lethargic state, although it certainly occurs but rarely, still it has been acknowledged by the most respectable authorities, and its occasional occurrence seems indubitable. That, however, which is rare as regards man may be common and even usual as animals are concerned.

Phenomena presented by hybernating animals with regard to the production of heat.—If during the height of summer and during the state of watching a dormouse or a bat be examined as to their temperature, this will be found the same as that of many other warm-blooded animals. But if either of these animals be examined whilst asleep at the same season of the year, the temperature will be found to have declined considerably. These changes have been determined by Dr. Marshall Hall, to whom we are indebted for many observations of high interest upon the state of the circulation in hybernating animals. The writer also observed the same diversities in the temperature of these animals according to their state of sleep or watching; but he had not published his observations at the time Dr. Hall's paper appeared. Here, then, we have several species of warm-blooded animals which, during the hottest season of the year, exhibit in the two states of sleep and watching a very marked contrast in regard to the temperature of their body, which is high during the waking period, low during that of sleep, the external temperature having no part in the phenomena. The difference of temperature coincides very evidently with the state of the nervous system—its energy in watching, its enfeeblement in sleep—a state which we have already seen to influence in a very great degree the rapidity of the motions of circulation and respiration, which are accelerated during the energetic condition, retarded during the period of inaction. A higher temperature in the one case and a lower temperature in the other are necessary consequences.

These facts are interesting under two points of view. 1st, They show precisely the kind and extent of the influence which the states of watching and sleep exert in general on the production of heat in animal bodies; 2d, they are remarkable in the particular instances under consideration, in this, that the differences exhibited during the two states are extreme. It must be allowed, therefore, that those animals in which they take place must have less energetic nervous systems than other warm-blooded animals. From this tendency in the animal economy, there must also be in different species a diversity rather than an equality in the degree in which the phenomena are exhibited. And this is confirmed by observation. Some cool to a much greater extent than others during their sleep in the summer season. They may be said severally to have just as much nervous energy as is requisite to sustain a high temperature in the summer season during their state of highest activity, i. e. during the period of watching, and no more. When the state of excitement ceases, and the collapse that follows excitement supervenes, the languor manifested is much greater than that of other animals in the same condition, and their temperature sinks in proportion. The energy possessed by hybernating animals seems barely sufficient to enable them during the summer season to maintain a temperature of body equal to that of warm-blooded animals in general. They subsequently present another phenomenon with regard to their temperature well worthy of particular attention, although it be no more than a consequence of the first. Since it is a defect of energy in the nervous system during sleep which prevents their maintaining the degree of rapidity in the motions of circulation and respiration so essential in their turn to the maintenance of a temperature of the body but little inferior to that pertaining to the state of watching in summer, how are they to preserve their temperature even during the watching state when the summer declines into autumn, and the autumn into winter?

It is evident that if they follow the general rule their respiratory and circulatory motions will be retarded with the fall of the atmospheric temperature, and this by so much the more as their nervous system shows a less degree of energy. It is even presumable that owing to the decline of atmospheric temperature in autumn, they will exhibit a temperature of body during the period of watching analogous to that which they manifest in the heat of the summer season during sleep. And this is precisely what happens. M. de Saissy paid particular attention to the state of these animals at intervals from the month of August onwards. On the 6th of August, the temperature of the air being at 22° c. (72° F.), a dormouse and a marmot marked 36,° 5 (98° F.), and a hedgehog 34° c. (93°, 5 F.) in the axilla. On the 23d September, the external temperature being

18° (64°, 5 F.), the temperature of the hedge-hog was lower by 2° c., that of the marmot by 5°, 25 c., and that of the dormouse by 5°, 5 c. than it had been at the previous date. This is a considerable depression, if it be remembered that the decline in the atmospheric temperature was by no means considerable; that the air was in fact still at a point which made it be felt as *warm* to the generality of persons. The same individual animals examined on the 7th of November, the atmospheric temperature being 7°, presented the following state. The marmot had lost 9°, 25 c., the dormouse 15°, 5 c., and the hedge-hog 21°, 25 c. of their respective temperatures during the month of August, so that their absolute temperatures were now as follows: that of the marmot 27° (81° F.), that of the dormouse 21° (70° F.), and that of the hedge-hog 13°, 75 c. (57° F.). Here, therefore, we have several warm-blooded animals which in autumn approach very closely to the cold-blooded tribes with regard to their calorific power.

If they be next observed during the period of sleep, the relationship will be observed if possible in a more striking degree. If, during the state of watching, they suffer such a loss of temperature as has been specified with the gradual decline of the temperature of the year, they will certainly suffer still more remarkable changes during the state of sleep, in conformity with the principles already fully developed. The sleep of these animals will also become longer and deeper in proportion as the nervous system loses its power, under the influence of the external cold, a loss which will be manifested by a farther retardation in the motions of circulation and respiration. But what is the increasing weakness of the nervous system during sleep but a more or less marked state of torpor? The same degree of cold continuing, or the degree of cold becoming gradually greater, the disproportion as regards the animal will increase also, and will necessarily attain a term at which the torpor during sleep will become *lethargic*. If the external temperature goes on declining, and attains a point at which it becomes dangerous to the life of the creature, the cold, within certain limits, ought to have the power of withdrawing the animal from its state of lethargy. The excitement which appertains to the waking period, by accelerating the motions of circulation and of respiration, will then cause the temperature of the body to rise. But if the external temperature does not become more favourable, or if the animal finds no means of abstracting itself from its influence, it has not sufficient resource within itself and must perish.

We have seen above that the changes in the seasons produced great modifications in the constitution of warm-blooded animals in general. But it were difficult to imagine any greater or more striking than those presented to us by the species which we have just named, which belong to the family of hybernating animals; changes which arise from their passing the winter months in a state of lethargy. When these animals are recalled from this state towards the end of autumn, and during the course of the winter, they may seem to resume the characters which distinguish the vitality of warm-blooded animals in general, but they are in a very different state at this epoch from what they are in summer. Their constitution has undergone important changes, which it is necessary to examine and appreciate exactly. These changes are inversely as those which the most perfectly constituted warm-blooded animals experience. These, under the influence of the increasing cold of autumn and winter, acquire new vigour, and their faculty of producing heat increases in consequence. Those, on the contrary, naturally much less energetic even at the most favourable period of the year, require to be excited and supported by the high temperature of the summer or warmer months, to permit them to exhibit all their activity and strength. It is in the warm season of the year that these animals have the greatest degree of energy—energy which has a certain duration even after the external conditions which have developed it have ceased to operate; for they have been as it were *tempered* by the continuity of favourable circumstances, especially of the high atmospheric temperature. This is the reason why they are so slightly affected by the diurnal variations of the warm season of the year; and even when this begins to wane, and they are no longer stimulated by the temperature proper to summer, they find sufficient energy in the store accumulated, as it were, during the fine season to enable them to resist for a time and to a certain extent the unfavourable influences with which they begin to be surrounded. These continuing, however, and even increasing, they gradually yield to their influence, and sink lethargic, till revived by the return of spring with its milder temperature. Their languor even augments not only with a progressively lower degree of atmospheric temperature, but with the persistence of a degree which in itself is not by any means excessive.

These hybernating animals, whilst they present the structure of the warm-blooded tribes in general, still approach in a very remarkable degree to the cold-blooded tribes in their defective energy, or their indifferent powers of reaction. This is to be regarded as the principal source of the phenomena they exhibit in the current of the year, phenomena which are unknown among the more perfectly constituted warm-blooded animals, but which are absolutely of the same nature as those presented by the cold-blooded Vertebrata in the same circumstances, and which only differ in degree. This analogy or resemblance in the phenomena appears to arise from analogy not of structure but of constitution. Very opposite organizations may have analogous constitutions; cold-blooded animals for example present the greatest diversities of structure, and all are affected and bear themselves in the same manner under similar circumstances in very many respects. They have thus a common constitution which characterizes them, the fundamental principle or distinguishing feature of which is a defect of energy, or of power of reaction. This principle, so simple in itself, and which is but the true expression of the various facts reduced to unity, renders plain and obvious much that otherwise appears anomalous or contradictory. In studying the phenomena of animal heat under new relations, we shall find the confirmation of what precedes.

Of the system upon which the external temperature acts primarily and principally.

Our sensations admonish us that it is the nervous system that is acted upon primarily and principally by changes of external temperature. In the first place the impression is felt instantaneously; in the second place the intensity of the sensation is in relation with the degree of external heat or cold; in the third place the impression is not limited to the various degrees of the corresponding sensation of heat or cold; it extends to the other faculties of the nervous system, increasing or diminishing the general or special sensibility; in the fourth place it acts powerfully in increasing or diminishing the activity of the muscular system, principally through the medium of the nervous system.

Influence of temperature on the vitality of cold-blooded animals.

If the functions of respiration and general circulation be destroyed by the excision of the lungs and heart of a cold-blooded animal, of one of the Batrachia for example, life may still continue for a time. Of the three principal systems of the economy the only one then left untouched is the nervous; so that the animal may be viewed as living almost exclusively by the agency of this system. If several animals in this condition be plunged in water deprived of air, they will live in it different spaces of time according to the degree of its temperature, the extremes compatible with their existence being zero and 40 c. It is towards the inferior limit, zero, that they live the longest. Towards the upper limit they die almost immediately. Temperature, consequently, presents in the scale of variations just mentioned very remarkable relations with the vitality of these animals. Towards the lower limit or that of melting ice, it is obviously most favourable to life; towards the upper limit, it is most inimical to life, extinguishing it almost immediately. Here it is impossible to mistake the system upon which the variety of temperature exerts its first and principal effects—the nervous system.

If respiration only be annihilated by plunging these creatures under water deprived of air, the temperature of which is caused to vary as above, they will be found to present the same phenomena according to the degree of the heat or cold, but in a more striking manner. Temperature in this case has the same kind of influence, but the effects are more manifest, from the circulation of the venous blood prolonging life at every degree short of the one at the upper limit of the scale, at which life is extinguished quite as suddenly as in the former instance.

Such are the direct and instantaneous effects of temperature upon the vitality of cold-blooded animals. But there are others which flow from its *successive* agency, during a considerable length of time. If the series of experiments just quoted be made in summer, and the different lengths of life at different degrees of temperature of the frogs immersed in water be noted, (between the limits which we have pointed out above,) and the same experiments be repeated in autumn, the length or tenacity of life manifested by the animals will be much greater at the same degrees of temperature—they will in general be found to live twice as long now as they did in summer, at corresponding and equal temperatures of the medium in which they are immersed. The depression of atmospheric temperature in the autumn has modified their constitution, and actually increased their vitality, precisely in the manner indicated above. The slight effects of each successive fall in the general temperature have accumulated in the constitution so as to render their vitality or tenacity of life much greater, a fact which is made abundantly manifest by the faculty of the animals to remain for a much longer time immersed in water without breathing than they could have done in summer. If a third series of experiments of the same description be made in winter, the tenacity of life will be found to have increased in a very high degree. At the same degree of temperature frogs will be found to live immersed in water deprived of its air at least twice as long in winter as they could have done in autumn. The same cause—the depression of the atmospheric temperature—has continued to act with greater intensity and for a longer period, and the constitution, gradually modified by greater and longer continued cold, has acquired greater tenacity of life.

