The main causes of severe pain are refractive, accommodative and muscular errors, and essential inflammation of the branches of the fifth nerve, especially the supraorbital. In the first classification, in which the refraction or the muscles are at fault, the absence of

severe inflammatory symptoms, together with diminished vision or diplopia and headaches, will plainly point to the cause of the trouble. It is worth while to note, however, that in the most marked neurasthenic cases of astigmatism and muscular weakness in which the patient may complain of severe headaches and symptoms even amounting to epilepsy, the acuity of vision may be normal. In the second group, inflammations of the eyeball, the pain is generally severe. Under this head will come keratitis, ulcers of the cornea, iritis, iridocyclitis, irido-choroiditis and acute and subacute glaucoma. Retinitis, choroiditis, optic neuritis and scleritis often pursue their course without severe pain. In the essential neuralgias, that of the supraorbital branch of the fifth will be recognized by the extreme tenderness on pressure at its point of exit. Supraorbital and temporal neuralgias, though occurring alone, are almost a constant accompaniment of the inflammations of the cornea, iris and ciliary body.

Burning and smarting must be distinguished from pain. These are generally due to inflammations of the lids and conjunctiva, and a careful examination will generally reveal conjunctivitis, trachoma, blepharitis or superficial abrasion of the cornea as the cause.

3. Redness accompanying manifest inflammations of the eye may result either from the conjunctiva or, as the ocular conjunctiva is transparent, may come from the deeper sclera.

The conjunctival trouble is diagnosed from the tessellated pattern formed by the injected conjunctival vessels. Owing to the transparency of the conjunctiva and the looseness with which it is applied to the globe, any scleral injection beneath is easily detected. The conjunctival redness is unaccompanied by severe pain and more or less secretion will be present, which will be mucous, mucopurulent or purulent, depending on the cause and on the degree of the inflammation. With the deeper redness the fine, straight circumcorneal ciliary vessels will be injected. These deeper injections occur in keratitis, iritis, glaucoma and scleritis. Pain is often severe. It must be remembered that these deeper inflammations are generally accompanied by a varying degree of conjunctivitis, this complicating the original affection. On the other hand, the conjunctival affections often extend to the cornea, giving, in addition to their own symptoms, those of keratitis. This complication of symptoms often renders diagnosis somewhat difficult. It is perhaps not out of place to mention in this connection edema of the conjunctiva. When this occurs early in the course of a purulent conjunctivitis in the adult, the infection is probably due to the gonococcus, and there is imminent danger to the cornea. Chemois often occurs as the result of trauma.

4. One other important symptom should be recognized, the sluggish or immobile pupil. The pupillary reaction should be taken: for (1) Direct light stimulus; (2) consensual reaction; (3) the reaction of accommodation and convergence. In direct light stimulus the light is thrown into the eye being examined, the other eye being excluded from any light whatsoever. The consensual reaction consists in the response of the shaded eye to light stimulus thrown in the fellow eye. This

test is useful in determining cortical lesions in the occipital lobe, in which case hemianopsia would be an accompanying symptom. The reaction of convergence is obtained by having the patient change his gaze quickly from distant vision to the observation of some object near by. It is useful, as will be mentioned later, in testing for the Argyll Robertson pupil.

A failure of the pupil wholly or in part, to react, may be due to a lesion. (1) In the iris itself; (2) in the third nerve; (3) in the brain centers; (4) in the light conduction paths. The lesion in the iris itself can generally be made out as a swelling or an atrophy of the iris, or an anterior or a posterior synechia. Immobility points to iritis, either old or recent, or to glaucoma; in the former the pupil will be contracted, in the latter dilated. The significance of immobility from other causes demands more minute and detailed statement than is possible here. I will simply refer to a few indications which may be useful. The pupil immobile to light-stimulus and yet responding to accommodation and convergence and known as the Argyll Robertson pupil, is one of the cardinal symptoms in locomotor ataxia. Irritation or paralysis of the pupil-contracting center in the floor of the third ventricle will produce a contracted or dilated pupil respectively. The contracted pupil then is found in the early stages of inflammatory conditions of the brain and meninges. The dilated pupil would follow sufficient pressure in the ventricles.

If these facts are borne in mind and the physiology of the pupillary tracts are recognized, the pupillary action will be intelligently interpreted and will form a valuable indication of the condition of the cerebral centers in constitutional diseases and in brain-surgery.

5. The tension of the globe is ascertained by palpation with the 2 index fingers, the patient in the meantime looking downward, thus bringing the lid over the globe and the sclera under the palpating fingers. The tension thus obtained is compared with that of the observer or with some normal eye. It is also well to compare the 2 eyes. One finds increased tension in glaucoma, certain forms of iridocyclitis, and as the result of trauma. Decreased tension may result from a ruptured globe, degeneration of the globe, and myopia with detachment of the retina.

6. In the final classification of gross lesions visible without the aid of the ophthalmoscope, we bring under one heading a few important aspects of the eye, which, being readily recognizable, should not pass unobserved. Roughness and elevation of the palpebral conjunctiva probably indicates trachoma, vernal catarrh, or a ruptured chalazion. Haziness of the cornea indicates a recent or old keratitis. Photophobia and laceration are generally due to some corneal lesion. A dirty color of the iris is found in iritis. A white spot over the pupil may mean cataract, or an inflammatory pupillary membrane, and a reflex observed from the pupil in a child may signify that rapidly fatal dread destroyer, glioma.

Freezing Mosquitos.—William C. Lovere, the City Treasurer of Evanston, it is said, thinks by working on the system by which steam heat is furnished from a central plant, he can perfect a plan by which liquid air may be suddenly turned on the north shore suburb and chill the mosquitos to death.

FORMALIN IN THE TREATMENT OF SUPPURATIVE OTITIS MEDIA.

BY

NATHAN G. WARD, M.D.,

of Philadelphia.

Otologist and Laryngologist to St. Agnes' Hospital; Assistant in Laryngology, Jefferson Medical College Hospital; Ophthalmologist to Charity Hospital.

There is no ear affection which the family physician is more frequently called upon to treat than otorrhea, and there is perhaps no ear trouble less amenable to treatment. The idea prevails among the laity that no attempt should be made to stop the discharge and so long as there is no pain advice is rarely sought.

Many children who live among the most unhygienic conditions, surrounded by filth, poorly clothed and half fed, suffer with a constant discharge from one or both ears. Hospital clinics are largely made up from this class, and it is extremely difficult to get them to carry out any mode of treatment, therefore the simplest must be adopted. In these cases I have obtained the best results with formalin, and have adopted the following plan, or slight modifications thereof: The ear is thoroughly cleansed, after which the canal and drum are examined, and note taken of the size and situation of the perforation, with the degree and extent of the inflammation. If the ear is filled with thick, tenacious secretions, and the perforation is small or unfavorably situated to allow free drainage, an incision is made in the posterior-inferior quadrant of the drum. This is rarely necessary, as in most cases there are large perforations, or the entire drum is destroyed. After cleansing, the head is inclined to the opposite side and an aqueous solution of formalin, 5 drops to the ounce, is instilled with a medicine dropper, enough being used to fill the middle ear and external canal. No packing is employed because this class of patients almost invariably remove it and stuff the canal with cotton, which prevents drainage.

Home Treatment.—If the secretions are thick, lysol is prescribed, 15 to 30 drops in a half glass of warm water; with this the ear is syringed, using a soft rubber pus-syringe; sufficient force to cause dizziness cannot be used, nor does it force the pus into the mastoid cells. All syringing is stopped as soon as the discharge is lessened to a degree so as not to block the canal. In those cases not requiring syringing, and also 10 minutes after syringing in those that do, the patient is directed to lie down on the opposite side and 5 to 10 drops of the formalin solution, warmed by pouring it in a spoon and holding it over the gas jet or lamp, or by setting the bottle in warm water, is dropped in the ear. The patient lies in this position for 10 minutes to allow the fluid to permeate and come in contact with all parts of the tympanum; this treatment is repeated night and morning.

I have treated 40 cases by this method. In 35 the discharge ceased entirely in from 3 to 15 days, the average time being about a week; in 5 cases the discharge was lessened but not entirely checked; in 2 of these the treatment was not faithfully applied and in the other 3 there was bone necrosis. In all these cases the fetid odor entirely disappeared in from 2 to 5 days before the cessation

of the discharge; even in the 5 cases not cured there was no odor so long as the treatment was faithfully carried out. After the discharge had ceased for a week the treatments were reduced to 1 a day, then every second day, and finally every third; I have found this necessary to prevent recurrences.

In acute cases 1 to 3 drops of formalin to the ounce is used, as stronger solutions produce excruciating pain. In the most obstinate cases and those with small granulations, alcohol is added.

Formalin	5 drops,
Alcohol (95%)	2 drams,
Aqua	q. s. ad 1 ounce.

Small granulations are quickly reduced by this solution and they do not reappear, but large ones require curetment. As a result of the treatment ulcerations were quickly healed but it had very little effect upon caries of bone.

In a few cases the fluid passed down the eustachian tube and produced severe burning and a choking sensation in the nasopharynx and throat. No serious results were caused thereby but it was unpleasant enough to cause the patient to stop its use; this was entirely prevented by directing the patient to lie on the back with the head partially inclined to the opposite side. Vacher reported a similar effect during his irrigations.

Proper treatment must be applied to the nose and nasopharynx in each case, and attention given to the general health. The excretions are stimulated by small doses of calomel, followed by full doses of sodium phosphate; if there are any indications of worms, anthelmintics are prescribed. As a tonic, arsenic sulfid gr. $\frac{1}{10}$ or calcium sulfid gr. $\frac{1}{4}$, 4 times a day to a child 8 years old, gives excellent results. If the patient's health is again reduced below the normal and the catarrhal process in the upper respiratory tract becomes worse, there are recurrences as from all other methods of treatment.

The reports of the use of formalin in suppurative otitis media prove its value in this disease and warrant its continued use.

Vacher¹ used a 5% or 10% solution. In his earlier experiments he cocaineized the ear before using the formalin. Later, he found that 5% solutions did not irritate and were efficacious, therefore the ear was irrigated with this solution and sterilized gauze or cotton dipped in the same left in the ear. When suppuration was profuse and fetid this application was made daily, otherwise longer periods intervened.

Randolph², in commenting on the use of formol in diseases of the ear (by the method of Vacher), said that his patients with whom he had used it complained so bitterly of the pain following the irrigations that he was obliged to forego its further use. He also adds, "I am constantly hearing of the good formol is doing in this class of cases and am disposed to give it a more extended trial." He thought it wise, however, to thoroughly cocaineize the ear before irrigating.

Cipriani³ reports 10 cases treated with prompt relief. A 2% solution was injected followed by insufflation of iodoform. His conclusions were that formalin assisted healing, protected against excessive granulations, and

improved the hearing by freeing the middle ear of pus.

The antiseptic powers of formalin have been the subject of many experiments and it seems to be pretty well established that it deserves a place in the first ranks. Kinyoun⁴ in his experiments found that a 1:2,000 solution prevented the growth of the bacillus of anthrax.

Walter,⁵ after an exhaustive series of experiments, states that formalin in the strength of 1:1,000 arrests the growth of the germs of anthrax, cholera, typhoid fever, and diphtheria, and of *Staphylococcus pyogenes aureus*. In 1% solutions it kills pure cultures of pathogenic germs in an hour. In dilute alcoholic solutions the effect is more intense.

Bird⁶ states that formaldehyd gas, 1:2,500 solution (which equals 1:100 of formalin) destroys the most resistant microorganisms in an hour. According to Bird, Hoffman discovered formaldehyd in 1867. Loew subsequently demonstrated its germicidal powers, and Trillat suggested its use as a powerful disinfectant free from poisonous properties. It acts as a powerful reducing agent, and Walter asserts that it almost immediately and entirely destroys the most offensive odors.

From these reports it is evident that high percentages of formalin in the treatment of suppurative otitis media are unnecessary. Besides, their caustic action inflicts needless pain, and equally good results can be obtained with weaker solutions. As in the use of other remedies in any branch of medicine, the dose or strength of the solution should be regulated to suit each individual case, following the rule to use the smallest quantity with which the desired effect can be obtained. In the use of formalin I find that the strength which causes momentary smarting produces the best results. In the average case, 5 drops to the ounce, which is practically a 1% solution, is sufficient; although I would not hesitate to increase its strength until this effect is obtained.

By the use of this method, cocainizing is unnecessary, and what is of still greater importance, the escharotic effects of the stronger solutions are avoided. Weak solutions increase cellular activity, which results in the casting off of the dead epithelium, stimulating the living cells to a healthier condition, reestablishing a more nearly normal secretion, and toughening the cells of the middle ear to withstand exposure to atmospheric changes, thus lessening the liability to continued infection through the external auditory canal.

Conclusions.—By the judicious use of formalin the following results may be obtained:

1. Fetid odor quickly disappears.
2. There is an early cessation of the discharge.
3. Protects against the formation of granulations, and small granulations are destroyed by alcoholic solutions.
4. Promotes healing of ulcerated mucous membrane, skin abrasions, and inflammation of the external auditory canal.
5. Retards, but does not entirely check bone necrosis.

SYNCHRONOUS AMPUTATION OF BOTH THIGHS FOR GANGRENE OF FEET UNDER SPECIAL COCAINIZATION.

BY

GEORGE G. HOPKINS, M.D.,

of Brooklyn, N. Y.

James Bell, aged 68 years, a farmer, was admitted to St. John's Hospital, October 26, 1900. His family history was good and he has always been healthy, never having had any serious disease, except pneumonia, when 7 years old. He is a great walker and living on a farm has led an outdoor life. About 5 weeks ago he came to the city to visit his sister and shortly

after was attacked with "chills and fever" of daily recurrence every afternoon. The physician who called diagnosed malarial fever. At the time there were no symptoms referable to the lower extremities. A week subsequent to the malarial attack, the toes of both feet became slightly edematous. The day after the swelling began there was a sense of uncomfortable heat in the feet. Antiperiodic treatment was instituted and in 24 hours the sensation of heat was relieved, to be followed 2 days later by a sensation of cold in both extremities. The supposed "malaria" lasted a week and "disappeared when the feet began to trouble him."

The patient was able to walk with difficulty for 2 days after the swelling in the feet had occurred. There was a sense of great weight in the feet, this with the increase in swelling after 48 hours prevented locomotion. There was no pain in attempting to walk, but the feet were clumsy and heavy. The feeling

weight continued and to this was added a crawling feeling. The sense of weight disappeared after a few days and what he describes as "crawling and creeping" sensations increased, growing more and more uncomfortable day by day. His chief complaint when admitted was inability to move his feet. Physical condition: Marked general hyperesthesia. Heart action weak. Lungs normal. Very slight atheroma of arteries.

Left Foot.—All the toes had turned black and were mummified. The rest of the foot was of a red-brown color. An indistinct line of demarcation extended from the internal malleolus (upper border back to insertion of tendo-achillis, coming up on the outer side below the external malleolus), passing across the arch of the foot to the internal malleolus. The skin on the outer side of foot was not affected. The circulation in the popliteal artery was feeble and in the femoral below the normal.

Right Foot.—Condition to toes same as on left foot. Line of demarcation $\frac{1}{2}$ inches nearer the toes than on the left foot. Circulation in the limb below normal. Pulsation in popliteal artery was feeble and in the femoral less strong than usual.

This bilateral gangrene appearing simultaneously, in both feet, with evident checking of the arterial flow in both femorals and below, indicated an interference with circulation in the abdominal aorta.

The examination of the urine was very carefully made and demonstrated the *entire* absence of either sugar or albumin.

At operation, owing to the poor blood-supply in the limbs it was desirable to avoid the use of a tourniquet or Esmarck bandage. I therefore had digital compression made and so skillfully was this done by Dr. Duffield that there was practically no arterial blood lost during the operation, which was done November 7, 1900, at 3 p. m. under spinal anesthesia with cocain.

Twenty minims of a 2% solution of cocain hydrochlorate, was injected into the sac of the spinal canal, the needle being entered between the 4th and 5th lumbar vertebrae. This solution had been in the sterilizer a long time and must have been decomposed, and it produced no effect on the system. I prepared a fresh solution having the water and container thoroughly sterilized and the cocain hydrochlorate dropped into it. Twenty minims of this fresh solution was now injected, and complete anesthesia of the whole body below the shoulders was produced.

I now proceeded to amputate the limbs at the lower third of the thigh on both sides. In order to save the tissues as much as possible from pressure the amputation was done by transfixion, cutting from within outwards, in this way avoiding any bruising of the skin. There were only 2 cuts made on each limb, each flap being made by a single cut. In this way we left as much muscle and adipose tissue as possible to support and nourish the flaps. The periosteum was pushed back well after being divided and each femur divided with the saw 6 inches above the kneejoint. The arteries were ligated with chromicized catgut. The muscles and flaps approximated with deep silkwormgut sutures. No drainage was used.

The only sensation experienced by the patient was a prick when the point of the amputating knife was entered through the skin, and when the first sciatic nerve was cut through he remarked, "something is going wrong in my foot."

The patient talked freely during the whole operation and did not seem to experience any shock. He was returned to bed in fine condition and a half-hour after the operation, in answer to my inquiry as to how he felt, said "I feel fine."

There was no nausea; this is the only case in which I have seen it absent when I have used cocain as an anesthetic.

At 9 p. m. he became very restless and had to be tied in bed. Normal saline solution administered by rectum. On the eighth, I ordered milk punch with $\frac{1}{2}$ ounce of whisky 3 times a day and beef peptonoids every 4 hours. In the night I gave 3 drams of whisky every 4 hours. He slept but little. On the ninth he picked at bedclothes and was very restless day and night. The next day the stumps were dressed and both were in good condition and perfectly healthy. The condition was about the same on the eleventh. The punch was continued every 4 hours and strychnin sulfate, grain $\frac{1}{16}$, was given every 3 hours. He was quiet during the day on the thirteenth, but delirious during the night. The stumps were inspected and their condition was good. On the fifteenth I found a stitch-abscess in 3 sutures on right leg and 2 in left leg; these 5 stitches were removed. Some discoloration was noticed in the flap of the right stump on the sixteenth and the flaps were separated and some pus discharged. A rubber drainage and tube was inserted. On December 14 a piece of chromicized gut that had been used to ligate the femoral artery was discharged from the wound of the right stump. Patient is gaining in health and strength, is about in a wheelchair.

On January 9, 1901, the patient was discharged with 2 good healthy stumps and apparently in perfect health.

This case is an illustration of the utility of spinal anesthesia in a certain class of cases. In this case chloroform and ether were contraindicated on account of the debilitated condition of the heart. Spinal anesthesia by cocain is being very much abused by indiscriminate use by the profession at large and is in danger of losing its proper place as a useful anesthetic agent in cases in which chloroform or ether are contraindicated. It is not a substitute for these, neither is it free from danger, as the number of fatal cases that have found their way into print go to prove.

In one case in my own hands I came very near sacrificing the life of my patient to this procedure, as there was no anesthetic effect, and only the cocain-poisoning symptoms were manifest.

PERMANENT GOLD PREPARATIONS.

BY

EMMA L. BILLSTEIN, M.D.,

of Highlands, N. C.,

Formerly Director of the Laboratories of Histology and Embryology of the Women's Medical College of Pennsylvania.

The marked selectivity of gold chlorid for nerve tissue and the fleeting beauty of the preparations made by the usual methods, are facts linked together by dictum and experience.

Three years ago, in February, 1898, I made some gold preparations of the intercostal muscles of a rabbit. They were successful, but with the authoritative and emphatic words of Bolles Lee in mind—"I warn the reader against indulging the hope that, with all possible precautions, his preparations will retain all their beauty for more than a few weeks" (*Vade Mecum*, fourth edition)—it did not occur to me to doubt their impermanence.

A year later, the appearance of the slides led me to reexamine them under the microscope. Contrary to authority and expectation, they were unimpaired; color, clearness and precision were as fine as on the day they were mounted. Then I repeated the work, again using the intercostal muscles of the rabbit and proceeding

according to the method previously followed. Again the impregnation was successful, and, as before, exhibited not only the motor axones with their terminal organs but also the plexus of sensory fibrils. The latter, as well as the earlier preparations, now 2 and 3 years old, respectively, are still in a state of preservation and apparently will endure indefinitely. This identity of results, which can scarcely be accidental, induces me to describe the method by which the preparations were made.

A mixture of 8 parts of a 1% solution of gold chlorid and 2 parts of formic acid is boiled 3 times and then cooled. Very thin pieces of tissue are put into the cold mixture, which must be kept in the dark. After 1 hour the tissue is washed in distilled water and then placed in a mixture of 10 parts of formic acid and 40 parts of distilled water, and exposed to diffuse daylight. The reduction occurs in from 24 to 48 hours, when the violet tissue is transferred to 70%—and after 24 hours to 90%—alcohol and kept in the dark for at least a week. It is then ready for the final manipulations and may be teased and mounted in acidulated glycerol or imbedded and cut into sections.

Böhm and Opperl¹ ascribe this method to Stöhr and the foregoing description will be found in his "Textbook of Histology." It is similar to Ranvier's² technic, "Procédé de l'or bouilli." But, although the 2 methods agree in some points—as in the reagents used and in the proportions of the mixtures—they differ in essential processes. Stöhr advises longer boiling of the gold chlorid and formic acid mixture, a process which is said to facilitate the reduction of the gold and thereby to promote its selective action on the nerve-tissue. Another important factor in obtaining successful and permanent results is the modus operandi of reduction. The tissue must be so exposed that it is penetrated by the light, which is conveniently accomplished in a test-tube or in a beaker placed on a sheet of white paper. Sunlight is unnecessary.

In the fifth edition of his work Lee insists less on the impermanence of gold preparations and says "that the greater care taken in preparation, and particularly the greater care taken to ensure thorough reduction of the gold, the longer will be the life of the preparation."

The Michael Reese Hospital, of Chicago, is the recipient of a gift of \$25,000 from the children of Jacob and Hannah Rosenberg. This sum is supplemental to a bequest of \$10,000 provided for in the will of Mr. Rosenberg, filed a year ago. The will also provided that \$5,000 be given to the United Hebrew Charities, which is affiliated with the Michael Reese Hospital. The gift is without condition, but it is understood to be the wish of the donors that it be used as a nucleus for a fund to erect a larger hospital building. Last year, 1,841 cases were treated at the hospital, 1,353 of these being charity cases.

Private Hotel and Sanitarium.—In view of the fact that the sick can have better attention in a hospital than in a home, and to fill the need for satisfactory quarters where opulent patients may be cared for during difficult operations or the process of cures, and to accommodate friends and relatives and secure for them quarters near the sick, the erection of a hotel combined with a sanitarium is purposed by 5 of the leading physicians and surgeons of Chicago. The cost is estimated at \$400,000, and in addition to the heads of the institution a staff of attending physicians and a corps of nurses will be enlisted.

AN IMPROVED BEDSTEAD FOR INVALIDS.

BY

E. E. MUNGER, M.D.,

of Spencer, Ia.

The late Mr. Lawson Tait made this observation: "There is no article in ordinary life-long use with which we are so closely related, with which we spend so much of our time, which we occupy with such affectionate readiness and leave with such affectionate regret as our bed. Yet how little care is given to the principles of its construction and use. It was this matter of the bed during illness, especially in surgical ailments, which first forced the question of its proper construction upon my notice. In cases of illness the nurses are fearfully handicapped, and the number of serious illnesses acquired by young women and caused by the strain of lifting heavy and helpless invalids has been very large in my experience."

Ashhurst's Encyclopedia, and the American Textbook of Surgery, are authorities, for the following statements respectively: "All patients who are obliged to lie in bed for any length of time are often greatly relieved by even a very slight change of posture, from the shifting

of the bearing points of the body," and "recovery is hastened by enabling a patient to gradually sit up after a serious surgical operation and during the repair of a wound."

In view of these facts it is apparent that there is need for a bed whereon the invalid may rest in comfort, and, without effort on his part, be afforded such desirable changes of position as are not contraindicated by his physical condition. The bed illustrated herewith is of such construction that the patient can be afforded every possible comfort in the way of position and conveniences; at the same time it serves as an assistant to the nurse or other attendant so that the patient, without regard to the cause or degree of illness, may be handled and have his wants attended to without undue labor or exertion.

Briefly described, the bed consists of a strong frame with an ordinary woven wire spring mattress, the frame of the latter being transversely pivoted near its center. This mechanism permits a depression of the head and trunk in cases of narcosis or extension, or an elevation to a semi-sitting posture. A back rest accentuates the latter until an upright position is secured. Sliding downward

in this position is prevented by a seat board placed between the hair mattress and the one of woven wire. To the seat board are attached two limb supports, each working independent of the other, and so adjusted that one or both of the lower limbs may be placed at any desired height without regard to the position of the trunk of the patient. A longitudinal central slit in the hair mattress permits the introduction of a bedpan, thus avoiding the elevation of the hips caused by using the ordinary bedpan. With the seat board in position

beneath the hair mattress, the bed may be readily converted into an upholstered chair form and the patient in many cases relieved from the strain of a long continued lying posture.

The bed is supplied with lateral revolving side bars or shafts, to which may be attached broad bands that pass underneath the patient. Suitable means are provided for rotating the shafts outwardly, thereby raising the patient above the mattress, thus facilitating a change of bedding, or the application of bandages, and affording access to any part of the body. This mechanism also permits the introduction of a suitable bathtub directly

beneath the typhoid patient, into which he may be lowered.

With this bed, fractures necessitating a long confinement may be treated and the patient made comparatively comfortable without danger of displacement. For the prevention and treatment of bedsores, in using enemas or douches, and in lessening the work of both physician and nurse, the utility of this bed is obvious. Its advantages are apparent alike to the surgeon, gynecologist, obstetrician and the general practitioner. It does not differ in general appearance from the ordinary hospital bed. It is simple in construction, certain in action and easily operated by anyone.

EXCESSIVE EOSINOPHILIA IN TRICHINOSIS.

BY

A. J. PATEK, M.D.,
of Milwaukee.

Since the discovery by Dr. Thomas R. Brown, of Johns Hopkins Hospital, in 1897, that the eosinophile cells of the blood suffered an enormous increase in cases of trichinosis, corroborative evidence has been brought forward; the reported cases, so far as I am aware, numbering 20. Considering the small number of the cases, and also the fact that trichinosis is rather an uncommon disease (one might more correctly say that it is a disease not often recognized, for doubtless it is less uncommon than we think) all additional evidence that places this new diagnostic sign upon a secure footing will be welcomed. I have but a single case to report:

A young man, aged 21 years, ate pork sausage that was not thoroughly cooked, and soon thereafter suffered from gastrointestinal disturbances. He suffered from severe muscular pains which in a few days became milder and then disappeared altogether. The sausage, being suspected, was examined and found to contain trichinae. I heard of this case and requested the attending physician, Dr. Fred. Weber, to furnish me with some of the patient's blood in order that I might examine it. My request was granted and I have the pleasure of corroborating the statements of the other observers.

It is probable that the degree of eosinophilia is dependent upon the severity of the muscle involvement and the attendant symptoms. Most of the cases described were seen in the acute stage and showed 50 to 60% eosinophilia. In this case late in the progress of the disease 30% of the leukocytes were eosinophilous, the differential count being as follows:

Eosinophile	30%
Polynuclear	55 "
Transitional	7 "
Large mononuclear	5 "
Small mononuclear	3 "
	100%

Added interest attaches to the cases in which diagnosis is made from blood examination, for here the utility of this sign is evident; although in this case the evidence was sought in the blood, after the diagnosis had been established. It affords one much pleasure to have an opportunity to contribute to the value of this new sign of trichinosis. So far as I am aware, in no other disease has such an excessive degree of eosinophilia been found, and therefore until evidence to the contrary is presented we are tempted to consider it diagnostic. There is no doubt that—as soon as the value of the sign is more generally recognized—it will be discovered that trichinosis is, after all, not very uncommon, and that for many an obscure (rheumatic?) muscle-pain we may thus find satisfactory explanation.

Dr. Ernst Stadelman, director of the medical department of the Urban Hospital, Berlin, and professor in the University of Berlin, has just died. Before coming to Berlin Dr. Stadelman was associated as privatdozent with Naunyn, then at Königsberg, and Erb at Heidelberg. He was also an assistant professor at the Russian University of Dorpat before the Russian Government began to so thoroughly Russlanize all its Universities. His chief scientific contributions dealt with disorders of metabolism. He was first to show the importance of the presence of oxybutyric acid in diabetes and especially in diabetic coma. He also thoroughly studied peptonuria, the origin of icterus and the metabolism of the albumins.

2. An Address on the Symptoms and Modern Methods of Diagnosis of Stone in the Bladder, Kidney and Ureter. P. J. FREYER.
3. Notes on 206 Operations for Stone. W. F. ADAMS.
4. A Method of Sterilizing Soft Catheters. HERBERT T. HERRING.
5. A Case of Almost Universal Ankylosis. T. K. MONRO.
6. Strangulation of Meckel's Diverticulum. KEITH CAMPBELL.
7. Case of Cancer of the Larynx with a Long Course. E. DONALDSON.
8. Furunculosis of the External Auditory Canal Simulating Mastoid Periostitis. JAMES GALBRAITH CONNAL.

1.—Renton for convenience divides the inflammatory affections of the vermiform appendix into 3 forms: Catarrhal appendicitis; appendicitis with swelling and acute perforating appendicitis. He says operation is recommended as a rule after a second catarrhal attack, that the appendix is apt to give way after 2 attacks and lead to a third and more serious form. When swelling is present always examine the rectum, bulging may be detected, and the abscess should be opened at that point. When the abscess is backwards, it may be opened without entering the free abdominal cavity, if downwards or inwards, this cavity must be opened and protected by gauze. Cases of acute perforative appendicitis should be classed with ruptured gastric or typhoid ulcer. Patients operated on before the third day may recover, but after the third day the chances of recovery are very small. Operate, if possible, within 6 hours of the beginning of the attack. [C.A.O.]

2.—Freyer mentions 4 characteristic symptoms of stone in the bladder: (1) Increased frequency of micturition is the earliest and most constant symptom. (2) Pain, reflex in character, situated near the posterior aspect of the glans penis, and gradually increasing in intensity toward the end of the act of micturition, is almost invariably present. The pain diminishes in intensity as life advances, being much more severe in children than in aged persons. (3) Hematuria, gradual in onset, occurring toward the end of micturition and increased by exercise is the symptom which generally causes the patient to seek medical advice. (4) Sudden stoppage of the flow of urine is more common in the earlier stages of stone. Many other diseases which present somewhat similar symptoms are discussed. Of 1,000 operations for stone in Freyer's practice almost 98% were in males. The diagnosis should be confirmed by the sound, having first made a rectal examination by the finger to ascertain the condition of the prostate. Mercier's solid steel sound is thought to be the best. The aspirator and cannulas employed in Bigelow's operation may be used as a means of diagnosis and are very valuable in many cases. A suprapubic operation may be necessary for a diagnosis and, as a rule, is the preferable one. Pain in the loin corresponding to the affected kidney is as a rule the earliest and most constant symptom of renal calculus. The testicle is generally retracted and gastrointestinal disturbances with reflex disturbances of the urinary tract are frequently present. The ex-ray is valuable as a means of diagnosis. The symptoms of stone in the ureter are usually extremely obscure unless the stone is impacted in the lower end of the ureter. Leiter's electric cystoscope has been valuable when the stone is in this position. [C.A.O.]

3.—Notes on 206 operations for stone by Adams show 6 deaths. Lithotripsy was the operation generally used and was successful in the smallest boys; 48 cases were in boys under 10 years; 15 were in children under 3 and all did well. Lithotomy was performed only when lithotripsy was impossible or inadvisable. The mortality was naturally higher, 3 of the 36 patients operated on died. [C.A.O.]

4.—Herring considers first the various methods commonly adopted for sterilizing soft catheters and then describes a process that he thinks more efficient. He finds that water at 150° F., even for 30 seconds, is a reliable sterilizer of catheters for ordinary work. An apparatus is described that allows the easy and rapid sterilization of instrument and lubricant by this

method, both being free from irritating chemical antiseptics. [C.A.O.]

5.—Monro reports a case of almost universal ankylosis. The articular affection was first noticed in the young man at the age of 18, and at the age of 20 he was forced to give up work. From the age of 22 till his death at 46 he was completely confined to bed. The disease in each joint began with pain, followed by swelling and ultimately by fixation. His death was apparently caused by an accumulation of bronchial secretion. Permission was refused even for an external examination of the body after death, but the case appears to correspond to the subacute type of the very rare disease described by Dr. Joseph Griffiths as universal bony ankylosis or arthritis ossificans. [C.A.O.]

6.—Campbell reports a case of intestinal obstruction due to strangulation of Meckel's diverticulum in a man of 70, which is of surgical as well as of pathologic interest. The diagnosis was strangulated left femoral hernia with peritonitis. Operation was decided against on account of the patient's general condition. Necropsy revealed the fact that the bowel joined the ileum at right angles, being attached 3½ feet from the ileocecal valve and arose from the lower and anterior aspect of the intestinal tube. The diverticulum was 4¼ inches in length and resembled the ileum. It is interesting that this fetal relic should have persisted in such proportions, and from a surgical point of view that this, evidently the most freely movable of the abdominal contents, should have been forced into the canal by the intraabdominal pressure, and that, having become adherent at its extremity, a volvulus, apparently secondary in point of time, should have formed. The chief danger in these cases is the presence of a fibrous band, but in this instance the diverticulum itself produced the obstruction which gave all the signs of being complete. [C.A.O.]

7.—Donaldson reports a case of cancer of the larynx of 9 years and 1 month duration. For a long time a benign growth was diagnosed. The fact emphasized is that a warty laryngeal growth in an elderly person may present symptoms of a benign tumor for about 8 years and in the end turn out to be malignant. The microscope proved that the growth was an epithelioma. [C.A.O.]

8.—Connal reports 2 cases of furunculosis of the external auditory canal, in which the clinical picture is that of mastoid periostitis. The difficulty in diagnosis is increased if there is—as sometimes happens—a coexisting purulent otitis media. A thorough inspection of the external auditory meatus when the presence or absence of a localized furuncular swelling with its attendant sensitiveness to touch with the probe will settle the diagnosis. [C.A.O.]

The Lancet.

May 25, 1901. [No. 4056.]

1. An Address on the Operative Treatment of Abscess when Situated in the Brain. CHARLES A. BALLANCE.
2. The Erasmus Wilson Lectures on the Pathology and Diseases of the Thyroid Gland. WALTER EDMUNDS.
3. The Surgical Treatment of Chronic Ulcer of the Stomach. A. W. MAYO ROBSON.
4. Analysis of Stools and Urine from Epileptic Patients Under Treatment with "Brominal," Compared with Similar Specimens from Patients Under Potassium Bromid. W. HARRISON MARTINDALE.
5. Two Cases of Carcinoma Treated with Cacodylate of Soda. EDWARD MARTEN PAYNE.
6. Acute Colitis in Children. EDMUND CAUTLEY.

1.—Ballance, in an article on the operative treatment of abscess of the brain, states that the abscess may be latent, producing only general symptoms until excited to renewed activity by some other condition. An acute abscess and an old encapsulated abscess may exist together; such a case is reported. An abscess replacing the right optic thalamus is reported, the capsule of which was very firm and ½ of an inch thick. Owing to a mistake in diagnosis, the abscess was not removed. The most important principle in the treatment is free drainage. When a purulent collection is encapsulated, enucleation is the

proper treatment. The details of operation are taken up step by step. The writer believes there is less risk of the abscess being missed when search is made for it with a sharp knife, than when any other instrument is employed. [C.A.O.]

2.—Edmunds, in the third Erasmus Wilson lecture on the **pathology and diseases of the thyroid gland**, discusses the various opinions held, and the results of experiments, regarding the nature of myxedema, cretinism, and Graves' disease. He points out especially the differences between myxedema and exophthalmic goiter, and suggests that one is due to deficiency of the thyroid secretion, the other to increase and perversion of the secretion. There follows also a critical review of the work of other observers, and of the indications for, and the results of, operations upon the thyroid gland. [A.O.J.K.]

3.—Robson believes surgical treatment to be the only satisfactory method of dealing with **intractable or relapsing gastric ulcer**, and that operation should be resorted to much earlier than has hitherto been the custom. When treated by general and medical means only, the mortality is from 20 to 50%. The mortality in operations for simple diseases of the stomach, excluding perforation and hemorrhage, is less than 5%. The surgical treatment of gastric ulcer is taken up in detail, as is also the treatment of its complications, which are no less numerous than serious. Any one of the following operations, or a combination of one or more, may be called for in each individual case: Exploratory gastrotomy; gastroenterostomy to secure physiologic rest to the stomach and relieve the hyperchlorhydria, or in other cases to short-circuit a stenosis; excision of the ulcer; pylorotomy; pyloroplasty; gastroplasty; gastrostomy; gastrolosis; pylorodiosis; and gastroplication. In the absence of special complications, gastroenterostomy is the operation to be relied on in the treatment of gastric ulcer. [C.A.O.]

4.—Martindale, with a view of determining whether the halogenised oil, brominal, passes through the system unchanged, or whether it is absorbed, undertook a series of investigations, and details the results of analyses of stools and urine from epileptic patients under treatment with brominal, as compared with similar specimens from patients under treatment with potassium bromid. It was possible under both treatments to account in the urine for somewhat more than $\frac{1}{2}$ of the quantity of bromin administered in the day. In the brominal treatment, small quantities of unaltered brominal and bromids are passed by the rectum. It is suggested that the digestion and absorption of the brominal is due to the pancreatic enzyme splitting up the compound and forming free, fatty acids, which are, to a large extent, saponified by the alkali present, and that the bromin is by the same agency converted into alkalin bromin. The bile then causes solution of this saponified mass of soap, fatty acid, and alkalin bromid, the latter by its easy solubility passing off in the urine. [A.O.J.K.]

5.—Payne reports 2 cases of **carcinoma**—1 of the uterus, the other of the tongue—treated with **cacodylate of sodium**, with marked improvement in both cases. The drug was given hypodermically in doses gradually increased to a maximum of 7.5 centigrams once daily. It is believed that arsenic has a specific action on epithelial cells—at first, beneficial; ultimately, destructive—and that, coming in contact with the epithelial cells in a person suffering with carcinoma, the deleterious action of the drug is resisted more by the normal cells than by pathologic cancerous cells. The latter are overcome and destroyed, whence the cure. [A.O.J.K.]

6.—Cautley records his observations of an epidemic of **acute colitis occurring in children**. Six out of 30 children were affected, and of these 4 died. Three out of 13 adult women were attacked less severely, and recovered. The cases occurred in a London barracks, and are thought to have been due to microbial infection or toxemia, although no source of infection could be determined upon. The disease was characterized pathologically by inflammation, superficial erosion, and hemorrhages into the mucous membrane of the entire colon, and clinically by sudden onset, vomiting, diarrhea with mucous stools, and pyrexia. The only organisms isolated from the intestinal discharges were *Bacillus enteritidis sporogenes* and *Bacillus coli communis*. [A.O.J.K.]

The **Journal of the American Medical Association**, **New York Medical Journal**, **Medical Record** and the **Medical News** for June 8, published in their Original Article Departments the addresses before the American Medical Association, and which appeared in **AMERICAN MEDICINE**, Vol. I, No. 10, which see.

Boston Medical and Surgical Journal.

May 30, 1901. [Vol. CXLIV, No. 22.]

1. The Diagnosis and Surgical Treatment of Renal Tuberculosis. F. TILDEN BROWN.
2. Asthma. F. P. EMERSON.
3. A Case of Trichinosis. GEORGE G. SEARS.

1.—Brown in an article on the **diagnosis and surgical treatment of renal tuberculosis** reports 16 cases. The author has had 5 operations, and reports having seen 10 done by others, where no fatalities occurred; but claims that with a full series no one could expect less than a 5% to 7% mortality. He strongly advocates the combination of surgical treatment and climatic influence and leads to the conclusion that too great pains cannot be taken by physician and surgeon to determine the location and extent of the disease before determining upon the treatment. The integrity of the other kidney has great bearing on the surgical aspect of any case. To determine in any particular case just what rate of progress the disease may pursue if left untreated, or what degree of immunity from some of the annoying symptoms can be promised the patient by a nephrectomy, is not easy. In ward hospital cases the immediate operation appears to be the only alternative. For those who can afford climatic changes and rest, a careful preliminary observation of the existing conditions of the urinary tracts should precede their travels, and the same examination, when at all indicated should be repeated in order to keep posted regarding such an advance of the disease as to call for operation. [C.A.O.]