The opposite effect takes place with the successive rises of the temperature from that of winter to that of summer; so that among cold-blooded animals the maximum of vitality, i. e. tenacity of life, corresponds to the depth of winter, the minimum to the height of summer. The slight and from moment to moment inappreciable effects produced by the external temperature, whether tending to increase or to diminish the vitality, accumulate with their repetition through the period of each season, and produce a corresponding change in the constitution with regard to tenacity of life. These accumulated effects of the different portions of the year constitute the influence of the seasons on the constitution with respect to many of the most important relations of life. The first of these we have just examined cursorily—that is, the faculty of living in air according to the influence of the actual temperature, or of that of the past temperature, in other words the season that has immediately preceded. The second of these fundamental relations consists in the various proportions of air necessary to the maintenance of life according to their relations with the temperature. We have seen that it is at the minimum of temperature that the cold-blooded animals possess the greatest tenacity of life, as regards the most essential relation, in other words they are in the condition the most favourable to enable them to do without air; at this point they are in a state to live for the longest time without breathing. It is obvious that here they must require less air than under any other circumstances; they must necessarily require so much the less, as their life will continue longer here than under any other circumstances without any access of air at all. It is, however, essential to appreciate duly this fundamental relation, namely, that at the lower limit of the scale of temperature mentioned, cold-blooded animals require less air to live, and what is more, they consume less air than under any other circumstances, and are even incapacitated from consuming more than they do. The minimum temperature of this scale consequently is an index of the maximum of vitality or tenacity of life, and at the same time of the minimum of respiration. In the same proportion as the temperature rises, the vitality or tenacity of life declines, which makes it necessary that this declension should be compensated by a corresponding increase in their relation with the air, in order that the vivifying influence of this fluid may neutralize the deleterious effects of the increase of heat. And this is what actually happens. With the rise in temperature the sphere of activity of the respiration extends, and the vivifying influence of the air, which increases with the quantity of the fluid consumed, compensates the successive decrements in vitality or tenacity of life, dependent on successive increments of temperature. We shall therefore express in a very few words this fundamental relation between the temperature of the air and the maintenance of life among the invertebrate series of animals,—a relation entirely deduced from direct experiment, which we can but refer to here, but which we shall lay before our readers with all the requisite details in our article on RESPIRATION. The rise of temperature in the scale from zero to 40 c. exerts upon the nervous system of cold-blooded animals an action the tendency of which is to diminish its vitality; the air, on the contrary, exerts a vivifying influence on this system. It becomes necessary, therefore, to the maintenance of life that their respective relations with the economy be such that their effects compensate or counterbalance each other.

The principle relative to the influence of temperature on the vitality of cold-blooded animals just laid down, is applicable in every particular to the changes experienced and the phenomena presented by the hybernating tribes among the warm-blooded series of animals. Their vitality changes with the wane of the year, i. e. under the influence of prolonged exposure to cold, in the same manner They are then in a condition to exist with a supply of air by so much the less as this influence has been more intense and more protracted; and precisely as the cold-blooded tribes, if entirely deprived of air in winter, they will live for a much longer time in this deleterious position than they would have done in summer.

Influence of temperature on the vitality of warm-blooded animals and of man in the states of health and disease.

These principles and considerations lead us to examine what happens among warm-blooded animals in the same circumstances. There being great and manifold analogies between them and the preceding tribe of animals, there must also be some community in the application of the principles laid down; but as they also differ in many important respects, this application must be correspondingly restricted. In the first place, then, there is complete analogy between the one and the other with regard to the influence of the superior thermal limit on the vitality of the nervous system. To seize the analogy properly, it is however necessary to regard the temperature which modifies this system in each series, from a point of view that is common to both. Whether the temperature proceeds from without or from within, we may presume that it will influence or modify the nervous system in the same manner, if not to the same degree, inasmuch as this system presents differences. Warm-blooded animals having in general a high temperature at all seasons of the year, they must be compared in this respect with cold-blooded animals in the height of summer. On the one hand, heat within certain limits tends to increase sensibility and motility; warm-blooded animals, therefore, with a few exceptions, which always present a high temperature, constantly exhibit also, with a few exceptions, a high degree of sensibility and motility. The same thing can only be said of the cold-blooded tribes during the continuance of the warm weather. On the other hand, again, high temperature tends to lessen the vitality proper to the nervous system, or the faculty of living without the agency of the ordinary stimuli. This is also the reason why, if respiration be interrupted among warm-blooded animals at all times, and among cold-blooded animals during the warmer seasons of the year, they all perish alike speedily or nearly so. The difference in the time that elapses before life is extinct still depends on, or is in relation with, the difference of temperature. For in the hotter season of the year, cold-blooded animals never attain the temperature of the warm-blooded tribes, even in the most burning climates of the globe. Their nervous system will consequently have a higher degree of vitality in the sense already indicated; that is to say, they will not perish so promptly in summer under deprivation of air; but if they be immersed in water at the mean temperature of warm-blooded animals generally, which is about 40° c. (104° F.), they will die as suddenly—(at least this is the case with those of small size upon which the experiment has been made)—as the warm-blooded Vertebrata when deprived of the contact of air.

The analogy on either hand consists in the effects of temperature. But the differences that must necessarily occur between natures that vary in so many other respects are especially encountered in the dissimilar effects of cold. Here we observe a general compensation which distinguishes in the most marked manner the Vertebrata having a constant or all but a constant temperature, from the hybernating tribes or Vertebrata whose temperature varies, and the cold-blooded series generally. The relation of cold, or of a low temperature relatively to the standard of the more perfect beings of creation, is one of essential importance, and requiring our most careful investigation.

Cold, as has been said, tends to diminish sensibility and motility; but cold itself is perceived by causing a diminution of the general sensibility; among animals of superior organization it even acts indirectly as a stimulus: the blood flows into the parts that had been chilled, if their temperature has not fallen too low, for then all sensibility is extinguished and reaction never occurs. The afflux of blood to the external parts is manifested by the increased redness; and the skin becomes red in proportion as the parts it covers are susceptible of acquiring a high temperature, such as the hand. We have shown that the consequence of the afflux of blood is an increase of temperature which tends to counterbalance the effects of the refrigeration. The compensation, however, is not perfect. For in winter the temperature continues above that of summer, although there is a greater production of heat in winter than there is in summer, as we have shown above.

The constitution of the Vertebrata having a nearly constant temperature differs essentially in the power of reaction it possesses; a power which cannot better be expressed than by the word energy, and which must necessarily be referred to the nervous system. The power of reaction under the influence of cold is exhibited in two modes: the first is that which has just been mentioned, in which the stimulus of the cold calls the blood into the capillaries of the surface, without exciting any kind of violent motions in the circulating and respiratory systems; the second consists essentially in this last kind of excitement. The sharpness of the cold stimulates the respiratory motions, which become accelerated, and the quickening of the motions of the heart follows or accompanies those of the lungs. These two modes of reaction must be viewed as two degrees of the same power: 1st, an afflux of the blood to the capillary vessels; 2d, acceleration of the motions of the thorax and heart. There is, however, between these two processes a difference which it is of the greatest consequence clearly to understand. The first, so long as it remains within certain and suitable limits, is a reaction that maintains the economy in a state of health. The second tends to produce salutary effects, but becoming excessive it brings the body into a state of disease. The first is sufficient to enable those creatures whose system is energetic to resist the effects of rigorous cold, by preserving their general activity and the normal state of their functions. The second is the resource of those animals, which, although of the same species, are so constituted that the energy of the nervous system is less than in the former. This is what occurs universally in very early life. It is a reaction the tendency of which is salutary, but which is not the less on this account the index and essence of a proper pathological state. It is one of the cases in which the *vis medicatrix naturæ* is peculiarly and most strikingly manifested. This position is made singularly evident by the following experiment:—when a young bird, bare, or but scantily covered with feathers, is taken from the nest, and exposed to the open air, even in the summer season, its respiration will be seen to be accelerated in the ratio of the cold it experiences. It is peculiarly worthy of remark that this salutary reaction, taking place under the influence of the nervous system, acting, in the case quoted, independently of the will, is in a great measure the same as that which we bring into play by means of the will to combat the same evil. When in health, for instance, we are exposed to and feel the impression of cold severely, and have no resource but in ourselves, we begin immediately to take exercise, and move about; and if we do this with sufficient vigour, the motions of respiration and circulation are very soon increased in rate, and our heat returns; it being always understood that the external cold is not at too rigorous a degree. From what precedes, we are in a state to appreciate the part which each function has in causing the developement of heat by exercise. The experiments of Messrs. Becquerel and Breschet, referred to in an early part of this paper, have proved that the contraction of the voluntary muscles is accompanied by the evolution of caloric, and that the heat increases by a succession of muscular contractions. The first source of the heat evolved in exercise, therefore, lies in the contractions of the muscles, that is, in the voluntary motions. These, vigorously called into play, are followed by increased rapidity in the action of the muscles of respiration, and of the central muscle of circulation, the heart; and these, by the increased energy they impart to the functions over which they preside, cause an increase in the temperature in conformity with the general principles already laid down. It is well to follow the effects of exercise in the various modifications under the influence of cold. They produce phenomena which extend farther than the state of health, and which appear in other conditions and circumstances from analogous reasons. Exercise, according to its degree and the degree of temperature of the external air, is adequate not only to compensate a chill, and to restore the body to its pristine temperature in every part, but even to do more than this. If the exercise has been sufficiently prolonged, but not been excessive, it may be suspended; and the body, now restored by its means to its temperature, will be apt to retain it longer than it had done when exposed to cold without any preparation of the kind implied; it will resist impressions of cold longer after exercise than it would after a state of perfect quiescence; the nervous system has acquired new energy; the economy is in a condition to react with greater effect than when depending on the process just described, that, namely, which takes place independently of the agency of the will. The repetition of the effects that follow exercise taken at due intervals, hardens the frame to such a degree that the body at length acquires the power, by means of the *insensible and involuntary* reaction alone, to resist degrees of cold which it could not have borne without the violent and voluntarily induced reaction of active muscular exertion.

The different states of the body in the circumstances just referred to deserve special attention, because they are reproduced in others, where the cause not being apparent they seem to be spontaneous, though they are in fact, as we shall have occasion to see, under the influence of an analogous cause. We suppose that on the first exposure to cold during rest, the reaction from the afflux of blood to the capillaries is slight, and that the cold is even sufficiently intense to produce an opposite effect, that is, paleness of the part chilled. To this symptom of the action of cold, shivering is superadded in various degrees of intensity. If recourse be now had to exercise, this state will last for a period long in proportion to its intensity, until violent and prolonged motion have restored the temperature. If the exercise be continued, the heat increases, and even rises above its degree at starting; in this case it first restores the proper heat of the skin, and then causes this tegument to assume a red colour, which may become extremely intense. To this second state succeeds a third, in which the skin, which had hitherto been dry and unperspiring, becomes soft and finally bedewed with moisture. Here, then, we have three different states induced under the influence of cold acting at first without opposition on the part of the system, and then combated by powerful and voluntary reaction. First, we have coldness, paleness, and shivering; secondly, heat and redness; thirdly, moisture of the skin and sweating. In making the application here of what has been said above upon the repetition of these acts, we perceive that at the same degree of external temperature the effects which at first, and under other circumstances, would follow the impression of such a degree of cold, may cease to be felt. This happens from the constitution having improved under the actions and their effects, which have been detailed, and that it is in a state, with the assistance of its own inherent powers of insensible and involuntary reaction, to resist refrigeration. But do we not, when we strengthen the constitution to such a pitch as enables it to resist an influence which was a cause of inconvenience to it previously, cure it of an infirmity? It is obvious from what precedes that the temperature of the body may be indifferently affected, either by a great fall in that of the air, or by an insufficient production of heat. The temperature of the body tends to sink equally when, producing a great deal of heat, it is exposed to severe cold, or when, producing little heat, it is exposed to a moderate warmth. In either case the effects upon the economy will be analogous without being identical. In each case there will be a keen sense of cold according to the depression of the external temperature on the one hand, or the slightness of the evolution of heat on the other. In the latter case the insensible reaction will be extremely limited, as well as the voluntary reaction, on account of the deficient energy. But there are still resources within the economy. It is then that the involuntary and violent reaction of which we have already spoken takes place. The circulation and the respiration increase in rapidity spontaneously. In the case which we have just supposed, there will be certain series of phenomena, analogous to those we have described as occurring in the instance of a strong individual exposed to the influence of severe cold, who suffers from it at first, and subsequently opposes and vanquishes it by means of a violent and voluntarily superinduced reaction. When the faculty of engendering heat sinks to a certain term, there will be not only a vivid sensation of cold even in summer, but all the other consequences of exposure to a low temperature, such as paleness, shivering, &c.; by-and-by the involuntary reaction will not fail to take place; the respiration and circulation are accelerated, and end by restoring the temperature, if the lesion of the calorific power have not been too extensive, the skin being first hot and dry, and subsequently hot and moist. Here, consequently, we have the three periods precisely as in the case previously described: 1st, coldness, pallor, and shivering; 2d, acceleration of respiration and circulation, accompanied in the second period by dry heat, and in the third by sweating. There is therefore the strongest analogy in the two cases. They resemble one another in the character of the phenomena, and the order of their succession. This is so obvious as merely to require mention; there can be no occasion for more particular illustration. They have also the strictest relationship in their causes, without these, however, being identical. In the first case the individual produces a great deal of heat, but he cannot engender enough by the ordinary and insensible reaction, in consequence of which he has recourse to the violent and voluntary reaction, which soon produces the desired effect. In the second, the individual produces little heat, and the economy may suffer from this diminution of the calorific faculty to the extent of finding itself incapable of restoring a sufficient degree of heat by means of a violent and voluntary reaction. The violent and involuntary reaction then succeeds, and produces all the effects of that which is put into play under the empire of the will. Nor is the resemblance limited to immediate results. It further extends to the remote and definitive effect. For in either case the violent effort ceases after a certain interval of variable extent, according to various circumstances; and a state of tranquillity comes on in which the body has recovered the faculty of engendering by the ordinary means the quantity of heat necessary to the comfortable existence of the individual. After this the repetition with greater or less frequency of the same acts ends by restoring the calorific function to the state in which insensible reaction suffices to maintain it in its sufficiency. In the first case it is a strong individual able to make the voluntary and energetic efforts required to remedy the inconvenience he suffers. In the other instance it is an individual who has not the strength requisite to make such efforts. In this case nature supplies the deficiency by exciting directly the motions of circulation and respiration by the painful impression of cold. Although the condition of the first be the state of health, and that of the second properly a morbid state, they nevertheless have many relations in common, which differ principally in degree. Does not the robust individual experience an inconvenience for which he finds a remedy in violent and repeated efforts? However robust he may be under ordinary circumstances, in the extraordinary condition in which he is placed the usual vital processes no longer suffice him. He must have recourse to violent means which disturb the economy; and by a repetition of the same efforts at different periods, that is to say, in fits or paroxysms, he ends by so far fortifying himelf as to be able to do without them. Is not this tantamount to remedying a relative infirmity of constitution? Let its degree increase but a little, and the infirmity becomes disease. This parallel is not founded on vague and superficial resemblances, but on determinate and fundamental relations. There is not one essential point in the comparison which does not rest on the result of direct experiments, most of which have been quoted in preceding parts of this article. What must be done to justify the similitude of these two states? With regard to the state of health the connexion of phenomena having reference to the hygienic and voluntary reaction is well known. With reference to the relation between the symptoms in the morbid state and the morbid reaction, it remains to be proved that under circumstances where there is but slight production of heat, the feeling of cold may induce acceleration in the respiratory and circulatory motions. Now it has been established by experiments already quoted, that there is reaction of this precise kind in such circumstances. We have seen, for instance, that when a bird, naked or scantily covered with feathers, is taken from the nest and exposed to the air even in summer, it speedily begins to shiver, and to exhibit a reaction in accelerated motions of respiration, which is followed by, and indeed implies increased rapidity in the motions of the heart and current of the blood. It were also proper to show that the cold state may, by means of the violent and involuntary reaction, induce the restoration of heat. This is also susceptible of proof by means of direct experiment. To this end an individual (a young bird from the nest) must be chosen of such an age that the temperature will not be apt to fall too low on exposure to the air. If the choice have been fortunate, it will be found that the temperature sinks in the first instance, and then rises, so that it may even surpass the degree it showed at first, under the influence of the reaction occasioned by the acceleration of the motions of respiration and circulation. The proof here is, therefore, extremely satisfactory. A creature in a state of health is taken and placed in circumstances in which the same essential symptoms are produced in the same order as in the morbid state which we have described. It can scarcely be necessary to say that the morbid state which we have described in man is that of simple intermittent fever. Not only in the beginning of this disease is there a feeling of cold, but recent accurate observations have shown, by means of the thermometer, that there is actual refrigeration. There is, therefore, lesion of the calorific function in the sense previously indicated, that is, there is decrease in the power to produce heat. Subsequently the temperature rises whilst there is still more or less of the sensation of cold remaining; but this only happens by virtue of a general disposition of the nervous system. The same thing, in fact, occurs in a state of perfect health; when the body has for some time been exposed to severe cold, the sensation continues for a certain interval after it has been restored to the normal temperature. It is of little consequence, as regards the subject which engages our attention, that there are some intermittent fevers which do not exhibit the phenomena of temperature that have been described. We are only interested in proving that some do occur which present them all,—a fact that has been demonstrated by the best authorities.

There is consequently in these cases a lesion of the calorific function, a lesion of which the essence consists in a diminution of the faculty of producing heat. In a constitution capable of re-acting by the acceleration of the respiration and circulation, we may observe upon this occasion two principal modifications of the morbid state, which both depend on the same cause, but which differ in degree. The first is that described in which the reaction suffices to restore the calorific power to the degree compatible with health after one or more fits or paroxysms. With regard to the second, the diminution of the function of calorification may be so great, that the reaction may prove inadequate to restore it, not only permanently but even momentarily. There are in fact diseases of this kind; there are many regular intermittent fevers that have no tendency to spontaneous cure; there is also one particular form of the disease which proves speedily fatal without the intervention of art. This is that form of intermittent which is known at Rome especially under the name of the *febbre algida*, or cold fever. It often happens that the patient, unless suitably treated, dies in the cold stage of the second or third paroxysm; sometimes he will even perish in the first.

It is easy to produce at will the essential symptoms of these affections even in their most formidable shapes, in animals in a state of health. All the young birds, for example, belonging to the group of those which at their birth have the weaker calorific powers, can be made to exhibit the phenomena in question. If, at the period of their exclusion or shortly after this, they be taken out of the nest, we have seen that they lose heat rapidly even in the summer season; and we perceive that any reaction of which they are capable by the acceleration of their respiratory and circulatory motions avails them nothing; their temperature sinks in spite of this, till all reaction ceases by the increasing and now benumbing influence of the cold, so that they speedily perish. In these two extreme cases of diminished production of heat, there is similarity in the symptoms which ensue, with this difference, that in the *algid intermittent* there is lesion or a morbid state of the calorific faculty; whilst in the other case the scanty production of heat is a normal condition in relation with the age of the subject. In the first, the constitution is seriously altered; it must be restored or otherwise the individual dies; in the second, there is no alteration of any kind; the individual only requires to be placed in circumstances favourable to the normal manifestation of the function to be restored. In the one the lesion is so great that there is no resource in nature abandoned to her own efforts; art must interfere. In the other, nature provides against the scanty production of caloric in giving to parents the instinct to warm their young by the heat of their own bodies, &c.

We have seen that cold, when not of too great intensity, tended to strengthen the body by increasing the faculty of producing heat; and farther, that with the progressive rise of the temperature in spring and summer the energy of this faculty diminished. This is what takes place with regard to those constitutions that are in the most favourable relation with the climate. Let us now examine the nature of those constitutions that do not adapt themselves thoroughly to the changes of the seasons, and see what the consequences are with regard to them. Let us begin with the relation of these to the cold season of the year. It might be presumed *à priori* that those constitutions that have a very limited capacity of engendering heat will not accommodate themselves well to the cold of winter. Their limited powers of producing heat will not enable them to repair the continually increasing loss of it arising from the depression of the external temperature. They consequently suffer in a greater or less degree from cold, perhaps not to any great extent in the first instance, as we shall have occasion to explain by-and-by, but still in some measure; and there are certain degrees of uneasiness and inconvenience that may be regarded as being still within the limits of health. There is even a certain, and that a pretty wide latitude in which the body may vary without trespassing on the line of disease. The uneasiness may only be experienced from time to time, and not even be always very manifestly referable to its proper cause. In other words the sensation may be something quite different from that ordinarily induced by cold; just as it sometimes happens that among weak constitutions the necessity of taking food is not always proclaimed by the feeling of hunger, but occasionally by some other distressing or painful sensation, with regard to the true nature of which experience alone can enlighten us. In such a low state of the calorific power, the faculty seems to lose strength still further, owing to the simple persistence of the same degree of cold, and still more from the ulterior depression of the temperature, in the manner we have seen when speaking of hybernating animals. This diminution in the temperature of the air sometimes occasions among weakly subjects morbid reaction, the principal features of which have already been explained. From all that precedes, the constitutions that will be the most apt to suffer from exposure to cold will be those of the earliest times of life observed in man and the warm-blooded tribes generally, since it is at this epoch that they produce the least heat; and as a corollary from this, we should infer that the mortality in early life ought to be greater during the winter season in this and other countries similarly circumstanced. It became a matter of peculiar interest to verify this inference from the experiments and reasonings of which we have just rendered an account. Messrs. Villermé and Milne Edwards accordingly undertook the necessary inquiries, entering upon extensive statistical researches with reference to the mortality of children in the different seasons of the year in France, and found that the mortality of infants from their birth to the age of three months was generally the greatest in those departments of which the winters were the most severe. For a similar reason, the natives of very warm climates who visit countries whose winters are excessively cold, run great risks of not being able to produce heat enough to compensate the loss they sustain from exposure to the low atmospheric changes, and thus of becoming obnoxious to disease and death in consequence. Those that have elasticity enough of constitution to meet this unwonted demand upon their calorific powers, experience an increase in the energy of the functions upon which the production of heat depends, by which they are brought into harmony with the climate. Others who are less robustly constituted complain loudly of the cold, languish, and finally perish if they do not find means of escaping from the destructive tendency of the cold.