2.—Emerson reports 5 cases of **asthma** with intranasal hypertrophies and ethmoiditis. The former were removed but relief did not come until local treatment had cured the ethmoiditis. [H.M.]

3.—This is the twenty-fifth case of **trichinosis** reported in which there was a marked eosinophilia. In some cases this has been found as early as the fifth day, and in 1 case the eosinophilic cells still composed 15% of the whole at the end of 4 months. Even 60% and 80% have been reached. The severity of the disease seems to have no effect on the relative number. Large numbers appear after reparation processes must have begun. [H.M.]

June 6, 1901. [Vol. CXLIV, No. 23.]

1. The Surgical Treatment of Gastric Ulcer, with report of Cases. F. B. LUND.
2. Idiopathic Abscess of the Kidney. A. T. CABOT.
3. The Effects of Training. Second Paper. EUGENE A. DARLING.

1.—In an article on **surgical treatment of gastric ulcer**, Lund considers active ulcer and its complications and reports cases. He states: (1) that in perforation immediate operation is absolutely indicated; (2) that in cases in which the symptoms fail to yield after medical treatment for a reasonable period, operation, consisting either of excision of the ulcer or gastroenterostomy should be performed, and this before the patient has become so exhausted as to render surgical intervention dangerous; (3) early operation is indicated where slight, frequently repeated bleeding promises to produce grave anemia or exhaustion; (4) when a patient has suffered more than one copious hemorrhage, operation should be performed, and the extent and nature of the procedure should be decided upon according to the power of the patient to withstand operative manipulations, and the conditions found during the progress of the operation. [C.A.O.]

2.—Cabot in an article on **idiopathic abscess of the kidney** considers mainly those cases of **kidney infection through the blood**, a rare condition if tubercular abscesses are excluded. The pathology of the subject is reviewed and a case reported of an extremely septic process in one kidney in which the infection was due to a pure culture of colon bacillus. Oper-

ation gave excellent results. Cabot believes an exploratory incision should be made in every case of doubt. If an abscess is not found, but only a tense, congested kidney, an incision of the capsule along the convexity will afford, usually, great relief. If there is any question of the existence of a calculus the exploratory incision will afford opportunity for a thorough search and for removal of the stone if one is found. If the kidney is movable and suffering from congestion or intermittent hydronephrosis, induced by the twisting of the vessels and ureter, it can be drawn up and stitched in the loin. The operation has little or no danger attaching to it, and if an abscess is found, the operation done early will stand a far better chance of cutting short the septic process than it would if it were kept as a last resort. [C.A.O.]

3.—The paper contains observations on the condition of the Harvard football squad for 1899 and the crews of 1899 and 1900. In the first, examinations of 17 men made before afternoon practice showed no disturbance of cardiac action in 14, although there was hypertrophy in all, which became less as the season advanced. Some showed irregularity in rhythm with or without abnormal sounds, but not in most cases amounting to a murmur. Two members had temporary murmurs and 1 a permanent one, probably due to an organic lesion. There is risk in allowing such men as the latter to take part in contests like football and rowing. In all cases after a hard game, as after rowing, acute dilation, always temporary and becoming less marked with each succeeding effort, was formed. During training the urine averaged 1,124 cc. specific gravity 1.027, urea 3.30%, total urea 36.2 gm. In 6 out of 16 cases albumin, hyalin and granular casts, excess of leukocytes and occasionally red blood corpuscles were present. The effect on the crew from an accident to the captain and stroke just before the contest is noted, there being an excessive loss of weight, attributed partly to indigestion, partly to insomnia, and partly to increased work. The effect on the substitute stroke is given in detail. Hypertrophy appears to be more or less permanent, but this is no more undesirable than a corresponding hypertrophy of the biceps. No ill-effects which could be reasonably attributed to training could be discovered 9 months after it ceased. [H.M.]

New York Medical Journal.

1. Hyperacidity (Superacidity, Hyperchlorhydria, Snperaciditas Chlorhydrica): A Clinical Study. H. ILLOWAY.
2. Nasal Condition Observed in the Aged. BEAMAN DOUGLASS.
3. What Route Shall We Adopt in Examining the Eye Muscles? ALEXANDER DUANE.
4. Ossiculectomy for Chronic Suppurative Otitis Media. J. A. STUCKY.
5. The Importance of the Early Recognition of Abdominal Infections. W. D. HAMILTON.
6. Antistreptococcus Serum in 2 Cases of Puerperal Septic Infection. A. J. PRIMROSE.

1.—Illoway, in the first installment of his paper on hyperacidity of the stomach, states that the normal acidity of the stomach is greater than .22% (the degree of acidity generally given), and reports some investigations of his own showing that the average percent. ranges from .29% to 3%. He claims that a diagnosis of hyperacidity cannot be based upon the total acidity alone, but must be largely dependent on the accompanying symptoms. The true explanation is that every stomach has a "physiologic individuality of its own, and thus the one organ may perform its function—digestion—perfectly with a degree of acidity that might be insufficient or more than sufficient for another. Any further addition to this normal proportion of hydrochloric acid must render that particular gastric juice hyperacid and provoke the manifestations dependent upon such a condition." He classifies the condition under 2 forms—the acute and the chronic, the acute lasting generally not more than a few hours, while the chronic form may be of any duration from 1 month to several years. [H.H.C.]

2.—Douglass, in discussing nasal conditions in the aged, states that nasal affections of the catarrhal or inflammatory character are more common during middle age, and that when such conditions exist in the aged they do not give rise to

symptoms. The theory is advanced that the gradual onset of the condition arising from internal blood or lymphatic irritation may explain the absence of active symptoms. Another cause may be the absence of neurotic tendencies and nerve irritation in the aged. [J.W.M.]

4.—Stucky has performed ossiculectomy in 20 cases of chronic suppurative otitis media with most satisfactory results. The anatomic construction of the middle ear favors pathologic conditions, and he considers the establishment of free drainage most important in the cure of this condition. In all cases in which there is a large-sized canal with chronic disease of the attic, perforation of Strapuell's membrane, and all the conditions attending suppuration and often necrosis, removal of the ossicles with a portion or all of the anterior attic wall and remnants of the drum membrane is considered the most conservative and satisfactory treatment. In chronic suppuration with cholesteatoma and necrosis of the posterior superior wall of the canal the radical operation should be performed. The following claims are made for the conservative method, viz.: (1.) It gives free drainage. (2.) It affords an opportunity to successfully combat the suppurative process. (3.) It is free from danger to life and health. (4.) In a large percentage of cases the disease is arrested, the hearing improved, only rarely made worse. (5.) There is no deformity or scar. [J.W.M.]

5.—Hamilton emphasizes the importance of the early recognition of abdominal infections, and makes a plea for the early use of every available means of diagnosis, so that if necessary operative intervention may be employed at the earliest time practicable. He believes that a properly conducted exploratory operation involves less danger to a patient than delay and speculation. [J.W.M.]

6.—Primrose reports 2 cases of puerperal septic infection successfully treated with antistreptococcus serum. It was administered in doses of 10 ccm., injected at intervals into the right leg, the left leg, and abdomen, causing rapid abatement in the high temperature and convalescence. In both cases there was subsequent pain and stiffness in the kneejoints, which, however, soon subsided after a few doses of sodium salicylate. [W.K.]

June 1, 1901. [Vol. LXXIII, No. 22.]

1. On Theories of Inheritance, with Special Reference to the Inheritance of Acquired Conditions in Man. J. GEORGE ADAMI.
2. Appendicitis Perforativa in Irreducible Right Scrotal Hernia, with a Report of a Case. O. THIENHAUS.
3. Muscular Action of the Arteries. ANDREW H. SMITH.
4. Hyperacidity (Superacidity, Hyperchlorhydria, Snperaciditas Chlorhydrica); a Clinical Study. H. ILLOWAY.
5. A Case of Sarcoma in the Muscles of the Right Shoulder, with Perforation into the Spinal Canal, and Paraplegia. LEONARD WEBER.

2.—Thienhaus gives statistics to show that an appendix, as well alone as together with omentum and intestine, situated in a hernia, chiefly an oblique inguinal hernia, is not uncommon. He believes the appendix demands strict observation, and removal if necessary, in all operations for hernia. It is probably true that in every case of hernia in which the appendix is an inmate it must be removed. When appendicular inflammation is present in a hernial sac, operative procedure must be advised immediately, and in incarcerations under such conditions he denounces the use of any palliative method, or attempts at taxis. In cases of appendicular abscess in a hernial sac or gangrene of the appendix, resection with free drainage is the appropriate treatment. [C.A.O.]

4.—In the second chapter of his paper on hyperacidity, Illoway deals exclusively with the symptoms of the disease. He considers the cardinal symptoms to be (1) gastralgic seizures, (2) burning in the stomach, (3) sour stomach, (4) ructus, and (5) bowel symptoms, which generally consist in constipation of varying degree. [H.H.C.]

5.—Weber reports a case of sarcoma developing in a young man beneath the superficial fascia in the fleshy part of the right shoulder between the scapula and spine. The growth followed trauma and it is believed that a gumma that would not yield to treatment was situated in the same region a few

years before. The cord symptoms in this case were due to hemorrhage and degenerative myelitis as shown by a microscopic examination. Weber believes the case teaches that it is wise to excise a supposed gummatous tumor located in accessible regions when it does not yield to proper specific treatment in due time. [C.A.O.]

Medical News.

June 1, 1901. [Vol. LXXVIII, No. 22.]

1. Some Factors Relating to the Etiology of Prostatic Enlargement. J. BENTLEY SQUIER.
2. Gastric Ulcer and Mucomembranous Colitis at the Paris Congress. JAMES J. WALSH.
3. Streptococcus Bronchitis in Influenza. F. FORCHHEIMER.

5. The Use of Methylene-Blue Injections in Pleurisy, with Effusion. CHARLES H. LEWIS.
6. The Appearance of the Soft Palate a Pathognomonic Symptom of Epidemic Influenza. LOUIS KOLIPINSKI.

1.—One out of every 3 men has some **prostatic enlargement** after reaching middle life, and 1 out of 5 symptoms for which he seeks relief. The function of the gland is described and it is shown how abnormal sexual indulgences, including masturbation, prolonged excitement without gratification, and coitus interruptus, which tend to keep up a chronic hyperemia, lead oftener to hyperplasia than senility, gout, rheumatism or atheroma. The statistics of 300 cases are given. The necessity of instruction in sexual hygiene is emphasized. [H.M.]

2.—Walsh reviews some points of special interest. **Gastric ulcer** is more frequent than has been thought, occurring often, not only idiopathically, but as a complication in infectious diseases and diseases of the circulation and metabolism, as anemia. There is little doubt they are due to self-digestion in conditions of hyperacidity, the immediate cause being certain irritative and traumatic influences. There is an acute as well as chronic form, almost the first symptom of which may be hemorrhage. Many of these are due to the pneumococcus, which may be present without involvement of the lung. They also occur in appendicitis, induced by septic elements carried in the circulation, and in puerperal cases as well. It is important in anemia and subseptic conditions therefore, to lessen gastric acidity and avoid coarse food and slight trauma of the abdominal walls. It may be simulated even to hemorrhage in neurotic conditions. Surgical measures should be resorted to more frequently because of disturbed function from contractile deformation and liability to the development of cancer on the scars. Olive oil, 100 to 300 gm. daily, is recommended. Morphine increases hyperacidity. **Mucomembranous colitis** is increasing. Statistics point to an essentially nervous origin, due either to increasing struggle for existence or abuse of laxatives, causing hyperexcitability and congestion of the colon. Were it an inflammation appendicitis would be a frequent complication. There may be either constipation or diarrhea between attacks. Intestinal lithiasis is noted in 8% of cases. Treatment must be directed to the nervous condition. [H.M.]

3.—**Streptococcus bronchitis** is so called because this is the predominant and in some cases the only organism present, the influenza bacillus having in most cases disappeared. Any type of influenza may be followed by this form, the symptoms of the influenza disappearing before the bronchitis develops. The attack begins suddenly and commonly will be fully developed in 24 to 48 hours. The dominant symptom is frequent spasmodic cough simulating pertussis, the expectoration not being proportionate. The principal localization is in the middle-sized tubes. The diurnal temperature range is abnormally great varying from 96 to 100. The pulse may be slow or rapid. The average duration is 2 weeks when properly treated; otherwise it may be months. Rudimentary and excessively developed forms are described. Protracted cases are differentiated from tuberculosis by the physical signs of a general bronchitis and absence of tubercle bacilli. In attacks of respiratory influenza quinin should always be given to prevent secondary infections such as this. When this bronchitis has developed 1 gram of sodium benzoate should be given every 2 and then every 4

hours with cough sedatives, etc. Unguentum Créde and anti-streptococcic serum have given good results in the severer forms. [H.M.]

4.—Every **Fourth of July** an epidemic of tetanus occurs because the bacilli are carried deeply into wounds before wads from blank cartridges, and these wounds are improperly cared for. Thorough cleansing and drainage under an anesthetic is indicated. As tetanus sometimes occurs after all precautions, and is so frequent after these cartridge wounds, it would be better to administer 5 cc. of tetanus antitoxin, the prophylactic dose. [H.M.]

5.—The objection to aspiration in **pleurisy with effusion** is the rapid reappearance of the fluid. The ordinary therapeutic measures to promote absorption are uncertain and debilitating. **Methylene-blue** is antiseptic and anodyne and diuretic and promotes adhesion of the pleural walls by exciting a deposit of fibrin. From 5 to 15 grains are mixed with serum which has been withdrawn by a specially devised aspirating syringe and which is immediately returned. This diffuses evenly throughout the effusion and appears in the urine in from ½ to 4 hours. The average duration of treatment for 23 serofibrinous cases was less than 14 days. Some cases received no other internal medication. [H.M.]

6.—Small convex projections of pearly whiteness or transparency are seen on the **soft palate**. They are the size of a sand grain, and either few or abundant. Direct or diffused sunlight, or bright artificial light are needed for the examination. Sometimes they are obscured by tenacious mucus, which must be removed. There is a peculiar rough feel. Alcohol consumption, tobacco, and tuberculosis modify the color. Hemorrhages sometimes complicate their presence. They will be found in all cases in which the diagnosis of influenza is certain, and their presence will clear up the diagnosis in anomalous cases. [H.M.]

Philadelphia Medical Journal.

June 8, 1901. [Vol. 7, No. 23.]

5. The Kneejerks in Chorea. AUGUSTUS A. ESHNER.
6. Heredity as a Factor in Mental Deficiency. T. ALEXANDER MAC-NICHOLL.

4.—Miller reports a case of **membranous enteritis** which had baffled all previous attempts at diagnosis, and had been treated unsuccessfully for phthisis. The case presented the usual diagnostic symptoms of phthisis, together with those of asthma and an unusually weak stomach. At the time Dr. Miller was called the patient was unable to retain either medicine or food of any kind. The treatment employed consisted of a daily washing out of the stomach and the thorough cleansing of both mouth and teeth with a solution of hydrozone in water. The nausea and vomiting soon subsided, and the following was administered:

R
Ext. filicis fl.
Chloroformi ãã 1 dram.
M. S.—A dose.

This was followed after 4 hours by repeated doses of olei ricini (gms. 5) in flexible capsules. The result was the passage of numerous shreds resembling tapeworm segments. Upon microscopic examination these proved to be mucous strips. Following this the routine treatment for mucous enteritis was employed, and a most favorable recovery followed. [H.M.C.]

6.—In a paper on the **heredity of mental deficiency**, MacNicholl cites statistics bearing on the subject showing that less than 12% of the children of drinking parents are normal in mind and body, while over 82% of the children of total abstain-

ers are normal. The author was able to trace the family histories of 463 children in 150 different families, through 3 generations. Seventeen (2 males and 15 females) were precocious in some one thing, as music, drawing, etc.; 403 were generally deficient (193 males and 210 females); 17 had neurotic fathers; 78 neurotic mothers; 313 had drinking fathers; 51 drinking mothers; 43 had neurotic grandparents; 265 had drinking grandparents; 246 had drinking parents and grandparents. Of these children 2% had parents of less than average intelligence. A most notable fact in these families was the constant relation of alcohol in the ancestry to abnormal physical conditions in the descendants. While 87% of these children of drinking and neurotic ancestry were mentally deficient, 76% suffered from some neurosis or organic disease. [H.H.C.]

1.—Albert has made a careful study of the subject of labor in cases having narrow pelves and presents the results in a tabulated form showing that out of 1,187 births in the clinic, in 4 years, there were 105 versions, 60 of these being in patients having contracted and flat pelves, resulting in 48 living children and no maternal mortality. From these statistics and those of other writers he concludes that when the pelvic contraction is not excessive, the true conjugate being from 7 to 9½ em., in the case of a primipara the aim should be a spontaneous delivery, and hence a waiting policy should be followed and early operation avoided; in multipara, with version, there should be no omission of external care since even here spontaneous delivery is possible; and in all women of this group, the dilation of the os uteri and the persistence of the fetal membranes are conditions most favorable for delivery, and on this account the use of the colpeurynter may be of great advantage. Chrobak advises its use: (1) When there has been a premature rupture of the membranes and the head is not yet engaged, for the protection of the fluids, the widening of the os uteri, and the stimulating of the labor pains especially in primipara. (2) When with persistent membranes there is incomplete dilation of the os uteri, and the head does not engage on account of narrow pelvis and oblique or transverse position. (3) When one cannot form any clear judgment as to the course of delivery, one with the colpeurynter may reach conditions favorable to version delivery namely, dilation of the os uteri and preservation of the fetal membranes. In the further course of labor, in primipara, use the Waleher position; the same in multipara if the head is well engaged. In a bad or high position of the head, version with immediate extraction is advised. Albert describes the process of delivery in such cases. When there has been premature rupture of membranes and loss of fluids and the uterine muscle is hard and unyielding determine the best instrument and the least dangerous method of operative procedure. [W.K.]

2.—The work of Bordet, Wassermann, Fisch, Uhlenhuth, and others, has developed the interesting fact that if animals are injected with the blood serum of another species, their blood acquires the property of dissolving the red corpuscles

of this species and, furthermore, of producing a precipitate in the latter's blood serum. By the injection of defibrinated human blood into rabbits, a serum is obtained which produces a decided cloudy precipitate when added to human blood. This precipitate occurs only in human blood, and not in that of other animals, except that of monkeys—a fact that throws an interesting side light upon the relationship of these animals to man. Dieudonné made similar experiments with human blood serum obtained from placental blood, with albuminous urine, and with pleural exudate. The serum of rabbits treated with human blood serum, added to a solution of human blood, produced a flocculent precipitate; normal rabbits' serum did not have this property. The serum of animals injected with albuminous urine, added to human albuminous urine, also produced a precipitate. No such reaction was obtained in the normal urine from human beings or rabbits, nor by the addition of normal rabbits' serum to albuminous urine. The serum of the animals treated with pleural exudate, added to the latter, caused a distinct precipitation. These different serums were reciprocally tested, and it was found, for instance, that the serum from the rabbit treated with human blood not only precipitated blood, but also the pleural and peritoneal exudate, although not in such marked degree as when the homologous serum was used. The reaction was produced only in blood, urine, and exudate coming from human beings; not in that coming from other animals. The forensic importance of these discoveries is apparent; with the serum obtained from animals, particularly by the injection of human blood serum, rather than urine or exudate, it is possible to test human blood that has been dried for weeks. [D.R.]

3.—Rosenbach calls attention to the fact that a cardiac hydrothorax may be confined to the right side, or, if bilateral, the effusion on the right side may be larger than that on the left. The cause of unilateral localization must be a local one. A left-sided effusion with atelectasis, or a catarrhal condition of the lower lobe of the left lung, is not rarely a sign of muscular weakness of the left ventricle. Attention is also called to isolated stasis in the liver and ascites in heart disease, and to passive congestion of the liver in diphtheria, as the result of weakness of the right ventricle. Rosenbach believes that it is possible to differentiate exudates and transudates by what he calls functional diagnosis. If iodine or iodids are given by the mouth, they will rapidly appear in transudates, while exudates will take up only traces. If, by means of nitric acid and choleform, the iodine test can be obtained in a fluid removed by exploratory puncture, a passive transudation exists, and not an inflammatory exudate. [D.R.]

4.—The laborers employed in chromate factories are subject to a variety of diseases. The principal one is necrosis of the nose, which in a large proportion leads to perforation of the septum. Intractable eczema of the hands and conjunctivitis are other lesions most frequently produced. Gastrointestinal disturbances and inflammations of the respiratory tract occur, but are not definitely attributable to the chromic acid. Renal changes were not observed by Hermann. The prophylaxis concerns prevention of the inhalation of chromate dust or vapor, and protection against its caustic action on the skin. Regarding the former, the laborers in the factory supervised by Hermann use wet sponges. Instead of these, respirators devised by Klein, of Giessen, may be employed. The prevention of dermal lesions consists in carefully treating with plaster the smallest abrasion of the skin, and in the use of gloves. [D.R.]

5.—Ghillini reports another case of reposition of a congenital dislocation of the hipjoint by means of his modification of Fabbri's bloodless method. He finds that in general the procedure leads to excellent results. [H.H.C.]

6.—A case of multiple fat necrosis in a woman of 69, which presented itself with the usual symptoms of intense pain in the epigastrium and signs of internal strangulation, and rapidly proved fatal. The pancreas was not diseased; the spleen was small; nothing is said of the existence of gallstones, so, presumably, none were present. Local peritonitis existed, particularly over the areas of fat necrosis. [D.R.]

7.—A case of aneurysm of the aorta successfully

treated with subcutaneous injections of gelatin. The dyspnea, vertigo, and pain were lessened, the aneurysm became smaller, and the pulsation grew distinctly less marked. [L. BOU.]

8. Sacher, of Munich, reports the case of a man of 60, who (7 years before) had suffered from an acute attack of suppurative pleuritis. At that time a thoracic fistula was performed and drainage established. The man finally left the hospital with a large thoracic fistula which never closed and continued to excrete large quantities of pus. The man's fingers were all decidedly clubbed. A bacteriologist examined the excretion for tubercle bacilli. But the Röntgen apparatus showed what appeared to be a foreign body in the neighborhood of the fistula besides the fact that the clubbing of the fingers was due to thickening of the soft parts and not to hypertrophy of the bones. An operation resulted in the removal of an old piece of rubber drainage tube from the pleural sac after which recovery was rapid. Three months after the operation Sacher noticed a decided reduction in the size of the clubbed fingers. [H. C.]

9. A case of urticaria in a boy of 13, associated with albuminuria (Piper, Millé, by Esback). Casts epithelial cells, and leukocytes, were absent. [M. D. R.]

April 9, 1901. [48 Jahrg., No. 15.]

1. The Transfusion of Blood, Especially of Heterogeneous Blood, and its Applicability to Therapeutic Purposes, Considered from a New Point of View. BREW.

2. The Treatment of Abdominal Gunshot Wounds. PEERSEN.

4. Multiplicity of Primary Malignant Tumors of the Skin. HENNING.

5. Further Studies of Serous Inflammation of the Skin. HENNING.

6. Two Cases of Embolism of the Abdominal Aorta. BEKKER.

7. The Value of Glutoid Capsules in the Diagnosis of Intestinal Diseases, Especially Those of the Pancreas. FROMME.

8. Bismuth Poisoning. MÜHLIG.

9. Nonmalignant Diseases of the Esophagus, Occurring in the Form of Stricture. SCHUTZ.

10. Hard, Slight Corrosion from Soft Soap in a Child 18 months old. LANGER.

11. A New Point of View for the Treatment of Whooping-cough. SPREISS.

12. A Case of Unilateral Luxation of the Inferior Maxilla. KAREHNKE.

1. Bier finds that transfusion of blood from animals causes transient hyperemia due to capillary stasis, and results in greatly increased appetite and consequent metabolism, but that repeated transfusions are followed by disagreeable reaction-phenomena. [H. C.]

2. In spite of the more favorable results obtained by the conservative treatment of penetrating gunshot wounds during the South African war, Peersen continues to favor during times of peace such abdominal wounds, especially when perforation is suspected, should always be followed by operation. [H. C.]

3. Thamer, in his paper on abdominal gunshot wounds, in the Boer war, observes that, of those cases coming under his own observation, the majority (12 out of 19 cases) recovered under the conservative treatment. This statement, however, does not include the cases ending fatally during transportation to the distant German field-hospitals. [H. C.]

4. Schirker reports cases of multiple primary malignant tumors coming under observation in the surgical clinic at Heidelberg. The combinations were mamma and uterus, bladder and uterus, uterus and rostrum and epiglottis and base of the tongue. [H. C.]

5. In unicellular organisms and in others provided with vascular system, chemotaxis occurs in the absence of inflammatory phenomena. Hahn made some experiments to determine whether a pure chemotaxis could be produced in white-blooded animals, and used in his experiments finely divided carbon in an artificial medium. In both cases, where chemotaxis occurred inflammatory phenomena coexisted, and he concludes from these results that chemotaxis does not exist independently of inflammation in animals provided with a circulatory system. In agreement with these studies, he observed as an interesting phenomenon

very distinct and prominent in the detached endothelial cells of the pleural cavity. [D. R.]

6. Bühler reports 2 cases of embolism of the abdominal aorta, both occurring in patients with mitral stenosis and thrombosis of the femoral and iliac appendices. In the second case there was also multiple embolism of other vessels. In both cases the development of the aortic embolism was characterized by sudden, intense pain in the lower extremities. Probably because of these pains the patients presented a peculiar state of anxiety and excitement. The subsequent symptoms of embolism of the aorta depend upon the size of the embolus and the possibility of a collateral circulation, and also upon the degree of secondary thrombosis. These symptoms are as follows: Pallor and coldness of the skin; lessening and suspension of the sensibility; paralysis; pulselessness, and finally, gangrene. Whether the paralysis is peripheral or central is not definitely known; it is more likely, however, that it is of peripheral origin. Even in complete obstruction of the aorta, some collateral circulation is possible, through anastomosis of the inferior epigastric artery with the internal mammary and the lumbar arteries, and of the ilio-lumbar artery with a branch of the epigastric with the lumbar vessels. In 1 case, despite complete obstruction of the aorta, and thrombosis of the iliacs, a line of demarcation formed above the knee. The parts above were, therefore, still supplied with blood. Psychic symptoms in the form of a state of excitation and severe pains were present. In the cases reported the temperature rose gradually, the pulse became accelerated, the urine contained albumin—in the second patient, also blood. Treatment was out of the question. [D. R.]

7. Glutoid capsules are gelatin capsules treated with formaldehyd, and thereby rendered resistant to the action of the gastric juice, but still amenable to that of the pancreatic juice. It is the trypsin in the latter and not the alkali that dissolves them. Peptic digestion after a time destroys the capsule, usually in 7.25 hours, while the pancreatic solutions act in 2.2 hours. The capsules are recommended as a test for motility of the stomach and for the activity of the pancreas. Those used by the author were filled with iodoforn, and the saliva was tested for iodine with nitric acid and chloroform. Normally the reaction is obtained in from 3 to 5 hours after the administration of the capsule. A reaction developing within that time indicates normal motility of the stomach and normal pancreatic activity. If the reaction occurs later than 7 or 8 hours after the administration of the capsule, the causes may be various: (1) The capsule may be retained in the stomach; (2) the pancreatic function may be inadequate. If, for any reason, the contents of the capsule should escape into the stomach, the reaction would be obtained too early, and a false notion formed as to the motility. To guard against this, the glutoid test should be combined with evacuation of the stomach; if the capsule has opened, the contents will have an iodoforn odor. [D. R.]

8. Mühlig reports 2 cases of bismuth poisoning following the local application of bismuth subnitrate to wounds. In both cases there was a well-marked stomatitis, with bluish-black discoloration of the tongue, gums, soft palate and uvula. Recovery followed. It is interesting to note that the bismuth was pure and not contaminated with lead or arsenic. [D. R.]

9. A case of poisoning by soft-soap in an child of 18 months. The child had found the soap on the table, and had swallowed an unknown quantity. Death occurred, and at the autopsy signs of corrosion of the mucous membranes, and of pneumonia were found. Whether the pneumonia was due to the poison could not be definitely determined. [D. R.]

10. In the belief that the spasm of whooping-cough is due to reflex action, originating in the superior laryngeal nerve, Spreiss recommends the production of typhlosthesia of the mucous membranes by means of orthoform. The orthoform powder is put in an instilling apparatus, by which the laryngoscope may be used to control the spraying. In children above 3 years of age a narrow admittable every 30 seconds. In infants, the nose is held and the child forced to breathe through its mouth at the time of the insufflation. In addition to the instillation the author sometimes uses the method of inhalation, which is done by means of a special apparatus. [D. R.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended June 8, 1901:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	Los Angeles.....May 18-25.....	1	
	San Francisco.....May 18-25.....	5	
Dist. of Columbia	Washington.....May 25-June 1....	1	
Illinois:	Chicago.....May 25-June 1....	7	
Iowa:	Ottumwa.....Apr. 27-June 1....	16	
Kansas	Leavenworth.....May 1-31.....	3	
	Wichita.....May 18-June 1....	42	
Louisiana:	New Orleans.....May 25-June 1....	4

Changes in the Medical Corps of the U. S. Navy, for week ended June 8, 1901:

BACKUS, J. W., ASSERSON, F. A., MURPHY J. F., SEAMAN, W., and RICHARDSON, R. R., Doctors, appointed assistant surgeons in the navy—June 1.

CORDEIGO, F. J. B., surgeon, detached from the Buffalo, June 10, and ordered home to wait orders—June 4.

CURTIS, L. W., surgeon, ordered to the Buffalo, June 10—June 4.

BOGERT, E. S., Jr., passed assistant surgeon, commissioned surgeon, from December 15, 1900—June 4.

PLUMMER, R. W., assistant surgeon, detached from the Nashville and ordered to the Princeton—June 6.

SEAMAN, W., assistant surgeon, ordered to the Independence, June 17—June 6.

HAAS, H. H., assistant surgeon, detached from Naval Hospital, New York, and ordered to the Norfolk Navy Yard, June 10—June 6.

RICHARDSON, R. R., assistant surgeon, ordered to Naval Hospital, New York, June 10—June 6.

BRISTER, J. M., assistant surgeon, detached from the Independence, June 17, and ordered to the Asiatic Station via transport Hancock—June 6.

Changes in the Medical Corps of the U. S. Army for the week ended June 8, 1901:

DORSEY, RUFUS T., Jr., contract surgeon, will proceed to his home, Atlanta, Ga., for annulment of contract.

MOSES, HOMER C., contract surgeon, is relieved from temporary duty at the Army general hospital, Presidio, and will proceed to Seattle, Wash., where he will report for duty as transport surgeon

of the Army transport Egbert, to relieve Contract Surgeon James L. Day. Contract Surgeon Day will proceed to Lebanon, Mo., for annulment of contract.

BARTLETT, COSAM J., contract surgeon, is relieved from duty at the Army general hospital, Presidio, and will proceed to Fort McDowell for duty at that post.

WINTER, Captain FRANCIS A., is granted leave for 1 month with permission to apply for an extension of 2 months.

BELL, JOSEPH L., contract surgeon, now in Washington, D. C., on leave, is relieved from further duty at Fort Crook, and will proceed to Fort Morgan for duty to relieve Contract Surgeon Lawrence A. Felder, who will proceed to his home, Atlanta, Ga., for annulment of contract.

ALLEN, Captain IRA A., assistant surgeon, leave granted March 26, is extended 5 days.

RICHARDSON, GEORGE II., contract surgeon, having reported to the surgeon general of the Army, in compliance with orders heretofore issued, will proceed to Plattsburg Barracks for duty.

GARRETT, NEVIL M., contract surgeon, is granted leave for 1 month.

WOLVEN, F. HOMER, contract dental surgeon, will proceed from Washington, D. C., to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

The following named assistant surgeons are honorably discharged as majors, surgeons, United States volunteers only, to take effect June 30, 1901: Captains Henry C. Fisher, Eugene L. Swift, John S. Kulp, Frederick P. Reynolds, Merritte W. Ireland, William F. Lewis, Paul Shillock, Alexander N. Stark, Powell C. Fauntleroy, Charles Willcox, Henry A. Shaw, First Lieutenant George W. Mathews.

HARTSOCK, First Lieutenant F. M., assistant surgeon, is granted leave for 1 month upon his being relieved from duty at Fort Warren.

DECKER, GEORGE M., contract dental surgeon, will proceed from Troy, N. Y., via Tampa, Fla., to Havana, Cuba, and report to the commanding general, department of Cuba, for assignment to duty at Columbia Barracks, Cuba.

HAGAN, CHARLES M., hospital steward, now in Washington, D. C., having performed the duties assigned him May 30, will return to that station with permission to delay 5 days en route.

DOUGHERTY, JAMES C., contract surgeon, now in New York City, will proceed to Albonito, P. R., for duty, to relieve Contract Surgeon Harry A. Eberle, for the purpose of enabling him to avail himself of the leave granted May 31.

WYETH, Major MARLBOROUGH C., is granted leave for 3 months.

KENDALL, Major WILLIAM P., surgeon, is granted leave for 14 days, to take effect June 5.

CHAMBERLAIN, First Lieutenant WESTON P., assistant surgeon, leave for 7 days granted May 31, is extended 23 days.

AMERICAN MEDICINE

1321 Walnut Street Philadelphia

Cable Address—AMMEDIC, Philadelphia

Subscription Price - - - - Four Dollars a Year in Advance

Postage in the United States and Canada, Mexico, Hawaii, Guam, Porto Rico, and the Philippines, free; foreign postage, \$2.50. Subscriptions may begin at any time. Volumes end with the last issues of June and of December.

News.—Our readers are requested to send us items of news of a medical nature, also marked copies of local newspapers containing matters of interest to members of the medical profession. We shall be glad to know the name of the sender in every instance.

Original Papers.—Articles are accepted for publication with the understanding that they are contributed solely to this journal.

Correspondence on all matters of clinical interest, particularly with reference to therapeutics, will be welcomed. Unobjectionable questions concerning formulas, treatment, etc., will receive attention in the department of Practical Therapeutics.

Copyright.—Matter appearing in AMERICAN MEDICINE is covered by copyright, but usually no objection will be made to the reproduction of anything appearing in its columns if the author's consent is obtained and proper credit is given.

Illustrations, such as half-tones, zinc etchings, etc., as in the judgment of the editor are necessary to illustrate articles, will be furnished when photographs or drawings are supplied by the author.

Reprints (250) of Original Papers will be furnished gratis to authors making the request. Covers to these and extra reprints will be furnished at net cost.

Advertisements.—Advertising forms go to press 8 days in advance of the date of issue. Therefore, in sending in copy, time should be allowed for setting up advertisements and for the sending and return of proofs. The advertising-rate is one dollar per page per thousand of issue. Double prices for preferred positions.

Change of Address.—In ordering a change of address it is important that both the old and new addresses be given.

Remittances.—Remittances should be made by check, draft, registered letter, money or express order. Currency should not be sent, unless registered. Stamps in amounts under one dollar are acceptable. Make all checks, etc., payable to American-Medicine Publishing Company. Address all correspondence to 1321 Walnut Street, Philadelphia.

Sentiment and Fact as guides of opinion and legislation are illustrated in the unfortunate controversy over the canteen question. One writes that "the sale of liquor and the regulation of vice are crimes against God and man." But it is plain that all such statements beg the question, and that if we govern our minds and conduct by such methods of reasoning we cannot govern them by the scientific method of dependence upon facts. At the recent meeting of the American Medical Association a competent observer brought out the truth of the interdependence of morals and disease in a way to throw a new light upon the canteen controversy. He said that statistics had shown in some posts that there had been twice as many cases of venereal disease since the canteen had been done away with, as compared with the records made during the existence of the canteen. It is not yet definitely settled that this is generally true at all army posts, and what we need is scientifically prepared statistics. These we are in the way of having, the Secretary of War having commanded them to be made by post commanders. Until these reports have been made public we have only sentiment and dogmatism upon which to base judgment, and these are certain to lead us astray. Let us wait for the facts.

Flies as Disseminators of Disease.—A number of investigators recently have called attention to the important role played by insects in disseminating disease. Because of their great numbers and active habits, flies are no doubt the most dangerous insects in this respect. After feeding on the expectoration of the tuberculous, on the feces of typhoid patients or other infective material, they carry disease germs into innumerable places and deposit them not only by direct contact with their filthy little bodies, but by their excreta and the dust formed by the crumbling of their dead bodies. Restaurants infested with flies are special abominations. The danger from this source is not small and as the summer will now soon be on us in good earnest with hordes of these pests, it seems desirable that everything possible shall be done to limit the amount of mischief done by them. More effective measures are needed for destroying flies and preventing their multiplication. The war on mosquitos by our sanitary department in Cuba has shown what can be done in exterminating insects, and the preparations which are already being made in several different places in our country to carry out the Cuban methods show that the people are willing to act

if they are shown the best ways. Until some successful method has been devised for exterminating flies special care should be taken to prevent their access to sputum, pus, or other infectious material; fruits and foodstuffs should be thoroughly cooked or washed if flies have been allowed to come in contact with them, and should be protected from flies after preparation for use.

Raising the Standards in Medical Colleges.—Wholesale denunciation of medical schools because they turn out so many imperfectly equipped graduates is rapidly becoming unjust, since so many schools are making positively heroic exertions to elevate the standards. We shall have to learn to discriminate carefully hereafter and place the blame where it belongs. There are a number of Faculties which have entered upon a systematic course of exclusion of the less fit which for many years almost means ruin for the institution and certainly does mean positive hardship for the teaching body. One instance has come to our notice in which this ruling would surely reduce the annual income from tuitions, etc., by at least \$25,000, and to that extent creating a deficit; and yet the vote was passed, and the refused applicants of course at once went to the rival schools with lower standards. The greatest need in medical education is today an extension of this spirit to all the schools. The overcrowding would not be so harmful as it is if it were an overcrowding by competent men.

Practical Applications of Extract of Suprarenal Medulla.—Some very interesting and important suggestions regarding practical uses of extract of suprarenal medulla have been made by Schafer in a recent number of the *British Medical Journal*. His first suggestion is that a trial should be made of the extract in all cases in which it is desired to strengthen or to induce uterine contractions. The observations that Schafer and his assistants have made show that this extract has a far greater power in causing contraction of the muscular tissue of the uterus, whether pregnant or nonpregnant, than any other drug having the same reputed action, and this whether the extract be applied directly to the muscular tissue or be introduced into the circulation. It appears that the active principle is unaffected by the gastric juice, and that in consequence the extract may be given by the mouth. It is suggested, however, that in

postpartum cases it would doubtless be more advantageous to inject it directly into the uterine cavity, where it would not only tend to produce immediate contraction of the uterine musculature, but also of the uterine arterioles, and thus more effectually control uterine hemorrhage. The solution recommended consists of an infusion of dry medullary substance, 30 grains to a pint of water, which should be sterilized by boiling, and injected while fairly hot. Such a solution is said to be a powerful styptic, but is rendered still more powerful by the addition of 60 grains of calcium chlorid. In addition, it is stated that another class of cases in which the extract in question may prove of the greatest clinical value are those of sudden cardiac failure, whether the result of shock, or of an overdose of anesthetics. In these cases the sterilized decoction, which may be of the strength of 5 grains to a fluid ounce, and must be filtered, should be injected with a hypodermic syringe very slowly into a superficial vein, or even in extreme and apparently hopeless cases, into the heart itself through the thoracic wall. Schafer reports that he has seen such remarkable results from the application of this method to animals in which the circulation had apparently ceased, and in which the heart had been completely resuscitated by the action of the drug, that he has no hesitation in recommending that it be tried in this class of cases in the human subject. The material used consisted of the separated healthy medulla of the ox or sheep, rapidly dried in thin layers at a temperature of not more than 50° C., then powdered and kept in well stoppered bottles. In this form it is said to retain its activity for a considerable time, and an infusion may be prepared from it in several minutes. The exact strength of the solution for purposes of intrauterine solution is said to be immaterial; any that might be absorbed into the general circulation would be beneficial rather than otherwise. For intravenous injection in cases of cardiac failure a weaker decoction than that above indicated can be used, but it should then be made with a 0.9% salt solution, and injected warm. It is said that a dose of 5 grains of the dry medullary substance may be introduced into a vein in this way slowly without fear of deleterious results, and that it may be repeated if found necessary. These suggestions seem of extreme importance and well merit the attention of careful clinicians. If the test of experience should confirm their practical utility the field of organotherapy will have become considerably enlarged. To the indications for the employment of the suprarenal extract will be added several others of not less importance than those already known. Perhaps we may find that the medulla and the cortex of the suprarenal gland subservise different functions, and that the range of the therapeutic applicability of the extract of the one is different from that of the extract of the other.