What happens, in as far as these different constitutions are concerned, when the change of season is the opposite of that we have just discussed? when the progress is from the colder to the hotter period of the year? The constitutions that have just been particularly mentioned, it is obvious, will find themselves benefited by the change; they are continually supplied with larger proportions of heat of which they were especially in want. But robust constitutions, in which the calorific faculty is largely developed, will they not be in an opposite position, unless the energy of the faculty in question diminishes in proportion as the external temperature increases? This in fact is what of necessity happens to those in whom the power of accommodation is defective. For when the calorific faculty continues in full force, when the temperature of the surrounding atmosphere is high, there is an excess of heat proceeding from within as well as from without; and if the body does not suffer in the first instance, which it is apt to do, it before long feels the deteriorating influence of this additional excitement, which then superinduces a series of morbid phenomena of various degrees of intensity according to circumstances. All this is observed to occur in the most distinct manner among the natives of cold climates who come to reside in very hot countries. The most robust are even observed to be the most apt to suffer from the change, and the effect is so decided, that few escape some derangement of health, occasioned solely by the influence of the high temperature. When the affection appears in the acute form, after recovery, the new comer is said to be seasoned. The constitution appears to have suffered a favourable change, which consists essentially in a decrease of the faculty to produce heat. In fact it is often only by a process of this kind that the calorific power can be brought into harmony with the new circumstances in which it is placed.

Something of the same kind even takes place in the constitutions of the inhabitants of the countries which have two very different temperatures during the two halves of the year. Here, however, the change of constitution generally passes insensibly or nearly so, the transition being both less in itself, and the natives being accustomed to the difference. Let us just remark that we have here another instance of the *vis medicatrix naturæ*, the tendency of which at all events is salutary, but of which the violence of effect by exceeding the proper limit frequently becomes fatal. We even perceive here that nature has two processes at her command, by which she adapts us to changes of external circumstances; the one is gradual and insensible, the other is sudden and violent.

From repeated observation, and from experiments upon the effects of exposure to high temperatures, it is easy to infer the general character of the disease in its simplest form, which the natives of cold climates will be likely to contract in hot countries. As a high temperature of the air accelerates the breathing and excites the circulation, it may arouse these functions to such a pitch, that the condition becomes truly pathological, and the disease which results is continued fever with excessive heat of surface in those countries where the external conditions are subject to little variety.

There are other phenomena accompanying changes of climate that are referable rather to the state of health than to any morbid condition that bears upon the sensations. It is a general remark that natives of the warmer regions of the earth, of a good natural constitution, when they visit countries within the temperate zone, suffer little from the effects of cold the first winter; on the contrary, they seem to live very much at their ease, except in extreme cases. Let us see if we can explain this fact with the assistance of the principles established above. If the natives of warmer climates come during the summer to temperate countries, they experience a change of no great amount indeed, and which, in the generality of cases, is not obvious. The heat grows less and less intense, declining gradually; freshness or coolness succeeds; then comes moderate, and at last severe cold. Well-constituted individuals, therefore, and they may be assumed as the majority, will experience the general influence of a gradual cooling process; that is to say, their faculty of producing heat will increase, whence will result a feeling of warmth and of comfort. But this faculty has its limits of increase, which in fact lie within narrower bounds than in the case of well-constituted natives of temperate climates. They are consequently apt at length to fall short of the mark, and so to remain, in regard to calorification, under the standard necessary to the economy. Whenever the progression of which we have spoken ceases, which happens in the course of the second winter, these individuals begin to experience the uneasiness which results from its deficiency. It is easy to confirm and render manifest the justice of the above deduction by means of a simple yet curious experiment. If a person having warm hands will keep one plunged for some time in water near the freezing point, it becomes chilled of course, but reaction will be observed soon to take place, and the hand will become red. If it be now taken out of the water and wiped dry, the individual being all the while in a cool atmosphere, at 10° or 12° c., the hand will by-and-by begin to glow, and the feeling in it will be that of a temperature considerably above the heat of the other hand;—judging by the feeling alone the hand seems hotter than the other; tried by the thermometer however, it will be found to be cooler; or if it be applied to the other, it will at once be discovered to be below the temperature of the hand that was not chilled.

Let us follow the effects upon common sensation produced by a change of climate of an opposite kind. When the inhabitants of cold countries visit the hotter regions of the globe, how do they contrive to endure the heat in the first instance? Experience has often shown that when they are of the same race, they endure it at first with even greater ease than the natives themselves, and that they brave with greater hardihood and less suffering the utmost ardour of the sun. This capacity of resistance, however, has its term, and those who possess it gradually lose it, as has been shown in a former passage of this article. The native of the colder clime is more robust, and his nervous system, less impressible, resists painful sensations in a greater degree, and is not overwhelmed by the first effects of noxious influences. This conclusion is also susceptible of demonstration by the way of direct experiment. If during summer a frog be completely immersed in a small quantity of water at the ordinary temperature of this season of the year, and the same experiment be repeated during winter with water heated to the summer pitch, the animal will live much longer in the latter than in the former instance. The nervous system of the animal, by the continued action of the cold of the autumn and winter, has been rendered much more capable of resisting noxious influences, as we have had occasion to see already. It is on the same principle that the Finlander, according to the account of Acerbi, can endure a bath at a much higher temperature than it could be borne by a native of a warm or more temperate climate.

Effects of various other causes of modification in external agents.

The effects of external heat and cold on the sensations and on the system in general are not altogether dependent on degrees of temperature. Even at the same degree atmospheric effects are often very different, being principally influenced by the state of dryness or moisture, and by that of motion or rest, of the air. Speaking generally, media exert modifying influences other than those comprised in their temperature upon the phenomena of animal heat. Evaporation is a powerful cause of cooling, which increases in the same measure as the evaporation. In the summer season, consequently, during a state of the weather in which the temperature is the same, but the hygrometric condition different, the heat of the body will be higher in moist than in dry air. In the same way we observe all the effects of excessive temperature upon the body to be much more intense with a moist than with a dry atmosphere. In the climate of northern France or England it would be impossible to stand a vapour-bath at a temperature between 40° and 50° c. (104° to 122° F.) for more than ten or twelve minutes; but with a perfectly dry state of the air it is possible to bear a temperature twice, or more than twice as high during the same space of time. M. Delaroche found that he could not remain in a vapour-bath raised in the course of eight minutes from 37°,5 to 51°,25 c. (100° to 125° F.) for more than ten minutes and a half, although the bath fell one degree. M. Berger was compelled to make his escape within twelve minutes and a half from a vapour-bath the temperature of which had risen rapidly from 41°,25 to 53°,75 c. (106° to 129° F.). Both of these experimenters felt themselves become weak and unstable on their legs, and were affected with vertigo, thirst, &c. The weakness and thirst continued through the remainder of the day. But in the course of Dr. Dobson's experiments, a young man continued for twenty minutes in a dry-air stove, the temperature of which was 98°,88 c. (210° F.), within a degree or two, consequently, of the ordinary boiling temperature of water. His pulse, which usually beat 75 times in a minute, now beat 164 times. This, however, is by no means the degree of heat that can be and that has been endured. M. Berger for five minutes bore a temperature of 109°,48 c.; and Sir Charles Blagden went still further, having exposed his body during eight minutes to the contact of dry air heated up to the extraordinary pitch of 115°,55 and 127°,7 c. (240° and 260° F.). In assigning 40° or 50° c. (104° or 122° F.) for the limits of moist temperature that can be borne by the inhabitants of these countries, we are perfectly aware that in other latitudes it can be greatly exceeded. Thus Acerbi, in his journey to the North Cape, informs us that the Finnish peasantry remain for half an hour or more in a vapour-bath, the temperature of which finally rises to 70° and even 75° c. (158° and 167° F.). We have already given the reason of this difference of constitution.

Experimental philosophers have not yet tried the precise comparative cooling effects of dry air and of watery vapour; but all are agreed that the powers of the moist atmosphere are by far the most considerable. To measure the comparative effects upon the economy the following experiments were instituted. In equal spaces, the one filled with air at the point of extreme humidity, the other with extremely dry air, were placed young birds of the same age, which were as yet incapable of maintaining their temperature at its proper height when taken out of the nest. It was found that they lost temperature nearly in the same proportion in the same space of time when the air was either at the point of extreme humidity or of great dryness. Therefore moist air tends to cool at least as much as dry air by evaporation. It cools both by the abstraction of heat and by its action on the nervous system. Its action on the nervous system is of a debilitating nature, and therefore tends to diminish the power of generating heat. The *sensation* of cold was evidently greater in the moist air, as was shown by the shivering of the animal. There can be no doubt that the action of vapour in this case is complicated by a physical influence in the one instance, and by a peculiar physiological effect on the nervous system in the other; for it is well ascertained that water, as contrasted with air, has a debilitating effect upon the economy. General experience comes in support of these results; men have ever agreed that moist and cold states of the atmosphere and humid and cold climates were more difficult to be borne than those of an opposite character. Such climes in fact are in themselves extremely insalubrious. By their peculiar effects on the economy they tend greatly to lessen the power of producing heat, and they also engender intermittent fevers, among other morbid conditions. According to the state of the economy and the degree of the external temperature, watery vapour tends to refrigerate still more in winter, and to add to the heat in summer.

The state of the atmosphere in regard to motion or rest modifies to a great extent the effects of a given temperature upon the body. Refrigeration by simple contact increases in amount with the rate of motion of the air. The same law holds good in regard to evaporation, and indeed this process always complicates the results proceeding from simple contact. The cause of refrigeration in this case is consequently double. It is easy, therefore, to imagine how powerful a cause of cooling a cold wind must be. But observation can alone give any adequate idea of the extent of its influence in this respect. Mr. Fisher, one of the surgeons in the expedition under the command of Sir Edward Parry to the Polar Seas, has given us an account of its extraordinary effects. In the frozen regions around the arctic circle, the hardy voyagers under Capt. Sir E. Parry found that they could stand a cold adequate to freeze mercury when the air was perfectly calm, much more easily than a temperature nearly 50° F. higher when it blew. The air in motion in this case, therefore, produced a sensation of cold that was equal to such a depression of temperature as is indicated by a fall of 50° of the scale of F.—a most prodigious difference.

Sudden transitions of temperature also exert a great influence independently of any limits; in the first place, because the intenseness of the sensation of cold or of heat is in proportion to the suddenness of the abstraction, or of the communication of heat; and again, because the faculty of adaptation to different degrees of external temperature is not acquired all at once, but is only attained in a certain lapse of time, and by gradual modifications in the constitution. We therefore see that those countries of which the temperature is very high in the day, but very low in the night, are subject to diseases that seem to belong more peculiarly to cold and moist latitudes, or to marshy lands where *malaria* prevails. But the transition from hot to cold is not limited to the suddenness of the thermal depression; it extends to the refrigeration by the action of the wind. This is another among the many reasons why in the latitudes of England, France, &c. spring is a more dangerous season than autumn. There are, however, certain cases of sudden transition that are useful and salutary, as for instance, when the heat of the body is excessive, and is doing mischief, whether it be induced by an elevated external temperature, or proceeds from the violent and involuntary action of our organs. Then refrigeration even of the most sudden kind, provided it be restrained within proper limits, becomes beneficial. It is thus that the affusion of cold water produces such excellent effects in cases of extreme excitement, and where the temperature is really above the natural standard. This process is even to be regarded as one of the most brilliant triumphs of modern medicine. It is much to be regretted that recourse is not had to it more frequently. It is evident that the proper time for the use of this powerful means is that in which congestion has not yet passed into obstinate engorgement, that is to say, in the beginning of the disease, in which by allaying excitement congestion is diminished. The favourable moment for using the cold affusion is that in which the skin is hot and dry, which is also the period of the highest excitation. The experiments upon the effects of baths, quoted above, tend also to show the propriety of the practice; in citing these, we mentioned that the diminution of temperature produced in the body lasted for hours, and that the reaction consequent upon the use of the bath did not carry the temperature higher than the pitch it possessed at starting. It is obvious that the effects of the cold affusion are to be derived from the principles previously established; since we have referred the production of heat to two general conditions of the economy, one of which is the state of the nervous system. Now the affusion of cold water acts directly upon this system. There is another powerful method of tempering animal heat, which flows from the other general condition, upon which the production of heat depends, viz. the state of the blood. We have seen above that the respective proportions of the serous mass of the blood and of its red globules exert an important influence; that in the class of vertebrate animals which produce smaller quantities of heat, the proportion of the serum was in the inverse ratio of the faculty of calorification. Whence it follows, that in cases of excessive heat of body, to reduce the quantity of red globules would prove an effectual mode of reducing the temperature. Now this is precisely what is done by bloodletting. The effect, however, in this way is not instantaneous. The first influence of bloodletting is simply to lessen the quantity of the blood, and this is the extent to which ideas of the influence of the abstraction of blood are generally confined. There is, however, a consecutive influence, which is at the least as important, and which proves much more lasting. As the person who has been let blood confines himself at the same time to low diet, and principally to liquids, it is obvious that the blood is recruited in its quantity principally by additions of watery particles, without any notable or even sensible addition of globules. The blood is therefore altered essentially in its constitution; the proportion of its component fluid and solid elements is changed, and this in direct proportion to the extent and frequency of the venesections. The consequence of this is a diminution of temperature, unless other causes oppose such an effect.

Bloodletting, it must be observed, is not the sole means of accomplishing such a change in the constitution of the blood. We can produce a similar effect by exciting one or all of the secretions which are thrown off by the body. Secretion is performed at the cost of the blood, which supplies both of its elements

—the solid and the fluid part. The more the secretion eliminated abounds in solid parts or matters formed at the cost of the solid constituents of the blood, the more is the blood impoverished in these elements—the more is its mass of globules diminished. Absorption then begins, as in the preceding case, to make up the quantity of circulating fluid; and if this faculty have only fluids to work upon, it is evident that, as in the case of bloodletting, the blood will become more serous than before. The perspiration and the alvine secretions act in this manner, and nature makes use of these, especially of the former, to temper the burning heat of paroxysms of fever. Art but imitates nature in the treatment of acute diseases; she strives to procure action of the skin, and especially action of the bowels. The use of diaphoretics and purgatives is therefore plainly borne out by the principles which have been laid down. The alvine secretions are those especially that carry off the largest proportion of solid matters from the blood, and which therefore, when excited, prove the most permanently efficient in keeping down the temperature of the body. There is another important reason for preferring the intestinal canal to the skin as the means, in the generality of instances, of reducing temperature in the treatment of disease, which ought not to be lost sight of: this is, that we can excite the intestinal evacuations to a great extent without arousing the circulating system in almost any degree; very different from what occurs when we attempt to unload the vessels by the way of the cutaneous exhalants, in which it is generally impossible to produce abundant diaphoresis without arousing the heart and arteries to unwonted action as a preliminary. Purgative medicines, therefore, next to the direct abstraction of blood, are the most potent means of tempering the heat of the body by modifying the constitution of the blood. Nothing that influences the economy can have an effect in one direction only. It were foreign to our purpose, however, to enter upon any other than that which bears immediately upon our subject.

There is another natural process analogous in its effects, which the preceding considerations place in a new point of view. This is the influence of diet and regimen. Low diet does not act merely in preventing the excitement which always follows the ingestion of solid food; it further alters the constitution of the blood. This fluid, receiving a more scanty supply of solid matters, continues nevertheless to supply the natural secretions as before, and consequently very speedily undergoes by this alone a diminution in the proportion of its globules, in the direct ratio of the duration of the system of spare diet. Low diet is therefore a means which acts in the same way as bloodletting and purging, with this difference however, that it is slower in its operation, and in the first instance less marked in its effects. This, therefore, is the slowest and least efficacious of the immediate means of reducing temperature when employed alone, although its conjunction is indispensable to the success of any of the others.

Of all these means, one only is the proper effect of art, namely, the application of cold; the others are processes of the same *natura medicatrix*, and processes which we merely imitate. These act directly in modifying the constitution of the blood, and thus definitively influence the nervous system. The other exerts its influence directly on the nervous system, in calming the excitement or violent action which it has engendered in the sanguiferous system, and those that depend on it.

The application of heat becomes necessary in morbid states the reverse of those that have just been discussed. The proper employment of this means depends especially on two general principles bearing upon animal heat, which we have considered above. 1st, The one is, that the economy has the capacity of bearing heat in the same proportion as the function of respiration is extended. In those cases in which this function is limited, or, what comes to the same thing, where any part that requires an accession of heat is indifferently supplied with arterial blood, it is necessary to be extremely cautious in its application. 2nd, The other, that the effects of external heat are not confined to the simple interval during which it is applied, but remain after it has been removed, and even increase the faculty of producing heat. The application of warmth is therefore not merely palliative or supplementary of lost heat; it has further a directly remedial influence, which may even be excited in excess. When the lesion of the calorific faculty has been great, without much or any organic lesion, other means of greater force than those usually resorted to by art, or employed by nature in such circumstances, must be called in to assist. Art has happily discovered what seems the most effectual means of winding up the nervous system, and enabling the calorific faculty to be re-established in its normal condition. This means is quinia, the first of tonics. This powerful medicine is consequently never administered in acute diseases until all violence of action has ceased, and the functions have resumed their habitual rythm. We find that the action of this medicine is exerted directly upon the nervous system from this, that it seems to have no effect on the secretions, or when it does influence these, we are convinced by the trifling amount of the effect, that it is not through them that the cure is accomplished. As it acts during the intermission, by restoring the normal production of heat, we have no reason to expect the phenomena which characterize the fit—the shivering, &c.; and then the violent reaction which we have in the hot stage becomes useless, and in fact is no longer observed.

Confirmation of the general results.

We have thus passed in review the principal phenomena of animal heat, reducing or approximating these at all times to the most simple conditions. These conditions themselves are, in the first place, assumed from comparisons of the organization of the two grand groups or series into which the animal kingdom is divided with reference to heat—the cold-blooded animals, and the warm-blooded animals. In this review we have avoided all hypothesis, confining ourselves to the severe method of deduction, always starting from well-authenticated facts, and even confirming each step in advance by new data equally indisputable. The harmony which reigns in this comprehensive whole, which embraces the different classes of animals and man, not only in the various modifications of health, but even of disease, in their relation to external agents, and the therapeutic processes of nature and of art, afford the surest confirmation of the reality of these relations. As the phenomena of animal heat are referable to two general conditions of the economy,—the state of the blood and that of the nervous system; and as we have only in the first instance deduced these from the comparison of natural facts, although we have confirmed them by new observations and particular experiments, one may be desirous of seeing them confirmed by experiments of a more general bearing. To the reasonableness of this wish we yield assent the more willingly, as the results we have to quote are deductions from some of the most admirable researches that have been instituted by physiologists;—I allude to the enquiries of Legallois, Sir Benjamin Brodie, and Dr. Chossat.

The first of these experimenters, by the employment of various means for impeding respiration, or limiting the consumption of air, found that *the refrigeration of animals is in the compound ratio of the difficulty experienced in breathing and of the quantity of oxygen consumed; so that when, in two experiments, the difficulty of breathing is the same, the greatest extent of cooling occurs in that in which the smallest quantity of oxygen is vitiated, and the contrary.* Now, the end of the process of respiration being to change the venous into arterial blood, this conclusion of Legallois confirms directly the one of the two principal conditions—THE STATE OF THE BLOOD, which we have laid down as influencing the production of heat among animals, and to the knowledge of which we had attained by induction.

The results of the direct experiments which we have still to quote also come powerfully in aid of our inferences concerning the other principal condition, which we have assumed from induction, influencing the production of animal heat: this is THE STATE OR ACTION OF THE NERVOUS SYSTEM.

Sir B. Brodie demonstrated by a series of the most ingeniously conceived and happily executed experiments, that when animals were decapitated and respiration was kept up by artificial means, so that the blood circulated as usual, and the process of change from the venous to the arterial state went on uninterruptedly, the ordinary quantity of carbonic acid being eliminated, all the while, that, nevertheless, the temperature fell rapidly, even more rapidly than when no artificial respiration was maintained.