The Analysis of Commercial Food Products is engaging the attention of some of the State laboratories in which splendid work is being done and it is a pity that such reports as that recently issued by the Connecticut Agricultural Experiment Station could not be placed more generally in the hands of physicians. The general

practitioner should be informed of the sophistications commonly present in the ready-prepared food stuffs so largely consumed by Americans. The percentage of baking powders which contain alum, gypsum, or talc as adulterants, is astonishingly high, and it is a satisfaction to learn the real constitution of brands made familiar by the ever present advertisements lauding their purity. Let us hope that in the near future some similar means will be found of making public analyses of the nostrums with which the people are deluded.

The Sacrosanct Tub-Bath.—The typical Englishman has been pictured as refusing to enter heaven when he found that he would not be allowed to carry in his bath-tub with him. We have never been able to determine whether this gentleman flattered himself more by his pronunciation of the word *baath* or by his reputation for cleanliness by means of it. Both the bath and the cleanliness are excellent things, far superior indeed either to the assumption of superiority, the pronunciation or the immersion. There is only one Lodge of Perfection above that of the tubber—the unexpressed contempt of the clean man for the tubbing egotist who advertises that there is no cleanliness without the tub. The simple truth is, of course, that perfect cleanliness of the body is far more easily secured by means of the sponge or a wet towel with a pitcher of water than by a huge tub full of water. We have no doubt that the rage for tubbing has not only harmed or (mercifully) killed thousands of tubbers, but has in a general way made the world a dirtier one. By everlasting inculcation of the untruth that there is no (sanitary) salvation except by immersion, millions of people go to another extreme and do not bathe at all or use an insufficient amount of water. Do half the people in the world wash their bodies once a year? Bathing in such water as we have in many cities may be considered dangerous or disgusting according to the amount of water used. In order to have pure water for bathing or anything else it must be filtered. This will inevitably bring the water meter. Then the financial argument will reinforce the sanitary one, that perfect cleanliness is as attainable with two gallons of water as with 200 gallons.

A Survival of Another Age.—Those who have looked a little carefully at the politics, the jealousies and the hatreds, half-smothered or in volcanic eruption, of some of our medical schools, may have been startled by a recent phenomenon wholly at variance with these ferocities. Two men of great scientific ability in the same specialty and in the same department of a college, expect that the coveted professorship must in time come to one or to the other. And yet there is not the least suspicion of one seeking advantage at the expense of the other; neither forms alliances, or enters cliques, and the friendship between the two is so pure and sincere that one dedicates to the other, his equal, his exceptionally fine surgical text-book. The fact is enheartening; may it encourage others to renounce the savage animosities and self-seekings that justify the pointed finger of scorn, and that cripple all our educational and professional progress.

A More Scientific Study and Treatment of Stammering is one of the demands of progress and humanity. It has been said that there are more "speech-hesitants" than there are blind, mute and insane combined. This large class of sufferers has been left in a shameless inconsideration. The affliction is always wide-reaching in its influence upon the patient's life and character and frequently results in the most pathetic of tragedies. There is reason to believe that proper attention and treatment would usually lead to perfect cure. Here is a reform and a work waiting for wide-awake and progressive school boards, and medical officials interested in our public schools. Stammerers have quite as just a claim for public guidance and help as have those afflicted with disorders of sight, hearing, etc. It is not sufficiently well known that the first regular professorship of disorders of speech in a medical college was established in Philadelphia several years ago and has in practice demonstrated the wisdom of those who advocated it. So far as we know there is not a second in the world. There should be a hundred, as the work is in the interests both of humanity and of science.

Journals edited and published by the insane, judging by a sample copy before us, are brighter and more sane than many that are sent out by supposedly normal-minded people. We are surprised to see Vol. IV., No. 4, upon the copy of the *Maryland Hospital News* just received. (How many such periodicals are there in the world?) We can scarcely understand in what way a man can be insane who has such good judgment as is shown by the editor, especially in his tart but just criticism of the *Lunatic Herald*.

Among the "Local Briefs" we note:

"Private instructions in dancing will be given during the coming summer. Special attention to physicians' movements."

"One ounce of mother is worth one pound of clergyman."

We cannot forbear making one longer quotation:

"The hospital physician always means well, and does a great deal of genuine good in his work as a medical man; but he is not a shoemaker, and his opinion that a number nine shoe is comfortable for a number seven human hoof does not add glory to his fame as a medical man. . . . But the hospital physician, in the subordinate relation to the superintendent, is sometimes chary and cautious, and while not neglecting the more important issues that confront him, he is inhibited with a feeling of social reserve. Sometimes what he says does not always meet with the approval of his chief; if he happened to be like his practising brother of the rubber-tired buggy and hob-tailed horse, he would frequently find physical complaints which would baffle his skill and cause him to seek consultation to clear his way for responsibilities of life. The hospital physician in the treatment of his patients has to deal with mental maladies as well as physical; therefore the man who is the best judge of human nature, and not necessarily the best diagnostician of mental diseases, is the one who is superior in results. When a person has been drugged, tricked, fooled and hood-winked by his friends and physicians, and arrives in the hospital for the insane, the new patient is sometimes intensely aggravated at the deception, and strangely alarmed by the condition in which he is placed. The hospital physician has to overcome this state of affairs and establish himself as the friend of the patient; to do this, preconceived ideas based on the history of the individual committed must be a minor consideration until the confidence of the patient is mutually created."

"The Cause was Traceable to Heredity," says the recent excellent report of a medical director of a hospital. In one-fifth of the cases of insanity the cause was directly traceable to this factor and the hereditary taint existed in one-fourth. "With predisposition and certain environments, insanity is but the natural sequence." And yet we smile at the old cosmogony which said that the world rested upon the elephant, the elephant stood upon the tortoise, etc., etc. What caused the heredity, becomes the pertinent and discriminating question. It is remarkable in our hunt for the pathogenesis of disease that we are so often satisfied with words and with secondary causes. Of course the word heredity explains nothing and we must search for the cause of the cause. What made the "predisposition?" It is all a repetition of the old error of much laboratory pathology—satisfaction with slide-making of the finished and dead products of disease. But the physician's function can only be to cure disease or to prevent it. If the bit of morbid dead tissue teaches no practical lesson of how to stop the living pathologic process it is useless. So, if insanity is due to heredity, as good physicians and citizens we must study heredity in the making. Is it not true that symptom-treating is usually our confession of ignorance of etiology? And if insanity, as well as many other diseases, are due to social evil, are we not social sinners as well as poor scientists if we refuse to follow up the etiology, and thus prevent the morbid results?

The Devil is an Ass, said the wisest American, and it is most fortunate that this is so. Were it not for the stupidity of the malignant, society, and especially medical society, would quickly and hopelessly degenerate. When cliqueism, medical college politics, or newspaperdom, for instance, inject themselves into medicine, some boorish blunder soon defeats the very ends sought. The old politician loses his tact, and goes stumbling to obscurity and death. Even Napoleon finally forgot to plan with the old time foresight. Hate and intense selfishness blind even the best intellects and obtund the best sensibilities, until good men at last come by their own. One of the most pathetic things is to watch physicians starting in life with good mental endowment and scientific ability, but with heathenish selfishness and recklessness of the profession or of the rights of others—to watch them deteriorate until friendship, honor, and at last even success, are all lost. Koch and Behring make no scientific discoveries after selfishness and success become their ruling motives.

Health Resorts and "Kurs" as a Substitute for Quackery.—There are no words in English that have the same significance as *Kur* and *Kurort* in German. Some enterprising German doctor discovers that the water of a spring near his village contains a large percentage of alkalis; he furnishes a few rooms in his house for the accommodation of patients, advertises the marvelous curative properties of his spring water in the treatment of various diseases, and if he has a good business head and a fair degree of skill in treatment he soon has a large sanatorium, his little place becomes a well-known *Kurort* or health resort and his system of

diating, bathing and exercise, with the few medicines which he judiciously uses and drinking the harmless mineral water becomes a recognized "Kur" or system of curing certain diseases. There is a "Kur" for every known disease and many of these, such as Schott's system of treatment for heart disease and the springs at Karlsbad and Marienbad now have a world-wide reputation. But not alone the virtues of mineral springs are used as an excuse for establishing a Kur: there are numerous *Molkenkürs* where the patients are expected to drink large quantities of whey to improve their health; *Traubenkürs*, where the patients eat several pounds of fresh grapes a day; *Luftkürs*, where the air is supposed to be specially favorable for respiratory troubles, and others too numerous to mention. Prices can be found suited to every purse; from the princes and barons who go to the expensive Karlsbad hotels to the petty official who goes to an inexpensive resort in the Black Forest. There are numerous people in every community who when their chronic ailments are not promptly cured by the rational treatment of well-educated regular practitioners of medicine are credulous enough to turn to ignorant quacks, Christian science, osteopathy, and kindred delusions. Intelligent people who would never allow themselves to be swindled by bunco-men are daily swindled by these forms of quackery and by patent medicines. In Germany, where the proprietors of patent medicines must make public property of their formulas, and where the strict laws discourage quackery, there must be something for the credulous to turn to and the Kurs supply this demand in the best possible way. No doubt much more good comes from the regime than from the mineral waters, etc. The carefully regulated diet, bathing and exercise, the quiet, rest and change of scene for several weeks or months, cannot fail to do almost any person good and in very many cases a real cure results. The proprietors of such resorts are by no means without justification for their extravagant claims. It would not be a bad exchange for us in America if we could see a part of the thousands which now go into the pockets of quacks turned to reputable members of our profession as proprietors of such well-regulated resorts.

Mr. Eustace Miles, in *Health Culture*, suggests that on ocean steamers there is too much and too expensive food eaten (at least served) and that a line of steamers which should furnish cheap, simple and wholesome food would be in the interests of the traveler's health and of his expense account.

A digest of the laws now in force, and a transcript of the laws, rules and regulations, and proclamations in reference to bovine tuberculosis in the several States and Territories of the United States has been issued by the Chief of the Bureau of Animal Industry, D. E. Salmon.

The *British Medical Journal* has received a report from a contributor ascribing an epidemic in Southwark of enteric fever as due to infection conveyed by the fried fish of a particular dealer. If proved true this is a new method of convection of the infection.

EDITORIAL ECHOES

Proofreading as She are Done.—From recent editorials in medical journals we quote a few pleasing sentences:

"In spite of the assiduous endeavors of certain philanthropic medical editors to guide the literary aspirant through the mazes of syntax and autography—"

"Patches of tinea versicolor frequently occur in the public region in both men and women."

"A well developed systolic murmur, significant either of vulvular atheroma and sclerosis, or—"

"The author culls from the literature a number of other reported cases, the most remarkable of which is that of a German surgeon, the pregnancy resulting in a tube implanted in the vaginal vault after hysterectomy."

Trephining.—At a recent meeting of the Society of Anthropologists a very interesting communication was received on the subject of trephining in the South Sea Islands. The operation appears to be done at the present time for the relief of headache, for injuries to the skull, and as an aid to longevity. The author of the paper, Rev. J. A. Crump, mentions that he has in his possession a skull which has been trephined in no less than five places; this was done for severe headache. After the reading of the paper Mr. Horsley pointed out that the fact that it was a common thing for the South Sea Islanders to resort to trephining for the relief of headache supplied the absolute proof that was wanting to corroborate the opinion expressed in regard to the trephine holes found in the prehistoric Peruvian skulls. —[*The Medical Press.*]

Bovine and Human Tuberculosis.—The *Journal of the American Medical Association*, describes the experiments of Dr. Dinwiddie of the Arkansas Agricultural Experiment Station which negative the belief that there is much danger that animals may be infected from man, and adds:

"There are a large number of exaggerated statements going about, many of these from medical sources, that may seem to some justifiable in view of the real peril that exists and the need of popular education in regard to it. Their publication, however, is not scientific, and it is just as well to have our attention occasionally called to facts that seem to indicate that some of the expressed views may not be as scientifically accurate as the impression created by their utterance would imply. Tuberculosis is enough of a peril; its real dangers, when stated, are formidable enough; there may, therefore, be some little consolation in occasionally recognizing facts which indicate that in some ways and in some cases the danger of infection may be less serious than some commonly-uttered statements would lead us to suppose."

The Treatment of Osteopathy.—What is the kernel of therapeutic truth in osteopathy? Simply that the more or less judicious movement of diseased parts cures such parts. This fact is demonstrated by the position of the Ling system in Swedish medicine, by the cures wrought among us by the imported masseurs and their imitative rubbers, and by the great popularity of osteopathy among the laity. What is the harm of it? The harm of it is its indiscriminate application as a "cure-all"—a system of cure—by its enthusiastic but poorly educated leaders. What is the profession doing to reclaim this lost territory to its own? With us the little done is left to the untrained or the imported. Nothing is done to popularize the method, and this remedy of undoubted therapeutic value is wholly neglected in our smaller communities. The time is ripe and the ground ready for a well-officered and well-equipped school of massage and physical culture.—[*Northwestern Lancet.*]

Christian Science and Life Insurance.—"In denying insurance to the dangerous fanatics of whom the

'Christian Scientists' are the best known variety, the New Jersey Grand Council of the Royal Arcanum has taken a stand that is open to criticism only because it was not taken long ago. Every other organization of the same character ought instantly to imitate the example thus set, and delay in doing so simply subjects to unjustifiable risk the property rights of the sane members of the societies. 'All persons,' to use the words of the resolution adopted by the Grand Council in explanation of its course, 'who reject, refuse or neglect the aid of medical science are a very dangerous risk from an insurance standpoint.' That is an unquestionable truth, clearly stated. Since the 'Christian Scientists' deny the existence of disease and of death itself, the commonest sort of consistency demands that they voluntarily get out of the mutual insurance organizations, allow their policies in the regular insurance companies to lapse, and carefully refrain from stultifying themselves by taking out any new policies. If they will not do this—and of course they won't, as consistency is something they know nothing about—compulsion should be applied exactly as the Royal Arcanum has applied it. A little discipline of the same sort, used in this and other directions where it is needed, would tend to bring back to their senses all the believers in 'faith cure' except those whose insanity is irremediable, and there are not many so far gone as that. The follower of any one of these delusions is not a safe person with whom to have either business or social relations. The means of applying pressure are numerous, and as soon as sensible people begin to utilize them 'Christian Science' and all the allied or identical humbugs will be dissipated as rapidly as are other filth-laden miasms by the attack of good fresh breezes."—[*The Times.*]

The Pathologic Unity of Tabes and General Paralysis.—Mott has examined twelve cases of the tabetic form of general paralysis, and found in the brain the changes characteristic of general paralysis and in the cords the general changes peculiar to tabes, namely, degeneration of the exogenous system of fibers. He emphasizes as supporting the general trend of his argument that juvenile general paralysis and juvenile tabes probably occur only in congenital syphilites. Krafft-Ebing's epigrammatic summary of the etiology of general paralysis, in the two words, "civilization" and "syphilization," with special emphasis on the latter, represents the general teaching of a number of prominent students of this perplexing malady. Many of the prominent London clinical neurologists took part in the general discussion, and on the whole the views expressed agree with those of Mott. All the speakers endorsed the view that syphilis is the preponderant factor in tabes, and this seems to have been generally accepted as true also of general paralysis. Indeed, Ferrier has come to the conclusion that if there were no syphilis there would be no general paralysis or tabes. Of course it is impossible to prove a statement like this, but certainly there is much in favor of this view. The question whether tabes and general paralysis are one and the same morbid process affecting different parts of the nervous system, although perhaps to a certain extent a question of words, receives an affirmative answer in so far as both are considered as the result of parasymphilitic lesions of similar pathogenesis. From the standpoint of prevention this is an exceedingly important doctrine, because all measures limiting the spread of syphilis will diminish the frequency of tabes and general paralysis.—[*Journal American Medical Association.*]

The *Medical Press* calls attention to a new symptom of paralysis agitans, immediately preceding other recognized symptoms of the disease. This consists of the contraction of the toes, so that these are curled and flexed under the foot, making the patient liable to be thrown down.

AMERICAN NEWS AND NOTES.

GENERAL.

To Act as Surgeon-General.—Col. William H. Forwood, of the Medical Department of the Army, who has been in charge of the important medical depot station at San Francisco for months, has arrived in Washington, D. C., to take charge of the Medical Department of the Army, during the absence of Surgeon-General Sternberg in the Philippines.

Yellow Fever in Costa Rica.—A report from Marine Hospital Surgeon Goodman, at Port Limon, Costa Rica, announces that no passengers are now being taken by the fruit companies there for southern ports of the United States. An official report to the Costa Rican national authorities tells of the prevalence of yellow fever at Liberia, a city of 6,000 inhabitants, in the Province of Guana Caste, Costa Rica.

Obituary.—CHARLES S. SEEBOLD, of Baltimore, June 12, aged 51; B. F. REYNOLDS, of Oakmont, Pa., June 12, aged 67; ARTHUR J. DRESSER, of Tewksbury, Mass., June 12, aged 28; LOUIS S. TESSON, at Vancouver Barracks, June 7; R. W. LINGLE, of Orleans, Ky., June 11, aged 63; ALLEN T. BARNES, of Louisville, Ky., May 30, aged 67; JOSEPH FARRAND TUTTLE, at Crawfordsville, Ind., June 8, aged 73; J. H. McCARTY, of Birmingham, Ala., June 11, aged 50; C. B. BROOK, of Baltimore, Md., June 11; WILLIAM J. CAMPBELL, at the Worcester City Hospital, June 14, aged 27; WILLIAM S. WORCESTER, of Danvers, Mass., aged 56; P. A. HARRIS, of Glendale, May 30; FRANCIS W. COLEMAN, of Tulane University, New Orleans, May 28, aged 55; LILLIAN E. ABBOT, of New York, May 28, aged 33.

EASTERN STATES.

The King's Daughters and Sons' Hospital, Springfield, Mass., has applied to change its name to "The King's Daughters and Sons' Hospital Company of New England." It was also voted to so enlarge the hospital that space might be secured for incurable patients.

NEW YORK.

Physician Declared Insane.—Dr. Charles J. Kane, of New York, was transferred to the Manhattan Asylum for the Insane, June 11.

The New York Institute for the Deaf and Dumb held its eighty-third annual commencement June 11. It has 432 pupils and 40 teachers. There were 20 graduates.

Rockefeller Institute for Medical Research.—Articles incorporating the institution, with its principal headquarters in New York City, were filed recently with the Secretary of State.

Memorial to Dr. Skene.—A monument will be erected in Brooklyn to the memory of the late Dr. Alexander J. C. Skene, at a cost of \$25,000. Dr. Skene was a man of great eminence, and well known to the medical profession all over the world.

Home for Incurables.—At the thirty-fifth anniversary of this institution, at Fordham, it was announced that \$30,000 would soon be received, to be used for improvements. There are 265 patients in the Home. Last year there were 75 deaths.

Suit Against Physicians.—The second trial of an action brought by Miss Lucy W. Kellen, of New York, against Drs. Morris Menges and Julius Rosenberg for \$60,000 damages, resulted in a victory for the physicians. Miss Kellen alleged that they had operated on her unskillfully and without her consent, and that she was permanently injured. The first trial of the action resulted in a disagreement of the jury.

PHILADELPHIA, PENNSYLVANIA, ETC.

The Jewish Seaside Home for Invalids, at Atlantic City, opened for the summer June 13. The home has been remodeled and renovated and is under the management of the Jewish Maternity Association.

The Delaware State Medical Association held its 112th annual session at Lewes, June 11. The officers elected for the year are Drs. E. S. Dwight, of Smyrna, president; Robert Elligood and H. G. Koilock, vice-presidents; John H. Palmer, secretary, and W. C. Pierce, treasurer. The next session will meet at Newark.

Pottsville Hospital.—From the stocks and bonds in the bequest of Joseph Jeans the hospital will enjoy a yearly income of \$737.50, while to the endowment fund has also been added the sum of \$5,000 by a friend who does not wish to have his name known. This makes the total endowment fund \$33,714, with an assured annual income of \$2,009.75. In this is not counted the Gressle bequest of \$10,000 and several others of equally liberal amounts which have been made.

State Aid for Hospitals.—In the House the following bills have been reported from the Committee on Appropriations: German Hospital, Philadelphia, \$53,000; Wilks' Eye Hospital, Philadelphia, \$10,000; Pottstown Hospital, \$12,000; Homeopathic State Hospital, \$300,000; Chester County Hospital, \$12,000; St. Francis Hospital, Pittsburg, \$15,000; Mercy Hospital, Pittsburg, \$80,000; South Side Hospital, Pittsburg, \$30,000; Bradford Hospital, \$19,000; Phoenixville Hospital, \$17,000; Western Pennsylvania Humane Society, \$2,000; Home for Feeble-minded, Polk (special), \$3,476.35; St. Mary's Hospital, Philadelphia, \$10,000; Women's Hospital, Philadelphia, \$25,000; Beaver Valley Hospital, Beaver, \$7,000; Mary M. Packer Hospital, Sunbury, \$8,000; St. Timothy's Hospital, Philadelphia, \$30,000; Charity Hospital, Norristown, \$23,000; West Side Hospital, Scranton, \$15,000; Christian H. Buhl Hospital, Sharon, \$13,000; Shenango Valley Hospital, New Castle, \$15,000; McKeesport Hospital, \$27,000; Butler Hospital, \$15,000; Women's Hospital, Philadelphia, \$5,000; Jefferson Hospital, Philadelphia, \$158,000; Institute for Feeble-minded of Western Pennsylvania, \$510,000; Hahnemann Hospital of Philadelphia, \$50,000; Garretson Hospital, Philadelphia, \$40,000. The following appropriations passed the House: Howard Hospital and Infirmary for Incurables, \$8,000; Philadelphia Lying-in Hospital, \$15,000; Western Pennsylvania Hospital for the Insane at Dixmont, \$25,000; for the care and treatment of the indigent insane, \$1,700,000; Easton Hospital, \$15,000; State Hospital for Injured Persons of the bituminous and semibituminous coal region, located at Blossburg, Tioga County, \$18,500; West Philadelphia Hospital for Women, \$2,500; Pennsylvania Epileptic Hospital and Colony Farm, \$10,000.

SOUTHERN STATES.

Mosquitos.—James Bosley, Commissioner of Health, of Baltimore, has issued a statement to the citizens, showing the efficiency of kerosene oil in preventing the breeding of mosquitos, and requesting that every householder pour 1 gill of the oil into their privy wells and a proportionate quantity into all pools and drains where stagnant water may collect, at least once every 2 weeks. He states that in 1902 the city government will be asked for an appropriation for this purpose. Dr. Alexander N. Stark, a surgeon in the United States Army, recently returned from Cuba, has tried the plan in Cuba with pronounced success. His experience was at Columbia Barracks. Crude petroleum was floated on the surface of the lagoons, the proportion used being 1 ounce to 10 square feet of surface. The result was that not only the larvae were destroyed, but the adult insects were deterred from depositing their ova. At the same time, all soldiers suffering from malaria were carefully confined beneath nets and subjected to the usual treatment for malaria until free from symptoms and the examination of blood showed absence of all evidences of the disease. The result of this experiment was the absence of a fresh case of malaria for a period of 18 months.

WESTERN STATES.

Bequests to Charity.—The will of the late Dr. Marie J. Mergier, who died last month at Los Angeles, Cal., leaves \$3,000 for a scholarship in psychology to the University of Chicago and the same sum to the Women's Hospital of that city.

Spencer Hospital for the Insane.—Dr. A. J. Lyons, of Parkersburg, W. Va., was elected superintendent. The resignation of Dr. A. F. Guthrie was accepted, he having been elected superintendent of the Home for Incurables at Huntington, another State institution.

Suicide by Suggestion.—An epidemic of suicides in Emporia, Kansas, caused the Mayor and Board of Health to forbid publication of details of suicides or attempts in local papers. The board is acting on the theory that publication spreads the contagion of suicide by psychic suggestion, and contends that the liberty of the press is secondary to public health, and is prepared to use force, if necessary, under the nuisance act. In the last 30 days there have been 7 cases, 3 successful.

CANADA.

Notre Dame Hospital.—Dr. Aldege Ethier, medical superintendent, who leaves in a short time for Paris, will be succeeded by Dr. Fleury. Drs. Brosseau, Chapdelaine, St. Pierre, and Grenier have been appointed members of the staff.

The Canadian Tuberculosis Association has recommended to the Canadian Government restrictions similar to those recently issued by the United States Superintendent of Immigration in refusing to allow into the United States immigrants suffering from tuberculosis.

The Halifax Board of Health recently reported that the city was free from contagious diseases and that there were no patients at the Infectious Disease Hospital. Dr. Venables wrote the Board in reference to his campaign of vaccination. He had recently covered a large territory and had met with great opposition in many quarters. In fact, in one section of the city he had received a personal attack in the discharge of his duties.

FOREIGN NEWS AND NOTES

GENERAL.

Obituary.—Surg.-Captain FRANCIS WELFORD, at Vlaktefontein, South Africa, May 29. JAMES AITKEN MYRTLE, at Harrowgate, England, May 27, aged 40. Prof. W. H. HEINEKE, at Erlangen, Germany, April 28. JAMES GRIFFITH HALL, at Swansea, England, May 28, aged 87. HENRY LLEWELLYN WILLIAMS, April 30, at London, aged 73.

The Vision of the Boers.—In view of the extraordinary powers of vision credited to the Boer soldiers by numerous war correspondents, it is of interest to hear the opinion of an expert ophthalmologist on this subject. Mr. R. Brudenell Carter, who some 5 or 6 years ago conducted the examination of the vision of a large number of London school children, and who is an authority on visual standards, stated very recently at the Society of Arts that, from the application of his experience to the course of the war in South Africa, he believed the great majority of British soldiers, after a fortnight's exercise on the veldt, would see distant objects as quickly and distinctly as the native Boers, and their interpretations of appearances were quite as accurate. This opinion is endorsed by several British army surgeons who served in the Transvaal.

Bubonic Plague.—A despatch from the Governor of Hongkong announces that 215 cases of the bubonic plague were officially reported during the week ended June 1, and that the total number of deaths thus far from the disease is 207. The report from Cape Town states that 700 cases have been reported, and that 58 Europeans, 61 colonists and 207 negroes have died from the disease. In British East India the disease appears to be increasing. In the Presidency of Bombay, during the week ended April 12, there were 1,947 new cases and 1,632 deaths. This is an increase of 172 cases and 127 deaths over the previous week. The increase is noticeable in Karachi, where, in the same week, 230 fresh plague cases and 209 deaths occurred. In the same week 715 deaths were reported and 492 others suspected in Bombay city. There are many thousands of plague deaths reported from other provinces of India, the largest number being in the Patna division of Bengal, where, up to April 27, a total of 437,681 cases were reported.

GREAT BRITAIN.

Gift to Charity.—Foxhall Keene has sent £2,650 to the Prince of Wales's Hospital Fund, the amount being one half of the Oaks purse.

F. Richardson Cross, of Bristol, delivered the annual oration of the Medical Society of London on May 20, on the subject, "Some Landmarks in the Progress of Medical Science."

CONTINENTAL EUROPE.

Berlin Hospital.—The intention of the Sultan of Turkey to present a wing to the Berlin Hospital, the plans of the addition having been sent to Emperor William for approval is announced at Berlin.

Absinthe consumption in France is markedly on the decrease. This is officially regarded as a consequence of the new liquor law, which greatly reduced the tax on wines; increasing their consumption, since the first of the year, 50%.

A Moscow physician, according to the *St. Petersburg Medical Wochenschrift*, charged with inoculating 3 of his patients with syphilis, has been condemned by the courts to 6 months of imprisonment and loss of all his professional privileges for a certain length of time.

Economy in the Use of Drugs.—The Secretary-General of the Bureau of Public Aid of Paris has issued an order to the hospital chiefs in which he points out that the expense of modern medicinal preparations is enormous; he begs the profession to be as economic as possible in the use of a number of drugs, such as crystallized digitalin, which costs 15,000 francs a pound. Musk, osmic acid, pilocarpin and its salts can henceforth be prescribed by no one but the hospital chief himself.

Diphtheria in Paris.—During the first 4 months of 1901 there have been reported in the city of Paris 1,262 cases of diphtheria, 225 of which were fatal. In the corresponding period of last year 563 cases, 121 deaths; in 1899, 624 cases, 180 deaths; in 1898, 624 cases and 138 deaths. Roux considers the increased mortality due to defective administration of the antitoxin. He emphasizes that the serum must be used as early as possible. Bayeaux proves from statistics that if the disease is treated during the first day, the mortality is reduced to between 1 and 13%; if used on the second day the mortality rate increases to between 6 and 10%, rising to 20-25% if serum injection is delayed to between the second and fourth days. The Prime Minister, M. Waldeck-Rousseau, has issued a circular to the medical men of France, pointing out these facts, and urging them to make immediate use of antitoxin.

SOCIETY REPORTS

NINTH CONGRESS OF THE GERMAN GYNECOLOGICAL SOCIETY.

May 29-31, 1901.

[Specially reported for AMERICAN MEDICINE by J. EDWIN SWEET.]

The German Gynecological Society, which meets every second year, assembled for its ninth session in the city of Giessen, in the grandduchy Hesse-Darmstadt, the seat of the University of Giessen. The society has some 350 members, about half of whom were present. The Congress began with the usual informal greeting on Tuesday evening. The first session, after the President's address by LÖHLEIN (Giessen), was devoted to the first main topic, **Carcinoma Uteri**. The topic had been referred to FREUND, Senior, (Berlin, late of Strassburg) and WINTER (Königsberg), who had compiled very elaborate papers; these papers, together with those on the second main topic, **Eclampsia**, referred to FEILING (Strassburg) and WYDER (Zürich), had been published and sent to the members of the society before the opening of the Congress, so that each member could inform himself at his leisure as to the present stand of the question. The plan has also the advantage of saving the Congress much time and patience otherwise spent in listening to lengthy theoretic discussions. The paper by FREUND, taking up the pathologic side of the question, **The Radical Operation for Cancer of the Uterus, with Especial Consideration of the Lasting Results**, is a very complete monography, reviewing exhaustively the late publications on the subject, with the view of finding whether the modern pathologic-anatomic study of cancer in general and cancer of the womb in particular has brought to light new facts which point out sure indications for a rational prophylactic or operative treatment. FREUND arrives at the conclusion that the clinician must wait for what the future has in store—the present stand of pathology throws no light on the question. From the theoretic standpoint the total extirpation with removal of the lymph-glands is the only rational procedure in every operable case. The vaginal route gives better immediate results, but the extent of the operation must be more limited than in the abdominal route. Freund specifies as follows the indications for operation: The portio carcinoma can be operated by vaginal total extirpation; cancer of the cervix and the corpus must be attacked by an early and widely extended abdominal operation, if one wishes radical cure. As regards a comparison of the 2 routes, one must operate all cases by the same method, not the early cases vaginal, the advanced cases abdominal, and then after 5 years we can arrive at some definite and just conclusions.

The paper by WINTER (Königsberg) discusses the so-called **Practical Methods of Operation for Carcinoma Uteri**, and endeavors to determine their utility and practicability. He examines carefully the 7 methods which have been devised, and comes to the following conclusions: (1) The amputation of the portio vaginalis cannot be considered a radical operation because it generally leaves carcinoma behind in the cervix, and pays no attention to the parametrium. He finds no scientifically founded objection to leaving the corpus uteri, and considers therefore (2) the amputatio cervicis supravaginalis indicated in cases when patient wishes to bear children, when there is great danger from the opening of the peritoneal cavity, where the removal of the corpus is extraordinarily difficult, or when patient is too weak to justify total extirpation. Nearly all those cases can be radically cured by (3) the vaginal method in which the disease has without doubt not gone beyond the bounds of the uterus. Only the ovarian metastases can be avoided by removal of the adnexa; recidivations in the lymph-glands cannot be prevented by the vaginal route. His statistics show about 10% lasting cures. Only cases of beginning disease or where the cancer has not spread to the lymphatics and the parametria can be operated by this route. (4) The sacral method must be struck from the list of the radical operations. (5) Freund's operation, *i. e.*, the abdominal extirpation of the uterus, paying no attention to the parametria and the lymph-glands, is justifiable in the same class of cases as is the vaginal method; it is advisable, however, to make full use of the laparotomy and remove lymph-glands, etc. (6) The amputatio corporis uteri supravaginalis is to be struck from the list of the radical operations. (7) The radical abdominal operation has 2 advantages over the vaginal route—it permits more thorough removal of the pelvic connective tissue and the removal of diseased glands. As regards the number of cases in which diseased glands have been found, Winter believes we cannot as yet form an opinion; careful studies in this direction are greatly needed. The abdominal route has given in Germany a primary mortality of 24.6%. The abdominal route can find its justification only in a consideration of the lasting results, and it is too early to know these, since the operation is but some 4 years old. When we consider the results of the vaginal method and what we can attain with this route by adding 10 early cases, and compare these results with the problematic success of the abdominal radical operation, it seems very probable that the vaginal uterus extirpation will remain the operation of the

future, and that the abdominal route will be attempted as a therapeutic measure where we can hope for no success with the vaginal route. Winter concludes: "The future of the surgical treatment of cancer of the uterus does not lie in the most extensive operation possible, but in the earliest operation possible."

Before the Congress FREUND speaks briefly: The discussion will bring nothing new. The main question is, **Shall we choose the vaginal or the abdominal route?** There are 3 factors to be considered in our decision: Has the pathologic-anatomic study of cancer brought us any light? No, for we are still in the dark as to the way in which cancer spreads and as to the real cause of the malignity of the disease. A second factor in our choice is analogy; surgeons operate in all other regions of the body—tongue, breast, etc.—as radically as possible; by analogy we must do the same in carcinoma uteri, and to do this radical operation we must choose the abdominal route. A third factor is the result of statistic study. Freund emphasizes that a statistic can only then be of value when we compare cases of the same kind operated upon under similar conditions. WINTER (Königsberg) speaks briefly, adding a few cases to his statistics.

The first paper is read by KÜSTNER (Breslau) on the **Abdominal Operation for Cancer of the Womb**. He prefers the abdominal route, because one can perform a more radical operation. He used Veit's modification, considering it a life-saving method. Before opening from the vagina he sews several tampons to the corpus, which absorb the blood in the abdomen, and then when the uterus is drawn out through the vagina sweep everything before them. Küstner thinks one should eventually resect the lower end of the ureter, since Winter has shown that the lymphatics run very close across the end of the ureter to the sacral glands.

SCHUCHARDT (Stettin): **The Paravaginal Method for the Extirpation of the Uterus, and its Final Results in Cancer of the Uterus**. Schuchardt points out first that cancer exists in different forms, that cancer of the rectum, for example, is less malignant than in other organs, and it is therefore unjust to compare the results of such cases with cancer of the womb. He considers it still an open question whether the extensive operation for cancer of the breast has really given better results. It is impossible to perform an unquestioned radical operation for carcinoma uteri, and we must therefore strive to remove the primary disease focus as early and as completely as possible. Schuchardt claims for his method, the so-called paravaginal incision, (1) that it is easily performed, hemorrhage is easily controlled, operative injury to neighboring organs is easily avoided; (2) indications for operation can be made much broader, in cases of stenosis of the vagina and where bladder and rectum are attacked by the disease, etc., and, further, the shock following the abdominal method in advanced cases is avoided.

LEOPOLD (Dresden): **Further Investigations on the Etiology of Malignant Growths**, reports on the organisms which he demonstrated at the Paris International Congress, as the cause of malignant tumors. Those organisms belong to the Blastomycetes; they grow in acid gelatine, best of all in bouillon. Leopold takes perfectly fresh and aseptic material, cultivating from this the organisms on the warm stage or inoculating animals and culture media. He has found the same organism in 8 cases of ovarian, uterus and mamma carcinoma. The results obtained from inoculation of animals were positive; the animals died, after a longer or shorter time, from extended tumor formations, which were sarcoma or carcinoma. In these tumors he found pure cultures of the original yeast organism. These second cultures proved more virulent than the mother culture. Leopold modestly sums up his results: Blastomycetes have been found in a number of malignant tumors; have been cultivated in pure culture and have caused tumors in animals. He does not claim that they are the only cause of malignant growths.

MACKENRODT (Berlin): **The Radical Operation for Cancer of the Uterus and Vagina, with Cleaning out of the Pelvis**, believes that the lymph-glands of the pelvis are infected more often than Winter has found—20%—or even than von Rosthorn—50%. A second more important point is the prevention of metastasis caused by the operative implantation of cancer particles. To avoid such implantations, Mackenrodt formerly performed the entire operation with the cautery. He has operated in 38 cases, of which 31 survived operation. Of 20 cases so far advanced that the vaginal route was impossible, he has 10 patients who are alive, 3 to 4 years since operation. He believes his results due to the prevention of implantations. He has now forsaken the cautery, believing that he has devised a better method for preventing inoculation, *i. e.*, operating with intact peritoneum. He makes 2 incisions on each side above the spine ant. sup., unites them by a cross incision, thus obtaining a large field for operation; the incision does not open the peritoneum. He then separates the peritoneum from the abdominal wall and the organs, sews it above the uterus and so removes the uterus without bringing it in contact with the peritoneal cavity. Sepsis is the main danger. He mentions that one of his assistants has discovered microbes of extraordinary virulence in the carcinomatous uterus.

At the close of the first session, KLEIN (Munich) describes the library of old medical books dating from the fifteenth century, which forms a special feature of the Congress. It

shows the progress made in the art of illustrating medical books.

The second session began with the paper by AMANN (Munich), **Remarks on the Therapeutics of Carcinoma**. He points out first that the better results of the last few years are to be ascribed in part to improved diagnosis. Local recidivation is most important. The results with the vaginal route are better than those for cancer of the breast with cleaning out of the axilla. Amann has operated in 14 cases, 3 of which he lost; in 4 cases the lymph-glands were affected. He has seen 2 cases where carcinoma of the retroperitoneal lymph-glands developed after 5 years, the pelvis remaining free. The vaginal and the parasacral routes do not permit an extended removal of the parametria. Amann has devised a new method; he first dissects the vagina from its surroundings and folds it in over the cancer, thus shutting off the purulent disease focus; then he incises above the os pubis without opening the peritoneal cavity, works forward by blunt dissection from the cavum Retzū, separating the peritoneum from the organs. He then makes a small incision in the peritoneum, draws out the corpus-uteri, and sutures the peritoneum behind the uterus. He claims that the method is practically extraperitoneal.

OLSTRAUSEN (Berlin), **The Statistics of and Operation for Cancer of the Uterus**, considers that the main danger is still from sepsis; formerly more than 60% died from sepsis; the improved results of modern operations are due to the thorough disinfection of the cancer before operation. He uses for this purpose Paquelin cautery, ferrum candens, or a 40% alcoholic solution of chlorid of zinc. His statistics show 683 cases, with 5% operative injury to the organs of the urinary tract. He has always preferred the abdominal route, considering that all our knowledge of cancer must lead us to choose the abdominal route. In his former operations he had 6% primary mortality; in the last 3 years 5%. In regard to the final results, his statistics show that of 169 cases 74% were free from a return of the disease for 2 years, 62% for 3 years, and 38.8% for 5 years. During the last 3 years he has performed the radical operation in over 50% of all cases. His views are in short, as follows: (1) When a collum carcinoma or a corpus carcinoma is but slightly advanced, the vaginal route is justifiable; (2) if a corpus carcinoma is further advanced, the abdominal route alone is indicated, in order to remove affected glands; (3) if the pelvic connective tissue is affected the chances of successful operation are small; (4) when the uterus is so enlarged that it cannot be extracted in its entirety, the abdominal route alone is indicated; (5) statistics showing lasting results of less than 5 years' standing are deceptive.

WERTHEIM (Vienna): **A New Series of Operations for Cancer of the Uterus with Extirpation of the Parametria and the Neighboring Lymph-glands**, first described his method; he operates with pelvis raised, incises from navel to symphysis. Catheterization of the ureters is superfluous and dangerous. He frees the uterus, parametria, etc., and the vagina, and then from above clamps the vagina tightly shut below the diseased part, and then removes the organs by severing the vagina below the clamps; he washes out the vagina before operation, but considers cautery, etc., unnecessary; by holding the vagina with clamps no septic material can escape into the abdominal cavity. He removes all glands to the dividing point of the aorta; swollen glands are not always cancerous, affected glands are not always swollen, so he removes everything. He advises not to free the ureter entirely from the surrounding tissue, fearing disturbance of the circulation. Twelve of his last series of 27 cases were too advanced for the vaginal route; of the 27 cases he lost 5, 2 from ileus with no demonstrable peritonitis, 1 miliary tuberculosis, 1 shock, 1 pyelonephritis. He believes with Gussenbauer that the lymph-glands are early affected, and illustrates his standpoint by schemata which show the glands which were affected in his cases. In regard to the indications, Wertheim emphasizes that infiltrated parametria are by no means always cancerous, and that cancerous parametria can often not be palpated, therefore he prefers the abdominal route to be able to operate radically if glands are affected.