Dr. Chossat completed these researches upon the nervous system in its relations with the production of heat, by demonstrating in a series of experiments the following very important fact, viz. *that the depression of animal heat is constantly in relation with lesions of the nervous system, whether these lesions implicate the cerebro-spinal system, or the system of the great sympathetic.*

We necessarily confine ourselves, in alluding to these admirable researches, to the most general results, and the conclusions flowing most immediately from the experiments instituted. We reserve a more particular mention of them for the proper place, namely, the article on RESPIRATION, to which we beg to refer. With regard to the opinions of writers generally, we shall be content to observe here, that they have for the most part regarded the single physiological condition which was the subject of their particular study as the only source of animal heat. The general result of their united labours, however, is, that there are two principal sources, the one depending on the arterial blood, the other on the energy of the nervous system,—a conclusion to which we have come by another way, by combining all the known facts that bear upon animal heat, and embracing the manifestations presented by the whole of the animal kingdom as well as the isolated phenomena exhibited by man, and this not in one but in every condition of existence, not only in the state of health but of disease likewise, not as beings independent of all things around them, but as living in intimate relationship with external agents.

OF THE PHYSICAL CAUSE OF ANIMAL HEAT.

With regard to the physical cause of animal heat, or to *its mode of production*, there was a time, which we have not yet left very far behind us, when natural philosophers and chemists imagined they possessed the secret, especially with reference to the mineral kingdom. They have now discovered their mistake; and as the evolution of heat is a mystery to them, it is not to be expected that it is less so to physiologists, as manifested in the domain which they cultivate in peculiar. The problem, in fact, becomes immensely complicated by a variety of phenomena when from the inorganic we ascend to the organic world. All that could be done has been accomplished; from the particular conditions of organization and of function upon which this effect seemed to depend, physiologists have risen to those that were the most general and comprehensive. This, in fact, was the end we proposed in commencing this article. That nothing may be omitted which can make the sketch more complete, and none of the great inquiries which have had animal heat for their object may be passed over in silence, we shall briefly cite the more important of those in which the mode of production of animal heat is discussed, always reserving to ourselves the opportunity of treating several of these more fully in our article on Respiration.

Lavoisier, from his labours on combustion, which laid the foundation of the chemical doctrines of the age that has just elapsed, conceived the ingenious idea of explaining the phenomena of animal heat by the combustion of the carbon and hydrogen of the blood by the oxygen of the air in the process of respiration, and the experiments which he instituted upon this point along with the illustrious La Place appeared to confirm his idea. Still it was found impossible to give an account of the production of the whole heat engendered by animals. All that Lavoisier and La Place inferred was, that the heat evolved by an animal was *almost entirely* produced by the combustion which occurs in respiration. As the calorific power was measured in one animal, and the consumption of oxygen in another, it is evident that the inference, vitiated in its elements, became much less precise than it would otherwise have been.

This consideration as well as others induced M. Dulong, who is as well versed in mechanical philosophy as in chemistry, to take up this subject again. After numerous experiments, conducted with every precaution that could secure accuracy of result, he found that the heat disengaged by the fixation of the oxygen in the act of respiration was not equal to the whole of that which was produced by an animal. This inquiry (which however stood in no need of confirmation) has been confirmed by the analogous inquiries of M. Despretz, who arrived at the same numerical results. The hypothesis in question, therefore, gives no solution of the problem.

(W. F. Edwards.)

HERMAPHRODITISM, or Hermaphrodism;* *Hermaphrodisia; androgynisme, gynandrisme; hermaphroditisme*, &c., of the French; *ermaphrodismo* of the Italians; *Zwitterbildung* of the Germans, &c.

Many different definitions of hermaphroditism, and almost an equal number of different classifications of the malformations usually comprehended under it, have been proposed by the various authors, ancient and modern, who have directed their attention to this subject. Without stopping to discuss the merits or errors of these definitions and classifications, and without inquiring, as some have done, into the propriety of the word itself, we shall content ourselves with stating that under it, as a convenient generic term, we purpose in the present article to include an account—1st, of some varieties of malformation in which the genital organs and general sexual configuration of one sex approach, from imperfect or abnormal developement, to those of the opposite; and 2d, of other varieties of malformation, in which there actually coexist upon the body of the same individual more or fewer of the genital organs and distinctive sexual characters both of the male and female.

To separate from one another, by as strong a line as possible, the two distinct varieties of hermaphroditic malformation marked out in this definition, we shall divide hermaphroditic malformations, considered as a class, into the two orders of *Spurious* and *True*; the spurious comprehending such malformations of the genital organs of one sex as make these organs approximate in appearance and form to those of the opposite sexual type; and the order, again, of true hermaphroditism including under it all cases in which there is an actual mixture or blending together, upon the same individual, of more or fewer of both the male and female organs.

Spurious hermaphroditism may occur either in the male or female; that is, there may, from malformation of the external sexual organ, be an appearance of hermaphroditism in persons actually of the female sex, or from a similar cause there may be an appearance of hermaphroditism in persons actually of the male sex. The differences derived from the diversity of sex in which spurious hermaphroditism occurs, and the particular varieties of malformation in each sex which may give rise to it, will serve as

* From the well-known mythological fable of the union into one, of the bodies of Hermaphroditos (the son of Ερμης, *Mercury*, and Αφροδιτη, *Venus*,) and the nymph Salmacis. See Ovid's Metamorphoses, lib. iv. fab. 8.

bases on which we shall found some further subdivisions of this order.

True hermaphroditism, as above defined, comprehends also, as shall be afterwards more particularly shewn, several very distinct varieties of malformation. If we conceive for a moment all the reproductive organs to be placed on a vertical plane, (as we may suppose them to be, though not with strict correctness, in the human body when in the erect posture,) we shall find that the principal of these varieties may be all referred to three sets of cases:—1st, those in which, if we drew a vertical median line through this supposed plane, the two lateral halves will be seen to present organs differing in this respect, that they belong to opposite sexual types; 2d, others in which, if we bisect the same plane by a transverse horizontal line, there exist organs of a different sex in the upper from what are present in the lower segment; or, in other words, the internal genital organs belong to one sex, and the external to another. In the two preceding classes of cases there is not necessarily, as we shall afterwards more fully point out, any malformation by *duplicity* in the sexual apparatus of the malformed individual; there is only one set of sexual organs present, but in some parts these organs are formed upon the male, and in others upon the female type. In the 3d and remaining set of cases, however, there is really present to a greater or less, though most generally only to a very partial extent, a double set of sexual organs, having opposite sexual characters, so that upon the same body, and usually upon the same side, or upon the same vertical line in our supposed plane, we find coexisting two or more of the analogous organs of the two sexes. In accordance with this view, we shall consider the cases of true hermaphroditic malformation under the three corresponding divisions of, 1st, *lateral;* 2d, *transverse;* and 3d, *vertical*, or, more properly, *double* or *complex hermaphroditism;* and each of these genera will admit of some further convenient subdivisions. But the mode in which we propose to classify and consider the subject will probably be at once more accurately gathered from the following table, than from any more lengthened remarks upon it in the present place.

Classification of hermaphroditic malformations.

- Hermaphroditism
  - Spurious
    - In the Female
      - From excessive development of the clitoris, &c.
      - From prolapsus of the uterus.
    - In the Male..
      - From extroversion of the urinary bladder.
      - From adhesion of the penis to the scrotum.
      - From hypospadic fissure of the urethra, &c.
  - True ..
    - Lateral......
      - Testis on the right, and ovary on the left side.
      - Testis on the left, and ovary on the right side.
    - Transverse ..
      - External sexual organs female, internal male.
      - External sexual organs male, internal female.
    - Vertical or Double ..
      - Ovaries and an imperfect uterus with male vesiculæ seminales, and rudiments of vasa deferentia.
      - Testicles, vasa deferentia, and vesiculæ seminales, with an imperfect female uterus and its appendages.
      - Ovaries and testicles coexisting on one or both sides, &c.

In commenting upon and illustrating the different varieties of hermaphroditism in the particular order in which they are placed in the above table, we shall, we believe, by following that order, be able to take a graduated, and, at the same time, a correct and comprehensive view of the subject, beginning with the more simple, and ending with the more complex and complete species of hermaphroditic malformation, as seen in the primary sexual characters, or the structure of the genital parts themselves. We shall then consider at some length the curious and important physiological subject of hermaphroditism as manifested in the secondary sexual characters of the system. After having done so, we shall endeavour to show how far the diversified forms of hermaphroditic malformation can be explained upon our present knowledge of the laws of developement; point out the actual anatomical and physiological degree of sexual duplicity which is liable to occur, and the numerous fallacies with which the determination of this question in individual cases is surrounded; and lastly, in conclusion, we shall offer some general observations upon the causes, &c., of this class of abnormal formations.

1. SPURIOUS HERMAPHRODITISM.

A. *In the female.*—There are two circumstances in the conformation of the genital organs of the female, the existence of each of which has occasionally given rise to doubts and errors with regard to the true sex of the individual on whom they were found—namely, 1st, a preternaturally large size of the clitoris; and 2d, a prolapsus of the uterus; the enlarged clitoris in the one case, and the protruded uterus in the other, having been repeatedly mistaken for the male penis.

1. *Abnormal developement or magnitude of the clitoris.*—In the earlier months of intrauterine life, the clitoris of the human female is nearly, if not altogether, equal in size to the penis of the male fœtus; and at birth it is still relatively of very considerable dimensions. From that period, however, it ceases to grow in an equal ratio with the other external genital parts, so that at puberty it is, as a general law, found not to exceed six or eight lines in length. But in some exceptional instances the clitoris is observed to retain up to adult age more or less of that greater proportionate degree of developement which it presented in the embryo of the third and fourth month, thus exhibiting in a persistent form the transitory type of structure belonging to the earlier stages of fœtal life. In some instances where this occurs, the resemblance of the external female to the external male parts is occasionally considerably increased by the apparent absence of the nymphæ. Osiander* endeavoured to show that at the third or fourth month of fœtal life the nymphæ are very imperfect, and so very small as not to be easily observed. Meckel,† however, has pointed out that these organs are not in reality of a small size at that time, but they are liable to escape observation from the folds of skin of which they consist, making, at the period alluded to, a perfectly continuous membrane with the prepuce of the clitoris, and forming indeed, in their origin, only one common mass with this latter body. When the ulterior changes, therefore, which these parts ought to undergo in the natural course of developement in the latter stages of fœtal existence, are suspended or arrested from about the end of the third month, there may not only coexist with the enlarged clitoris an apparent want of nymphæ, but the resemblance of the female to the male parts may be still further increased by the persistance of the original intimate connexion of the nymphæ with the prepuce and body of the clitoris, and by the consequently continuous coating of integuments, as well as the greater size and firmness of this organ.

Excessive size of the clitoris would seem to be much less common among the natives of cold and temperate than among those of warm countries. The frequency of it in the climate of Arabia may be surmised from the fact of directions having been left by Albucasis and other surgeons of that country for the amputation of the organ; an operation which Ætius and Paulus Eginetus describe as practised among the Egyptians. According to the more

* Abhandlungen über die Scheidenklappe, in Denkwurdigkeiten für die Heilkunde, Bd. ii. p. 4-6.

† Manuel d'Anat. Gén. tom. iii. p. 666.

modern observations of Niebuhr* and Sonnini,† circumcision would seem to be still practised upon the females of that country.

This variety of conformation of the female parts appears to have been well known to the ancient Greeks, and several of their authors have mentioned the women so constituted under the names of τριβαδις and ιταιριστριαι, a class in which the celebrated poetess Sappho (*mascula Sappho*) is well known to have been included. Martial, Tertullian, and other Roman authors have noticed the same malformation, (*fricatrices, confricatrices,*) and alluded to the depravity to which it led.‡

* Beschreibung von Arabien, s. 77.

† Voyage dans la Haute et Basse Egypte, tom. ii. p. 37.

‡ Mart. Epigr. lib. i. ep. 91.; see also lib. viii. ep. 66. The frequency of this crime in the ancient gentile world may be inferred from the pointed manner in which the Apostle Paul alludes to it, Romans, chap. i. 26. In Greece it was in some places forbidden by law, and in others, as in Crete, tolerated by the state. Seneca, in his 95th ep., when speaking of the depravity of the women of his own age, remarks, "non mutata fœminarum natura, sed vita est. . . . Libidine vero, nec maribus quidem cedunt pati natæ. Dii illas deæque male perdant, adeo perversum commentæ genus impudicitiæ viros ineunt." Op. Om. Genev. 1665, p. 787. Clemens Alexandrinus, in his Pædagogus, exposes the same vice: "et contra naturam fœminæ, viros agunt (ανδριζονται) et nubunt et etenim uxores ducunt." Also Athenæus, Deipnosoph. lib. xiii. p. 605. Justin Martyr, in his Second Apology, makes a still broader accusation. This author lived in the second century, and in declaiming against the vices of that licentious age, he alleges that multitudes of boys, females, and hermaphrodites (*androgyni ambigui sexus*) "nefandi piaculi gratiâ per nationem omnem prostant." Op. Om. Col. 1686, p. 70. See also Marcus Antoninus, De Seipso, ed. Gatakeri, Cambr. 1652, lib. iii., note at the end by Gataker. On the extent, among the ancients, of the vices above alluded to, see Meiner's Geschichte des Verfalls der Sitten und der Staatsverfassung der Roemer, Leipzig, 1791; Neander's Denkwurdigkeiten, Bd. i. s. 143; Professor Tholuck's, of Halle, Exposition of St. Paul's Epistle to the Romans, in the Edinburgh Biblical Cabinet, vol. v. p. 102, and in an Essay on the licentious vices, &c., of the ancients, translated into Robinson's American Biblical Repository, vol. ii. p. 441. In the essay last referred to, Tholuck incidentally mentions (p. 422,) that the deity Mitra (Mithras of the ancient Persians) was hermaphrodite. For our own part we are inclined to believe that many of the idols of the heathenish mythology of Asia could be traced to the deification of various monstrosities in man and quadrupeds. (See the figures of these idols *passim* in C. Coleman's Mythology of the Hindus, Lond. 1832; and E. Upham's History and Doctrine of Budhism, Lond. 1829.) It perhaps is not unworthy of notice that the Jewish Talmudists, taking the Hebrew noun in the Pentateuch answering to man in its individual and not in its collective sense, considered, from Genesis, chap. i. v. 21, that our original progenitor was hermaphrodite. (See Jus Talmud. Cod. Erwin. c. 2; Heidegg. Hist. Patriarch, t. i. 128; C. Bauhin De Monstrorum Natura, &c., lib. i. c. 24; and Arnaud's Mémoire, p. 249.) It is further interesting to remark that Plato, in his Symposion, introduces Aristophanes as holding the same opinion. "The ancient nature," he observes, "of men was not as it now is, but very different; for then he was androgynous both in form and

The dimensions which the clitoris occasionally presents are such as to render it, in respect of size alone, not unlike the male penis. It is not unfrequently found of two or three inches in length, but sometimes it is seen five and six inches long. Dr. Clark frequently found the organ an inch long, and thick in proportion, among the Ibbo and Mandingo women.*

Haller † and Arnaud ‡ have collected numerous instances of preternatural size of the clitoris. The former author alludes, among others, to two cases in which the organ was stated to have been seven inches in length; and to another, mentioned by Chabart, in which it was alleged to have been twelve inches,—a size which we can only conceive to have been the result of disease.

When the female clitoris is increased greatly in size, it is not wonderful that it should be sometimes mistaken for the male penis,—the female organ in the Mammalia naturally differing from the male only in regard to its smaller dimensions, its not being perforated by the urethra, and its wanting the corpus spongiosum,—a peculiarity or defect of structure that exists as the natural type of formation in the penis of male reptiles. In the human subject the organs are composed internally of the same kind of erectile tissue, and when we descend in the animal scale, and examine their relations in the males and females of the same species, we find some still more striking analogical peculiarities of structure. Thus, in several of the Carnivora and Rodentia, as in the lioness, cat, racoon, bear, marmot, &c. the clitoris contains a small bone like that belonging to the penis of the males of the same species; and amongst the Monotremata and Marsupiata the clitoris of the female, like the penis of the male, is surmounted by a bifid glans. In a species of lemur (*Loris gracilis* or *Stenops tardigradus*), the clitoris is of a very large size; and the urethra, as first pointed out by Daubenton,§ runs forward and opens at its anterior extremity between the branches of its glans, imitating, in this point of structure, the penis of the male among the Mammalia.

In the human subject the mere enlargement of the clitoris alone has seldom of itself given rise to errors with regard to the sex of the individual, except in young children; but it has frequently happened that along with it other minor malformations have coexisted, so as to render the sexual distinction much more ambiguous. In women possessing this peculiarity of structure we sometimes observe, for instance, the clitoris not only resembling the penis in size, but it has an indentation at the point of the glans, imitating the orifice of the urethra; and occasionally the glans is actually perforated to a certain extent backwards, or the body of the clitoris is drilled more or less imperfectly with a canal like that of the male urethra. In other instances the canal and orifice of the female vagina are, by an excess of development in the median line of the body, much contracted or nearly shut up, the vulva being closed by a strong membrane or hymen, and the labia cohering so as to give the parts a near resemblance to the united or closed perinæum and scrotum of the male. Further, in one or two very rare cases which have been put upon record, the ovaries and Fallopian tubes seem to have descended through the inguinal rings into the labia, thus giving an appearance of the presence of testicles; and a fallacy seems to have occurred in some cases from the presence of roundish masses of fat in this situation simulating more or less the same male organs.

Besides, it often happens in those women who present more or fewer of these peculiarities of conformation in the external genital parts, that the general or secondary sexual characters of the female are wanting, or developed in a slighter degree than natural, owing probably to the malformations of the external organs being often combined with some coexisting anomalies in those more important internal reproductive organs, the healthy structure and action of which at the time of puberty appear to exercise so great an influence on the development of the peculiar general conformation and moral character of the female. Thus the features are sometimes hard, the figure and gait rather masculine, the mammæ slightly developed, the voice is deep-toned, and the chin and upper lip are occasionally covered with a quantity of hair. In fact, in some marked cases the whole external character approaches to that of the male, or, more properly speaking, occupies a kind of neutral ground between that of the two sexes. Some of the more striking examples of this first variety of spurious hermaphroditism in the female will sufficiently illustrate the above remarks.

Dr. Ramsbotham * has briefly described the genital parts of an infant, that was christened and looked upon as a boy, until dissection after

name," (ανδρογυνεν και ειδος και ονομα.) Probably from the licentious purposes alluded to by Justin Martyr, or from the weak and imbecile character of hermaphrodite individuals, the word ανδρογυνος came in latter times to signify effeminate and luxurious. The ancient lexicographer Hesychius gives it this meaning; and Theodoret, in his Therap., speaks of Bacchus as being licentious, effeminate, and androgynous—(γυννις ων, και θηλυδριας, και ανδρογυνος.)

* Home's Comp. Anat. vol. iii. p. 317. On the peculiarities of the external genital organs in various African tribes, see a learned paper by Prof. Müller in his Archiv fuer Anatomie for 1834. Ht. iv. s. 319., with ample references to the observations and opinions of Levaillant, Barrow, Peron, Lesner, Lichtenstein, Burchell, Somerville, &c. See also Otto, in his Neue Seltene Beobachtungen zur Anatomie, p. 135, shewing the very prominent external female parts of different African tribes to consist differently, 1, of enlarged nymphæ, 2, of enlarged labia, and 3, of the enlarged clitoris.

† El. Phys. tom. vii. part ii. p. 81, 82.

‡ Dissertation sur les Hermaphrodites, p. 372. See also Homberg, De Excrescentiâ Clitoridis nimia, Jena, 1671; Tronchin, De Clitoride, Lugd. 1736; and Plonequet's Literatura Medica, art. Clitoris Magna, tom. i. p. 299.

death shewed that the sex was actually female. The uterus and other female organs (*fig.* 287, *c c c*) were present and apparently naturally

Fig. 287.

formed; but the clitoris (*b*) was fully as large, and in appearance closely resembled the penis of a male of the same age. At its anterior extremity there was a sulcus (*a*), which was not the entrance of the urethra, but terminated in a cul-de-sac.

Columbus* and De Graaf† give two similar examples of the same form of spurious hermaphroditism in young children, in which the true sex was only fully ascertained by dissection after death. In relation to the clitoris in the case described by Columbus, that author states that this organ was furnished with two muscles only, and not with four, as in the perfect male.

In a reputed hermaphrodite woman, Gallay‡ found after death the clitoris to be three and a half inches long, and three inches and four lines in circumference. The glans and prepuce were well developed. The urethra ran as in man through the body of the penis and its glans. The labia, nymphæ, vagina, &c. were natural, and the internal female organs, the ovaries, Fallopian tubes, and uterus, are described as scirrhous. This woman had been married, but never had any children; her catamenia, however, had been very regular. She had a considerable quantity of hair upon her face, and her voice was harsh and masculine.

In a child of two years of age, Schneider,§ on dissection after death, could find neither the labia externa nor interna, nor any trace of the ordinary cleft between them. The clitoris was an inch and a half long, and externally resembled most perfectly a male penis furnished with a glans and prepuce; but it was imperforate, having only at its anterior extremity a small spot marking the situation of the opening of the urethra in the male. Some lines below there was an opening by which the urine was evacuated. This opening formed the entrance to the vagina, which was found of the usual length, and with the characteristic rugæ. The canal of the urethra was found entering its roof, but in such a manner that the urine was always evacuated very slowly and by drops only from the external opening. All the internal female sexual organs were natural.

§ Jahrbücher der Staatsarzneikunde, (1809), s. 193.