LATZKO (Vienna) favors the catheterization of the ureters, not as Wertheim stated as an aid in finding the ureters, but to prevent injury to the ureters during operation.

FREUND, junior (Strassburg), has operated 15 cases by the abdominal route. He considers this method accompanied by less hemorrhage and cleaner. He uses Wertheim's method, and has never had septic peritonitis, although he does not even clamp the vagina as advised by Wertheim, to prevent the escape of septic material into the abdomen. He lost 2 cases from injury to the urinary tract. He does not fear implantation of tumor particles, holding that such implantations degenerate sooner or later. He thinks he placed his indications too broad, but would still use the abdominal route exclusively, and place the indications according to the case.

ZWEIFEL (Leipzig) considers that emboli are due to septic infection; he formerly had cases of embolus, but since then ligates, severs, and cauterizes, and has no trouble. Of the 246 cases recorded in the Leipzig clinic, 219 were operated by the vaginal route, 22 combined, the rest parasacral. Statistics show 4.8% operative injury to neighboring organs. The statistics are not complete as regards lasting results.

STANDE advises the double-sided incision according to Schuchardt. The operation is not easy, however, as Schuchardt

claims, and the hemorrhage can be enormous. Of 42 cases, Stande has lost 5, 1 from shock, 1 heart trouble, 1 six weeks after operation from diffuse carcinomatosis, 1 septic peritonitis, 1 died 12 days after operation with a constantly sinking temperature—cause not clear—autopsy refused. Of 36 of his cases, 15 have a return of the disease, 4 are lost from control, the rest cured, for how long Stande does not state.

HOFMEIER (Würzburg) thinks that the results of the last few years show the complete failure of the vaginal method as thus far performed. The hope of the future is not in a more extended operation, but in earlier operation. He thinks it impossible to completely clean out the pelvis, and the danger of the operation is great. Ten years hence we will consider the operation with cleaning out of the pelvis a mistake.

CHROBAK (Vienna) thinks we must wait and see which route is best. He records 212 radical operations, of which 37.1% were cured up to 5 years; results about the same as those of Olshausen. He has had no case of operative injury to other organs. He thinks cancer an infectious disease, and that we should use prophylaxis.

VON ROSTHORN (Graz) emphasizes the great difference between different cases of cancer, as regards malignancy, affection of the lymph-glands, etc. He operates always by the abdominal route because he has a better view of the field of operation; he advises long-continued preparation of the patient with syringe, cautery, etc. There is also a great difference in operations. Von Rosthorn tells how he operated 40 cases without losing a case; he thereupon described the operation to his students as simple and safe; "the punishment of God was swift, the next week I lost 3 successive cases." Death is not due to infection alone; the long narcosis, position of the patient during operation, anemia, suppurations of the pelvic tissue following the maltreatment to which it was subjected during operation account for a good deal. He believes in short, that one should individualize his cases; in many fresh cases the high amputation will suffice.

In the evening the members of the Congress were entertained at the "Philosophenwald," by the city of Geissen.

Thursday morning from 7 to 9, before the regular session, was devoted to demonstrations in the clinic. Of the numerous demonstrations might be mentioned AHLFELD'S method of disinfecting the hands. LEOPOLD demonstrates 2 cultures of his yeast organisms. VON ROSTHORN shows a rare case of cervix infarct. The third session was devoted to the second main topic, **Eclampsia**. The paper by FEHLING (Strassburg) treats of **The Definition and Pathogenesis of Puerperal Eclampsia**. He advances and endeavors to support the following propositions: (1) Definition: puerperal eclampsia is a definite, well characterized disease, which is connected with the reproductive period of woman; (2) there is no such thing as a characteristic eclampsia placenta; (3) there is no form of kidney disease pathognomonic of eclampsia; (4) a connection between eclampsia and dilation of the ureters is to be denied; (5) albuminuria is lacking only in the rarest cases of eclampsia; (6) there is no such thing as a specific eclampsia liver; (7) a definite characteristic anatomic picture of eclampsia does not exist, according to the autopsy findings known at present; (8) the view that eclampsia is infectious is at present entirely without proof; (9) Bouchard's view that the cause of eclampsia is an increased toxicity of the blood-plasma, continued with a decreased toxicity, or an entire absence of toxicity of the urine, cannot be held; (10) the explanation of eclampsia as a hepatotoxemia, or as a leukomaiemia is not proven; (11) some substance which causes coagulation, and which courses in the circulation seems to be of significance for the origin of the eclampsia changes in the body; (12) eclampsia is an intoxication of fatal origin. It will be noticed that the first paper of the session by SCHMORL (Dresden) overthrows a number of the propositions advanced by Fehling.

[To be concluded.]

AMERICAN MEDICAL ASSOCIATION.

ANNUAL MEETING AT ST. PAUL, MINN., JUNE, 1901.

[Specially reported for AMERICAN MEDICINE.]

Joint Session of Sections on the Practice of Medicine and Hygiene and Sanitary Science.

[Concluded from page 178.]

FOURTH DAY.

Further Report on Pseudo or Modified Smallpox: Dr. T. J. HAPPEL (Trenton, Tenn.) said that at the Atlantic City meeting of the Association last year he reported to the section his experience with 300 cases of pseudo or modified smallpox, which was made from a bedside study of the cases in all stages of the disease. This paper dwelt with some of the anomalies met in 400 cases recently coming under his observation. In many cases the disease was noncommunicable. That many vaccinated persons had the disease whilst many who had not

been vaccinated escaped the disease was a point made by him. He took up the diagnostic points between the disease, or epidemic that occurred in Gibson county, Tenn., and the variola vera of the writer's prior to 1895. He asked whether it could be classed as variola vera, or was it a hybrid? The following differential points were presented: in the modified form there did not appear to be any prevailing types of the prevailing diseases; that had the same general character, differing in degree only. The incubation was from 14 to 18 days. In smallpox, the varies were varioloid, discrete, hemorrhagic and confluent, and the incubation period was from 14 to 21 days.

Symptoms.—*From the first to the third day.* In the modified form, at the onset the patient complained of cold; felt as though an attack of gripe or tonsilitis was coming on. Temperature 102° to 105°. Little or no vomiting. Pulse full and rapid. Little or no prostration. No delirium. No convulsions in the young. In a few cases there may be sleeplessness. In smallpox the onset is sudden, violent chill, persistent vomiting, agonizing pain in back and head, shooting pains in the limbs. Temperature 103° to 104°. Pulse full, strong and rapid. Prostration great from the onset. Eyes injected. Sleeplessness, delirium and convulsions in the young. *The third day.* In modified smallpox no coarse red spots appear. In smallpox, coarse red spots appear on the lips and forehead. With appearance of these spots the temperature falls to the normal and the patient is comfortable. *Fourth day.* In the modified form an eruption appears, whose character is generally that of an acne. In some instances the shot-like papules appear, but rarely. Temperature falls to the normal and the patient almost invariably gets up, if he has gone to bed, and says he is well. The eruption first appears on the face. In men about the forehead, cheek and chin; in women and children irregularly about the face. There is usually a sore throat. In smallpox the small red spots appear on the forehead at the juncture of the hair, and are followed by their appearance on the extremities. Papules follow the red spots. They have a shot-like feel. *Fifth day.* In the modified form the acne-like eruption and papules develop into vesicles which assume an opalescence at once. These vesicles are unicellular and are not umbilicated. The serum which exudes at their apices dries and turns brown, which in some cases, gives them the appearance of umbilication. There is no puckering of the vesicle, at its border. The temperature is generally normal unless it rises from abscess formation or other causes. The vesicle may dry up and the disease may be said to have aborted. A rapid recovery follows. In smallpox, papules appear on the wrists and forehead. *Sixth to the ninth day.* In the modified form the vesicles become filled with an opaque lymphoid fluid; in some cases with a brown nucleus in the center, which gives it an umbilicated appearance. This vesicle with its opaque fluid, miscalled pus, shrinks to ½ its diameter and becomes a thin brown scab, perfectly circular. There is no stench. The patient is well after the appearance of the eruption, and insists upon getting up and having plenty to eat. If the eruption is copious he looks bad but he will tell you that he feels good. The eruption in a few cases affects the conjunctiva. There is no secondary fever. From this time on it is simply a matter of scabs dropping off. By the tenth day the patient may be entirely clear. If the eruption spreads over the entire body he may not be clear of scabs until the fourteenth day. In true smallpox the vesicles appear in place of the papules, and the eruption spreads gradually over the entire body. The vesicles are umbilicated and multilocular. On the eighth and ninth days the vesicles become pustular and each is surrounded with broad, red bands, or efflorescence, the features becomes distorted, there are severe rigors and fever, the original symptoms appear, stench is beginning, etc. There is great delirium and convulsions in the young. This is a very critical period. *Tenth to twelfth day.* In smallpox, pus oozes and forms scabs, and the stench is particularly bad. *Seventeenth to twenty-first day.* In smallpox the scabs drop off, leaving red glistening pits which soon become white. Ulceration is deep, reaching the corium. Ophthalmia is generally present. Pustules pervade the mouth, larynx, pharynx and trachea. Petchia forms on the lower part of the abdomen and inner aspects of the thighs on first and second days in some cases. *Papules.* In the modified form papules, when present, are the same size as in smallpox, perhaps a little smaller, but fewer in extent. There may be no papules. Vesicles range in size from the head of a pin to the size of a split pea. They are not umbilicated, and when punctured, collapse. The vesicle is unilocular. Convalescence begins on the appearance of the eruption. The so-called pustule does not extend into the derma. The epidermis is the only structure of the skin involved; hence, there is no pitting. The vaccinated take the disease. In smallpox the papules are about the size of No. 4 shot and have a translucent appearance, encroaching on the entire body including the palms and soles. It appears first on the face and hands. Vesicles are umbilicated and multilocular. So is the pustule, and neither will collapse in toto if pricked with a needle.

Smallpox—the Old and the New: Dr. W. L. BEEBE (St. Cloud, Minn.) stated that he had been identified with 2 epidemics (20 years apart), and though they were evidently both species of smallpox, they were very dissimilar in many characteristics. He thought that many of the recent cases had been better diagnosed chickenpox than smallpox.

Remarks Covering the Sanitary Features of Smallpox:

Dr. LOUIS LEROY (Nashville, Tenn.) said that in the event of an outbreak, a competent physician should be placed in charge and given absolute power to act; he should communicate with Boards of Health, and there should be police backing. Daily official reports should be made to newspapers, stating exact condition of affairs. Smallpox treatment in private is really a makeshift. Complete and perfect isolation was insisted upon. All articles should be disinfected in the usual way. Everything possible should be destroyed by burning after the patients have been discharged. In Tennessee this year he had introduced on a large scale the hypodermic needle as a means of introducing the vaccine beneath the skin. He had first used this method in Philadelphia in 1895, using then the aqueous solution; he now uses the glycerinated lymph. A solid piston hypodermic needle is used. The skin is cleansed in the usual manner and the needle inserted into the skin—not through it—and a drop of the lymph is forced between the epithelial cells and diffuses at exactly the locality desired. It has many advantages. In cases of compulsory vaccinations it cannot be washed off; there is absolute freedom from infection at the time of vaccination. It is painless and no immediate dressing is necessary.

The Diagnosis of Mild Smallpox, as in the Present Outbreak of the Smallpox in this Country: Dr. HERMAN SPALDING (Chicago) read this paper, in which he stated that, February 15, 1899, smallpox was introduced into Chicago from Cincinnati; in the 17 months following there had been 72 cases of smallpox, 25 of which were direct importations. For a period of 3½ months they were entirely free from the disease. Then there occurred another outbreak. These 2 outbreaks gave him an opportunity to study 310 cases in the Chicago Isolation Hospital. There was 1 hemorrhagic case (fatal); 13 confluent variety (3 deaths); 24 semiconfluent variety (2 deaths); 54 severe discrete cases (no deaths); 179 mild, discrete cases, with no deaths; 39 modified forms, no deaths. He thought the term varioloid should not be used. Many are under the impression that varioloid is not smallpox, and think that if taken to the smallpox hospital while sick with the former, that they are liable to contract the disease. The term he considered to be a useless one, for smallpox is smallpox, whether mild or severe. In Chicago they placed all patients with smallpox—whether hemorrhagic, confluent or so mild that they would go to work unless prevented—into the same wards in the hospital. Two hundred and seventy-one of these never were vaccinated. None of those afflicted with the mild form of the disease contracted smallpox from the severer typical cases in the wards, where the exposure had been prolonged and certain. The mild form of the disease gives immunity from smallpox, and yet will transmit typical confluent or hemorrhagic smallpox, of which statement he had abundant proof in Chicago.

The Distinguishing Characteristics between Mild Discrete Smallpox and Chickenpox: Dr. FREDERICK LEAVITT (St. Paul) made the following summary:

	Smallpox.	Chickenpox.
Age.....	Any age.	Childhood.
Incubation.....	Two weeks.	13 to 17 days.
Invasion.....	Marked headache, backache, fever, general malaise, lasting 3-4 days.	Is none, or at most only slight, in the covered portions—thorax.
Surfaces attacked.....	Worse on the exposed parts—extremities. Invariably on the palms.	Rarely or never seen on the palms or soles.
Character of the eruption.....	Progressive; papules, vesicles, pustules, crusts.	Papules and crusts. Lesion very superficial. Easy to rupture.
Histology.....	Lesion includes the lower layers of the derma. Hard to rupture. Multilocular.	Unilocular.
Temperature.....	Remains high (103-105) till eruption appears. Then drops and does not rise again for a week, and not then in the milder discrete forms.	Rises with the severity of the attack.
Contour of the eruption.....	Quite uniform in size. Has a reddened area at base. Frequently umbilicated.	Not uniform. Also inflamed area about the vesicle, but less marked.
Sensation.....	Painful to the touch; may itch.	Not painful to touch.
Duration, including period of invasion and desquamation.	Two to four weeks.	One week to fourteen days.
Vaccination.....	Protects.	Does not protect.
Pitting.....	When confluent on face; will occasionally mark in the discrete form.	Seldom unless infected.
Complications.....	Generally none.	None.
Mortality.....	High in severe confluent and hemorrhagic types.	Nil.
Resolution.....	By crisis.	By lysis

Variola: Dr. H. M. BRACKEN (St. Paul) stated that in the State of Minnesota there had been reported 7,211 cases of variola, with 49 reported deaths during the past 2½ years. He did not think we could be governed in our diagnosis of all cases in this present epidemic by the usual textbook descriptions of variola. Typical prodromal symptoms may be present, but the rash may vary in degree, in form, in type of progress, and in final disappearance in a way that is described in but few textbooks. He asked if vaccination protected against the disease. Of 662 cases in 244 houses but 10 patients had been successfully vaccinated at any time prior to their infection, and of these 10, 30 years had elapsed since successful vaccination for 2 of them, over 25 years for 4 of them, 20 years for 1, and 6 years for 1. The Chicago Board of Health made the following statement: "Out of a total 171 cases of smallpox found in Chicago between November 30, 1900, and April 10, 1901, 140 had never been vaccinated. Of the remaining 31 cases, 29 were adults showing faint, poor or irregular scars, claimed to be evidence of attempted vaccination in infancy or childhood—the most recent being 23 years old. Only 2 out of the 171 cases exhibited typical scars of successful vaccinations. Since vaccination had been made compulsory in the schools of Chicago smallpox had disappeared from them. The degree of immunity depends upon in part at least the intensity of the infection." Marson gives the following deatheate among those who have been vaccinated: One cicatrix, 7.73%; 2 cicatrices, 4.7%; 3 cicatrices, 1.95%; 4 or more cicatrices, .55%.

Section on Surgery and Anatomy.

[Concluded from page 483.]

THIRD DAY.

A Synopsis of 267 Cases of Amputation at the Hipjoint by the Author's Method: JOHN A. WYETH, M.D. The operation was first described at a meeting of the American Medical Association, in 1890. The 267 cases were classified in 3 groups: neoplasms, 137 cases, of which 131 were sarcoma, 5 epithelioma, and 1 osteocarcinoma. Fourteen died, or 10.2%. All fatal cases were sarcoma; septic infections, 94 cases, 16 deaths, or 17% mortality. Subdivided into a pyogenic osteitis or osteomyelitis (not tuberculosis) 36, with 5 deaths, or 14% mortality. Tuberculous osteitis or osteoarthritis (hipjoint disease) 41 cases, with 4 deaths, 9.7%. Gangrene, moist and diabetic, 12 cases, 6 deaths, 50%. General cellulitis, 3 cases, with 1 death. Two cases of extensive ulcer, both recovered. Injuries; 36 cases, with 23 deaths, ratio of mortality, 63.9%. Twenty-four of these were performed on account of extensive injury to one or both lower extremities by railway trucks or heavy machinery. Of these 16 died, deatheate of 66%. Although this rate of mortality seems large these injuries were of the most severe type, with one or both lower extremities crushed into a condition of pulpification, while several were complicated with rupture of internal organs with hemorrhage so that they were practically dead when the operation was undertaken. Moreover, no doubt some of these could have been saved by the intravenous injection of hot salt solution, which was not done in a number of fatal cases. The great improvement made in the saving of life may be appreciated when we compare the statistics given in Ashhurst's International Encyclopedia of Surgery, issued in 1881, where in a total of 633 cases of amputation at the hipjoint by other methods than the one here reported the ratio of mortality was 64%, while in 267 cases reported by my method the deatheate is 19.8%. In other words, the deatheate in 1881, 20 years ago, for all causes being 64%, is now 19.8%. The deatheate 20 years ago for all causes being equal to that for crushes from railway trucks or heavy machinery at this date. In the *Lancet* (London) of March 5, 1892, Mr. Frederick Page gives 16 cases in which the amputation was done by other methods in the Royal Infirmary at Newcastle-on-Tyne, a ratio of mortality of 37.5%, against 17% by the method here described. Dr. John Erdmann, of New York, collecting the figures of 8 hospitals of this city, gives 18 cases, done by all methods, with 8 deaths, a mortality ratio of 44%. Of these 18 cases, 7 were performed by the method of hemostasis herewith advised, and all of these recovered, leaving in the list 18 fatal cases in 11 amputations done by other methods. Antiseptics must share with the improved hemostasis the credit of this diminished rate of mortality. The simplicity and efficiency of this method is evident in the fact that from the country practitioner with inefficient assistance and limited experience in major surgery to the metropolitan surgeon with all the accessories of modern technic, it has almost without exception, met with full approval and adoption.

Discussion.—MEANS (Columbus) has used the Wyeth pin in amputation of the hipjoint in 2 cases and 1 emergency case recovered permanently and the other case of carcinoma recovered from the operation but died 3 months later from recurrence. Means believes that the pins are of great value in these cases, and uses them also in the amputation of the shoulderjoint.

SYLVESTER (Ohio) has used the Wyeth pin in 2 cases. In 1 case a boy's leg was cut off completely by a locomotive, and he died while on the table while the operation was being made.

Sylvester suggested that in cases where there is much oozing, that the wound should be packed with gauze and long sutures inserted which may be tied in a bowknot and in removing the gauze, the sutures can be drawn tight.

WRIGHT (Bridgeport, Conn.) uses a heavy rubber bandage and converts it into a roll, passing it around the groin. He has been able to produce a hemostasis which was quite satisfactory. It occluded the vessels and saved the necessity of the pins.

WYETH, in closing, emphasized the importance of using infusions of normal saline solution in cases in which there was a great deal of shock.

Antoplastic Suture in Hernia and Other Diastases: While at work upon the inguinal hernial operation it occurred to McARTHUR to utilize a strip of the tendinous portion of the external oblique, which, possessing fibers in the adult from 5 to 6½ inches in length, would have sufficient strength to act as a substitute for the absorbable kangaroo sutures. Experiments on dogs and operations on the human being having proved the feasibility of the procedure, it remains for the future to determine the actual value of the suggestion. Any of the accepted operations can utilize this material without great variation in the technic. White fibers which enter into the formation of the *internal pillar* of the ring are split off from the edge of the internal flap of the external oblique quite up to their insertion in the muscle belly, where they are cut loose from the muscle but left attached to the spine of the pubis. This strip should vary in width from ½ to ⅓ or ⅔ inches, according to the development of the tendinous fibers, which in children and women are not so strong as in the male adult. In case a Bassini is done, a similar strip is taken from the outer flap, the lower end of which strip terminates in the fiber of the external pillar of the ring. These strips are used as suture material for *running* stitch. McArthur has had 12 cases in which to try this method, in all of which a perfect primary union was obtained, with an unusually satisfactory convalescence, the temperature not rising as it usually does during the absorption of the animal suture, and in these few cases there was less than usual of the indurated boggy area surrounding the wound. Some colleagues have likewise tried the operation, making in all 17 cases. Realizing how nearly perfect our absorbable suture material has now become, McArthur presents this paper, believing it to possess undoubted additional merits, viz., (1) The obtaining of a living suture; (2) lessened chance of failure through avoidance on introduction of dead or foreign tissue; (3) the incorporation in the resisting cicatrix of organized white fibrous tissue; (4) the applicability of the same procedure to other situations. Strips of tendon of sufficient size for use as suture material will stand a tensile strain from 11 to 24 pounds without breaking. Sufficient time has not elapsed since any of my operations to state that the method is any *more* successful than with animal suture. It is logical to conclude, however, that if the identical technic is followed using these living strips as is followed with aseptic animal tendon, and a primary union with normal convalescence is obtained, that if they die and be absorbed, they accomplish all that the foreign material does, while if they live (as experiments prove) it remains to offer permanent resistance to future stretching. Experiments are now in progress by means of which after the elapse of sufficient time I shall study the histologic changes, if any, which grafts of this nature may undergo, and hope to have the honor of presenting to this section the findings.

New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery: G. KOLISCHER and L. E. SCHMIDT (Chicago) have used the following method to perfect the knowledge of the topography of the kidneys and ureter, location of calculi and aid in differential diagnosis. For locating the ureteral openings in the bladder and sounding the ureters in most of the cases, Brenner's cystoscopes are used; only in a few cases where special peculiar conditions prevail an improved modification of Casper's cystoscope is substituted. Extensive cadaver work determined that the most desirable material for the sound is lead, blended with antimony. This kind of lead wire is extremely flexible, so that the natural course of ureters would be changed by introducing the sound. These sounds are soft and their surface polished up to perfect smoothness, so that injuries to the lining of the renal pelvis and of the ureter are not to be expected, and, in fact, are not to be observed as careful examination in cadavers has proved. They sum up the results and possibilities of their method as follows: Our method is free from danger. We can determine (1) the course of the ureters; (2) the location of the renal pelvis; (3) We can diagnose dilations of the renal pelvis; (4) we can determine the location of the renal calculi; (5) we are able to determine the seat of the ureteral obstruction and we are in a position to judge to a certain extent upon the nature of the ureteral obstruction; (6) we have the possibility of differentiating gallstones from renal stones, which differential diagnosis occasionally is a very hard one or even impossible to make by other means; we have the possibility of distinguishing between nonrenal neoplasms and dislocated and enlarged kidneys. When a surgical kidney cannot distinctly be made out by bimanual palpation, cases which quite often present greatest difficulty in finding the kidney after incision was made, our method will give most valuable information concerning the topographic location of the kidney.

Discussion.—POWERS (Denver) believes that McArthur's method promises to prove a useful addition in surgical treatment of hernia.

EISENDRATH (Chicago) has used McArthur's method in several operations. In 1 case he used this method on a young boy, and found that the aponeurosis held well. He is not aware that the operation has been tested in young persons with possibly weak aponeuroses before.

EASTMANN (Indianapolis) inquired how it was possible to obtain an aponeurotic strip for suturing that was longer than the wound itself, and if splitting off a strip of the aponeurosis did not weaken it?

Dr. McARTHUR said that he had found that the edge did not tear out any more than it would in using any other suture material.

Prostatectomy as Prostatotomy: RAMON GUIERAS (New York). Will be treated editorially.

Prostatectomy, the Method of Choice in the Management of Prostatic Obstruction: EUGENE FULLER (New York). Prostatic hypertrophy, directly or indirectly, is the cause of death in such a large proportion of elderly men that its surgical management is a question of great importance. Formerly, Fuller did not operate on patients over 75 years of age, but recently he has obtained several good results in men considerably older. Two cases were mentioned one occurring in a man of 78, and the other in a man of 77 years. The surgeon should always be influenced by age, but other factors should be taken into consideration, such as the physical and mental condition, the condition of the arteries, pulmonary, cardiac, or other defects. Putrid urine and the presence of ascending pyelitis, should not stand in the way of operation, but should strengthen the plea for speedy relief of the obstruction. In many such instances in which infective complication appears extensive and serious, radical operation is followed by perfect recovery. In the relief of prostatic obstruction, Fuller believes that it is usually a question of prostatectomy or nothing. In the minority of cases, castration, or the Bottini operation may be considered. There are a few well-authenticated cases in which relief has followed castration, but they are so few that the operation is at present practically abandoned. The ease with which the Bottini operation is performed is its chief advantage over prostatectomy. Others urge the freedom from after-discomfort, and brief confinement in bed. There is a great difference between relief of symptoms and radical cure, however, and in most cases there is considerable residual urine after the Bottini operation. In a good percentage of cases it fails entirely to relieve, and the mortality is about 10%. The cases suited to this operation are those free from complications, and in which the obstruction is a moderate-sized, middle lobe, or hypertrophy and rigidity of the prostatic fibers about the vesical neck. In many cases, the operation must be repeated. After prostatectomy, on the contrary, the results obtained are perfect and permanent. There has been complaint about the large mortality following prostatectomy, but this is probably because of 3 reasons: because many know nothing about the operation; many are incompetent to perform the Bottini operation; and others have tried the operation in a limited number of cases, and have been unfortunate in their results. Prostatectomy is not an easy operation, and old patients do not bear long-continued anesthesia well. Fuller believes that we should not hesitate, however, to operate, even where the surgical risks are great, for in the bad cases, death, accompanied by great suffering surely occurs if nothing is done, while if prostatectomy, associated with drainage, is performed, death, if not averted, is peaceful. The patient is rendered comfortable and, in a large majority, even of the worst cases, recovery is complete.

A Further Report on Permanent Catheterization: J. RILUS EASTMAN (Indianapolis) reports permanent catheterization in 15 cases. The catheter was retained for more than 10 days in all instances, and in 2 cases, for more than 60 days. The results obtained were quite satisfactory, and Eastman gives the following reasons why permanent catheterization should be selected as the method of choice for routine use in selected cases, in draining the bladder: By its use the urine is removed by the natural exit. If used for operations in opening the posterior urethra, the period of convalescence is shortened, since the wound closes more promptly than if the urine be drained through the wound. The caliber of the urethra is maintained, or even increased, and the subsequent passage of instruments is rendered easy. Much of the tedious work of after-treatment such as passing sounds, is rendered unnecessary. After perineal section involving the removal of a portion of the posterior urethra, catheterization or sounding is difficult; hence, the maintenance of the urethra is a serious problem. If the retained catheter is used, however, this is unnecessary. The urine may thus be drained into a receptacle and bed-sores, dermatitis and discomfort avoided. The danger of uremic poisoning is reduced, since the area exposed to infection is slight. Pain and fever are slight during catheterization, if care is exercised that the instrument does not project too far into the bladder. The soft and hard infiltrations which may narrow the caliber of the urethra, are removed or reduced by pressure absorption.

Perineal Prostatectomy: PARKER SYMS (New York) advocates prostatectomy by a median, perineal incision to bring the prostate down so that it can be readily reached. He uses a retractor, consisting of a soft rubber bulb cemented on the end of a soft rubber tube. The bulb is inserted into the bladder through an opening into the urethra. It is then distended with a definite quantity of water to a diameter of 2½ to 3

inches. The tube is then clamped, and by pulling upon it the rubber bulb acts as a retractor to draw the prostate downward through a small, median incision. The prostate can then usually be readily shelled out. When properly performed, the operation is not formidable, hemorrhage is slight and there is comparatively little shock. Syms believes that prostatectomy will be proved to be a thoroughly sound and proper procedure; that the deathrate will be no more than is compatible with a condition in itself so grave. It should not be left as a last resort, but should be performed before the patient is in a dying condition, or not at all. In men, not physiologically very old, whose arteries are in a fair condition and who are not suffering from severe kidney lesion, recovery may be expected, provided the condition has not been neglected until the bladder is badly inflamed, and the patients are suffering from sepsis. Syms feels sure that every hypertrophied prostate may be removed by simple, median, perineal incision, and, in most cases, the patients are better the day after the operation than the day before, on account of the relief from drainage of the bladder. He has operated in 9 cases, the last 6 by the method which he described. Patients have ranged in age from 53 to 75; all have had cystitis, but only 2 were suffering from stone. All the patients recovered, and in only 1 case was relief partial, the others being completely relieved. In 2 cases there was incontinence of the urine for some weeks, but the patients gradually regained control.

Fallacies in the Treatment of Urethral Disease: ROBERT HOLMES GREENE (New York) states that 8 years ago he advocated that local treatment for urethritis should not be commenced until the acute symptoms had subsided; that is, in from 6 to 8 weeks after the onset of the disease. He has later become confirmed in this belief, as the result of clinical experience, and study, and pathology. The advocates of the irrigation treatment have considerable in support of their method of treatment, but the difference of opinion as to the proper material solutions to be used is so great as to make it evident that this treatment is by no means certain. Greene reported studies by German writers which indicate that prostatic hypertrophy of the aged is an inflammatory disease, and he showed drawings from specimens of his own supporting this view.

Discussion.—WARNER (Ohio) believes that prostatic hypertrophy is usually of very long duration, and that operative intervention should be undertaken early, before changes occur in the bladder and in the kidneys, which would make success impossible.

ANDREWS (Chicago) has used Bottini's operation in 17 cases. In only 3 cases did he obtain a complete cure; 1 patient died of hemorrhage. Some of the other patients were somewhat improved, but his experience has not been such as to lead him to favor the operation. Good results are probably obtained in cases where there is a collar-like condition of the prostate. He prefers the perineal route in performing prostatectomy. The apparatus shown by Syms for drawing down the prostate into the wound seems admirably adapted for this purpose. Andrews has also used Ferguson's prostatic retractor, which is introduced into the bladder and the prostate is pushed downward, using the pubis as a fulcrum for the lever of the instrument. The traction in these cases tends to prevent hemorrhage. A small incision he considered quite important in these cases in weakened people where there is considerable absorption of urine, which might result unfavorably.

McGOWAN (Los Angeles) believes that Schmidt's method will not come into general use because of the difficulties in catheterizing the ureters, and because few perfect themselves in x-ray technic. During the past 50 years McGowan has operated about 50 times, performing prostatectomy and prostatotomy in patients between 65 and 81 years of age. He believes that the perineal operation is impossible in some very fleshy persons with deep perineums. He believes also that Fuller has made the operation of prostatectomy appear too easy. In some cases McGowan has seen very severe bleeding.

GUIERAS, in closing, emphasized the importance of not emptying the bladder entirely, in cases of retention from prostatic hypertrophy, for this may cause inflammation, and even acute suppression of urine. The bladder never regains a perfectly normal condition, if before operation it is trabeculated and contains diverticulae; but the improvement is very marked and patients get on very comfortably. Prostatectomy is the ideal method if the condition of the patient permits it. Bottini's operation seems crude and imperfect, but the results are often very good. In 23 operations which he has performed, all the patients were relieved. In 2 cases there was more or less burning and in 1 case, frequent micturition, but many of the other recoveries were most remarkable. One patient who had had complete retention for over 4 years, was completely relieved by the operation. It is not always possible to shell out the prostate. Guieras mentioned a case in which he found it impossible to do so, even at the necropsy; but in these cases it may be removed piecemeal.

FULLER, in closing, expressed the hope that the discussion would bring increased attention and interest to this field of work. He excises the prostate in certain cases where he finds enucleation impossible. Inflammation in the region of the prostate urethra and seminal vesicles is often taken for enlargement of the prostate. It is difficult to determine what is the cause of prostatic hypertrophy. Probably it is not an inflammatory condition alone, as Green suggested, for a prostatic

hypertrophy is unknown in Asiatics, although they have a great deal of venereal disease. The idea that the bladder has not sufficient expulsive force in cases of prostatic hypertrophy with retention is incorrect. This used to be given as a reason for not operating. Fuller has never seen but 1 patient in this condition, and in this case there was a tuberculous pericystitis.

EASTMAN believes that Green is right in his belief that inflammation is the cause of prostatic hypertrophy. He bases this belief on the results of examinations of 40 prostates, which he carried out in Virchow's laboratory.

SYMS, in closing, emphasized the importance of early operation. He believes that Bottini's operation is an unsurgical procedure.

Pneumectomy and Pneumotomy: J. B. MURPHY (Chicago). Pneumectomy is frequently indicated. It can be performed with safety to the patient. The danger of pneumothorax is not great. The unpleasant manifestations from pneumothorax are entirely overcome when the causes of the symptoms are understood. Portions of the lung may be amputated without danger of hemorrhage and without danger from pneumothorax from division of the branches of the bronchi. Pneumotomy is frequently indicated; is not a dangerous procedure; may be accomplished with or without adhesions of the lung; the hemorrhage is easily controlled. The scalpel should be used in place of the Paquelin cautery in opening pulmonary abscesses, interlobar abscesses and bronchiectatic cavities.

Removal of Foreign Bodies from the Air-passages: DEFOREST WILLARD (Philadelphia). Foreign bodies such as seeds, nuts, toys, food, etc., are exceedingly liable, especially in children, to be sucked into the trachea during laughing, crying, etc. The immediate effects are most alarming. The violent efforts at coughing usually dislodge the offender if it has not reached the larynx, but it may be arrested at the vocal cords, or may pass on and become impacted in one of the bronchi, usually the right, from anatomic reasons. It may partially or totally occlude the bronchus; in the latter case $\frac{1}{2}$ the respiratory functions being destroyed, dyspnea will be very great, and septic pneumonia will speedily follow, possibly with gangrene of the lung. Inversion of the child and succussion are dangerous unless the means for immediate opening of the trachea are at hand, as lodgment in the larynx may quickly suffocate the patient. A careful physical examination, with study of all the symptoms is absolutely essential to determine the lung condition. A low tracheotomy should be at once performed; a large opening made, the sides of the slit being kept wide apart by silk stitches. Through this opening expulsion is common, and is ordinarily to be expected. A cystoscopic tube with lamp may be employed down the trachea to discover an object at the bifurcation. Suction upon the foreign body may be employed through a rubber tube by a Bigelow evacuator. Search by tracheal forceps should be cautiously attempted through the tracheotomy opening extreme care being exercised not to wound or tear the bronchi. Unfortunately the sensations imparted by the cartilaginous rings and a seed or bean are not dissimilar, and failure to extract is not uncommon. If the object is a metallic one an x-ray representation may prove of great value, provided fixed angles of illustration are employed. If the object cannot be secured through the trachea, an opening into the chest and incision of the bronchi themselves is only justifiable when the Fell-O'Dwyer artificial apparatus is at hand and oxygen is available. Without these accessories, combined with the skill of a cool, cautious operator, the search for a foreign body within the chest walls is attended with such dangers that it is ordinarily unjustifiable. By the means of these helps, however, it may, in selected cases, be advisable in children to saw the sternum longitudinally and forcibly retract its halves so as to reach the root of the lung through the mediastinum. The bronchus may also be reached through a large trap-door flap anteriorly, or it can be approached through a posterior thoracotomy flap. If these large openings are made suddenly, and an artificial respiration apparatus is not at hand, the sudden collapse of the lung is most dangerous and may result in speedy death. Under any circumstances the operation is a formidable one, since even when the bronchus is reached it is not easy to locate the foreign body. Should gangrene of the lung occur, a free incision should be made down to the pleura which should then be stitched to the lung by the use of a long-handled curved needle, so as to shut off the open pleural cavity. A free incision should then be made into the diseased lung-substance, and thorough drainage instituted.

The Treatment of Empyema: JAMES H. DUNN, M.D. The treatment of empyema is still decidedly behind the present state of surgical science. Tardy diagnosis, inefficient drainage, and slovenly after-treatment, are the most frequent causes of failure; retarded convalescence and deformity, though less frequent than formerly, are not seldom encountered. Treatment is too often undertaken by those unfamiliar with surgical methods. Prompt recognition and adequate drainage minimizes ruptures into bronchi, systemic infection, loss of lung expansion and pleural thickening. The degree to which the collapsed lung recovers depends largely upon the length of time during which the lung has been compressed. Pulmonic sclerosis and pleural thickening are causes of difficulty in obliterating cavities. Having early recognized the presence of suppurating pleurisy by the needle, bacterial diagnosis of the variety of infection is desirable. It is further necessary spe-

cially in encysted empyema, to map out the location of the collection that the drainage may be most conveniently placed. In certain benign infections, the chest should be aspirated, and in the others the chest should be more or less freely opened and drained. Operation, without rib resection, even in children, is rarely advisable. The opening should be large enough to allow removal of all clots and debris, to remain open until the cavity will close, and large enough to admit of examination of the cavity. The resection of at least 1 $\frac{1}{2}$ or 2 inches of a rib below and posterior to the effusion is necessary. In case prolonged drainage is anticipated it is often advisable to make the opening larger. In pure pneumococcal pleuritis aspiration should be tried and it not rarely succeeds. A second, or possibly a third, evacuation by the aspirator may be tried before opening the chest. In pure tuberculous pleuritis, opening should be delayed until the advent of mixed infection, where, as a rule they are benefited by free drainage. In large and double effusions gradual evacuation by paracentesis is advisable as a preliminary measure, the rib resection being delayed a few hours. The opening should be placed at the lower and posterior part of the collection. Effusions vary in their location, hence to place the drainage opening at any set place is manifestly absurd. In the majority of cases, the eighth rib, well back, just outside the angle of the scapula is best chosen. Dunn has never seen the incision too far backwards for the best results, but many times too far forwards. Irrigation of the cavity is unnecessary, in many cases objectionable. A careful aseptic occlusion dressing ought to be maintained throughout the treatment, from the first opening to the closure of the cavity. Acute empyemas, promptly recognized, freely and adequately drained, and aseptically treated, as a rule close in from 3 to 12 weeks. Estlander, in 1877, proposed to mobilize the thoracic wall by resecting that portion of the ribs covering the cavity. In practice the cause of failure of most of these cavities to close is to be found rather in the pleura than in the ribs. The walls of these persistent cavities and fistulas become indolent and quite analogous to the edges of certain old indolent ulcers, and removal of the superimposed ribs alone rarely proves entirely successful in their complete closure. Hence this type of thoracoplasty has been superseded by the Schede type of operation, in which the whole chest wall, save the skin, is removed over the cavity. Of late years, cases requiring extensive plastic operations are much less frequent than 10 or 15 years ago, but in 5 cases during the past 6 years I have found it necessary to remove more or less extensive portions of the chest wall and secured complete and prompt closure in such instance, whereas 10 or 15 years ago a much larger number of operations of the Estlander type were observed, in the majority of which sinuses remained as long as the cases were followed. Thus with prompt and efficient treatment of acute empyemas, chronic cavities and fistulas are rare, and these may, with few exceptions, be closed fairly promptly by thoracoplasty. When the general state is very feeble, when amyloid disease is advanced, when the cavity is enormous, failure is probable, but there are few absolute contraindications to a well-timed attempt to close these chronic cavities. Tuberculosis is unfavorable, but by no means an absolute contraindication.

DR. CHARLES A. POWERS, of Denver, was unanimously elected by the Surgical Section to the House of Delegates of the Association for 2 years. Dr. A. D. BEVAN, of Chicago, 1 year.

Discussion.—BERNAYS (St. Louis) reports postmortem experiments in 10 cases, on patients who had died from pulmonary tuberculosis. The attempt to remove the diseased portion of the lung was made, and it was found possible to pull off the diseased area without opening the lower pleural sac, which was shut off by adhesions. In a case of abscess of the lung, he advises opening by Hilton's method, pressing into it a pair of Clow's dressing forceps, opening the blade and withdrawing the forceps. He thinks that these cases may be safely treated in the same way that we would deal with a nephrosis or appendicitis, by draining the abscess cavities. He agrees with Dunn that the treatment of empyema depends upon the character of the organism causing the infection. Even country doctors should feel the necessity for making bacteriologic examination in these cases.

WILLS (Los Angeles) stated that the patient upon whom he operated, draining a tuberculous cavity in the lung, is still alive and well, 3 years after the operation. He has gained 75 pounds, and is able to go about his work, that of a stable man.

KEN (Philadelphia) mentioned some cases in which he had cut down to the chest wall, made an incision, and sutured the lung to the parietal pleura, before pneumothorax could occur. Then, packing gauze into the wound, he waited 3 days, when adhesions were sufficiently formed to permit operation on the lungs. In 1 case, in which he removed a large sarcoma of the chest wall, the lung collapsed, but caused very little trouble. The lung was seized and sutured around the bone to prevent pneumothorax. The patient had a slight infection, but eventually made a good recovery. He mentioned these 2 cases to bring out and emphasize the point that it is possible to bring about adhesion where none exists, and to suture the lung over a large area.

MEANS (Columbus) reported a case in which he has resected the chest wall and found the lung adherent, but on exploration, had been able to find no pus, in spite of the fact that the patient had been expectorating pus.

WILLARD, in closing, stated that firm adhesions may occur in 24 hours if the lung be sutured around a rectangular space, and an opening may be made the following day. In resecting a rib for empyema, Willard never uses bone forceps, but always employs a flat-bladed rongeur, which avoids a splitting of the bone.

FOURTH DAY.

The Indications for Operation in Calculous Nephritis and Urethritis: CHARLES L. LEONARD (Philadelphia). Recent advances in the diagnosis of calculous conditions of the kidneys, indicate that more than half the calculi that originate in the kidneys, pass into the ureters before they occasion sufficient symptoms to make their presence known. This increased frequency of ureteral calculi, and the numerous small calculi passed with but slight symptoms, make it probable that many such calculi remain during life in the urinary tract, without symptoms or without disturbing the function of the kidney. The x-rays have shown the greater frequency of ureteral calculi, but their presence does not indicate operation in all cases. The differentiation between cases demanding immediate operation and those in which conservative, expectant treatment should be followed, is based on the results of the Röntgen method of diagnosis. By this means the position and size of calculi are accurately given. The accuracy of this means of diagnosis, Leonard has demonstrated in 165 cases in which there was confirmation furnished. Negative diagnoses were found to be as accurate as the positive diagnoses. The calculi, both multiple and single, bilateral and unilateral, were found in 45 cases. Contrary to previous belief, over 50% of the calculi were found in the ureter. The employment of instruments to determine the presence of such calculi, is considered unsafe, and there is danger of infection of the ureter. In case small calculi are found in the ureters, an expectant course of treatment is indicated. The precision of the x-ray diagnosis has rendered such conservative treatment safe and rational, where formerly, it would have been bad surgery. The risk involved in delay is less grave than risk of infection in such cases. These small calculi usually pass without operative intervention. By exploratory operations, unless a calculus has been detected, an incision into the substance of the kidney is contraindicated, except for other obvious pathologic lesions.

Acute Cholecystitis and Cholangitis as a Complication of Gallstones: DANIEL N. EISENDRATH (Chicago) reports the case of a girl of 17, who was operated upon for gallstones and purulent cholecystitis. The colon bacillus was found in pure culture. The girl died 3 days after the operation with symptoms of cholemia, and her liver showed evidences of acute hepatitis and nonsuppurative cholangitis, which undoubtedly disturbed the hepatic functions to such an extent as to cause death. The history of the case was given in detail, with the results of microscopic and macroscopic postmortem study. The death of this patient was considered unquestionably due to the condition formerly called cholemia, this name being given because it was thought that the blood contained bile in large amounts. Eisendrath considers it now settled that it is a form of auto-intoxication, due to a lack of functional activity of the liver cells, so that toxic products are retained in the system; hence, the name hepatargy, or liver inactivity, has been proposed, to designate the group of symptoms, chiefly of a nervous character, as in this case. These symptoms may develop gradually or suddenly, resembling greatly the symptoms of uremia, or diabetic coma. They are: delirium, high temperature, muscular twitchings, or even convulsions. They may be present in a lesser degree in some cases and entirely disappear. Usually, their onset precedes death by a few days. Eisendrath believes that whenever gallstones are accompanied by high temperature we should think of the concomitant infection of the intrahepatic bile-ducts, with its resulting pernicious influence upon the liver parenchyma. Such a change may cause sudden death through hepatargy. In order to avoid such a possible complication, an immediate operation is advised in general, as soon as the diagnosis of gallstones is made.

Dissecting Abscess of the Abdominal Wall Producing Deformity Simulating Pott's Disease: JAMES B. BULLITT (Louisville) reported a case of a boy of 16, who had had a typical attack of typhoid fever. During the recovery there was an inability to raise the left leg, and 5 months later he developed a general anteroposterior curvature of the spine, with a lateral deviation of the convexity to the right side. There was fullness in the right loin, causing a suspicion of paranephritic abscess. Under rest in bed, he decidedly improved, but about 6 months after the typhoid fever, the lad was taken with high fever, pain under the left costal border, and abscess, pointed at the umbilicus, ruptured spontaneously, discharging a quantity of thin pus. When seen 6 months later, about a year after the typhoid fever, a sinus was still discharging and the boy persistently refused any operative attempt at relief. The deviation of the spinal column is believed to be due to an effort on the part of the patient to relieve pressure from the abscess in front by assuming this position. Bullitt discussed the literature of these cases in a thorough way and he concludes that abscesses of the abdominal wall, without connection with the abdominal cavity, occur most frequently as a result of typhoid fever; they heal readily after incision and drainage. Larger dissecting abscesses of the abdominal wall communicate at their inception with

some portion of the intestinal tract, and occur most frequently, also, as a sequel to typhoid fever or appendicitis, with adhesion between the parietal peritonum and some viscera, with perforation of the latter. After rupture, such abscesses follow the course of fecal fistula, healing sometimes spontaneously as a result of incision with drainage, only after communication with the intestine has become obliterated. Obliteration sometimes occurs spontaneously, sometimes must be accomplished by operation. A dissecting abscess may produce the symptoms and deformity simulating Pott's diseases. On the other hand, Pott's disease with abscess, appearing after an attack of typhoid fever, may be confounded with abscess resulting from the typhoid process.

Anatomic Treatment of Fractures of the Femoral Neck: C. E. RUTH (Keokuk, Iowa), after study of the anatomy concerned in fractures of the neck of the femur, has adopted the following method of treatment: The thigh is flexed on the abdomen to relax the psoas-iliacus, bringing them above the fracture line and preventing them from being caught between the fragments. This position also relaxes nearly all the external rotators, or changes them into abductors. Vertical traction is then made on the shaft of the femur at right angles to the trunk and moderate eversion is maintained; next abducted to the normal line and make extension in the long axis of the trunk, while an assistant makes traction $\frac{1}{2}$ to $\frac{3}{4}$ as strong as outward, slightly upward and forward from the upper end of the femoral shaft. These manipulations should be made by firm, steady traction, not by jerks, which is to become continuous by Buck's extension with a weight of from 10 to 20 pounds, according to the muscularity of the patient, with elevation of the foot of the bed enough to counteract the tendency of the patient to slide down to the foot. This means an elevation of from 6 to 15 inches. A binder's board or other splint material should now be moulded to the upper inner aspect of the thigh over which a band of adhesive plaster from 4 to 6 inches wide should pass outward, upward, and sufficiently forward, that the weight over the pulley shall overcome the internal pull of all the rotators and abductors, and at the same time raise the lower fragment to its normal level and maintain it there. It must entirely overcome the tendency to external rotation. The weight on this lateral pulley will be from 5 to 15 pounds, according to requirements. The side of the bed corresponding to the injured side of the patient must be raised enough to prevent the individual from being drawn out of position toward the lateral pulley. Most patients so treated will have absolutely no pain whatever, after a spasmodic, muscular action is entirely overcome. Ruth has treated 25 cases of fracture of neck of the femur in this way. In 22 union and useful limbs were obtained in patients from 10 years old to the extreme limits of old age. The shortening was no more than 1 inch, and, after careful measuring, no shortening was discovered in 6 of the patients. The action of various muscles was demonstrated and a femur was shown which was examined postmortem in which the result was extremely perfect.

Discussion.—SMYTHE (Memphis), in treating gallstones, advocates swabbing out the gallbladder with nitrate of silver, and closing it. He has never seen leakage if the gallbladder was not seriously diseased at the time of operation.

MCGOWAN (Los Angeles) inquired whether the x-rays could be depended upon for negative and positive diagnosis in case of renal calculus? He had always regarded such evidence as unconfirmatory. He mentioned a number of cases in which he had seen serious x-ray burns. He inquired if there was any way in which this accident could be prevented?

THOMAS (Pittsburg) mentioned a case in which blood and pus was demonstrated as coming from the right kidney, by means of the Harris segregator. No stone was shown by the x-rays, but a stone was passed some time afterward.

CRANE (Vermont) called attention to the relation between anatomic weight and substance and the x-ray shadow, which they would give. If tissues of like density are in contact, no shadow is produced. He believes that burns arise usually from long exposures at short distance.

DAVIS (Omaha) has examined a number of gallstones which he has removed, and has found the colon bacillus most commonly in them. In 1 case he found the typhoid bacillus. He believes that in most cases the stones form about bacilli which clump together. He believes that operation should be performed in all cases in which the diagnosis of stone has been made. It is always safer to carefully wall off the peritoneal cavity, as in operation for appendicitis, for it is never possible to tell when the bile is infected. He does not believe that the ideal operation of closing the gallbladder, as suggested by Smythe, is a safe procedure.

DUNSMORE (Minneapolis) does not believe that x-rays burns occur when the static machine is used.

RODMAN (Philadelphia) considers the x-ray an extremely valuable means of diagnosis in cases of renal calculus. Mistakes, while possible, are extremely rare, and he has never known of a mistake in diagnosis by this method in his experience at the Medico-Chirurgical Hospital, at Philadelphia. The clinical symptoms are also important in deciding whether operation is necessary or not. Rodman has never seen a serious burn in 3 years' experience in the use of the x-rays.

BLOOMGOOD (Baltimore) suggested that the patient should be examined more carefully when suffering from severe abdominal symptoms. In many cases, no doubt, patients having

symptoms of gallstones, are, in reality, suffering from appendicitis, and probably 1 or more such cases occur in the practice of every surgeon every year. He reported a case that came to the hospital with a history of recurrent cholecystitis. The patient entered during an attack of intense pain, in a collapsed condition. At operation acute hemorrhage was found, the gall passages being normal. At the necropsy, Opie found that at the papilla of Vater, there was a small stone occluding the opening into the intestine completely. The bile had passed down the gall passages and had been forced upward into the pancreas, the pancreatic ducts being stained green from it. Opie thought at once of the regurgitation as the cause of the pancreatitis, and later he was able to produce acute hemorrhagic pancreatitis experimentally, by injecting bile into the gall duct.

PORTER (Fort Wayne) believes that gallstone colic arises only when there is infection as well as stones present, for in many cases gallstones exist for years without producing colic.

MAXWELL (Kookuk) reported a case of a patient suffering from severe, tearing abdominal pain. At operation the gallbladder was found adherent to the stomach, twisted and occluded, and in the gallbladder were over 100 stones. The twists of the stomach had given rise to the symptoms of obstruction.

LEONARD, in closing, stated that he had been successful in making negative as well as positive diagnoses of renal calculus. Cases which had been operated upon by Keen, Weir, Deaver and McGuire, in patients after a negative diagnosis, no stone were found. The x-ray burns occasionally arise, but if carefully used, with an aluminum screen, the danger is slight. By this method we are able to determine accurately and positively the position and size of renal calculi.

EISENDRATH (Chicago) thinks that in most cases infection is the cause of gallstones, rather than the reverse. He believes that the experience of the best operators has conclusively shown that immediate suture in operations upon the gallbladder should be abandoned.

BULLITT, in closing, expressed the belief that gallstones are more common than is generally believed, and intervention for them may soon be as important as for appendicitis. Nothing gives us more valuable information in the diagnosis of renal calculus than the x-rays, and Leonard's work was especially commended. Comparatively few are so skillful that they can always make negative and positive diagnoses with certainty. Bullitt mentioned a case in which in experimenting with a kidney which he had removed for calculous disease, he found a second stone by the use of the x-rays which he had not recognized at the time of the operation.

Section on Obstetrics and Diseases of Women.

[Concluded from page 187.]

THIRD DAY.

Dr. EMIL RIES (Chicago) read a paper describing a **New Operation for Retrodisplacement of the Uterus**. He prefers the vaginal route to the abdominal incision, for these reasons: (1) The vaginal route, exposing only a limited portion of the abdominal cavity, is less liable to lead to infection or so-called shock; (2) the vaginal route, requiring no exposure or handling on intestines or omentum or perital peritoneum to any extent, avoids the postoperative troubles liable to follow such exposure or handling (adhesions with their consequences, loss of water from evaporation with the disagreeable subjective symptoms caused by it); (3) the vaginal route does away with the visible scar and the possibility of ventral hernia; (4) the vaginal route excludes the possibility of long confinement on account of wound-suppurating; (5) operations by the vaginal route are followed by a very short detention of the patient in the hospital; (6) the after-treatment of vaginal operations is extremely simple and the patients are able to resume their work very early. He described a new operation which he had devised and claimed for it the following advantages: (1) a vaginal operation which would allow all necessary operations on the appendages at the same time and through the same incision with that for the treatment of the retrodisplacement; (2) an operation that would preserve the mobility of the uterus so as not to interfere with a possible pregnancy; (3) an operation that would not depend on serous adhesions, as these had proved unreliable; (4) an operation that would not interfere with the physiologic function of the tube. The method of performing this operation was described in detail.

FRANKLIN H. MARTIN (Chicago) read a paper on **The Surgical Treatment of Retroversion of the Uterus**. He considers his operation superior to all others for the following reasons: (a) Because it insures a uniform shortening of the ligaments; (b) it insures a permanent and strong fixation of the ligaments; (c) it accomplishes this result without the necessity of placing sutures of any kind, temporary or permanent, for the purpose of fixation and shortening; (d) this eliminates the possibility of fistula tracks being established, because of the infected deep permanent suture, and obviates the occasional suppurating wound due to the buried absorbable suture. He then presented a tabulated report covering a period of nearly 5

years, and including 61 cases. His method of ventrosuspension of the uterus was also described, and consists literally of suspending the uterus on a strip of peritoneum taken from the side of the wound, as was illustrated in his accompanying photographs. He stated that he had finally adopted this operation exclusively for all cases requiring a ventral suspension of the uterus, for the following reasons: (1) Because of its simplicity and ease of accomplishment; (2) because of the thoroughness of fixation; (3) because it positively does away with any form of permanent buried sutures; (4) because it accomplishes a fixation which allows of a large range of movability; (5) because the fixation does not directly involve the appendages; (6) because experience demonstrates that the point of fixation is not the source of subsequent irritation or pain; (7) because of the possibility of pregnancy occurring and going on to normal confinement after this operation. He presented a tabulated report covering a period of 4 years and including 173 cases, of which the following is a summary: In the 173 cases, representing all cases operated on for ventral fixation by this method in the 4 years, beginning January 1, 1897, to June 1, 1901 (many of the cases including operation for laceration of the perineum, cervix, removal of the appendages and even myomectomy for fibroids), there were 6 deaths, or a primary mortality of 3.5%. In but 13 cases were there no complicating conditions requiring operations other than the laparotomy for the ventral fixation. In these cases there was no death. The appendages were removed for septic lesions as an accompanying operation for the ventral fixation in 114 cases. In 5 cases large ovarian cysts were removed. In 4 cases the appendages were removed for tuberculosis. In 5 cases for parovarian cysts. In 12 cases the appendages were removed and myomectomy was performed for accompanying fibroids of the uterus. In 29 cases the appendages were not removed. In 12 of these 29 cases conservative surgery was necessary on 1 or both ovaries. One case was accompanied by an operation for appendicitis. Of the 173 operations, there were 4 which had an accompanying operation for ectopic pregnancy. Perineorrhaphy was an accompanying operation in 25 of the 173 cases. Curetment of the uterus was performed in 28 of the 173 cases. Trachelorrhaphy was performed in 19 of the series.

Discussion.—Dr. GOFFE (New York), when operating, passes through the abdominal wall. He believes that cases which are uncomplicated should be operated. The danger of hernia should deter us from using the abdominal route. He considers that hernia is apt to follow the Alexander process, and prefers vaginal shortening of the round ligaments, and asserts that hernia after this operation is practically unknown.

HUMISTON (Cleveland) thinks the round ligaments are only gut ropes, and believes that their shortening will materially encroach upon the bladder space and cause irregular micturition. He believes that curetment and the use of pessary are indicated in uncomplicated cases.

Dr. GORDON (Maine) protests against the use of the so-called conservative surgery. He believes that when appendages are removed, the uterus should also be extirpated. It is then a useless gestation sac with the arteries pumping blood into it, producing discomfort, and should be extirpated.

Dr. GOLDSPOHN (Chicago) denounces all uterine fixation methods, such as intrasuspension. He believes that the round ligaments are the only rational structure for sustaining the uterus forward. He employs a method similar to the Alexander operation, and contends that in all his tests they sustained pregnancies better than any other.

Dr. KELLY (Baltimore) said that there was some 70 methods for the treatment of posterior uterine displacement. In 1887 he had described the ventrosuspension operation, and believed that when properly performed, complications would not arise. In analysis of 214 cases, 43 patients became pregnant, and experienced no difficulty in labor. The uterus remained in good position subsequently in the majority of the cases. He has performed the operation in 600 cases without a death, and has estimated recurrence of about 2%.

Obstetrics as a Specialty, Dr. JOSEPH PRICE (Philadelphia), was read by title.

Dr. ZINKE (Cincinnati) read a paper on **The Practice of Obstetrics as It Is and as it Should Be**. He spoke of the difficulty in educating the laity in regard to the necessity for aseptic confinement. Slight preparations are made for parturition, the obstetrician has hard work, poor reward and often unmerited blame. He believes in hospital care of cases of parturition, and argues that the best care can be given in hospitals rather than at home. It is the best and most convenient place for confinement purposes. Maternity hospitals should be so conducted that they would please the humblest as well as the most fastidious. There is no good reason why the smallest village should not erect a hospital for this purpose alone if not for any other.

Dr. W. D. PORTER (Cincinnati) read a paper on **Position of the Woman During Delivery**. It has been his invariable custom to deliver in the following position. The woman lies on her back across the bed, her hips well to the edge and on a Kelly pad so arranged as to carry fluids into a vessel on the floor; the patient's legs are separated or extended, they are supported by the assistance of a couple of suitably placed chairs, or preferably over the knees of the obstetrician, who sits on a chair facing the bed at a convenient distance. She should wear her stockings, her thighs should be enveloped in clean towels

and she should be covered with a sheet. This position should be maintained from the end of the first stage until the termination of labor unless the second stage should be tedious. In that event she can resume her ordinary position in bed, being again brought into the position described before the end of the second stage. This position is not tiresome to either patient or physician and can be maintained for hours without discomfort to either. His reasons for employing it are as follows: (1) There is less liability of infection with fecal bacteria; (2) fewer examinations are necessary; (3) there is better control of the head at the time of delivery, and consequently less danger to the perineum; (4) the woman can be more thoroughly cleansed after labor and clothing and bed are not soiled; (5) there is less danger of infecting the eyes or cord of child and less risk that it may aspirate fluids into its air passages; (6) in managing cases under the unfavorable environments of the lower classes the position is especially valuable to the young physician whose experience is gained rather among these classes.

Dr. JOHN T. MORAN (Washington) read a paper on **The Prophylaxis and Treatment of Puerperal Sepsis**. He discussed the recent developments in bacteriology and pathology. He believes that routine douches before and after labor should be discarded and attention be directed to thorough cleansing and the disinfection of the external genitalia, by the hands of the physician, instruments, dress, etc., and avoid or restrict the internal examinations. He believes that the repeated giving of the intrauterine douches and the use of the curet in streptococcal infection is decidedly harmful. The general treatment will embrace the use of strychnia, nitroglycerin and stimulants strengthening the heart. Antipyretics should not be used as they depress the heart. The use of normal salt solution is a rational measure as it flushes the kidneys, eliminates the toxins and stimulates the heart. The use of antistreptococcal serum has been disappointing, although in cases of pure streptococcal infection it seemed to have a beneficial influence. In conclusion then, the treatment of the sepsis will depend upon the skill and judgment of the physician and the condition of the patient. It would not be justifiable to open the abdomen without some physical reason. The different forms of sepsis should be thoroughly understood, for operation will hardly be required except in pathogenic infection. When the operation is done early many organs will be unnecessarily sacrificed, if performed late, the mortality will be increased. When there is attendant fever with the increased physical sign, the operation is permissible without the later general symptoms, as in systemic infection the surgical measure can but hasten the end.

Dr. HENRY D. FRY (Washington) discussed **Indications and Contraindications for the Use of the Curet in Obstetric Practice**. The indications for its employment to remove retaining products of suspension and blood clots are clear. But when the infection is streptococcal the use of the curet is harmful. Nature throws out a protective zone of inflammatory tissue at the point of infection in these cases. The curet simply breaks down the earthworks, scatters the defenders, and opens the door to entrance of the invaders, and the infection, instead of being localized, is made general. Cases of streptococcal infection invariably get worse after curetage. The use of the curet is uncalled-for in these cases when the infection exists in some laceration of the vulva, vagina, or cervix. In the absence of foul discharge, curetage should be omitted, but the cultures taken, preliminary injection employed. After 24 hours the culture growth will demonstrate the nature of the infection and the physician can be guided as to subsequent treatment. The clinical history of the case presented, as well as the history of the confinement, aid materially in making diagnosis before the bacteriologic test is available.

Dr. WILLIAM H. HUMISTON (Cleveland) reported a **A Case of Streptococcal Infection Following Labor**: He performed drainage of the peritoneal cavity through an incision in the cul-de-sac through the vagina. A gray slough on the outer surface of the cervix was proven by microscopic bacteriologic examination to have been produced by the colon bacilli. The infection of the uterine cavity was a mixed one of staphylococci and colon bacilli, and the infection of the peritoneal cavity reduced by streptococci and colon bacilli. The patient recovered.

Dr. GEORGE J. ENGELMANN (Boston) read an interesting statistic paper on **The Increasing Sterility of American Women**: This investigation is based upon numbers which may seem small to admit of deductions as to conditions existing throughout a great country, but the data are exact and cases are carefully sifted; in addition, many details are corroborated to a decimal by independent observers in far distant points; by Dr. Wilbur in the census of Michigan and Drs. Abbott and Kusznysky in that of Massachusetts, by the careful observations of Dr. Chadwick in Boston, and for the eighteenth century by town records from Massachusetts communities. Certain data are taken from each, as no one investigation covers all the points I have developed, and some have never before been presented, so that no record for comparison exists; all are indirectly corroborated by correlated facts. Whatever may be thought of the results obtained, the data presented certainly suffice to indicate the imperative need for further and more extended investigation in this direction. The sterility of women has increased hand in hand with the much-discussed decrease of fecundity, everywhere to some extent, but in the United States to an excessive degree, precisely as fecundity has diminished more rapidly than in other countries; from a sterility of 2%

in the eighteenth century, and a fecundity of 5 children to the marriage, conditions better than in any other country, and such as led to the Malthusian theory of superfecundation, through the fear of overpopulating the earth's surface. After a lapse of 1 century from first we have passed to last, and the other extreme is now presented: sterility greater and fecundity less than that of the women of any other nation, unless it be of France, who for this reason must yield her proud position of one-time supremacy and retrograde to the rank of a second-class power. Among the laboring class in St. Louis, 21% of all marriages are sterile; 24% among the higher classes; of foreigners, only 17%. Throughout the State of Massachusetts, Americans 20.2%; foreigners, 13.3%; and in the city of Boston 23.7% among the laboring class, American of American parentage the fecundity in the eighteenth century, 5 children to all marriages, at the beginning of the nineteenth century 4.5; is now and was at the end of that century 1.8 to 2.1; 2.1 in Missouri, 1.8 in Michigan, 1.8 in Boston, somewhat more among American born of foreign parentage, much more among foreigners, among the Irish 4.2 in St. Louis, 3.5 in Boston, 5 in Michigan; among Germans 3.4 in St. Louis, 6 in Michigan; and in Massachusetts for all foreigners 4.9 children to the marriage. Fecundity is somewhat less among the native American, also among the higher classes, least of all among college graduates; 1.3 or for a smaller number, 1.6 children to the married couple; in England 1.5, while for the population at large it is there 4.2. I have called attention to the frequency of miscarriage and divorce as concomitants and causes of sterility, mainly to emphasize that barrenness is not altogether due to physical causes, to pelvic disease amenable to local treatment, and that sterility is but too often artificially produced, the result of moral causes or the sequence to intentional miscarriage and the methods which precede it, the prevention of conception, both of which competent investigators have shown to be far too frequent. Concomitant with this apparently artificial sterility is the progress of divorce, in Canada 1 to 13,000 marriages; in France, 1 to 12,500; in all United States, 1 to 185; Massachusetts, 1 to 18.8; Rhode Island, 1 to 8.2 marriages. Miscarriages, too, are correspondingly frequent, and are found in the proportion of 1 to 2.8 labors at term among Americans; 1 to 5.5 is the usually accepted standard; among Americans of American parentage the frequency is somewhat greater, 1 to 2.7; among American-born of foreign parentage somewhat less, both in St. Louis and Boston; among negroes worse, 1 to 2.7. There is an absolute and primary barrenness due to uteroovarian disease, mainly to atresia, gonorrhoea, and to endometritis, with acrid discharge destructive to the spermatozoa; this is, here for the first time, clearly distinguished from relative, or secondary sterility, *i. e.*, conception and miscarriage; this primary sterility is much less frequent, 12% among Americans, 10% to 11% among foreigners, which, of course, means relative sterility for Americans 9% to 12%, foreigners 3% to 6%, showing that among American-born there is a much greater proportion of sterility or childlessness due to abortion; this may be due to disease or traumatism accidental, more often authorities say not; the frequency of relative or secondary sterility clearly indicates that much of the barrenness of women is intentional. All sterility was, in the American colonies, 2%; in parts of Russia it is today 2.8%; in Norway 2.5%, hence primary barrenness cannot, under normal conditions among a people in good moral and physical health, be much over this; in the United States all sterility is 21%, and for primary sterility my records show 9%; 9% of 20% to 23% of the childless; even in absolutely primarily barren marriages sterility is, once in 4 or 5 cases, due to the male, showing that absolute sterility in woman is not common; that sterility is not mainly due to uteroovarian disease is evident from its rapid increase, hand in hand with the astounding progress of gynecologic science, which we have every reason to believe would reduce the number of childless women to a minimum were sterility referable to tangible physical causes.

Sterility is a sad affliction for the innocent sufferer, and for her our best efforts must be exerted; but, if so rarely due to pelvic malformation and disease, why do I present these thoughts to the gynecologic section of a medical society? Not because of their significance for the future of the country; it is for the sake of the individual, because we must seek to stay the progress of this abnormal state—because men and women are in ignorance of the suffering prone to follow wilful and self-inflicted sterility, and it is this subject which claims a prominent chapter in the gynecology of the future—in preventive gynecology.

Dr. W. H. WATHEN (Louisville) discussed **Ectopic Gestation**. The etiology was described and the treatment detailed. Before the sac ruptures the vaginal route for operation is usually preferable, and may be used after rupture where the blood is confined between the layers of the broad ligament, or in Douglas' cul-de-sac, and in intraabdominal rupture where there is but little hemorrhage, and in all other conditions the suprapubic method of operating should be adopted.

FOURTH DAY.

Dr. T. J. BEATTIE (Kansas City, Mo.) read a paper on **Puerperal Eclampsia**. He discussed the various theories as to the etiology of this condition. He believes that its cause is still obscure, and that the consensus of opinion is that it is due

to the apparent toxemia. Many cases present symptoms which give some forewarning of the possibility of its occurrence. The prophylactic treatment is of the greatest importance and examinations of the urine should be made frequently and attention paid to the elimination of the urea. If the attack occurs the chloroform should be administered with chloral and morphia. Bleeding, followed by transfusion with normal salt solution, is commended, and *veratrum viride* is useful when indicated.

Dr. W. J. GILLETTE (Toledo, Ohio) discussed **The Cesarean Section as a Method of Treatment of Placenta Previa**. He reviewed the literature of this operation. Dr. Bernays (St. Louis) was probably the first to perform successfully the cesarean section for placenta previa and thinks that cesarean section if generally adopted for placenta previa will reduce the fearful fetal mortality to at most 10%. When 3 cesarean sections in the hands of 3 men can be done without the loss of the mother or child we certainly have reason for our faith that it can be done without any increased danger to the mother, from that usually most incurred by any of the later methods of treatment and must therefore be considered the correct procedure. A classic section can be adopted where the uterus contracts firmly, where there is no probability of infection, and where the patient is in condition to withstand a shock necessitated by prolonged operation. But on the other hand, where the uterus does not contract firmly, thus rendering hemorrhage probable, and the patient unable to withstand a shock, then the Porro cesarean section is, in his opinion, the only procedure warranted. The only indication for a new operation for this condition is the very high fetal mortality.

Dr. MAHER (Oakland, Cal.) read a paper on **Intrauterine Amputations**, describing a number of cases and discussing the etiology.

The session was concluded by a paper on **Gynecology: its Contributions to Surgery**, by Dr. HENRY O. MARCY (Boston). This paper was an admirable historic review of the progress of this science during the nineteenth century, particularly in America.

Dr. J. H. CORSTENS (Detroit) and Dr. C. L. BONNIFLEUR (Cincinnati) were elected as chairman and secretary of this section.

Section on Diseases of Children.

[Concluded from page 489.]

THIRD DAY.

Diabetes Mellitus in Childhood: A. C. COTTON reported a very interesting case, and called attention to the care with which these cases should be managed. He also pointed out the importance of examining the urine as a part of the routine practice in the diagnosis of the disorders of childhood, so rarely done by the average physician. This perhaps accounts for the seeming rarity of this disorder in young children. That heredity plays a role in the predisposition of diabetes there seems to be little doubt. It seems to the writer that the inclination of many to attribute to the infectious diseases of childhood a causal relation to diabetes, is not based upon careful analysis of the evidence, and that the glycosuria following such diseases is usually of the transient class. The advanced case of diabetes presents a picture of extreme inanition, emaciation, muscular weakness, dry skin and hair, brittle nails, extreme irritability, and extreme sensitiveness to cold, while the urinary symptoms are always present. Furunculosis and other skin lesions rarely appear in children. No routine treatment is applicable to even the majority of cases. At the present time the regulation of the diet seems to be the most important therapeutic measure. The death certificate follows hard upon the diagnosis, and the rate of mortality is very high. Elimination is most important in these little patients, while they should be protected from mental strain, shocks, frights, trauma, and exposure to inclement weather. The importance of an early diagnosis is evident, since success in treatment bears an inverse ratio to the previous continuance of the disease. Too much stress cannot be laid upon the importance of always protecting the child from any sudden lowering of the temperature.

Discussion.—Dr. C. F. WAHRER emphasized the view that medical treatment had little or no influence on the progress of diabetes nor could much more be expected from the diet. Both may have some effect in improving things and holding the disease in check but not in curing it. He could not recall any patient under 10 years of age who had recovered. Why should we take away from the patient things that he can eat and insist upon him eating things that it takes a strong adult stomach to digest? We should not commit ourselves to a routine treatment that may do more harm than good.

Albuminuria in Infancy and Childhood: JOHN R. RATHMELL said that diseases of the kidney in infancy and childhood are chiefly hyperemias and nephritis following the contagious diseases, especially scarlet fever. Physiologic albuminuria may occur at any period of infancy or childhood. It is most common between the ages of 5 and 15 years, and rarely persists. While albumin in the urine does not necessarily indicate serious organic disturbance in the kidney, yet its presence, however slight, commands the utmost watchfulness and care. Albumin is found in the urine after a rich meal,

heavy muscular exertion, intense emotion and cold bathing. Even when every other constituent of the urine is normal and functional albuminuria can be differentiated, yet these cases require the most careful consideration, for sooner or later, it may be after months or years have passed, grave lesions may show themselves and we wake up to the fact that insidious degeneration has been going on in the meantime. It is very important, therefore, to decide whether the albuminuria was simply functional or due to organic change. The prominent symptoms are albumin, high specific gravity and edema. These symptoms are especially found in interstitial and chronic parenchymatous, active hyperemia, catarrhal nephritis, parenchymatous degeneration, passive hyperemia, and acute nephritis. In acute nephritis the amount of albumin depends upon the extent of involvement of the glomeruli, and the amount of casts depends upon the extent of tubules affected. To meet the symptoms of edema and ascites and treat them, requires some thought concerning the condition of the patient. When threatening uremia exists, diaphoretics, diuretics and cathartics are indicated. Podophyllin compound, jalap powder and other watery purges may be used. Hot baths and hot packs should be used to cause profuse sweating where ascites is extreme, tapping is of value. For stimulation, teaspoonful doses of infusion of digitalis every 4 hours for a child of 5 years old can be given.

Discussion on Gonorrhoea in Boys: Dr. EDWIN ROSENTHAL. Gonorrhoea is seen so frequently that I begin to look for it as an epidemic. When the gonococcus is present, we can positively determine the existence of the disease and often trace the guilt of the crime when it occurs in the young child. The overcrowding in tenement districts is responsible for perhaps the most of it in the poor.

Dr. CLIFTON SCOTT did not think that it was confined to tenement houses. There is a great need for education even among men and women of the better classes. When people come to understand that there are not only vicious men but also vicious women, these questions will be looked at in a different light than they are now. For the dissemination of gonorrhoea in young boys, servant girls and maids, who force connection with the boy in absence of his parents and give him his first lesson in vice, are largely responsible. Formerly it was not thought unsafe when sleeping accommodations were limited by reason of visitors or for other causes, to allow the young boy of 10 or 12 years of age to sleep with the maid. Often the result was that the innocent boy had been infected with this vicious disease.

Dr. C. F. WAHRER referred to the fact that it was not such an unusual matter for children under the age of puberty to indulge in sexual gratifications. A case came under his notice in which a boy of 13 was invited by one of his companions to meet a certain girl of 16 years of age at a barn where he was shown how by his companion and was then given his first lesson. When the matter was traced up, the girl confessed with unblushing effrontery that she had been engaged at this sort of thing for a long time and spoke of the special enjoyment it was to instruct the new subject.

Dr. A. C. COTTON referred to the astonishing ignorance of the laity, even well-informed, people on this subject. The number of alleged assaults upon little girls is remarkable in number, and it is astonishing how many cases of gonorrhoea occur in small children. One source of this in the cases of the little girls is when some infected man, while he does not lacerate or cause an injury to the little child, seems to get a peculiar gratification on the contact in rubbing his organ against the little one's thighs. The girl, of course, develops gonorrhoea. I have seen so many cases that I believe that sort of thing is not so rare. Copulation among children before the age of puberty oftentimes occurs. In my dispensary service there was a string of 18 or 20 little girls whom we found on investigation had come from the same neighborhood. They were of a variety of nationalities. On tracing the matter up it was found that a boy of 10, with complete ignorance of what he was doing, had been infecting these 10 or 20 little girls. Mothers and fathers, especially the latter, with an old gleet not uncommonly infect the innocent child by allowing them to use the same chamber that they have previously used themselves.

Dr. Cook thinks that the time has arrived when the public should be educated on these matters and when they should all know the life history of the gonococcus outside of the human body. Prophylaxis and a thorough knowledge of the dangers of the disease should be taught thoroughly to every patient who comes for treatment. Many persons spread the disease innocently, laboring under the delusion that they are cured themselves, when, as a matter of fact, latent germs exist within their own bodies.

Physical Culture in Children: Objects to be Obtained: J. MADISON TAYLOR said that it should be clearly understood at the outset what is meant by the term physical culture. Two objects are aimed at, first to raise the general bodily efficiency of the child, as found in the schools, by aiding the natural spontaneous processes of growth and development, both mental and physical; and second to assist in improving the conditions of those who are found to be below par in any direction and bring them up to the standard for their age and conditions, so that they may progress in the same degree as ordinary individuals. It is essential that all school children should have the benefit of skilled medical supervision during their growth.

With all the ordinary opportunities for spontaneous development that are enjoyed by the young, nevertheless, it is plain that often many faults of attitude are acquired involving impairment of the full activity of the vital organs. Children cannot be trusted to properly grow up unless directed and unless beginning faults of attitude are corrected they will remain and probably grow worse unless promptly and accurately corrected. Many of these are due to original errors of construction, some are hereditary, and some are acquired by extended imitation or the conditions of environments. If these are allowed to go on the result will be postural errors or interference with symmetric growth. Defects in the organs of special sense, notably the eye, ear, and nasopharynx may be enumerated as some of the causes and must be dealt with by the specialist. Relatively local disorders are capable of producing great functional disorder when the physique is a little below par, whereas if the general mechanism of the body is good they cause very little mischief. It is not commonly known that many defects in the ocular or hearing apparatus are remediable by specialized movements of the head and upper parts of the body. In many cases they have been practically cured by physical culture alone. This statement seems extravagant, but it can be proven by the very men who had given the adverse opinions. It needs no proof to establish the fact that the heart and the lungs, and the very important lymphatic mechanism of the thorax can certainly be assumed to be in far better functional efficiency if the shape and mobility of the thorax is normal. Unless the spinal column be maintained in a healthy condition of straightness, and the bones and ligaments of the ribs and shoulders and the soft tissues controlling them retain their normal flexibility the lungs must inevitably suffer and the heart likewise fail of its normal activity. These organs should be perfectly free from external pressure, and from no other cause than mechanical pressure serious conditions of a most disabling sort oftentimes arise. The first main object of physical culture for children, therefore, is to teach them to assume right normal attitudes. Physical culture teachers are usually neither physicians nor physiologists and often not good observers. Their methods, therefore, are too often empirical or prejudiced and their knowledge of the subject not sufficiently thorough. In the study of the chest and shoulders one error was long taught as a truth, and may still be of value if properly carried out, and that is to throw the shoulders back, and the chest out, the head up and the chin in. A simple rule which can involve little error is to let the shoulders alone, free from tension, but keep the back straight and hold the chest as far up as possible and keep the abdomen held in. Then the arms and shoulders are free from constraint and can be moved in any direction. Almost the most important factor is the position of the pelvis which should be maintained as nearly as possible at a level. Then the action of the thigh bone at its junction with the pelvis is so easy that the slight forward leaning of the body as in stepping forward, allows the leg which is raised to swing forward with almost no effort. A child or even an adult trained in this particular can walk at a much higher rate of speed and maintain this for a longer distance than a very much stronger person who fails to observe the condition. The subject of breathing is one about which many fallacies are taught. The diaphragm is a muscle of unrecognized importance and is capable of high training and development, just as are the muscles of the arms and legs. The object in right breathing is to obtain the fullest degree of elasticity of the thorax, and the greatest degree of freedom. Unless the largest measure of freedom is allowed, stiffness and contractions in the tissues in certain localities, such as about the hips, the upper part of the chest, and the back of the neck may result. Nine-tenths of the ordinary movements of life are flexions. Little more than one-tenth involve definite extensions. We often see in children even 5 or 6 years of age the commoner forms of adult anamorphosis. These stooping shoulders, sunken chests, drooping or protruding heads, half bent knees are chiefly due to lowered muscular tones. Asymmetries arise, lateral pulls or twists in back or neck or legs, showing that degenerative changes have begun. Another group indicate occupation warpings, lowered right shoulder, tilted pelvis, pigeon toes, exaggerated lumbar or dorsal curves, clawed hand, etc. These defects arise principally from lack of extensor tone. Extensor power may gradually lessen or become almost lost from disuse, and yet flexor power remain. The assumption is that in the motor areas of the brain there are 2 sets of cells, 1 for extension and 1 for flexion. The development of flexor activities may not be accompanied by the development of extensor activities, and thus asymmetry results. Normal development involves the idea of the acquirement of symmetrical activities. The teacher needs to know the basic principles and to be able to adjust his methods to the exigencies encountered.