M. Beclard* has left us a very detailed and interesting description of an example of spurious hermaphroditism referable to the present variety, and exhibited at Paris in 1814. The subject of the case, Marie Madeline Lefort, was at that time sixteen years of age. The proportions of the trunk and members, and of the shoulders and pelvis, and the conformation and dimensions of this last part of the body, were all masculine; the volume of the larynx also, and the tone of the voice were those of an adolescent male; a beard was appearing on the upper lip, chin, and region of the parotids; some hairs were growing in the areola around the nipple; and the mammæ were of a moderate size. The inferior extremities were furnished with an abundance of long hard hairs. The symphysis pubis was elongated as in man; the mons veneris rounded, and the labia externa were covered with hair. The clitoris was 10½ (?) inches (27 centimetres) in length when at rest, but somewhat more when erect; its glans was imperforate, and covered in three-fourths of its circumference with a mobile prepuce. The body of this enlarged clitoris was furnished inferiorly with an imperfect canal, which produced a depression in it, instead of that prominence of this part which exists in the male penis. This canal was pierced along its under surface and median line by five small holes capable of admitting a small stylet; and one or more similar apertures seemed to exist in it after it reached backwards within the vagina. The labia were narrow and short, and the vulva or sulcus between them was superficial, being blocked up by a dense membrane, which, under the pressure of the finger, felt as if stretched towards the anus over a cavity. At its anterior part, or below the clitoris, there was an opening capable of admitting a sound of moderate size, and this sound could be made to pass backwards behind the membrane closing the vulva, which, when felt between the point of the instrument and the finger, seemed about twice as thick as the skin. The urine was passed by this opening, and also, according to the report of the individual herself, through the cribriform holes in the canal extending along the inferior surface of the urethra. By the same opening the menstrual fluid escaped, as Beclard ascertained on one occasion by personal examination. She had menstruated regularly from the age of eight years, considered herself a female, and preferred the society of men.

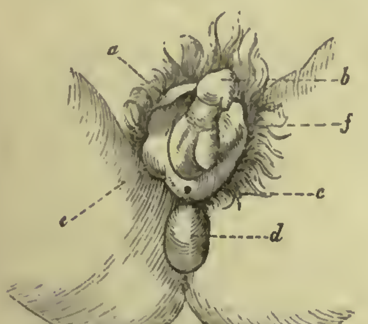
In this interesting case we have present all the secondary sexual characters of the male,

* Bulletins de la Faculté for 1815, p. 273.

with some of the female genital organs developed in so excessive a degree as to approach in several points the more perfect structure of them in man. The impossibility, however, as mentioned by Beclard, of finding any bodies like testicles in the labia or in the course of the inguinal canals, and more particularly the well-ascertained fact of the individual menstruating, can leave no doubt as to the nature of her sex. The perforation of the enlarged clitoris with the imperfect urethra is interesting, when compared with the peculiarities that we have formerly alluded to, of this part in the female Loris, as pointing out, what we have so often occasion to observe in human monstrosities, a type of structure assumed by a malformed organ similar to the normal type of structure of the same organ, in some of the inferior animals.

Arnaud* has represented and described at great length an interesting example of hermaphroditic malformation that seems referable to the head of spurious hermaphroditism in the female, although there are two circumstances in the history of the case which have led some authors to doubt the accuracy of this opinion; and the opportunity that was afforded of ascertaining the true structure of the parts after death was unfortunately lost through carelessness and neglect. The subject of the malformation, aged 35, passed in society for a female, and came to Arnaud complaining of a small tumour (*fig.* 288, *e*) in the right groin, which

Fig. 288.



had incommoded her much during her whole life. On examining this body, Arnaud was led to believe that it was a testicle, and he found a similar tumour (*f*) situated nearer the inguinal ring on the left side. The bags that contained them represented very exactly the labia externa. The clitoris (*a*) was two inches and nine lines in length, and placed between the labia at their upper angle. The glans (*b*) was well formed, and though imperforate at its extremity, it presented a small depression which ran backwards along the whole inferior border of the clitoris, indicating the situation of a collapsed urethral canal, that seemed pervious for some length at its posterior part, as it became distended when the patient evacuated the bladder. The orifice (*c*), however, from which the urine actually flowed, occupied the situation in which it exists in the perfectly formed female. There was not any vaginal opening, and the individual menstruated per anum. At each menstrual period a tumour (*d*) always appeared in the perinæum, which gradually increased in size, becoming, in the course of three or four days, as large as a small hen's egg. When the perinæal tumour had reached this size, blood began to flow from the anus, although no hæmorrhoids or other disease of the bowel was present. At these periods the individual had often experienced very alarming symptoms, and in order to avert these, Arnaud was induced to make an opening into the soft yielding space at which the perinæal tumour above alluded to appeared; and at a considerable depth he found a cavity two inches in circumference, and about two and a half in breadth, having projecting into it at one point an eminence which was supposed from its situation to be possibly the os uteri. At the next period the menstrual fluid came entirely by the artificial perinæal opening, and the usual severe attendant symptoms did not supervene. From inattention, however, to the use of the tent, the opening was allowed to become completely shut, so that at the sixth return of the menses they flowed again by the anus, and were accompanied by the old train of severe symptoms. The individual lived for several years afterwards. Her conformation of body was remarkable. Her skin was rough, thick, and swarthy; she had a soft black beard on her face; her voice was coarse and masculine; her chest narrow; her mammæ were flat and small; her arms lean and muscular; her hands large, and her fingers of very considerable length and strength. The form, in fact, of the upper part of her body was masculine, but in the lower part the female conformation predominated. The pelvis was wide and large, the os pubis very elevated, the buttocks large, the thighs and legs round, and the feet small.

In this remarkable instance, if we do not go so far as to conceive the coexistence of some of the internal organs of both sexes, we must, from the well-ascertained fact of the menstrual evacuations, allow the person at least to have been a female. In that case we can only suppose the tumours in the labia to be the ovaries descended into that situation; and to the same excess of development which has produced this effect, we may attribute the closure of the vaginal orifice, and the formation of the imperfect urethral canal in the body of the clitoris.

Spurious hermaphroditism from preternatural enlargement of the clitoris has been recognised among some of the lower animals. Rudolphi* has noticed a mare of this kind that had a clitoris so large as almost to shut up the entrance into the vagina. Lecoq† has detailed

the case of a calf which Gurlt* believes to belong to the present head. Neither testicles nor scrotum were observed externally, and the penis or enlarged clitoris, which occupied its normal situation, was apparently perforated by the urethra, and crooked upwards so as to throw the urine in that direction. Mery † shewed by dissection the true sex of a monkey, the length of whose clitoris had deceived some observers with regard to the true sex of the animal. The enlarged clitoris was furrowed on its inferior surface. The clitoris of the female Quadrumana is, as shall be afterwards more particularly mentioned, relatively larger than in the human subject, and retains in a greater degree the size and type of structure of this organ in the embryo.

We may here further mention that, as pointed out by Blumenbach,‡ the clitoris and orifice of the urethra are placed at some distance from the vagina and in front of it, in the rat, mouse, hamster, &c. This normal structure has sometimes been mistaken for an hermaphroditic malformation.§

2. *From prolapsus of the uterus.*—It may at first appear strange that this occurrence should ever lead to any difficulty in ascertaining the sex of the individual, though not only non-professional observers but even the most intelligent medical men have occasionally been so far misled by the similarity of the protruded organ to the male penis, as to mistake a female for a male. Of this circumstance some curious illustrations are on record.

M. Veay, physician at Toulouse, has inserted in the Philosophical Transactions of London, vol. xvi. p. 282, a brief account of the case of Marguerite Malause or Malaure, who was entered as a female patient in the Toulouse Hospital in 1686. Her trunk, face, &c. presented the general configuration of a female, but in the situation of the vulva there was a body eight inches in length when on its fullest stretch, and resembling a perfectly formed male penis in all respects, except in not being provided with a prepuce. Through the canal perforating this body she was alleged to evacuate her urine, and from its orifice M. Veay had himself an opportunity of seeing the menstrual fluid flow. After being examined by several physicians she was pronounced to be more male than female, and ordered by the civil authorities to exchange the name of Marguerite for that of Arnaud, and to wear male attire. In 1693 she visited Paris in her male habiliments, and reputed herself endowed with the powers of both sexes. The Parisian physicians and surgeons who examined her seem all to have accorded in opinion with the faculty of Toulouse, until M. Saviard|| saw her and detected the supposed penis to be merely the prolapsed uterus. He reduced the protruded organ, and cured the patient. Upon the enigma of her hermaphroditism being thus solved, she was permitted by the king, at her own request, to assume again her female name and dress.

Sir E. Home* detected a case of reputed hermaphroditism of the same description as the last, in a French woman of twenty-five years of age, who exhibited herself in London, and pretended to have the powers of a male. The cervix uteri was uncommonly narrow, and projected several inches beyond the external opening of the vagina. The everted mucous surface of the vagina had, from constant exposure, lost its natural appearance and resembled the external skin of the penis. The orifice of the os tincæ had been mistaken for the orifice of the urethra. The prolapsus had been observed at an early age, and had increased as the woman grew up.

Valentin† mentions another analogous instance of sexual ambiguity produced by a prolapsus of the uterus. In this case the husband mistook the displaced organ for the penis, and accused his wife of having "cum sexu virili necquicquam commune."

A case quoted at great length by Arnaud‡ from Duval, of reputed hermaphroditism in a person that was brought up as a woman, and married at twenty-one years of age as a male, but who was shortly afterwards divorced and imprisoned, and ordered again by the Court of Rouen to assume the dress of a woman, appears to us to belong very probably to the present division of our subject, the reputed penis being described as placed *within* the vagina. The recorded details of the case, however, are not so precise as to leave us without doubt in regard to its real nature.

In cases such as those now mentioned, in which the prolapsed uterus, or, more properly speaking, the prolapsed uterus and vagina have been mistaken for the penis, it appears probable that the neck of the uterus must have been preternaturally long and narrow, otherwise it would be difficult to account for the apparent small diameter and great length of the prolapsed organ. Among Professor Thomson's collection of anatomical drawings of diseased structures there is one of an uterus containing in its body a fibro-calcareous tumour, and having a neck of three inches in length. M. Cruveilhier§ has represented a similarly diseased uterus with a neck of between five and six inches. An organ shaped in this manner, whether from congenital malformation or acquired disease, would, when prolapsed for some time, represent, we conceive, a body resembling in form and size those observed in Saviard's and Home's cases. The prolapsus arising from a protrusion of an ordinary shaped uterus is generally of a greater diameter and roundness.

This second species of spurious female hermaphroditism is not observed among the lower animals.

Malformed males have been more often mistaken for females than the reverse. The varieties of malformation in persons actually male, that are liable to lead to mistakes with regard to their true sex, appear to be, 1st, extrophy or extroversion of the urinary bladder; 2d, adhesion of the inferior surface of the penis to the scrotum; and 3d, and principally, fissure of the inferior part of the urethra and of the scrotum and perinæum.