Speech as a Factor in the Diagnosis and Prognosis of Backwardness in Children: G. HUDSON MAKEN thought this subject very important, and it is very necessary that there should be a definite and uniform nomenclature in its discussion and classification. After defining the backward child, and pointing out some of the difficulties in arriving at a correct diagnosis and prognosis, the author enters into speech as an aid in backward children in formulating conclusions with reference to their exact mental condition. Speech is a tool of the mind. Children are dependent upon good speech and expression for the normal development of their mental faculties. It is not

possible to determine at a glance always the backwardness of a child. The child must be carefully watched and a careful analysis of its psychologic processes noted. The condition of backwardness is not always due to a central lesion, but it may be the result of arrested cerebral development due to some abnormality in the structure of peripheral organs. A common cause may lie in some structural abnormality of the peripheral organs of speech. The speech centers and the centers for ideation are so closely related to each other that any impairment of one generally results in a corresponding impairment of the other. The best method of arriving at an approximately correct prognosis in cases of backward children is to apply the speech test, or in other words to ascertain by careful study and experiment to what extent the faculty of speech may be improved. It will usually be found that those who are susceptible to training in what may be called the refinements of speech are the ones that give promise of the best results and that the possibilities for general improvement will be proportional to the capacity for speech development.

The Pubescent Schoolgirl: WM. EDGAR DARNALL dwelt on the great importance of the period of puberty. The girl at puberty is very susceptible to mental, moral and physical influences, and her environments and tendencies should be studied with the utmost care and discretion. This time may be the starting point for perfected womanhood on the one hand if properly managed, or for a physical wreck on the other if neglected. The average schoolgirl under the modern high pressure system of education is straining every energy to keep up with her duties and using all her vital force in mental effort. This system is largely responsible for the nervous irritability and dyspepsia that have become such prominent characteristics of our people. During the period from 9 to 15 years of age the body is developing so rapidly that brain weight is actually lost by the lessening of the blood-supply which goes to nourish the rapidly growing organs. The child brain is easily fatigued. What is crammed into the tired brain is soon lost because it makes no impression. Memory is demoralized, and the very end for which one is striving is thus defeated. The physiologic processes of the girl make even greater demands upon her than the boy's on him during this period. In addition to performing the same work at school she is also expected to acquire the accomplishments such as music and painting at an early age. Too much time must be given to practice or books when she ought to be out in the open air. Then come the exacting examinations. After this is a period of 4 years at the high school, 4 years of endless antagonism between brain growth and body growth, 4 years, perhaps, the most important of her whole life, when the menstrual period is just beginning or is struggling to assert itself under difficulties. These 4 years are very needful for the perfect development of the sexual organs, and the woman's whole future health and happiness may depend upon the result. Hysteria, crossness, and irritability, neurasthenia and sexual incompetency may be the result of this strain. Painful menstruation is the bane of the existence of the school girl. From 66% to 75% probably have some history of painful menstruation. The fact of the pains being increased with hours or intensity of study, with worry and emotion; and being diminished or ceasing entirely without treatment of any kind during vacation time is a fitting commentary on the underlying causes. The nervous or mental element is a more prominent factor than we take it to be, and shows the importance of general management and the elimination of all injurious conditions of worry and debility, mental and physical. A large percentage of the neurotic class of women have arrested development of the sexual organs. The most common defect is a failure in the development of the uterine cervix, which retains its infantile characteristics. It is usually anteflexed and less patulous than normal. The tubes and the ovaries may share in the lack of development. The girl's life should be carefully watched during the oncoming of puberty, and her studies restricted if necessary. In some cases she should be taken from school altogether for a year. Especial attention should be paid to a regular evacuation of the bowels and bladder. All stimulants and excitements, such as late hours, children's parties, and other forms of excitement, should be forbidden. Sleep is nature's upbuilder, and plenty of this should be had by the growing child. Proper diet should be supplied and the habit of eating between meals prohibited. Undue excitement, mental worry, or anything that may divert the vital forces from the great work they are performing in the development of the perfect woman should be jealously guarded from the pubescent girl, for this short period is of unmeasured importance to her future happiness. Teachers must learn that health is more important than knowledge; schools must realize the futility of the forcing process and guard the health of their girls by diminishing the studies at this time rather than increasing them, and it must be remembered always that a sound mind depends upon a sound body. It is only thus that we may hope to diminish the pitiable army of neurotics and sexual incompetents among the womanhood of the land who so largely fill up the hospitals, and who are to be the mothers of the men of our country.

Gonorrhoea in Boys: A. L. WOLBARST said that the frequency of this disease in young boys has of late attracted much attention. The author has seen 22 cases ranging in ages from 18 months to 12 years. In order to be accurate the secretions were in every case stained by the Bram method and the presence of the gonococcus demonstrated. The history of such cases has

been generally attributed to infected water closets, soiled linen, etc., but a study of the prevailing social conditions leads to the conclusion that where children are crowded together, especially in the tenement districts, they are alive to the enjoyments of sexual gratification at an extremely early age. The dark closets and cellars and the roofs afford excellent opportunities first for experiment, then for enjoyment, and it is not at all uncommon to find that boys and girls who have not yet reached the age of puberty indulge in sexual gratification. Some of these cases, it is true, were infected by sleeping with those who had gonorrhoea. The period of incubation and the general characteristics of the disease in children do not differ especially from the disease in adults. The discharge is usually profuse and the pain out of proportion to the clinical picture presented. This hypersensitiveness, however, is often coincident with contracted prepuce or meatus, which prevents free drainage of the urethra. The author makes a plea for circumcision. Every case of gonorrhoeal urethritis offers a most eloquent plea for the circumcision of all male infants, when the possibility of a future gonorrhoeal infection is thought of. Complications occur in young boys similar to those of adults after the disease has lasted several days. Posterior urethritis, prostatitis and epididymitis have occurred in this series, and one patient was unable to pass his urine. The disease lasted from 4 to 6 weeks, but the prognosis as to complete recovery seems better in children. Prophylaxis consists in the education of the people to the dangers of the disease, and care that those suffering from it do not sleep with them, or come in contact with the discharges in any way. Stringent laws should be passed for the protection of children. Cleanliness is a primary requisite in treatment, and if thoroughly carried out will prevent many of the complications. The prepuce and glands must be frequently bathed with mild antiseptic solutions. Injections of protargol are given for anterior urethritis. Irrigations of $\frac{1}{1000}$ of permanganate of potassium or of Thiersch's solution may be employed in posterior urethritis and should be given through a very fine catheter. Alkaline mixtures containing hyoscyamus oil of wintergreen in milk or water will be found valuable. Complications should receive appropriate treatment when they arise. Ten percent guaiacol ointment is recommended for epididymitis. Gonorrhoea bags must be used to collect the discharges and to prevent the possibility of conveying the discharges to the eyes.

Some Suggestions Regarding a Department of School Hygiene: LEIGH K. BAKER. Those nations which have exercised a powerful and elevating influence have been those which have exercised a care for the health of their citizens. In a democracy, self-preservation demands an educated citizenship. An elemental condition of useful citizenship is a fair degree of physical health. It is both the interest and the duty of the State to insist that the physical basis in the educational structure be adequately and properly laid. It is strikingly true of the children of the cities that the desired improvement in health has not been attained. The dark noisome alleys and tenements contain millions of the miserable offspring of ignorant foreigners, poorly born, poorly housed, and fed, with crooked spines and misshapen skulls, with pathologic eyes or ears, and little in their environments to produce self-supporting, self-respecting citizens. The question resolves itself, Shall we put sufficient money into the school system to produce self-supporting citizens; or shall we later, on account of half-supporting them and paying insufficient attention to the health of the children, spend larger sums for the construction of hospitals, dispensaries, police stations, reform schools, etc. Physicians, who of all classes of men are forced to carry this burden of indignity perhaps more than any other, should combine to place the right kind of men on school boards. The author outlines a systematic plan of organization with reference to the composition of the school board, the superintendent and teachers, and points out the dangers of allowing political influences to enter. The head of the department of school hygiene must be a medical man, who is at the same time a school sanitarian. Regular inspection of school children should be made, and plenty of assistance should be available to do it.

Diagnosis of the Backward Child: A. W. WILMARTH: The term backwardness is so vague that it is very difficult to formulate any definition that will exactly describe the backward child. There is really no sharp line of distinction between the normal and the so-called backward child. No standard of mental activity has been fixed or can be fixed. A child is not necessarily dull or backward because he cannot follow the curriculum formulated in the schools. However excellent this may be for the average child, there are many boys who have been classified as dull ones who have turned out to be most successful men afterward. What they may lack in memorizing, they perhaps make up in reasoning and acuteness of judgment. The estimate of mental strength must be formed from the power of attention, the strength of memory, the efficiency in the method of reasoning which comes to us all instinctively in our early days, and which is known as "common sense." On the other hand, abnormally slow perception, lack of power to fix the attention, distorted judgment feeble memory, or a decided lack of moral sense are mental symptoms which would tend to place the subject in the backward class. If the cultivation of these powers does not yield in a reasonable time to the different methods, they indicate not only a backward child, but a feeble mind. The lack of articulate speech is perhaps the most significant physical symptom indicative of lack of mental growth. Gait and posture are of

some value when taken in connection with other symptoms. In the backward child observations would tend to show that the sense of touch is less acute, and sensibility to pain is less acute, which would tend to indicate a lack of tone in the general nervous system. The family history may generally give some clue, as the individual is the sum total of his ancestral traits. The lack of moral sense is so radical a defect that a child will persistently do evil and not good, in spite of all efforts to lead him into right paths and right methods of action and thought that one is forced to regard it as a perversion of mental development. The first thing in the development of the child's brain is the awakening of the power of attention. Without this all attempts at education are futile. Next comes memory and inquisitiveness, and on this the child's probable capacity for acquiring information can be gauged. The will power later exhibits itself, then the reasoning power, and the value of ideas, and respect for the rights of others. A child may have a weak memory and make a poor showing in school, and yet have acute reasoning powers and the ability to make good use of what he does learn. Such a child should not be classed as backward. Education, however, will not completely remove in a few years weaknesses which may have been generations in developing.

A Plea for the Backward Child: C. F. WAHRER. The line between a normal and an abnormal child is a little hazy, and many a child a little backward in his studies, has been condemned as a dunce or even as a defective by the hasty observer, and the fallacy is due to contrast with the very bright or so-called forward child. If the child is unusually observant, has a good memory and power of expression it is called bright or even precocious and in comparison all other children seem more or less dull. The very bright child is taken as a standard of comparison instead of the medium child. There is often nothing the matter with the child who is considered slow. His powers are latent, and may be really developing in a direction different from the course expected. The mistake may be made of rating high the child with good memory but of ephemeral mental development, and giving a low estimate for the duller slow pupil whose powers are latent, and when made manifest show the strong and unwavering intellect of a perfectly balanced mind. Instances were cited of Shakespeare, Milton, Sir Walter Scott, Edison, Peter Cooper and many others who were proclaimed stupid and dull and hopeless dunces during their early school days. The ordinary "tests" and curriculums of the schools are not calculated to develop the mind, but only to show what can be accomplished with a good memory. Where are the bright boys and girls who were such splendid reciters and stood at the head of the classes, furnishing the valedictorians and salutariorians? Did they become President, Judge, Bishop or eminent man of science? No; they did not. It was the steady light of the persevering man working out his own evolutions and developing its own processes of reasoning. It is thus not how early but how well a given person develops and how effective are the results of his development.

Some Considerations Regarding the Hygiene of Early School Life: J. STORER. Children work too much, too soon and badly; that is to say, under unfavorable hygienic surroundings. We are reminded of the long list of studies, the rushing through of courses, the long duration of hours and the useless studies, the method of teaching unscientific, and its disregard of the laws of physiology and purely in favor of psychology, the evil of home tasks which rob the children of their short periods of recreation. The fact that mental and physical abnormalities exist in school children must be realized, and also that these abnormalities are always aggravated, if not, indeed, produced by pedantic and pseudo educational methods of teaching. It is eminently proper for the physician to interfere in matters relating to school hygiene. The protests of medical men may be summarized as follows: There is no evidence by which educational values may be determined except through the study of material manifestations transmitted through the nervous system. Education produces nothing new in the child. It simply unfolds and brings into intelligible activity the latent forces in the nervous system. One of the most important prerequisites for good education is good nutrition. Vigorous intellectual activity is possible only through the medium of brain-cells that are well nourished and physiologically active. All methods, therefore, which ignore the physical development are faulty and open to criticism. There is such a variability in individuals that it becomes absurd to attempt to lay out a uniform system of training and education applicable to all alike. The early discovery of the dull and the backward and the defective child and their segregation for special training is one of the problems of public importance in school life. The child is an exceedingly immature and delicate animal, undergoing important developmental changes. His delicate tissues and plastic nerve cells are easily warped and injured by long continued mental and physical efforts, and for this reason children are often injured by injudicious school work. Cases of this sort are of common occurrence. These abnormal consequences can and must be prevented, and the child's intellectual development must be allowed to proceed without detriment or hindrance.

Discussion.—Dr. Work thought that the cry that came up from all parts of the country proved that there was something radically wrong with the school system, and it was not confined to any one locality. The classification of scholars should be according to their intellect, and schools should be selected for

children which were fitted to their needs. He was particularly impressed with some of the facts brought out in Dr. Darnall's paper with regard to the close fitting and often unhygienic dress of the girl. The 2 important factors in all dress are equal pressure and equal warmth. Another most important factor is the food of the child, which often is badly and carelessly prepared. Regular habits should be taught the child with regard to baths, elimination, eating, etc. Every child should be taught what the organs of the body are, and for what purpose they are intended, and how they should be taken care of, and how they may be injured. If a child goes to school without a proper evacuation of the bowels or bladder, he cannot study properly. His intellect is dull and clouded. If a child does not have plenty of water to drink his mind will be more or less affected from the lack of it. The greatest trouble in most of the schools is not so much with the school or with the child. It is because we have not got trained mothers who understand these things themselves to teach the child at home. The duty of the profession is to educate the mothers of the community how to take care of the health of their school children.

Dr. A. W. WILMARTH referred to the importance of special training for the backward child and the work that might be done by schools set apart especially for this purpose. Such a school has been provided in Philadelphia and in a few other localities.

Dr. LEARNED thought that the highest ideals of development might be reached by plenty of outdoor exercise and good air and plenty of sleep. It is a mistake to start the child to school so early, and begin to burden its little mind, pushing it always to an extreme and keeping it on a tension. The child would learn faster and more thoroughly, and really make more progress in the long run if he were not started to school until he were 8 or 9 years of age, at least. The child's brain is fatigued and stunted by overwork when he is started so early.

Prevention of Tuberculosis in Babes Born of Tuberculous Parents: CLIFTON SCOTT. Two cases were reported, one in which a mother known to be tuberculous was confined. The child was immediately removed and placed with its aunt, fed on modified milk. When the infant was 5 months old the mother died. The child has continued to live, is now 3 years old and the picture of health and vigor, is well developed and has no symptoms of infection or hereditary taint. The second case of tuberculosis occurred in a woman of 20 just married. She claimed perfect health during pregnancy, but it was afterwards found she was suffering from tuberculosis in its incipient form. The child was not seen for 3 weeks after it was born. The mother, in the meantime, had been up and going about the city as usual, had taken part in literary entertainments, etc. When she was again seen her temperature was 103°, pulse 120, and she was ordered to bed. After microscopic and clinical examinations and consultation her case was diagnosed tuberculosis. The child in the meantime had been nursed. The mother's condition progressed rapidly to the end, and she died within 16 weeks after confinement. The child had nursed 5 weeks. It was, after this time, put on modified milk. It began, however, to exhibit loss of weight, pallor, and rales could be detected in the lung. It passed through a well marked history of acute tuberculosis, and died 1 week after the mother. As evidence that the second child suffered from hereditary tuberculosis, he cited that in the first the child was not allowed to nurse its mother; in the second it was. It is more reasonable to suppose that the second child did not inherit tuberculosis, but was infected with it from the mother through the milk or possibly from kisses, caresses, or other modes of contact. Infection of tuberculosis in fetal life through the membranes of the placenta cannot positively be denied, but its occurrence is certainly very infrequent, I think. The author thinks it is highly important that during the last 2 or 3 months of pregnancy the lungs of every pregnant woman should be examined, as well as other organs, and that by this means perhaps many cases of tuberculosis hitherto unsuspected will be found, and preventive measures may at least be taken to protect the child when it is born. The mother's milk must be prohibited and all contact with the mother. People should be educated to the importance of the case, and if so instructed, children born to tuberculous parents may, in a great many cases, be saved.

Discussion.—Dr. JOHNSTON thought that something could be learned from veterinarians who watch the milk coming from the tuberculous cows. Calves of such cows have been found not to be infected congenitally. They do not inherit tuberculosis, and if fed on other and pure milk they develop into strong and healthy cows, and there is no question that a mother can infect her offspring with the disease.

Dr. J. NOER stated that milk from tuberculous cows was not necessarily infective unless there was a local lesion on the udders.

Dr. I. A. ANT protested against the idea that there were such a limited number of cases of congenital tuberculosis. He thought the number of congenital cases must far exceed the origin of the disease in any other way. When such a number of children less than a year, and even less than a week old, have died of a widespread tuberculosis and who have been under the best possible conditions of hygiene, it seems reasonable to suppose that these cases have been of congenital origin. To prove the contention, however, the bacillus must be demonstrated in the placenta and the endometrium.

The officers elected for the ensuing year were: Chairman,

H. M. McClannahan (Omaha, Neb.) and Frank X. Walls (Chicago). The section chose as their 2 delegates Drs. A. C. Cotton and Samuel W. Kelley.

A committee consisting of Drs. Victor C. Vaughan, Charles Donglass and John C. Cook were appointed to investigate certain charges against Dr. Edwin Rosenthal, who it was claimed had used his official position for advertising certain products. The report of the Committee is as follows:

MR. CHAIRMAN AND MEMBERS OF THE SECTION:

Gentlemen.—Your Committee appointed for the purpose of deciding whether or not Dr. Edwin Rosenthal, Chairman of this Section in 1900, used his official position for the purpose of advertising the product of a certain drug firm, begs leave to submit the following brief statement of the facts presented in the case and the findings determined upon.

Dr. Rosenthal's address, as Chairman of this Section in 1900, contained a statement of the results obtained by the antitoxin treatment of diphtheria. In this statement he reported 325 cases treated with the antitoxin of one manufacturer, and less than 900 cases treated with the products of all other manufacturers, and the results seemed to show the superiority of the product of the firm that furnished the lowest number of cases. This firm has used Dr. Rosenthal's address widely for advertising purposes. Dr. Rosenthal assures us that this use of his paper was not only without his consent, but that the firm have continued this use of his address after receiving a protest from him. Your Committee offers the following findings which are respectfully submitted to the Section:

1. That the conclusions stated in Dr. Rosenthal's paper, being founded upon cases so unequal in numbers, are wholly without value in showing the relative merits of the products of the different manufacturers.

2. That Dr. Rosenthal, as Chairman of this Section, did use his official position to advertise a certain firm of manufacturers of antitoxin. Whether this improper use of his official position was intentional or unintentional, we cannot decide from the evidence before us.

3. That this Section will look with disfavor upon any firm of manufacturing chemists which uses for advertising purposes any paper, parts of papers, or statements written, or verbally made by any member of this section in its proceedings.

Respectfully submitted,

VICTOR VAUGHAN,
CHAS. DOUGLASS,
JOHN C. COOK.

Section on Materia Medica, Pharmacy and Therapeutics.

[Concluded from page 422.]

THIRD DAY.

Gastric Disorders: This subject was dealt with in a series of papers at the morning session. Dr. BOARDMAN REED (Philadelphia) read the first paper, which was entitled **The Influence of Certain Common Remedies upon Gastric Functions**. The conclusion at which he had arrived after a number of experiments and the careful watching of cases was that organs that were acting normally were likely to be injured by drug stimulation. He had found that hydrochloric acid and pepsin, when given separately, both tended to impair the digestion, whereas when given together they had the opposite effect. Perfectly normal stomachs were probably in a minority, especially among persons employed in trades. In the case of such persons the digestion might be injured by a simple bitter tonic, even when used only a short time. More care should be exercised in the indiscriminate taking of drugs, even those that were supposed to be harmless.

Dr. GUSTAV FÜTTERER (Chicago) followed with a contribution on the **Treatment of Gastric Ulcer**. He differed from those who looked on the prognosis of ulcer as very favorable. The immediate prognosis might be very good indeed, but not so the remote. Ulceration of the stomach was frequently followed by carcinoma. There was a time when he thought that carcinoma would not originate from small ulcers, but some cases he had seen convinced him that he was mistaken, and he did not differentiate any more, but made the same remote diagnosis. The treatment of such cases was promising and satisfactory in this respect, that it permitted them to pursue thoroughly rational methods. He was in the habit of giving the juice of beef properly prepared. Beyond that all he looked to was the rest cure and control of the hemoglobin percentage. It was not safe, however, to conclude that the disappearance of the symptoms meant that the danger of carcinoma had been avoided. It might be forming all the time. In cases where there was obstruction of the pylorus he was in favor of an early gastroenterostomy.

A paper on the **Treatment of Gastric Hyperesthesia** was read by Dr. CHARLES C. STOCKTON (Buffalo). He advised a bland diet, commencing with milk and going on to farinaceous foods, eggs, etc. It might be gradually increased as the patient improved. Electricity was of service, and hydrotherapy of great value, though it was necessary to guard against overdoing the use of cold water. The treatment should always be rational and suitable to the conditions. The contents of the stomach should be examined, frequently, and care should be taken not to allow the stomach to be kept too long on one diet. It was a mistake to regard hyperesthesia as a disease of the stomach; it was a derangement of the organism of which the stomach was the index.

Discussion.—Dr. J. B. HERRICK (Chicago) referred to the complications that might arise from gastric ulcers, notably hemorrhages, peritonitis, and the development of carcinoma, as well as the mechanical interruption that frequently resulted in certain cases. He was acquainted with the character of the work that Dr. Fütterer was doing in connection with this matter, and he thought it deserving of all praise. Dr. Fütterer had laid more emphasis than ever on the condition of the blood as a factor in the production of ulcer, and in this respect the experimental work fitted in with clinical results, both tending to show that cases in which the blood was deficient were most likely to acquire carcinoma. The best treatment that could be advised was one that would prevent the formation of ulcers. In other words, they must do away with the causes of their production. For a patient thus affected there was practically only one thing to recommend, namely, the giving of rest to the stomach. The experience of physicians would seem to show that the more nearly this rest could be absolute the better would be the results. He put his patients to bed, and fed them by the rectum for weeks if necessary. He stopped for the time all giving of food by the mouth, even water. In regard to diet, he relied more on milk than on beef juice, and when the patient was commencing to get better, he added a little iron. Only when the hemoglobin became normal did he allow the patient to sit up and take ordinary food. He agreed with Dr. Fütterer as to the wisdom of early operations in cases where there were obstructions of the kind referred to, his reason for so doing being that in these cases they had always to fear the formation of carcinoma.

Dr. W. W. TOMPKINS (Charlestown, W. Va.) said that in these gastric disorders it was very difficult at times to distinguish between ulcer, catarrh and carcinoma. For this among other reasons he objected to turning over these cases to the surgeon, who in his opinion did too much cutting at present.

Dr. FÜTTERER, discussing Dr. Reed's paper, expressed the opinion that the facts he had ascertained would be of great use in carrying these experiments further.

Dr. OSBORNE observed in regard to the subject discussed by Dr. Stockton that they could not be too careful in guarding against the common mistake of treating cases of hyperesthesia as dyspepsia. By prescribing too rigid a diet they were in danger of causing denutrition.

Dr. JOHNSTON (Clinton, Iowa) said he found that in cases where disorders of the stomach were accompanied by pain mild anodynes were of considerable use.

Dr. MARY MCCOY (Duluth) called attention to the proper preparation of patients' food. This was one of the prime factors in the treatment of disorders of the stomach, as well as of many other complaints. The best way to treat a patient with gastric ulcer was never to let them have it. A study of the compatibility of foods was also necessary.

Dr. MARY WHEATSTONE (Minneapolis) said she was glad to see that some of the best medical colleges were beginning to require students to take courses in the preparation of foods for the sick.

Dr. THOMAS McCRAE (Baltimore) agreed with what had been said as to the necessity of looking after the general nutrition of patients suffering from hyperesthesia.

After some remarks from Dr. DORA G. WILSON (Kansas City) the authors of the papers replied. Dr. REED remarked that the term "dyspepsia" had been much abused, and it might be well to abolish it altogether. Dr. Fütterer stated that he had tried many of the beef juice extracts on the market, but he preferred one made directly from the meat. Dr. Stockton, in emphasizing the advisableness of operations in certain cases, said they were comparatively safe and did not involve much suffering. Fermentation in the stomach, he added, though thought to be very common, in reality was extremely rare. What was supposed to be fermentation was disturbed mobility.

Organotherapy: The last session of the congress was devoted to a symposium on this subject. Dr. CHARLES T. MCCLINTOCK (Detroit) was to have opened it with a paper on the **Mode of Manufacture of Serums and Organ Extracts**, but he was not present. The author of the second contribution on the program, Dr. S. SOLIS-COHEN (Philadelphia) was likewise absent, but an abstract was read of his paper, which dealt with the Theory and Practice of Organotherapy.

Dr. SYDNEY KUH (Chicago) then read a paper on **Akromegaly Treated with Pituitary Body**. The subjective symptoms were relieved in 2 out of 3 cases in which the author gave the extract in powdered form, and they got worse when the medicine was stopped. A considerable number of similar cases were recorded in the literature on the subject.

Dr. JOHN M. DODSON (Chicago) discussed the **Treatment of Graves' Disease with Thymus Extract**. In 1 case a man who had suffered from bronchitis and pneumonia was found to have symptoms of Graves' disease, and after fruitless experimenting with a number of drugs, he was placed on thyroid tablets, more for diagnostic purposes than anything else. The result was to aggravate his symptoms. He was then put on thymus extract, and his condition immediately began to improve, and had gone on improving since. The patient had tried the effect of suspending the use of the drug, but he said that he could not live without it. The literature on the subject showed that the extract had not been much used, and those

who had used it had obtained very different results, but he thought it was deserving of further trial.

The papers were discussed by Dr. OSBORNE (New Haven), Dr. BOARDMAN REED and Dr. FRANK WOODBURY (Philadelphia), Dr. SHELLEY (Atchinson, Kan.), and the chairman, the comments being generally of a commendatory character.

The Pharmacology of the Suprarenal Gland and a Method of Assaying Its Products were described in a paper by Dr. E. M. HOUGHTON (Detroit). After giving credit to Addison and Brown-Sequard for their work in connection with the functions and utility of the glands, the author proceeded to speak of the partially successful efforts of Abel, Fürth, and others, to discover the active principle of the suprarenal gland, but said it had been left to Takamine to complete the solution of the problem. He exhibited diagrams for the purpose of showing the pharmacologic action of the various preparations obtained from the gland, with special reference to their influence on blood-pressure. He mentioned that adrenalin, as the active principle had been named by its discoverer was 600, 800, or perhaps 1,000 times as strong as the aqueous solution of the suprarenal gland. Experiments were still in progress he added, which it was hoped would result in throwing light on many points that were still unsettled as to the properties of the blood, the matter of dosage, and other things.

Dr. JOKICHI TAKAMINE (New York), the discoverer of the active principles of the suprarenal gland, was then introduced, and read a paper describing the experiments he had made which had resulted thus happily. He began by discussing the therapeutic uses of the suprarenal capsule and the early modes by which it was administered. Thereafter he reviewed the efforts of different investigators to isolate the active principle, making special mention of Abel's substance, to which the name of epinephrin had been given, and Fürth's which was known as suprarenin. Though both these investigators had made advances, neither, he maintained, had obtained the real active principle in a sufficiently clear form. He gave full credit to these and other predecessors for what they had done, but adduced evidence to show that none of the products they had obtained could be regarded as the genuine active principle. In adrenalin for the first time had the active principle of the suprarenal gland been isolated in a free, basic, crystalline form. The speaker then proceeded to describe the physical and chemical properties of adrenalin, the mode of its preparation, its physiologic activity, and the therapeutic uses to which it was being put, with highly satisfactory results.

Dr. VICTOR C. VAUGHAN (Ann Arbor) expressed his great gratification at the most excellent and scientific work which was exhibited in both papers. They showed that pharmacology was certainly becoming a science. Dr. Takamine was to be congratulated on the fact that he had carried to a successful termination the efforts to solve a problem which had for so long a time engaged the attention of some of the most eminent men in this country and Europe. As to the utility of the extracts of certain glands, there could be no question. The thyroid gland had been of great service, almost marvelous results having been attained by its use in the treatment of cretinism and other diseases. The same was true of extracts of the suprarenal gland, and altogether he did not think it was safe for them to predict what might or might not lie in the future of organotherapy. Certainly if any one had predicted 15 years ago any of the wonderful results that had been obtained already, he would have been put down as crazy. These achievements had, of course, led to a good deal of very thorough study of those glands which furnished internal secretions, but there was still much room for experiment, both on the chemical side of the matter and in regard to the physiologic effects and the therapeutic uses of the products. He had used both the thyroid extract and adrenalin in many cases, and in not a few instances he had obtained extraordinary results. In long standing hemorrhages he had used adrenalin with particularly good results. Of course the quack was always ready to take advantage of any success made in medicine, and probably there was no other field in which the quack of the United States had reaped so rich a harvest as in the use of goat lymph, scalled, and other preparations of a similar kind. But this was all the more reason why organotherapy should be thoroughly investigated and placed on a scientific basis.

Dr. HEINRICH STERN inquired as to the dosage and how long the drug could be used. Dr. TAKAMINE had said it did not accumulate. Perhaps Dr. Vaughan could tell them how long he had given it to a patient.

Dr. BOARDMAN REED observed that Dr. Takamine had said that adrenalin was nonpoisonous. It was of importance to have this fact established. He was himself suspicious in regard to all these extracts which had such powerful properties. He did not see how they could avoid having toxic effects if given in large quantities.

Dr. OSBORNE said that while they got good results with the suprarenal extract in the nostrils and some other organs, it did not do well in the stomach. He would like to know how adrenalin acted in this respect.

Dr. VAUGHAN, being appealed to to answer the questions, said he was unable to do so positively and fully, but he had prescribed adrenalin tablets for one patient, 1 grain 3 times a day. The man was suffering from hemorrhage of the bowels, and he continued taking them for 3 months without any apparent untoward effects. Thereafter the man moved

away, and only the other day happening to think of the matter he wrote to him suggesting that he had better not take any more tablets. He agreed with those who thought that such a powerful drug could not be taken with impunity for a long time unless it was eliminated somehow, and it was a question whether it was eliminated or not.

Dr. DONSON remarked that some of the most powerful drugs had no effect in the way of producing tissue changes. As examples he mentioned nitroglycerin and arsenic.

Dr. HOUGHTON and Dr. TAKAMINE, in replying on the discussion, gave such information as they possessed as to the points raised, but said that there were many questions which they could not answer until the experiments now in progress were further advanced.

Other papers on serumtherapy and organotherapy, which stood on the program in the names of Dr. JOSEPH McFARLAND and Dr. J. C. WILSON (Philadelphia) and Dr. E. A. DESCHWEINITZ (Washington), were not read on account of the absence of the authors.

A paper by Dr. B. T. WHITMORE (New York), entitled *America's Contribution to Medical Science* was at the author's request, read by title.

New Office Bearers: Chairman, Dr. George F. Butler (Alma, Mich.); secretary, Dr. C. S. N. Hallberg.

Section on Cutaneous Medicine and Surgery.

[Concluded from page 495.]

THIRD DAY.

Rhinoscleroma.—By invitation C. W. ALLEN gave notes on 2 cases of this very rare disease. Both cases have been previously reported, and show the long and chronic nature of the disease. One case is in a widow, aged 64, a native of Hungary, and has been under observation for 11 years. The lesion first appeared 16 years ago as a small nodule between vermilion border of upper lip and nose. Diagnosis was made from clinical appearance as bacteriologic findings were negative and patient refused until recently to allow excision. Retrogressive changes are well marked in this case. Second case is also in a foreigner, 49 years of age. Growth started 19 years ago, and the course was slow until 6 years ago, when it was aggravated by injury. She has been under treatment 6 weeks; the uvula is absent, and the nasopharynx shut off with glistening bands of cicatricial tissue. Bacteriologic examination reveals numerous bacilli resembling Friedländer's pneumonia bacillus.

Dermatocycoses in their Relation to Allen's Iodid Test: JACOB SOBEL (New York City); **Squamous Erythroderma:** AUGUSTUS RAVOGLI (Cincinnati, Ohio), and **Phototherapy in Cutaneous Medicine:** WILLIAM S. GOTTHEIL (New York City), were read by title.

Lichen Hypertrophicans: D. LIEBERTHAL. The pathologic part of this paper was given on the second day. Clinical characteristics were described and differential diagnosis carefully elaborated. Notes on 2 cases were given, from which the following conclusions were drawn: (1) The absence of typical elementary lesions does not justify the exclusion of hypertrophic lesions from the class lichen planus; (2) elementary lesions will be found at one time or another during course of affection; (3) this (verruccous) manifestation of the process is due to circulatory derangements; (4) for cases in which elementary lesions are also present and especially extensive in distribution the prospect of treatment seems better than for those which present the verrucous growths only; (5) in some cases only repeated surgical interference will remove the affection and arsenic is more likely to prove serviceable at periods when elementary typical lesions are also present.

Notes on Recent Cases of Extragenital Chancres: L. D. BULKLEY gave notes on series of 21 cases of extragenital chancre as follows: lip, 9; finger, 5; anus, 2; hand, 1; hard palate, 1; tonsil, 1; nose, 1, and eyelid, 1. Sixteen of these cases were in males, and only 5 in females. That there are other sources of infection from syphilis aside from venery is a fact not well enough recognized by physicians and laity. In these cases diagnosis is often delayed or wrongly made and specific treatment not instituted.

Clinical Features of Blastomycetic Dermatitis as Observed in 3 Cases: A. W. BRAYTON. Read by title.

Miscellaneous Business: The chair, on motion, appointed Corlett, Anthony and Montgomery, of San Francisco, to act as nominating committee to nominate 2 members to the House of Delegates. Committee nominated W. L. Baum and C. W. Allen as delegates. Secretary instructed to cast favorable ballot.

Section on Nervous and Mental Diseases.

[Concluded from page 496.]

THIRD DAY.

The paper of Dr. FRANK R. FRYE (St. Louis, Mo.) was read by title.

Dr. J. G. BILLER (Cherokee, Iowa) then read a paper entitled **Treatment of Neurasthenia**. There is no ready made, hand-me-down treatment for neurasthenia; the principal causes of the disorder are toxemia, overwork, emotionalism, etc. The first consideration in its treatment is, to my mind, a very careful examination of the patient to discover all possible organic disorders of the body, and be sure that nothing in this line is overlooked. Next, learn accurately the habits of life of the patient; the complete confidence of the patient in his doctor is absolutely necessary to success. I do not take cases when there is any doubt in my mind as to my patient's confidence in me. Positive reassurance that the condition is a curable one, and this repeatedly is of great importance, because the physician must be his support. Feeding with good, substantial, nutritious food is of great importance, and the starvation by rule or exclusively liquid diets should not be used for any considerable length of time. The concentrated foods and condensed liquid preparations, which are supposed to contain large quantities of nutrition in teaspoonful doses, are not to be depended upon. Delicate stomachs in these conditions are not so frequent as is generally supposed. Fresh air, rest and sleep, are all important.

Discussion.—Dr. PATRICK (Chicago) very highly commended the writer's methods.

Dr. McBRIDE emphasized the importance of studying the mentality of the patient; also of prescribing exercise definitely as to when, where, and how much. It should not be on the sidewalk or pavements, or floors, but upon the ground. Hills should be carefully avoided.

Dr. PUNTON (Missouri) raised the point that many cases of this class occur among the poor people who have not the means to carry out the course of treatment suggested by this discussion, and suggests that the State should provide for the means of care of this class of people.

Dr. ROGGS (St. Paul) commended the common sense methods of the essayist; he believes that faith in the doctor is of great importance, but that it may be inspired by results even when it did not exist at first. Travel is like a two-edged sword and should be prescribed with care in this class of cases.

Dr. MOYER (Chicago) spoke of the different results of treatment in different parts of the country and suggested that climatology be made a part of this study; give these patients always a large dose of the doctor.

Dr. PEARCE (Philadelphia) urged the use of horseback exercise; it is not too severe, and the patient cannot think continuously of himself while putting it in practice.

Dr. TOMLINSON (Minnesota) quoted in this connection the sentiment of Sidney Smith: "that the Lord made food, while the devil made the cook," hence good food is frequently spoiled in preparation. He also emphasized the importance of elimination of all impurities from the system so far as possible.

Dr. BILLER in closing emphasized the importance of trifling things in the care of these cases; he also urged the use of good beefsteak and plenty of it, instead of "straw biscuits," or other fanciful articles of food.

Dr. MOYER (Chicago) read a paper entitled **The Psychoses of Chorea**. He pointed out the necessity of distinguishing between cases due to infection and those which are dependent upon gross structural changes in the nervous system. He gave a detailed report of a case occurring in a girl 15 years of age, without neurotic heredity. He is inclined to the view of Regis, rather than that of Spitzka, as to the nature of this class of cases. The older the child the more liability there is of mental disturbance. Those cases which occur late in life have very unfavorable prognosis; the literature upon this subject is very meager and very unsatisfactory. This paper was discussed by Drs. RIGGS, CARPENTER, MAYER, PUNTON, and MOYER in closing.

Dr. AUGUSTUS A. ESINER (Philadelphia) then presented a paper entitled **Three Cases of Paralysis of the Serratus Magnus and the Trapezius Alar Scapula**. He gave a detailed and comprehensive review of the anatomy of the shoulder in this connection, and pointed out the importance of the scapula as a point of attachment for the muscles that move the shoulder and the upper extremity; also the complexity and association in the movements of these muscles. Their innervation is principally from the brachial plexus. He reviewed in detail the causes and symptoms of paralysis of the serratus magnus and the trapezius muscles, and reported in detail 3 cases of this class, showing pictures illustrative of the condition.

Dr. PEARCE pointed out the necessity for physicians to be cautious in the use of the Trendelenberg position, because of its proneness to produce pressure neuritis from the hanging position of the arms.

A paper entitled **Mirror Writing and Inverted Vision** Dr. ALBERT E. HALE and Dr. SYDNEY KUII (Chicago) was presented by the latter gentleman; they gave a detailed review of the theories advanced by various writers upon the production of this phenomenon, and showed specimens produced by 2 children within their experience.

Dr. SWEENEY (St. Paul) discussed the paper at considerable length, and referred to a case published by him in the *St. Paul Medical Journal* within the past year.

Drs. DEWEY and GASSER also took part in the discussion. Dr. JOHN PUNTON (Kansas City, Mo.), then presented a paper entitled **Fear as an Element of Nervous Diseases and Its Treatment**. He stated that fear as a cause of disease has

been greatly underestimated. Morbid fear is a very important element. The imperative idea is very different from the fixed ideas of the insane. The power of resistance varies greatly in individuals, and in some these ideas may lead to impulsive acts. The treatment consists in isolation, upbuilding, and the teaching of self-confidence and self-reliance.

Dr. W. A. JONES (Minneapolis) read a paper entitled **Ten Cases of Multiple Neuritis**. He gave a detailed account of 10 cases occurring within his own experience within a few months. The 2 last cases of the series were of the apoplectic type, 1 proving fatal within a few hours, and the other at the end of 3 days. No postmortem examination was permitted, but he believed these 2 to be of the fulminating type of multiple neuritis. Many of the cases suggest, in the manner of onset, the Landry type. In view of the occurrence of so many cases at a time when influenza, pneumonia and other infectious conditions were very prevalent, he draws the conclusion that they were the direct result of these infections.

Dr. PATRICK spoke of the close relationship between multiple neuritis, nuclear disease, Landry's type and other diseases difficult of definition. The neurone has added practically nothing to our knowledge of mental diseases, yet it may be well in our discussion of these diseases to talk the neurone theory, because it aids us in our conception of them. Multiple neuritis is really a misnomer, because it is due to an infection. The theory advanced by Dr. JONES that his cases were due to the infection from influenza, etc., is tenable.

Dr. MOYER emphasized the difficulty of distinguishing between the peripheral lesion and the nuclear lesion.

Dr. EDWARD MAYER (Pittsburg, Pa.) read a paper entitled **A Case of Localized Amnesia, with Remarks Thereon**. He describes the case of a man who was in a railroad wreck 17 years ago, and in February of the present year he became unconscious, and when he awoke, after 24 hours, found that the period dating from the accident (12 years) had been obliterated. Memory of events and things within this period was entirely gone; he did not remember his age; he did not recognize his wife and child, but declared that he was 24 years of age (the age at which the accident occurred) and that he was unmarried. Upon inquiry, it was found that he had been subject to periods of depression during those 12 years, and that on 2 or 3 occasions he had suddenly disappeared for a short time, once going to his mother's home, whence he wrote to his wife, she having had no previous knowledge that his mother was living. It was only by constant reiteration of the truth, the presentation of pictures of himself taken at various periods, and the manner of his family toward him, that his reason was appealed to and he became convinced of the truth of their statements, although the period of 12 years remained a blank in his mind. Some weeks later he suddenly disappeared, and has not since been heard from.

This paper was discussed and similar cases related by Drs. CROTHERS, MCBRIDE, RIGGS, MOYER, JONES and PEARCE.

Dr. MAYER in closing thought that some of the cases related were of the type of precursive epilepsy or somnambulism.

Dr. T. B. CROTHERS (Hartford, Conn.) then read a paper entitled **Dementia Following Inebriety**. Traumatism and wounds are often followed by alcoholism. Extreme grief or joy may also be the cause of the individual resorting to the use of drugs or alcoholics. Physical drain upon the system, as hemorrhage, acute fevers and sunstrokes often act in the same manner. Spirit drinking is not only an active cause, but is really an early stage of dementia. Even the use of strong tea and coffee in early life may act as a predisposing cause of a subsequent use of stronger stimulant and the resulting development of dementia. Dementia more frequently occurs among steady drinkers than those who drink periodically. The early treatment of these cases is often successful, but later not much can be hoped for; they should be taken from the hands of quacks and receive regular treatment by both the family physician and the specialist.

Dr. DREW (Massachusetts) heartily supported the teaching of the writer, and believes that no man can be a steady user of alcoholics without becoming changed; his inhibitory powers are lessened and he may be properly called a dement. In 77 cases of insane criminals admitted to the hospitals of Massachusetts in 1 year, 65 had intemperate fathers and in 13 cases both father and mother were intemperate.

Dr. CROTHERS in closing said that in the years to come this subject will be discussed with keener interest for the reason that every year we are coming closer and closer to face the great fact of these conditions.

The paper of Dr. JAMES G. KIERNAN (Chicago) on the **Problem of Heredity** was read by title.

Dr. ARTHUR C. McDUGAN (Kalamazoo, Mich.) then read his paper entitled **The Importance of Heredity as a Cause of Insanity**: He said insanity is not a disease, but a defect. Nearly every person that is admitted to an asylum for the insane presents the stigmas of degeneration. This may also be seen in most cases among the relatives of the patient who bring him to the hospital. In a large majority of cases the relative will stoutly deny the existence of the hereditary tendency in their family. Heredity is the cause of insanity in 90% if not 95% of all cases. Treatment, therefore, in order to be effectual must be begun before the birth of the individual. Vigorous promulgation of the truth should therefore be provided for in all communities. Careful observation upon several hundred cases

admitted to the hospital for the insane at Kalamazoo, Mich., during the past 6 years has established this belief. These premises being admitted legislative control of the production of offspring among this class of people should be everywhere advocated and urged.

Discussion.—Dr. MAYER (Pittsburg) entered a vigorous protest against the high percentage of cases in which the writer claims heredity as a cause. He believes it to be extreme pessimism and that the view leads us backward rather than forward in this matter.

Dr. DEWEY (Wisconsin) spoke warmly in favor of the educational methods recommended by the writer to overcome hereditary tendency.

Dr. CROTHERS favored the essayist's estimate of the hereditary tendency. From 60% to 70% of all cases of insanity are traceable to the faults of the parents.

Dr. DREW (Massachusetts) recommends the hospital methods applied to all parts of the body of the patients in our State institutions, and beyond that the education of the masses against the reproduction of this class of individuals.

Dr. PEARCE (Philadelphia) advocated that the physiologic chemist should take the place of the present pathologist in our State institutions.

Dr. TOMLINSON (Minnesota) believes that the discrepancy between the institution man and the neurologist has been the tendency to mistake morphology for pathology. The conception of heredity has been befogged by the view of what it is. If we take the view that instead of a transmission of confirmation it is simply a limited potentiality of the individual, it gives us a clearer conception.

In closing Dr. McDUGAN suggested that he would place the percentage higher than stated in his paper rather than lower; also that this view need not cause us to go backward, but rather to face the fact as it is and meeting the truth go forward to better things.

Dr. LEO M. CRAFTS (Minneapolis) then read a paper entitled **Persistent Brachial Neuralgia from Hypodermic Injections: Incipient Lateral Sclerosis with Recovery: Severe Burn and Paralysis of the Arm from an Electric Current of High Voltage**.

A case of **Amyotrophic Lateral Sclerosis** in a young man accompanied by wasting in the muscles of the left hand especially the thenar eminence and the interossei muscles, weakened grasp and tremor. There were no fibrillary twitchings and no reaction of degeneration. Treated for 6 months with galvanic current applied 3 times a week, 30 to 50 minutes to a sitting; recovery has taken place which seems complete and permanent, 1 year having elapsed since the treatment was discontinued. A case of brachial neuralgia as the result of the use of the hypodermic syringe at the wrist was very persistent and painful. This also yielded to the galvanic current applied with large electrodes and for long sitting; he infers that in order to get appreciable results from the use of electricity these 2 points are essential; viz.: the large electrode, and a long continued application from 30 to 60 minutes. A young man in operating a street car took hold of a part which was charged with the motor current and for a space of 1 minute was subject to a current of 500 volts passing through his body by way of the left hand. The result was severe burning of the flesh and a complete paralysis of all parts supplied by the brachial plexus. At the present writing, 1½ years after the injury, the arm remains useless. The writers not being present, the papers of JOHN E. PURDON (Turlock, Cal.), GEO. F. BUTLER (Aina, Mich.), HERMAN GASSER (Platteville, Wis.), SAMUEL AYERS (Pittsburg, Pa.), HALDOR SNEVE (St. Paul, Minn.), and DOUGLAS GRAHAM (Boston, Mass.), were read by title.

Section on Ophthalmology.

[Concluded from page 498]

THIRD DAY.

The Nominating Committee presented the names of Drs. Lippincott, Risley, Jackson, Würdemann, De Schweinitz, and Wood, 2 of whom were to be chosen by ballot as delegates to the general convention for 1 year. Drs. Lippincott and Würdemann were unanimously chosen.

Economic Limitations of the Visual Acuity in the Various Trades and Professions: Dr. IL. V. WÜRDEMANN (Milwaukee) said that to properly study this question, a division into 2 great classes should be made; namely, skilled labor and unskilled labor. It is evident that a man who does the work of a farmer or laborer can get along with a much reduced acuity of vision, 50% or even less being sufficient to allow him to properly perform his duties. But a professional man, a skilled mechanic, or a clerk, needs considerably more visual acuity, 75% enabling him to satisfactorily and comfortably do his work. This grade of visual acuity need not obtain in each eye individually, but be the acuity of both combined. An employe of the marine service or railway train service is required by most roads to have at least 20/30 vision with both eyes.

Further Report on the Visual and Aural Qualifications of Transportation Employes: Dr. FRANK ALLPORT'S

(Chicago) paper was supplementary to the one read before the section one year ago. He had received replies from many railroads which had heretofore failed to report. The original report with the appendix was passed around for inspection.

The report of the committee appointed 3 years ago, to look up the question of the visual and aural qualifications of transportation employes, of which Dr. Allport was chairman, was received and resolution which they had drawn up adopted. The incoming chairman was authorized to present the resolutions to the general meeting.

Discussion.—Dr. TAYLOR (Wilkesbarre, Pa.) thought it a great injustice to disqualify a man from train service who had 20/20 vision in one eye and poor vision in the other. Dr. C. F. CLARK reduces his own vision to that of the man examined, tests himself and then uses his own judgment in passing him. Dr. YOUNG (Burlington, Ill.) had gone out on an engine in all kinds of climatic conditions with the purpose of familiarizing himself with conditions as they are actually met with. He urged that 20/20 in one eye and 20/40 or 20/50 in the other should be sufficient and was safe. He could see no great harm in wearing correcting lenses of low degree. Dr. WILLIAMS (Boston) spoke of some roads allowing plane lenses worn in spectacles as a protection in storms and in sandy countries. Without exception the doctors discussing the subject believe in a high standard for new men but differed somewhat as to concessions to old employes.

Mule's Operation. With Cases: Dr. FRANK TODD (Minneapolis, Minn.) gave a history of the origin of the operation. The operation is indicated in injury to eye with loss of sight, anterior staphyloma, glaucoma, loss of cornea through suppurative conditions and panophthalmitis. The contraindications are malignant growths, sympathetic disease, extreme laceration of sclera, so glass ball cannot be easily retained and extreme ptosis bulbi. The glass ball is preferred to the gold, silver or aluminum, as it is less irritating. The prosthesis is inserted in about 2 weeks. Most failures recorded are due to the use of too large a ball, not thoroughly cleansing the cavity before inserting the ball, and failure to put in a sufficient number of sutures in the sclera. Several cases were shown to the members.

Discussion.—Dr. FRANK ALLPORT thought that the failures were due to anxiety to fit the glass ball too closely in socket. He makes it a rule to use a small ball and has plenty of slack sclera. A most important factor is the stitches, of which he puts in as many as possible. He uses a nonabsorbable suture. Before closing sac he swabs it with 95% solution of carbolic acid, neutralizes with alcohol and dries it with iodoform gauze. Dr. BLACK believes that the modified Snellen eye which has been so satisfactory will displace Mule's operation.

Report of 2 Cases of Orbital Surgery: Dr. ADELIN PORTMAN (Washington). The first was a case in which an enucleation had been done some months before, the stump allowing almost no movement of the shell (prosthesis). The conjunctiva was raised, the cut ends of the muscles found, and the ball was placed in the socket. The vertical muscles were now brought together, followed by returning the horizontal muscles, the conjunctiva last of all. Convalescence was uneventful. Ultimate result, movement equaled $\frac{1}{2}$. Case 2 was the result of a burn which caused the entire cornea to slough away and contents of the globe to escape. To complicate matters there was an old cicatricial trachoma. The lids would not close, and a most unsightly hole resulted. Grafts from the lip were removed and placed upon the denuded orbital surface, under proper antiseptic precautions, then the shell was introduced to retain grafts in the proper place. There was an uneventful recovery. The lids closed nicely, and the cosmetic result was good.

Enucleation in 2 Minutes with Demonstration: Dr. A. F. MITCHELL (Vicksburg Miss.). This operation is performed by first passing a strong suture through sclera, then incising the conjunctiva at the insertion of external rectus, the lower blade of a curved scissors was now passed under the tendon and rapid and single cut made through tendon, subconjunctival tissue, and conjunctiva. This procedure is repeated on the superior rectus, then inferior rectus, now grasp the suture and make tension on eyeball and cut nerve, then internal rectus and overlying tissue. No demonstration was made, as the patient did not materialize.

The Newer Pathology of the Retina, with Special Reference to the Changes Produced in the Ganglion Cells by Certain Toxic Agents: Dr. H. FRIEDENWALD (Baltimore, Md.). New stains reveal different intimate nerve elements which act differently to different stains. In regard to quinin, the pathologic changes in the retina and nerve were minutely detailed, the conclusion being that quinin intoxication causes blindness by acting on the retina and not on the nerve. Amaurosis produced by methyl alcohol depends upon the lesion of the retina and secondary changes in the nerve. The same is true of ethyl alcohol and Jamaica ginger. There is a general ganglion cell degeneration.

A Case of Blindness due to Drinking Bay Rum Compared with Reported Cases due to Methyl Alcohol and Jamaica Ginger: Dr. H. MOULTON (Fort Smith, Ark.). This paper first compared the similarity of the symptoms and the ophthalmoscopic appearances produced by methyl alcohol and Jamaica ginger. Unless coma was produced the first day no symptoms occurred the first day, but on the second or third

day, dizziness, retching and gastrointestinal symptoms appeared, with loss of vision in from 12 to 24 hours. Ophthalmoscopic examination shows edema of retina and nerves. The case described was that of a man who drank bay rum and next day had an uneasy sensation about the eyes, vomited and felt very sick generally for 2 days. Vision was much poorer at dusk, and finally total blindness ensued. A slight lateral nystagmus also developed. Atrophy became complete.

Discussion.—Dr. RAY (Louisville, Ky.) said clinically the effect of wood alcohol is first upon the nerve. In a case under his observation blindness occurred the second day. There was edema of optic nerve and retina. Blindness was complete for 3 or 4 weeks, when vision cleared up from the periphery and attained vision of 20/30. Later blindness became total and optic atrophy complete. All pathologic changes were in the nerve and not in the retina. Dr. Woods (Baltimore) described cases of blindness from Jamaica ginger, which on inquiry was found to contain 95% of methyl alcohol. Dr. Wood (Chicago) thought these cases were idiosyncrasies. Frequently several parties had partaken of the liquor and only 1 was affected.

Complete Recovery from Double Neuroretinitis, Clinically Resembling Albuminuric Retinitis, in a Case of Prolonged Hematuria with Symptoms of Bright's Disease: Dr. C. A. VEASEY (Philadelphia, Pa.) The patient 8 months previous to examination began to pass bloody urine, lost flesh, had vertigo, tinnitus aurium, pain in back and constant headache. Two weeks previous to the examination of the eyes, her vision began to blur. Ophthalmoscopic examination reveals a clear medium, full vessels, arteries and disc covered with an exude, hemorrhage in retina and, what appeared to be a stellate albuminuric deposit. Medical treatment was instituted and recovery was very slow. In 9 months there was not a vestige of disease to be found in the fundus and vision was 6.6 in each eye. The probable cause was an acute inflammation of the kidneys.

The Value of Excision of the Superior Cervical Ganglion of the Sympathetic in Certain Eye Diseases: Dr. GEO. SUKER (Toledo, O.) The operation was done for the various kinds of glaucoma and Basedow's disease. In every case that had been operated upon there had been some benefit. The immediate effect is reduction of tension, removes pain and sometimes improves vision. The operation was described and according to writer, is not difficult. Several cases were enumerated with the results which was uniformly good.

Discussion.—Dr. BLACK (Denver, Col.,) thought it a good operation and has its field of usefulness, in fact, should he have glaucoma he would prefer to have this operation before trying an iridectomy.

FOURTH DAY.

Herpes Zoster Ophthalmicus with Brief Report of 5 Cases: Dr. W. C. BANE (Denver, Col.) said that herpes zoster ophthalmicus being a neurotic affection is limited to the course of the nerves, the seat of the disease lying in the Gasserian ganglion. The symptoms are an intense pain and sensation of burning over the course of the nerve, followed by an eruption over the course of the nerve (forehead, eyelids and nose) which leaves a scar upon healing. The cornea may have varying numbers of small ulcers. The disease is frequently confounded with erysipelas but if this is borne in mind a correct diagnosis can usually be made. The most distinctive features of difference being that erysipelas usually involves both sides of the face and the rash is diffuse while in herpes zoster ophthalmicus it is limited to one side of the face and the eruption is over the course of the nerves. Three of the 5 cases reported in this paper were originally diagnosed as erysipelas, and 1 case was treated through its entire course for that affection. Visual acuity is usually diminished.

Discussion.—Dr. JACKSON reported a case in which the pain existed for 2 weeks before the eruption appeared. He had found no remedies which would cut short the disease. Dr. STANKEY thought that a uric acid diathesis caused an irritation of the Gasserian ganglion and nerves. Dr. RISLEY reported that in his 4 cases the rheumatic and gouty diathesis had been marked.

The Corneal Lesions of Acquired Syphilis: Dr. WM. WILDER (Chicago, Ill.). The manifestation of acquired syphilis in the cornea as compared with congenital syphilis is infrequent. The lesion is a somewhat dense, deep-seated infiltration with little or no vascularity, and no tendency to ulcerate. Several cases were reported in which the history was perfectly traced. The usual constitutional treatment was instituted, and atropia, hot applications and protective glasses as local treatment. Occasionally treatment showed no visible improvement for 2 or 3 weeks, then a rapid clearing up of the opacity from the periphery would take place. It was pointed out that the lesion affected always one eye only while in inherited syphilis it involves both eyes.

Discussion.—Dr. RISLEY called attention to the greater frequency of this affection in negroes and the difficulty in excluding inherited specific disease in this race.

Lacrimal Stenosis in Infants and its Treatment: Dr. DUNBAR ROY (Atlanta, Ga.) said that in looking over the literature, he found that no specific mention was made as to the treatment of infants, so conclusion was natural that the same treatment was necessary which applied to adults, a conclusion to which the writer could not reconcile himself. Stenosis is

usually due to injury, congenital malformation of some portion of the lacrimal passages, spasmodic contraction, or catarrhal inflammation. The treatment should almost without exception be nonoperative. One case of epiphora was reported, which immediately disappeared after circumcision.

Metamorphosis Various, with a Report of 3 Cases: WILLIAM H. DUDLEY (Easton, Pa.) said that in the examination of these cases absolutely no pathologic conditions existed. The visual acuity was normal; media clear; retina, macula and nerve normal in every respect. The ophthalmometer showed corneal curvature regular, skiascopy negative. A chart was exhibited which showed the variations of shape of several given objects or drawings. The change took place sometimes as rapidly as 3 in a second, but with dim or colored light the change was only once a second, the rapidity of change being due to light stimulus. These cases were under observation for from 3 to 5 years, with no change. The cause of this condition is usually a macular disease.

Injuries of the Choroid: E. O. SISSON (Keokuk, Iowa) described the case of a boy who was struck on the eye with a stone thrown by a motorman. The anterior chamber was filled with blood, so no ophthalmoscopic examination was made. Treatment for absorption was instituted, but patient was lost sight of until 1 year later, when he returned, saying that he had been blind in the eye since the injury. Ophthalmoscopic examination revealed a large choroidal rupture on the nasal side of the papilla. The medico-legal question brought up was whether the blindness was caused by the rupture of the choroid or a spinal injury, which was received when a child. As sight had been good before the ocular injury, the spinal lesion was easily eliminated as the cause of blindness.

Section on Laryngology and Otolgy.

[Concluded from page 499.]

SECOND DAY.

Asthma as a Result of Nasal Conditions: D. J. II. FANELL (Chicago). The amount of deviation of septum cannot always be known. Large numbers of asthmatic cases due to some irritation in nasal cavity, either by some alteration in lumen and consequent difficulty in breathing and formation of mucus on the mucous membrane from some lesion or malformation. A polyp and spur in nasal cavity showed complete relief after removal of offending bodies. A broken bone, middle turbinate enlarged, will be complete relief after removal of all asthmatic conditions.

Discussion.—Dr. JAEH (New York) stated that asthma was due to a blood condition, a pathologic lesion of the blood, producing 3 distinct types. The oxygen is not taken up by the blood, and engorgement takes place, producing a toxic leukocytosis, then a gradual enlargement of the laryngeal glands, the obstruction always appearing first in the larynx—almost a complete closure—suddenly there is a breaking down of the glands. The mucus is squeezed out and expectorated in worm-like particles. We have the anemic variety which comes on at night, which is due to lack of sunlight.

The Effect Which the So-called Catarrhal Disease of the Nose and Throat May Have Upon the General Health: Dr. C. M. COBB (Massachusetts) cited several cases where nose conditions were relieved and the general health improved. He believes bacterial diseases are more readily induced in these abnormal conditions of the nasal passages.

Discussion.—Dr. CASSELLBERRY is led to believe from his experience that the nasal affections are a secondary matter and by improving the general health the nasal conditions will be relieved.

Empyema of the Frontal Sinus: E. FLETCHER INGALS (Chicago). This is a rare affection, is an acute disease, pain over frontal sinus relieved by discharge of pus through the nose. The pain lasts but a few hours. Obstruction to outlet, pain and swelling over eyebrows, frontal sinus is small, the turbinated cavity extending up. There are also bony defects, actual communication is rare, it is filled by mucus membrane. Defects are often congenital. Septic meningitis followed rupture in some cases where the wall is very thin. These cases cannot occur before 7 years, as there is no frontal sinus previous to that year. It is a very difficult matter to pass a probe into the frontal sinus, very often it is passed into the maxillary. Sometimes discharges take place in antrum of Highmore, where hyperplasia extends up, lateral focus will interfere with discharge. These abscesses are often caused by acute infectious diseases, chronic cases by polyps and other obstructions, after an operation on the inferior turbinate. The pus will be discharged drop by drop. To define the area the transillumination method is used, but cannot be relied on, where there is an unusually dense wall, or absence of sinus, and in cases where there is no pus, and yet no light is seen. It is not diagnostic.

Anomalies of the Frontal Sinus and their Bearing on Chronic Sinusitis: RAYMOND W. PAYNE (California) cited several cases in which there was an opening in the septum, in which there was no frontal sinus on 1 side, 1 case no septum, another in which only 1 side was sinus found.

Carcinoma of the Nasopharynx: CHEVALIER JACKSON (Pittsburg) believes in the early and complete extirpation of the offending growth. The age does not indicate any particular tendency, although 57% of cases were in men. Symptoms first show by pain, fetor and hemorrhage. These tumors have a tendency to extend downward.

Sarcoma of Nasal Passage with Report of Case: DUNBAR ROY (Georgia) said there is a greater frequency around the turbinals, not as malignant as in other parts of the body. Cause, disturbance of the embryonic tissue. Has been carried by instruments. Symptom, closure of nasal cavity, gradual difficulty in breathing, pain on deglutition, death within 7 months. Treatment, ligation of both external carotids.

Discussion.—Dr. FREER does not believe malignant growths can arise from benign growths. It is characteristic of benign growths to retain their character; this change is purely a hypothesis.

Dr. MACKENZIE. The textbooks are faulty, will have to be rewritten; objects to removal of small pieces for diagnostic purposes. Danger of infection, hemorrhage, and a stimulation of growth. It should be resorted to only as a last measure. The diagnosis should be made without resorting to this dangerous method. Often means beginning of the end.

THIRD DAY.

Dr. E. B. DENCH (New York) read a paper on **The Diagnosis and Treatment of Mastoiditis**, calling attention to swelling over the mastoid and tenderness and pain over and in the mastoid region, increase of temperature, a full pulse, drowsiness and frontal headache. Paracentesis of the membrana tympani while giving relief in a number of cases is not always to be relied on; in fact, the author desires to be emphatic in espousing the radical method. The first important point is through antiseptic preparations, and should be made to open into the cranial cavity and arrangements made to control hemorrhage. The author considers an opening into the mastoid cells as justifiable; even though the symptoms are not marked, an exploratory operation can be done with no greater risk than an exploratory incision of the abdomen.

Discussion.—Dr. SICERMAN (Cleveland) does not believe the radical operation to be advisable in the larger number of cases. Many a death has been caused by a hasty operation. There is an intimate connection of the circulation of the mastoid and the meningeal membranes that should not be lost sight of. The paracentesis of the membrana tympani will give entire relief, and is devoid of danger. The use of the 1 to 5,000 solution of bichlorid is dangerous. The mastoid swollen and tender does not indicate operation, leeches and hot application. There is danger of fatal hemorrhage and death from infection in opening the mastoid cells. I am opposed to it, except in cerebral involvement; you open up an avenue of infection and it takes a long time to heal.

Dr. COBR (Lynn, Mass.) said that in a large number of cases pus will have to be removed by artificial means. Where drainage is good, there is no necessity of opening mastoid cells.

Dr. COTT: In exploratory operation it is as favorable as abdominal exploratory operation. There is a very small percentage of deaths. The operation should be as radical as the disease is severe. Every cell involved should be opened; if not a small pocket is left, and a second operation will be necessary. An incision should be done early.

Dr. FRENCH (Illinois): I take the point that I will decide the operation, if I consider it necessary to operate, and will not consult with patients. A patient with severe pain or without pain or a small amount of pus escaping from meatus are the proper cases that require operation. Most are too long delayed, and meningitis results.

Dr. BAKER (Bay City) has observed more procrastination in these matters than in any surgical operation in other parts of the body. If you do not operate you do not do your duty. We should educate the profession as the surgeon has instructed the people in appendicitis. The physician knows less about this than any special subject, and there is none in which there is greater danger to life.

Dr. DENCH does not believe pus in the mastoid cells will be absorbed. In every case we do have serum and that is absorbed. It is absolutely important to carry your spoon down to and scrape the hard bone. You must evacuate every cell containing pus by sharp spoon.

Dr. HIRAM WOODS, JR. (Baltimore), read a paper on **Mastoiditis after Subsidence and without Recurrence of Tympanic Disease**. He cited a case of inflammation of the tympanum in which the local inflammatory symptoms had disappeared. Twelve days later mastoiditis developed and pus was found in the mastoid cells. He thinks the mastoiditis was present from the first and tympanitis, showing first, was cured. The more severe disease was dormant. He suggests exploratory operation in all cases. Cold he considers a dangerous remedy, as the symptoms are masked; it increases the trouble from hemorrhage, and a sufficient degree of cold cannot be secured to kill all germ formation.

Discussion.—Dr. DENCH (New York) believes in the use of cold, and has seen cases aborted in this manner.

Dr. HOLLANDER called attention to the method of sewing up the wound after a radical operation for mastoiditis and allowing the cavity to fill up with blood.

Report of a Case of Unusual and Interesting Tertiary Manifestations, by G. HUDSON MAKUEN (Philadelphia). A school boy contracted syphilis at a boarding school. He was treated by the local physician. On returning home he said nothing about the trouble and was treated for malaria. After being under the care of several physicians, none of whom secured any history of syphilis, he was brought to Dr. Makuen for a chronic throat difficulty, a small ulcerated point was found on the soft palate and a sear on the frenum of the penis. The boy finally acknowledged that he had contracted syphilis at school. There were no other manifestations of the disease.

Section on Hygiene and Sanitary Science.

[Concluded from page 500.]

THIRD DAY.

Tuberculosis in the Middle States and Its Curability: Dr. JOHN A. ROBISON (Chicago) said the mass of information concerning the climatology of these States and the factors which might cause or cure tuberculosis is very meager. Therefore, he arbitrarily selected the following States for consideration: Michigan, Ohio, Indiana, Illinois, and other western, northwestern, and a few southern and middle States. The altitude of the Mississippi Valley varies from 400 feet to mountain tops of 3,000 feet. Michigan has a varying climate, but the climate is healthful, and the deathrate is low in the northern portion of the State. The annual mean temperature of Ohio is from 50° to 54°, and the interior of the State is 1,200 feet above the sea level. In Indiana the State has few hills; the highest elevation is 540 feet on the Ohio river, and the deathrate is usually low. The climate of Illinois is healthful, although in the lower portion, along the river bottoms, malaria prevails. The highest altitude is 1,150 feet above the Gulf of Mexico. Illinois stands fifth in the list of mortality from tuberculosis, which must be due to the fact that Chicago furnishes so large a number of cases as to increase the State's deathrate. Kentucky affords a climate which is generally delightful, the mean average being 57° F. The State has a splendid record for healthfulness. Some of its mountains are 3,000 feet in altitude, i. e., of the summits of the Cumberland mountains. Wisconsin; the climate in winter is bracing in the northern portion of the State, and as a whole the climate is healthy and invigorating. There are elevations from 600 to 1,500 feet above the sea. Minnesota's salubrity of climate is well known—its purity of air and dryness of the winters. Its lakes are numerous, and the surface of the State is an undulating plane, with an average elevation of 1,000 feet above the sea. It stands low in the group of States having a large number of deaths from this disease. Iowa is the healthiest State in the Union. The highest point of elevation in the State is 1,650 feet. Missouri has a most rigorous climate. The winters are extremely severe, and the summers hot, but the State is healthful. Elevations range from 500 to 1,000 feet in height. North Dakota has a dry and salubrious climate. The winters are cold and there are heavy snow-falls, while the summers are hot and dry, and tuberculosis is almost unknown in the State. The altitude varies from 670 feet to 1,900 feet. South Dakota has a milder climate, and the climate is healthy. Some of the peaks of the Black Hills reach 7,000 feet above the sea, while the altitude at Huron is 753 feet, Yankton 1,222, and Deadwood, 4,600 feet. Nebraska has an altitude as high as 2,841 feet. Kansas has pure atmosphere, and affords a chance for continuous outdoor life; an elevation of 750 feet up to 3,800 feet on the western border. At Wichita it is 1,363 feet, Atchison 1540, Garden City 3,000 feet. Crowded cities favor the development and spread of tuberculosis. The greatest mortality from tuberculosis in the States is: Ohio stands third, Illinois fifth, Tennessee sixth, Missouri seventh, Kentucky eighth, Indiana ninth, Michigan thirteenth, Wisconsin eighteenth, Texas nineteenth, Iowa twentieth, Minnesota twenty-first, and Mississippi twenty-fourth. The average deathrate from tuberculosis during the year 1890 throughout the United States was 268.81 per 100,000.

The establishing of sanatoriums was dwelt upon, and the fact that the legislators of the United State were interested, shows that the sentiment is growing in favor of these State institutions.

The second paper was on **Tuberculosis Sanatoriums:** Dr. C. P. AMBLER (Asheville, N. C.). Among the poor class of people, because they cannot see the disease at first, they take it as a visitation of Divine Providence. The State pays more attention to tuberculosis in cattle than to the care of her poor class of citizens who have tuberculosis.

Tuberculosis of Animals in Some of its Relations to Human Tuberculosis: D. E. SALMON, D.V.M. (Washington, D. C.) referred to the great medical problem of the twentieth century, frequency of tuberculosis in animals, and spoke of the increase of the disease on account of use of meat and milk from tuberculous animals. He pointed out the infectiousness of meat from animals with generalized tuberculosis, and the infectiousness of milk, and discussed animal and human tuberculosis and the communication of disease from animals to man. He laid special stress on the importance of sanitary measures.

The paper dwelt largely upon the statistics of tuberculous lesions which occur in animals, of swine, cattle, rabbits, guinea-pigs, sheep, goats, etc., throughout the United States as well as in foreign countries, as shown at experimental stations of various agricultural colleges. Generalized tuberculosis is not rare in the cow, and a larger percentage of tuberculous cows give milk containing tubercular bacilli than is usually admitted; hence a larger proportion of milk is infected than we have heretofore been led to suppose. He showed that while tuberculosis in human beings was decreasing, yet tuberculosis in the bovine was increasing, and yet this is a milk drinking age. Therefore it seems that tuberculosis in man is more frequently contracted by inhaling the air, than by drinking milk. In *Tuberculosis mesenterica*, occurring in children, however, it appeared that milk ingestion played an important role. He believed that animal tuberculosis can be transmitted to man.

The Experience of Syracuse, N. Y., with the Compulsory Tuberculin Test of all Dairies Furnishing Milk to the City: B. S. MOORE (Syracuse, N. Y.) said municipal abattoirs were established first in France in 1810. He favored the tuberculin test to ascertain the existence of the disease in cattle. In certain dairies tested it was found that about 5.5% of the herds contained bovine tuberculosis, while in other dairies the test proved that as low as $\frac{1}{2}$ of 1% only were found tubercular. The laity look to us to suppress the disease pulmonary tuberculosis.

The Climatology of Arizona With Reference to the Treatment of Pulmonary Tuberculosis: R. W. CRAIG (Phoenix, Arizona) referred to the altitude of the highest place, Flagstaff, 7,000 feet, to that of Yuma, which practically is on a sea level, and eulogized the State as a land of sunshine for the open-air or outdoor treatment of the disease, and that spontaneous cures do occur, due to this outdoor existence. Specific treatment, as creasote, ichthyol, guaiacol, etc., in his belief, has hurried more to a fatal termination than it has resulted in curing them. He gave the following summary as regards treatment: Pure and abundant air, day and night; pure food and plenty of it; absolute avoidance of fatigue.

Tuberculosis of State Institutions: H. M. BRACKEN (Minneapolis, Minn.) dwelt upon tuberculosis in hospitals for the insane, in the feeble-minded institutions, in prisons, and in other State institutions. In prisons, the disease, he thought, was a simple matter to be placed under control. In the Minnesota State prison, at Stillwater, there is not a tuberculous patient confined in a cell at the present time. The importance of isolation was recommended, especially in the feeble-minded children institutions.

Discussion.—HENRY D. HOLTON (Brattleboro, Vt.) said the trend of opinion is the outdoor treatment and diet of the individual. He inquired of Dr. Salmon what was the percentage of infection due to eating meat. Dr. SALMON said that this question was yet to be ascertained, both from eating meat and drinking milk. More danger from the later, as it is generally admitted. Dr. HOLTON spoke of the State Cattle Commission in Vermont, and when cattle are slaughtered owners are paid by the State, by their having been found to have the disease ascertained by the tuberculin test.

M. H. REYNOLDS (St. Anthony's Park, Minn.) said many cases in cattle are mild and latent, as where they look sleek and fat and they are kept up under artificial conditions, the disease is not easily discovered. He thinks there is an unusual cry in exaggerating that the human does contract the disease from cattle, and yet we must not belittle the idea. Sweeping measures are hopelessly impracticable; to slaughter cattle that are tuberculous or found so after they were tested. Dairymen replace them with other cows which may also be diseased, although unsuspected, as were those who were found to be so by the tuberculin test.

NORMAN BRIDGE (Los Angeles, Cal.) commended all the papers. We should encourage dairymen to have their dairies free from tuberculosis, but the dairymen must be reimbursed in some way, either by the increase in price of milk, or reimbursement by the State when their cows are slaughtered. Health Departments of cities should inspect dairies as to their hygienic conditions and to see that the milk supply is not diluted and that proper amount of cream is in the milk. An increase of sanatoriums by the State is an important step and agitation along this direction should be done to take care of the indigent classes, as this is a reform, and even though few at first can be cared for it is some benefit accomplished by the State in this direction. Dr. BRACKEN thought sanatorium was preferable to sanitarium as a general term since the latter term is employed by quacks. He strongly favored the tuberculin test, but this will not furnish us with a nontubercular milk supply, as we cannot get around to test the herds at frequent intervals of every few months. Dr. B. S. MOORE (Syracuse, N. Y.) said we have jurisdiction beyond the city confines, tuberculin is not now in the experimental state and he hoped that the use of it will become universal instead of exceptional as seems to be now done. Dr. SALMON said that to exclude cattle from other countries we must get the influence and support of the medical profession. The last paper was read by Dr. C. L. MINOR, (Asheville, N. C.) on **The Relation of Sputum to the Spread of Tuberculosis.**

The section elected HENRY D. HOLTON and ERNEST WENDE as delegates to the House of Delegates of the Association for next year.

ORIGINAL ARTICLES

THE TREATMENT OF ABDOMINAL AORTIC ANEURYSM BY A PRELIMINARY EXPLORATORY CELIOTOMY AND PERITONEAL EXCLUSION OF THE SAC, FOLLOWED AT A LATER SITTING BY WIRING AND ELECTROLYSIS, WITH THE REPORT OF 2 HITHERTO UNPUBLISHED CASES.¹

BY

RUDOLPH MATAS, M.D.,

of New Orleans, La.

In view of the undoubted improvements that have been made in recent years in the technic of wiring and electrolysis (Moore-Corradi method) as applied to the cure of aortic aneurysm—more especially since the writings of D. D. Stewart and his followers in this country have given a new impetus to this mode of treatment—it is a matter of great importance to determine by actual clinical experience to what extent this purely technical progress has contributed to prolong life or improve the chances of recovery in this usually hopeless class of sufferers. It is evident that a true estimate of the value of the method can only be obtained by a careful study of the reported cases, and as the number of instances in which the more recent suggestions have been applied is still relatively small, especially in the abdominal phases of this disease, and have thus far been inadequate to permit us to arrive at definite conclusions as to the actual value or even the special indications of the method, I have been led to contribute the following recent observation in which the Moore-Corradi method, modified to meet the special exigencies of abdominal aneurysm, was faithfully and yet unsuccessfully applied. In addition to this personal observation I avail myself of the opportunity—thanks to the courtesy of the operator, Dr. F. W. Parham, of this city—to add to this report another unpublished case of abdominal aneurysm, treated by wiring alone (Moore method), which presents several features of exceptional interest.

CASE I. (Personal observation).—*Spontaneous (idiopathic) aneurysm of the abdominal aorta (upper celiac region) in a young subject, treated by various methods, including laparotomy and peritoneal isolation of the sac, secondary wiring and electrolysis (Moore-Corradi method); death 54 days after exploratory laparotomy and 19 days after wiring.*—A. H., aged 23, a native of New Orleans, nearly 6 feet in height and thin; father and mother (both of German origin) living and in robust health; father of distinctly gouty diathesis; mother also rheumatic; 2 brothers and 1 sister, all in excellent health. The patient is a telegraph operator and clerk in a broker's office; unmarried. His history is remarkably good from every point of view—very quiet, frugal, temperate and industrious; he never indulged in alcoholic drinks or tobacco and had an exemplary reputation. His previous history is absolutely negative as to syphilis or other infectious diseases that might account for his present trouble. There is no history of trauma or of indirect violence that would furnish a clue to the causation of the present trouble except, possibly, that he may have "strained" himself while "punching a bag" in a gymnasium, though he himself never noticed any evil effects from the very moderate exercise that he took in this way.

Until February, 1900, he felt perfectly well. After this date he began to suffer periodically with vague pains in the epigastrium, which radiated to the left hypochondrium and back. He could not account for this pain, as he did not suffer from indigestion and his appetite was not impaired until later, when the pains increased in frequency and severity and sedatives were required to allay them. About 3 weeks before my first examination (about May 28, 1900), he first noticed a pulsation in the epigastrium, which became progressively more perceptible and vigorous every day. Dr. Moore, who was called to attend him about this time, made the diagnosis of aortic abdominal aneurysm, and prescribed sedatives to relieve the pain, which now kept the patient constantly in bed and entirely incapacitated

him for his business. When I saw him, in the last week of May, 1900, I found him in bed, looking very pale and emaciated, his whole expression indicating great distress and physical suffering. He was lying on his left side in his favorite attitude, curled on himself, with his limbs flexed and with his hands clasping the sides of his chest and epigastric region. As he turned on his back to speak to me he complained of the pain caused by the movement, and I noticed a prominent bulging mass pulsating vigorously in the epigastric region, where it was limited to the left half and extended under the left costal arch. On deep palpation the pulsating mass could be felt springing apparently from the depths of the abdomen near the vertebral column, its lower boundary limited by a line drawn across the tenth costal cartilages and sloping gradually upward so as to fill the entire epigastrium somewhat in a conical shape, the apex of the cone projecting to the left of the median line. A distinct thrill could be felt superficially, and on auscultation a loud, harsh systolic murmur could be heard with every beat of the pulse. The diagnosis of abdominal aneurysm probably involving the celiac axis and extending in the upper or subdiaphragmatic portion of the abdominal aorta was then established. Apart from the aneurysm, a careful examination of all the organs failed to reveal any abnormality. The heart and arteries were normal, the urine normal, and, in fact, the patient had no disease except in his abdominal aorta. The gravity of the case as explained by the attending physician, Dr. Moore, was then reaffirmed and the relatives were informed of the scant prospect of permanent relief. It was suggested, however, that the prognosis would be more exactly determined by an exploratory operation, which would possibly permit the application of various therapeutic measures that had been found valuable and even curative in similar cases.

This suggestion, in spite of its uncertainties, was immediately accepted by the patient and his parents, who at once transferred him to the Touro Infirmary. He was admitted to the Infirmary on June 1, and on the fourth day after his admission an exploratory laparotomy was performed under chloroform. A 4 inch incision was made in the median line to the left of the most prominent part of the tumor. Upon opening the cavity the first organ that made its appearance was the pancreas, which was stretched over the highest point of the convexity of the tumor, and was in immediate contact with the abdominal wall. The splenic vein and artery, both of unusually large size, were seen stretched immediately above the pancreas, directly in the path of a trocar or needle had this been used to explore the tumor or to wire it without previous laparotomy. The stomach was displaced downward, and the cardiac end and lesser curvature were stretched in a curved line immediately below and to the left of the dome of the tumor, leaving the pancreas, splenic vessels, and third portion of the duodenum on a more superficial plane. A careful palpation of the tumor with the hand introduced through the wound demonstrated that the aneurysmal sac was connected with the abdominal aorta, and involved its immediate subdiaphragmatic portion, extending down in an ovoid shape to a point approximating the superior mesenteric vessels. Palpation of the tumor gave the impression that it was as large as a fetal head at term. It pulsated vigorously all over its surface, but in the right half of the sac there were some thick (probably fibrinous) deposits. The aneurysm in the course of its rapid development had displaced the posterior peritoneum upward and forward, carrying with it the pancreas, splenic vessels, and duodenum, which now rested upon its surface and in immediate contact with the abdominal wall. Having in view the trial of the Moore-Corradi-Stewart method of treatment, I decided to suture the peritoneal envelope of the tumor to the anterior parietal peritoneum, thus excluding the general cavity and favoring all subsequent treatment by establishing a direct extraperitoneal route to the aneurysm. This point of the program was carried out by partially detaching and displacing the pancreas and splenic vessels upward and thus clearing a space between them and the duodenum and stomach and suturing these organs in place, thus leaving a small interspace the size of a dollar, which represented the free peritoneal surface of the aneurysm. The parietal peritoneum in the wound was then sutured to the periphery of the exposed areas, and the abdominal wound was closed by (catgut) sutures in layers, leaving the center of the incision open where the surface of the aneurysm was exposed. A gauze pack was left *in situ*, and the patient was sent to bed in good condition.

The patient recovered from the effects of the exploratory laparotomy without incident worthy of special mention. The wound healed *per primam*, leaving a round surface the size of a silver quarter in the center of the incision, which healed completely by granulation in 2 weeks. In this way a direct and safe route to the center of the aneurysm had been created. Five days after the operation the patient was put on the Valsalva-Tuffnell treatment, and an ice-cap was kept constantly over the aneurysmal region. On June 9 he was given, in addition, 3 minims of Norwood's tincture of veratrum viride every 6 hours. Codein was given to relieve the pain, which had become less severe, but still persisted in keeping the patient awake at night. On June 13, 12 ounces of sterile gelatin, in normal salt-solution, 10% (Lancereaux's treatment) was injected under the skin in the left subscapular region. The patient suffered considerably from pain at the site of the injection, and the temperature rose quickly to 105° F., but this finally subsided to normal and did not return. The patient, however, was so much disturbed by

¹ Condensed from complete paper which is published with appendix containing report of published cases in Transactions of the Southern Surgical and Gynecological Association, for the meeting held in November, 1900.

this treatment that he begged me not to repeat the injection. The gelatin solution should have been made 3 or 5%, and the intense reaction was evidently due to the excessive concentration of the solution. The severe reaction caused by this strong gelatin solution is worthy of notice.

Up to July 5 (1 month under observation and treatment after exploratory laparotomy) no marked improvement was noticed. The pulsation in the aneurysm was not so marked, the swelling was less prominent and the pains were less severe, but all this was easily accounted for by the great rest, the constant application of the ice-bag over the aneurysm, diet and arterial sedatives which diminished arterial tension and slowed the circulation. In reality the patient was growing worse; he was weaker; and inability to rest at night, with codein and even morphin, was evidence enough that the aneurysmal process was going on.

Therefore, on July 5 (1 month after laparotomy) the abdominal cicatrix was cocainized with a Schleich No. 1 solution, and the aneurysm was needled on the Macewen plan. A long, sterile, steel hat-pin was used for this purpose, and its point was made to rub gently over the posterior and lateral walls of the sac. Two aseptic needles were introduced and left *in situ* for 1½ hours, after which they were removed and the punctures closed with collodium and cotton. No noticeable local change followed this procedure, and in view of the patient's progressive decline we decided to give him the benefit of wiring, combined with electrolysis (Moore-Corradi method). After considerable experimentation with various kinds of wire in artificial aneurysms (bladders, rubber balloons and bottles) on the part of my able assistants, Drs. Urban Maes and John Smyth, it was finally decided to use drawn silver wire. This wire was especially made by a manufacturing jeweler, and formed a perfect coil after passing through a 4-inch straight needle. This wire, when drawn, corresponded in size to the No. 00 Hartmann combination spool wire such as is used for banjo strings, and is about No. 28 gauge and 0.0085 inch in diameter. A 4-inch pointed anula (caliber of a No. 2 Dieulafoy aspirating needle) was insulated (by a professional electrician) by coating with shellac and was tried with the wire, which fed through it without trouble.

On July 9, after anesthetizing the cicatrix with Schleich No. 1 solution, the insulated needle was introduced directly into the center of the cicatrix. No blood appeared until the needle had penetrated 2½ inches, when it began to flow freely, but ceased promptly as soon as the wiring was begun. At 11.55 a. m. the wire was introduced, with the patient in good condition. Pulse 90, good quality. At 12.10 p. m. 10 feet had been introduced and much more could have been used, but we stopped at 10 feet in accordance with our program. The positive pole of a galvanic battery (dry chlorid of silver cells) was attached to the wire and the negative was connected with a large flat metal electrode applied to the lumbar region. Seventy-five milliampères were gradually reached, the patient feeling the negative pole burning slightly. A large wet absorbent cotton pad was applied under the electrode on the back. At 12.13 there was slight pain, and an ice-cap was applied to the abdomen over the tumor. At 12.25 the current was increased to 125 milliampères; pulse unchanged. From this time the needle of the meter began to oscillate and registered 102 milliampères with the same number of cells, apparently indicating little increase in resistance. As the patient was very comfortable at this time, the current was very gradually increased to 200 milliampères. After this the current fluctuated considerably, registering at

1.26 p. m. 200 milliampères.
1.45 " 210 "

At this time the current was discontinued and a new wet flat electrode applied to back; pulse 82. At 1.50 p. m. current gradually brought up to 200 milliampères, and fluctuated as follows:

2.13 p. m. 150 milliampères.
3.00 " 120 "
3.20 " 85 "
3.40 " 80 "
3.50 " 90 "
4.24 " 120 "
4.30 " 120 "

The electrolytic sitting, which had lasted 4 hours and 20 minutes, was discontinued at 4.30 p. m., with the meter pointing to 120 milliampères.¹

At the end of the sitting the patient was very cheerful and apparently as strong as at the beginning of the operation. He complained only of some burning in the back at the seat of the large electrode. His pulse was 82, respiration and temperature normal. He took fluid nourishment several times in small quantities during the procedure. The wire was cut close to the skin while the abdomen was being pressed down, so that when the pressure was removed it completely disappeared from view. The opening was sealed with cotton and collodium.

At the close of the sitting there was evidence that a decided impression had been produced upon the tumor; the pulsation was markedly less vigorous; there was a tendency to epigastric retraction rather than fullness, and the tumor was much firmer,

¹ I desire especially to thank my faithful assistants, Drs. Maes, Smyth and Clark, who carefully observed the patient with me throughout this long electrolytic sitting.

harder to the touch. Auscultation showed that the bruit was much fainter and could only be heard over a space 2 inches in diameter just to the left of the line of the cicatrix.

On returning to his room the patient slept from the effects of a hypodermic of morphin given while on the operating-table. He was very hopeful, complained less and the tumor in the epigastrium gave evidences of undoubted improvement, becoming more markedly retracted every day, but the improvement was only transitory; after 3 days the patient began to complain again of severe pains in the back and left upper lumbar region. The temperature ranged from 98° to 100° F.; the pulse, 96 to 100. He found relief only in morphin, and he took practically little or no nourishment. The emaciation became still more marked, and finally complete discouragement took possession of the patient. In the meantime it was evident that coagulation had taken place in the most prominent part of the tumor, as the murmur and pulsation had greatly diminished anteriorly. The aneurysm had retracted, however, only in one direction; it was evidently subdued only in one place (anteriorly) to become more aggressive in another. The constantly increasing pain and perceptible bulging in the left hypochondriac and lumbar regions pointed to the posterior surface of the tumor, to the left of the vertebral column, as the chief seat of mischief. About this time the patient manifested a desire to return home, and he was taken to his residence July 17, 8 days after wiring. From this time on to the end he was seen by his attending physician, Dr. Moore, and was only heard from occasionally. He suffered greatly and grew constantly weaker, paler and thinner, finally expiring in the midst of a convulsive tremor on July 23, 19 days after the introduction of the wire and the application of electrolysis. During the last days of his life he had to have a quarter of a grain of morphin every 3 hours to secure any rest at all.

No autopsy could be obtained, but the family allowed a small exploratory incision. This was done by Dr. Maes, who found that the sac had retracted from the abdominal wall and was very firm to the touch. On opening the sac the wire was found firmly imbedded in organized and laminated clot, which filled the sac with the exception of a small area where the sac was adherent to the abdominal cicatrix. The wire was gradually withdrawn and its course definitely and clearly mapped out with the finger. It was found to occupy nearly two-thirds of the sac below an opening, 1 inch in diameter, which communicated with a diverticulum of huge size which filled the left hypochondriac region. The sac containing the wire was fusiform in shape, about 1 inch in diameter, evidently very much contracted and in process of obliteration. The aorta, however, practically emptied itself into a vast pouch, apparently of recent formation and with very thin walls, which had ruptured on the night of July 27. The wire after removal showed no marked signs of corrosion, except staining, and formed a small bunch which weighed exactly 24 grains (10 feet).

* * * * *

The lessons to be gathered from this case are numerous and instructive, notwithstanding the unfortunate termination and the fact that we were denied the opportunity of making a complete and satisfactory examination of the aneurysm and abdominal cavity and thus studying its exact anatomic characteristics and relations. Before proceeding with the conclusions which refer to the value of the method it will be well to note, first, the unusually early age of the patient (23 years, the youngest in the series of 15 cases of abdominal aneurysm treated by this method); secondly, the absence of any antecedents—syphilis, alcohol, or trauma—that would favor the development of arterial disease; thirdly, the comparative acuteness of the aneurysmal process, which ran its course in less than 6 months, if we count from the date of the first symptoms to the date of death. Then, as bearing upon this particular mode of treatment, the high celiac or subdiaphragmatic position of the tumor, and the fact that it was a sacular aneurysm, though this could not be absolutely determined by the physical signs before death. In regard to the treatment it is worthy of note that, notwithstanding the most rigorous dietary, absolute rest, constant application of ice over the tumor, and the use of arterial sedatives, the tumor progressed uninterruptedly in its onward march. It is well to observe the very high reaction and decided local disturbance produced by the large administration of strong gelatinous saline solutions; in this case fully 1 pint of a 10% solution was injected by hypodermoclysis, causing a rise in temperature to 105°. It is evident that large injections, especially of such exceedingly concentrated solutions, should not be tried, but that Lancereaux's rule to inject small quantities (6 to 8 ounces) of 2% to 3% solutions continu-

ously and at regular intervals should be followed. In my personal experience with this method, which I have tried systematically for thoracic aneurysm in 3 cases, the results have been invariably negative; nevertheless, in view of the relative benignity of this treatment and the success obtained by others, I would be in favor of trying those injections systematically in all cases as an adjuvant to other treatment.

As to the procedure itself, we must notice the long electrolytic sitting (the longest thus far recorded, 4 hours and 20 minutes) and the high milliamperage of the current. I must confess that I am somewhat at a loss to account for the remarkable resistance and lack of complaint of the patient with so strong a current as 210 milliamperes; and were it not that the canula had been very carefully insulated and the milliamperemeter was tested and found perfectly reliable, I would be inclined to doubt that so strong a current had ever been passed into the aneurysm.¹

The most important fact to be noticed, however, is that the passage of this strong current for so long a time did have a very positive and prompt effect in favoring the coagulation of the blood in the sac, and, as the necropsy showed, that part of the sac which had been invaded by the wire had been completely consolidated with firm and adherent clot and was practically cured. What, then, caused the failure of the method? Death was caused ultimately by rupture of the sac, or, rather, by a diverticulum of the sac which had evidently developed after the introduction of the wire and after the rapid formation of a large coagulum in the main cavity of the tumor. We must presume that in this instance the aneurysm was formed by a multilocular sac, and that only a part of the sac was filled with clot, while another section which had not been reached by the wire remained uncoagulated and had continued to receive the whole force of the aortic current. Under the strain of this increased intraaneurysmal pressure the sac yielded rapidly at this point and formed a diverticulum or secondary sac which ruptured finally into an undefined, extraaneurysmal space in the left hypochondrium. Here, then, is a danger which no amount of intelligence or foresight on the part of the operator can possibly eliminate, and which must remain a serious menace to the patient even when all the other conditions for success have been otherwise fulfilled.

Another point to which we would direct attention was the adoption of a plan of operation in 2 sittings, with 4 weeks' interval between them, the advantages of which do not appear to have been considered by previous operators, who have invariably explored the tumor, and, after wiring and applying electrolysis, have closed the abdomen. By operating in 2 sittings there are at least 2 distinct advantages to be gained. In the first place, by the exclusion of the general peritoneal cavity through systematically suturing the parietal peritoneum to the edges of the wound to the retroperitoneal covering of the surface of the tumor, adhesions are produced between the aneurysm and the abdominal wall over a well circumscribed area. When this is done as a preliminary procedure it undoubtedly diminishes the dangers of peritoneal contamination and shock which are likely to occur during a long electrolytic sitting. The wiring of the aneurysm is then accomplished at a later date, when the wire can be inserted and electrolysis applied under simple local anesthesia. In this way the electrolytic current can be applied for an indefinite period with deliberation, and under the same simple conditions in which it is applied in thoracic aneurysms.

¹ That currents stronger than 70 milliamperes are liable to cauterize and do harm is shown very clearly in Dr. Hunner's recent paper (Johns Hopkins Hospital Bulletin, November, 1900) and by the sloughing of the skin of the back at the place where the negative electrode was kept in contact with the skin in one of Dr. Finney's cases. In this case a current of 70 milliamperes was kept up for 1 hour. In our patient the only observable local effect on the skin was to produce a marked erythema which passed away without leaving any trace.

Dr. Parham was the first to resort to the open method of observing an abdominal aneurysm by simply walling off the sac with gauze. He did this, however, (as will be shown in the report of his case which is to follow), after wiring had been done, and chiefly with the view of controlling hemorrhage from the point of puncture and better to observe the subsequent course of the aneurysm. I regard this suggestion as a distinct advance in technic.

* * * * *

In submitting the report of this case it is not the writer's purpose to discuss the purely technical features of the method adopted,² it being his chief object to consider this subject in the light of clinical results as observed in the treatment of the abdominal type of the disease. While the Moore-Corradi method has found its largest field of application in the treatment of thoracic aneurysms probably because these are more frequent than the abdominal (175 thoracic to 59 abdominal, Crisp; 83 to 9, Lebert), and because in advanced thoracic aneurysm the subcutaneous character of the tumor favors this mode of attack even at the hands of physicians not especially skilled in surgical manipulations, it is nevertheless true that abdominal aneurysms, as a class, are better adapted to test the real value of the method. With the advance of abdominal surgery, abdominal and intraperitoneal exploration has been made comparatively safe, and in this way the character of the aneurysm its mode of origin, approximate site, and other important topographic relations and anatomic characteristics are more easily determined than with the thoracic aneurysm, which can only be studied at a distance and chiefly by physical signs. Limiting our inquiry, therefore, to the abdominal aortic aneurysms, let us bear in mind first the essential principles which underlie the therapeutic and curative action of the wiring and electrolytic process as applied to the condition. The Moore-Corradi method aims fundamentally at arresting the circulation of the sac by inducing a coagulation of its contents. It aims at the production of a firm, resistant, adherent clot which shall fill the sac and coagulate its orifice of communication with the vessel of supply. The formation of this plug is essential to block the orifice of the sac and arrest the circulation. At the present moment, in view of the experimental evidence which has accumulated on the subject, no one will deny that the modification first proposed and practically applied by Corradi (1881), to the effect that the mechanical action of a wire in favoring the deposition of fibrin would be very much intensified by passing through it a galvanic current of definite strength, which would act upon the blood in virtue of its electrolytic qualities, is a distinct advance on Moore's simple method of wiring (1864). The influences that are therefore brought to bear in inducing coagulation of the aneurysmal contents by the combined method are threefold—mechanic, biologic (tissue or cellular reactions), and chemic, the last being probably the most important feature in inducing the prompt precipitation of fibrin through the decomposing power of the electrolytic current.

Without attempting to trace the various historic stages which have marked the gradual evolution of the technic from 1864 to the present time, suffice it to say that under favorable conditions these three agencies—mechanic, biologic, and chemic—amply suffice to bring about the desired results, viz., prompt coagulation of

² This aspect of the question is very fully and ably presented by Dr. Guy L. Hunner, of Baltimore, in his masterly essay published in the Johns Hopkins Hospital Bulletin of November, 1900, vol. xi, No. 116. This contribution, which is the most comprehensive and instructive that has recently appeared on the subject, reached me after this paper had been written, and the bibliographic research had been completed. In the revision of this article, after it had been sent to the Secretary of the Association, I have been able to strengthen my original conclusions by reference to many suggestions made by Dr. Hunner, and also by availing myself of the most instructive and carefully reported cases operated upon by Drs. Halsted and Finney in the Johns Hopkins Hospital, which have been abstracted and added to the supplement appended to this paper.

blood, with the formation of a firm, adherent clot. As a result of the modifications brought about by the combined efforts of surgeons and physicians who have labored to perfect both the surgical and the mechanic-electric phases of the technic, the essential features of the method resolve themselves as follows:

1. A thorough exploration of the tumor, made safe by aseptic celiotomy, which permits a recognition of the approximate anatomic seat and relations of the tumor and furnishes important information as to its anatomic characteristics—an advantage that is denied in thoracic aneurysms.

2. The safe exposure and even permanent isolation of the point of attack in the most accessible part of the tumor by the formation of adhesions between the sac and the abdominal wall—a point which we believe has been shown to greater advantage in the 2 cases that are reported in this paper, though the methods adopted by Dr. Parham and myself were different and we were guided by different purposes—is worthy of adoption in all cases, as it diminishes shock and the liability to peritoneal contamination.

3. The introduction at a second sitting (when adhesions have formed and the sac has become practically extraperitoneal) of a highly drawn fine snarled silver wire, which should not exceed a No. 28 gauge (0.0085 of an inch) in diameter. The wire may be of gold, as suggested by Stewart, or of silver blended with copper alloy, as suggested by Hunner; but it is evident from our experience and that of others that sterling silver will meet all the indications.

4. The wire should be fed or carried into the aneurysmal sac through a fine and carefully insulated trocar or canula (shellac, celluloid, or rubber being used as the insulating agents, shellac being most convenient), the caliber of the canula not exceeding a No 2 Dieulafoy aspirating needle.

5. The wire should be always tested before its application, to determine the following points: (a) That it will coil after feeding through the canula; (b) that it will coil in large, irregular loops, in order that its distribution over the largest possible surface may be insured; (c) that it will not form a short continuous spiral with such spring and force as to exercise injurious pressure upon the aneurysmal walls, or, after finding its way into the aorta through a large orifice, spring, as it were, into the heart itself. Furthermore, it is important that the quantity of wire used should be adjusted to the size of the aneurysm, in order that the retraction of its walls after coagulation may not be interfered with (as happened so disastrously in several instances) owing to the resistance offered by the wire itself. As a rule, 10 feet of silver wire, highly drawn and snarled, will suffice for the average aneurysm, though larger quantities (15 and 20 feet) are advised according to the size and approximate capacity of the aneurysm. Practically it may be said that 10 feet are amply sufficient, as is proved by the fact that in the 3 recorded cases in which a permanent cure has been obtained (Morse, Langton, Noble) the maximum length of the wire was 10 feet.

6. As to the electrolytic current, this should be furnished by a galvanic battery (the portable dry chlorid of silver appears to have been most generally used in this country), with the positive pole attached to the wire and the negative electrode, well covered with a wet cloth, to the back. A milliampèremeter should be connected with the circuit to indicate the strength of the current, which, according to the most authorized opinion, should not exceed 70 milliampères, for fear of caustic effects. The intensity of the current and the duration of its application will vary within wide limits, according to the condition of the patient and the effect upon the tumor. By following the plan adopted in our case the sitting was prolonged 4 hours and 20 minutes without any appreciable bad effects. Without a previous celiotomy and the preliminary formation of adhesions, which made the sac prac-

tically extraperitoneal and rendered general anesthesia unnecessary, so long a sitting would have been impossible without great risk of peritoneal contamination and shock.

7. The coincident administration of gelatin (3% gelatin dissolved in decinormal saline solution, .7% salt) in 6 or 8 ounce doses by hypodermoclysis, as suggested by Lancereaux, may prove beneficial as an adjuvant to rest, diet, and other general measures of treatment.

So much, then, for the technic of the method. Now as to the indications. Is the Moore-Corradi method applicable to all forms of abdominal aneurysm, or are there special anatomic conditions which are decidedly more favorable than others for its successful application? Thus far we have been able to collect the records of 15 published cases of abdominal aneurysm, treated either by wiring alone or by the combined methods, since the distinguished Professor Loreta first introduced Moore's method in abdominal surgery in 1885; and after investigating these records carefully we notice that in no instance did the operators specially attempt to define the conditions which they regarded as particularly favorable to the application of the method. In every instance it appeared to be taken for granted that, as other nonsurgical modes of treatment had failed and the patients were hopelessly drifting toward certain death, they were justified in resorting to this expedient with the hope that it would determine a cure by process of coagulation. In 3 only (Morse, Noble, Langton) out of 15 abdominal aneurysms has this hope been realized and the courage of the patient and of the operator has been rewarded by a permanent cure.

In 2, or possibly 3 other instances (Loreta, Pringle-Morris and Finney's case No. II.) wiring alone and wiring with electrolysis has been followed by a decidedly favorable impression upon the tumor, though the beneficial effect on the patient was, with the still doubtful exception of Finney's case, only temporary. Loreta's patient died in 92 days from rupture of the aorta below the aneurysm, which had been cured; and in Pringle-Morris' case the tumor was undergoing coagulation when the patient succumbed, on the fifth day, from traumatic delirium and exhaustion. In Finney's case the patient's subjective sensations improved, but the aneurysm was practically unchanged 1 month after the operation. If we class these cases as improved, either in a local or general sense, we would be justified in stating that in 5 out of 15 cases (33.3%) a favorable impression was produced by this treatment, in 3 of which only (or 20%) the cure was permanent. In the remaining 10 cases the aneurysmal condition was either not improved or was aggravated by the procedure, thus in 66.6%, the method failed to improve the local condition or to prolong life.

In view of these facts, it is evident that there must be a certain comparatively small percentage of cases of abdominal aortic aneurysm that come to us for treatment which are favorable to this method, and another, a much larger group, which is not amenable to this procedure and in which it is contraindicated.

It may be argued that in some of these fatal cases a better technic might have avoided some of the bad results or that in some of these patients the disease was so far advanced that the cases were hopeless when the treatment was applied. Granting that this may be true in a few instances, we believe the bad results were in the main attributable to inherent dangers of the method itself apart from all questions of technic.

It is evident after a careful consideration of the anatomic and pathologic conditions which obtain in abdominal aneurysm that there are many fallacies and unavoidable sources of danger in abdominal aneurysm which distinctly preclude the possible success of the method in a large proportion of the cases, no matter how perfectly the technic may be carried out. The important question that at once presents itself is, Can these favorable

and unfavorable conditions be clearly differentiated by the means of investigation now at our command? A moment's reflection upon the clinical conditions that exist at the time when the majority of these patients seek relief will convince us that, notwithstanding all the advantages of an exploratory laparotomy, many of the essential points in the diagnosis, such as the exact origin of the aneurysm, the part of the aorta in which the aneurysmal orifice is situated, the size of the orifice, the relation of important visceral branches to the sac, the condition of the walls of the sac, etc., must remain unknown. In other words, with all the improvements that have been made in the technic and the exact knowledge obtained of the capabilities of the method when applied experimentally *in vitro*, we really know nothing positively of what this procedure will accomplish on the living subject except, perhaps, the empiric and gross fact that the method has been instrumental in saving the lives of 3 out of 15 recorded cases of abdominal aneurysm.

Notwithstanding this discouraging conclusion we must recognize that in so intractable a condition as abdominal aneurysm, even so small a percentage of recoveries must not be disregarded; but, while still clinging to the method, it is also evident that it is not universally applicable and that it is much less justifiable in some cases than in others. Under these circumstances some effort should be made to define the indications for or against this operation in this class of cases.

[To be concluded.]

THE SOCALLED TRAUMATIC NEUROSIS.

BY

HAROLD N. MOYER, M.D.,

of Chicago, Ill.

In presenting the subject of so-called traumatic neurosis, I recognize that an immense amount has been written upon this topic and that there are widely varying opinions. I shall not enter into the controversies of the last few years, except in so far as they serve as an introduction to the views that shall be presented in this paper. I will also not burden you with long accounts of clinical cases, but will present a paper which is in the nature of conclusions, based upon a study of over 700 examinations of cases presenting nervous troubles, attributed by the individuals affected, to a trauma.

Traumatic neurosis is any deviation from the normal in the nervous system, caused by violence. Thus a fracture of the humerus involving the musculospiral nerve, is, strictly speaking, a traumatic neurosis. Of late there has been an increasing tendency to restrict the term neurosis to those conditions of the nervous system, not accompanied by appreciable alterations in the central nervous system, of which the symptoms are largely subjective and do not ordinarily present the sensory and motor phenomena associated with organic changes. Hence, the term traumatic neurosis is by common consent, largely restricted to cases of a functional character.

The term spinal concussion, as used by Erichsen nearly 40 years ago, has served as a foundation for an extraordinary superstructure that has maintained itself decade after decade in spite of the advances in our knowledge of neural pathology. Volumes could be filled with the description of the distinctions, and the controversies arising therefrom, that were made between a spinal concussion and *the* spinal concussion, the former referring to the immediate effects of a traumatism upon the spinal cord, and the latter to a more or less prolonged departure from the general health which Erichsen attributed to a "molecular vibration" in the cord.

Those who recognized the inherent difficulty in the use of such a term as spinal concussion, expressing as it did two different ideas in pathology, sought to substitute another term. Clevenger proposed "Erichsen's disease," while Oppenheim used the term, "traumatic neurosis," as applied to a more or less functional disturbance of the nervous system following trauma. Other writers substituted for the term spinal concussion, railway brain, and others less euphonious and still more obscure.

An unfortunate element in many of these cases is the accompanying litigation. Railway surgeons contend that traumatic neurosis is simply the subjective conception of the patient, injured in a railway accident, and brought into court for the purpose of obtaining money from an already impoverished corporation. On the other hand, the attending physician invokes that appalling entity, spinal concussion, with its molecular perturbations, making a condition which would render the person sick, sore, and disabled so long as he lived. The physicians in the defence of these cases devised new terms, among which were litigation symptoms, to characterize the subjective statements which the patient made, and which were said to disappear entirely under the revulsive action of a greenback plaster!

All such controversies are quite valueless in advancing knowledge on the subject, and it is the purpose of this paper to endeavor to indicate a few landmarks which may serve as guides in the study of a very obscure subject.

To arrive at a correct appreciation of these cases, one should at once dismiss the ideas of traumatic neurosis, of Erichsen's disease, or of spinal concussion, particularly if these are held with the view that there is a certain functional trouble of the nervous system due to accident or violence, which can be recognized as such in the absence of a statement that the patient has sustained an injury. In the description of Erichsen's disease, something like 30 symptoms, running all the way from tremor and increased reflexes to uneasiness in the neck-muscles, or pain in the back are included. Some of these patients are clearly hysteric; others have a neurasthenic character; some are distinctly hypochondriac; and, even a fourth group might be made, having the so-called "litigation" symptoms. If the symptomatology of Erichsen's disease is obscure, what shall be said of the pathology and prognosis, the latter especially being important in a litigated case? No one can tell the outcome of a case of Erichsen's disease, as the symptoms may vary from slight functional alteration to those which involve structural changes in the nervous system. The diagnosis, at best, whether we use the term traumatic neurosis, Erichsen's disease, or spinal concussion, is devoid of limitation; it does not define symptoms nor pathologic changes, nor does it lead to a prognosis. Hence, unless it can be clearly shown that there is a definite symptom-grouping that with average constancy results from injury, those terms should all be abandoned. In the examination of a case, we should view the symptoms as a medical problem and endeavor to make a prognosis upon the same lines that we do in disease and changes of the nervous system not caused by traumatism.

That traumatism may cause disturbance in the central nervous system scarcely admits of question; also that it may be organic or functional, though the latter is by far the more frequent. The organic disturbances of the nervous system may include any of the systematized or general degenerations of the brain and cord. In some cases there have been well defined spastic paraplegias. We are not sure that tabes can be caused by traumatism, but we are confident that with the predisposing factor of syphilis, traumatism may act as an exciting cause. The grosser lesions, such as fracture, hemorrhage from ruptured bloodvessels and pressure from the consequent hematoma, call for no extended description.

The functional group, by far the most important,

is the one which has caused all the controversy, and has led to the effort to substitute various names for an actual study of the nervous conditions. That grave functional disturbance of the nervous system may result from accident or injury, is, to my mind, an absolute fact, and this, in the absence of fracture of the skull or dislocation of the spinal column. When, however, we discover these symptoms, we find that they naturally fall into certain groups—hysterie, neurasthenic, and hypochondriac. This is not to say that every patient will present a pure type of one or other of these affections, but there are often mixed cases in which the hysterie or neurasthenic element is more pronounced. So far as my experience goes, neurasthenia was by far most common where a previous history of nervous weakness or a marked hereditary element was absent. Those cases which had a previous history of an hereditary or acquired nervous weakness most frequently presented the hysterie type. A small number were clearly hypochondriacs, presenting the typic manifestations of that psychosis, oftentimes with no other symptoms. I shall leave out of consideration the so-called litigation-symptoms, which, after all, are mere cases of feigning, and as a group have never merited the attention bestowed upon them. The confusion that has arisen regarding this subject is largely owing to the terms which have been employed. If we can divest ourselves of the idea that it is a terrible malady which no one understands, which is liable to rest as an incubus upon the patient all his life, without definite symptomatology, pathology, or prognosis, and come to the study of this functional group with the knowledge that the symptoms naturally divide themselves into 3 groups, the neurasthenic, hysterie, and hypochondriac, then we shall have cleared the ground of an immense amount of debris.

To those who have followed my argument so far it will be apparent that I accept the view that traumatism is a not infrequent cause of functional disturbance of the nervous system, but that I do not recognize a special form as the result of such cause. You may well ask what is the value of such a contention? It is, simply, that we bring to the study of these cases something tangible. The symptomatology of neurasthenia, its prognosis and treatment, has been well differentiated of late years. The same is true of hysteria and hypochondria. You may ask, what is the difference between a traumatic hysteria or traumatic neurasthenia, and traumatic neurosis? A traumatic neurosis may mean anything from a grave involvement of the nervous system, to forms so trivial as to be scarcely worth noticing; while in traumatic neurasthenia or traumatic hysteria, we are dealing with clearly marked divisions of the functional nervous diseases whose prognosis and treatment are well understood.

There is no difference between neurasthenia caused by traumatism and that due to auto-intoxication, or that following acute fevers. The essential feature of neurasthenia is that of undue fatigue upon slight exertion. To be sure, this symptom is one upon which the patient lays little stress; he significantly calls attention to the pain in the back or head or the peculiar sensations from which he suffers. What the patient describes as a pain, is usually a distress or discomfort that is oftentimes harder to bear than acute pain.

Hysteria, without the elements of heredity or previous well-marked signs of disorder, is rare. Here we have the characteristic anesthesia, narrowing of the field of vision, the almost characteristic inversion of color perception, sudden attacks of amblyopia and the peculiar mental state of the patient to guide us to a diagnosis.

In hypochondria we deal with a real psychosis in which the subjective condition of the patient's health is the matter upon which he has delusions, or, at least, morbid introspections. A hypochondriac is never a malingerer, but his statements regarding his physical condition are the developments of a perverted mental

state, just as are the delusions of poisoning or of persecution in melancholia and paranoia.

In the diagnosis of spinal concussion, too much importance has been attached to pain over the vertebrae. In some way this symptom has come to be associated with an intangible change in the spinal cord or alteration in its circulation. There is no evidence in support of such a view. In all organic diseases of the spinal cord, even including myelitis and tumor, we find that pain over the vertebral spines, either on pressure or spontaneously, is exceptional, and yet this symptom has largely served as a foundation for the various traumatic neuroses. A moment's thought will convince one that the innervation of the skin over the spinal column is not different from that of other parts of the body. It is supplied by mixed nerves, and these are, in every sense, quite as peripheral as are the nerves of the extremities or other parts distant from the column. There is no more reason to believe that tenderness over one of the dorsal vertebrae is indicative of disease of the spinal cord than is pain along one of the intercostal nerves, or, in the termination of the ulnar. These spinal pains, in the majority of cases, are fatigue symptoms of neurasthenia. Next to the heart muscle and the muscles of respiration, the erector spinae are the most constantly used muscles in the body, and naturally they are the first subject to fatigue. Except when the body is lying prone on a perfectly flat surface, these muscles are always in action.

Another point in reference to spinal pain which I think has never received the attention it deserves, is the fact that contusions and sprains of the articulations of the spine are a significant source of pain. When one thinks of the damage that may be done to a kneejoint by a simple concussion—the accumulation of fluid and the formation of adhesions in the synovial sac, together with the long train of symptoms which may result from it—we must conclude that a similar process is easily set up in the more than 50 articulations composing the spinal column, each lined with a synovial membrane, and in which adhesions and pathologic changes cannot be demonstrated clinically because of the smallness of the articulations and their deep situation.

To sum up a very brief paper, I suggest the following points for discussion: That concussion neurosis in all its various appellations, is an unfortunate and misleading term; that clearer understanding of functional nervous troubles renders such a term unnecessary; that pain and tenderness of the spine is rarely an evidence of change in the cord, but is usually due to fatigue of the spinal muscles, or sprains and concussions of the column; that most of the symptoms of spinal concussion, as the term is commonly used, are cerebral in origin, and that a correct diagnosis and prognosis may usually be reached by analyzing all such cases after the same manner that we do functional nervous troubles having their origin in non-traumatic causes.

University of Königsberg.—With the opening of the spring semester, Professor Garre, who has for some years been director of the Surgical Clinic of Rostock University, will take the chair in surgery left vacant by Professor V. Eiselsberg, who has been called to Vienna.

Benefit of Good Water and Sanitation.—To the artesian water supply and the sanitary sewage system of Montgomery, Ala., is attributed the decrease in the percentage of mortality. Comparing the rate of April, 1901, with that of April, 1881, it is found to be 20% less than at that time. This great improvement is due to the institution of these two great health promoters.

Alfred Fripp, assistant surgeon to Guy's Hospital, who recently received the C.B. in recognition of his services as Senior Surgeon to the Imperial Yeomanry Hospital, South Africa, has been invested by the king with the Insignia of the Royal Victorian Order, third class (C.V.O.). Mr. Fripp, who was Surgeon-in-Ordinary to the king when Prince of Wales, was recently appointed Honorary Surgeon-in-Ordinary to the king.

RESECTION OF SUPERIOR SYMPATHETIC CERVICAL GANGLION FOR NONINFLAMMATORY GLAUCOMA.¹

BY
JOSEPH MULLEN, M.D.,
of Houston, Texas.

Panas, of Paris, is opposed to this operation and reports a case in which vision is rapidly declining 3 months after the removal of the ganglion. It is claimed that removal of the superior cervical ganglion alone is

as well as a slight sinking of the eyeball and pupillary contraction. Lowered intraocular tension may be tardy. The pathologic state of the ganglion is that of sclerosis and is supposedly dependent upon pressure and inhibited nutrition.

There are 2 ways of performing the operation. First, reaching the ganglion by the posterior triangle, and second, by penetrating the anterior triangle. A line drawn across either triangle on a level with the fourth cervical vertebra will run almost directly across the superior ganglion. Jennesco prefers the anterior or pre-mastoid route. The posterior or mastoid is less difficult to perform and by far less dangerous. The patient on whom sympathetomy was performed is a female aged 48.

Family history good and health excellent. Twenty-three years ago she had a bilateral iridectomy performed for acute glaucoma. The symptoms then, as she recalled them, were: pain in both eyes and temples, associated with diminished vision. There had been a gradual decrease in vision since that time, as well as increased and more persistent pains in the eyes, temples and occiput. By February 8, 1899, the pain in the eyes, temples and occiput had become intense, confining her to bed for 5 days at a time. Tension, +2 in both eyes. Vision in right eye, counted fingers at 5 feet; vision in left eye, 2/10. Operative coloboma of both irides, and deep glaucomatous cups were present. Eserin sulphate and the usual medicinal treatment was tried for some time without any improvement of vision or amelioration of pain. On March 18, 1900, resection of the superior cervical sympathetic ganglion was performed. The mastoid or postcervical route was chosen and the ganglion removed in its entirety. The spinal accessory nerve was not severed. The ganglion was found to be sclerosed. Pinching of the ganglion with forceps before its removal produced increased lacerimation.

sufficient in glaucoma, because all of the sympathetic fibers go to the eye from this ganglion. It is held by Jennesco that excision of the superior ganglion destroys all of the vasoconstrictor fibers of the eye, relaxing the arteries, lowering the blood-pressure and diminishing extravasation; also the nerve fibers which excite secretion, thereby modifying the volume of aqueous humor, and likewise the fibers which dilate the iris, permitting the pupil to contract, and enlarging the iris-angle so the obstacle to the outflow of aqueous is removed. Destruction also occurs in the fibers which supply the unstriped muscles of Tenon's capsule reducing pressure on the efferent veins and thereby enhancing the normal ocular circulation. In other words it is believed that removal of the superior ganglion completely breaks up the connection between the eye and the brain center, and it is claimed this is the starting point of the glaucoma. The immediate effects of excision are relief from pain, contraction of the pupil, increased lacerimation and sweating of the same side of the face. There is also conjunctival injection and oftentimes immediate reduction of intraocular tension. In my case

Immediately after removal the tears ran copiously from the right eye. The cheek was slightly suffused. The coloboma prevented any observation of myosis. The opposite eye was in no way affected. The deep cervical muscles were sutured with gut and the integument with silk. Primary union took place throughout. Pain ceased several days after the operation, and tension immediately fell to normal, after excision in both eyes. The tension and pain returned, however, June 26, 1900, about 3 months after the operation of excision.

periodical formication and flushing occurred and continued several weeks. Ptosis may occur as a remote effect,

Immediately after removal the tears ran copiously from the right eye. The cheek was slightly suffused. The coloboma prevented any observation of myosis. The opposite eye was in no way affected. The deep cervical muscles were sutured with gut and the integument with silk. Primary union took place throughout. Pain ceased several days after the operation, and tension immediately fell to normal, after excision in both eyes. The tension and pain returned, however, June 26, 1900, about 3 months after the operation of excision.

Chart No. 1 shows the field of both eyes 5 days before operation.

Chart No. 2 shows improvement in field 1 month after operation.

Chart No. 3 was taken June 25, since which time the pains in both eyes, the temples and occiput have steadily increased, and at the present time have reached their former frequency and severity.

An examination, December 12, 1900, shows the condition of the vision to be as follows: Right eye, 1/200; left eye, 2/200. Perimeter charts (No. 4) show a decrease in both fields.

No microscopic examination of the excised ganglion was made, but a macroscopic investigation showed it to be sclerotic. My case is very similar, at the present

¹ Read at Third Pan-American Medical Congress, Havana, Cuba, February 5, 1901.

time, to the one reported by Panas, and, like his, has declining vision, so that I, too, desire to put my case on

the next step was to infect melted agar from which plates were made. The method of making plates was as follows:

record as proving that sympathectomy in glaucoma does not always produce permanent curative results.

A petri dish was sterilized and half a tube of melted agar poured upon the bottom dish. With a sterilized glass brush (made sterile by passing directly through the Bunsen flame) the degree marks were thoroughly brushed upon the agar spread in the dish. The lid was lifted carefully and quickly, and as quickly replaced. In the remaining half of the melted agar in the tube, the thermometer was rotated for a few minutes, then withdrawn, the tube agitated, and its contents poured into the dish containing the first part of the agar, and the lid replaced. The plate was then allowed to set.

Inoculations were also made in bouillon by rotating the thermometer in the medium which was then set aside for 24 or 36 hours, and when cloudiness appeared, plates of agar were made. The results obtained by this method were used only for the purpose of establishing the character of the organisms present, being controls to the agar plates made as already described.

THE BACTERIOLOGIC EXAMINATION OF CLINICAL THERMOMETERS.

BY

RANDLE C. ROSENBERGER, M.D.

Demonstrator of Morbid Anatomy and Baeteriology, Jefferson Medical College; Pathologist to St. Joseph's Hospital.

[From the Laboratories of the Jefferson Medical College Hospital, Philadelphia.]

I have been impressed with the fact that while surgeons, obstetricians, and many specialists recognize the necessity of guarding against infection by the sterilization of instruments used in operations as well as instruments of precision, the general practitioner not infrequently entirely neglects such precautions, especially in the use of tongue-depressors and thermometers. Upon inquiry many of the general practitioners have been found to make an attempt to limit infection by thermometers, resorting to some antiseptic or germicide kept in the thermometer case. While admitting the possible efficacy of such a method, its routine use in the careless manner commonly adopted is probably more dangerous than no attempt at disinfection, because an inefficient and unreliable method offers a sense of security not at all justified.

One physician whose thermometer I examined used a 1% solution of formalin, with which he saturated a small pledget of cotton kept in the thermometer case. Another practitioner applied carbolic acid in a similar manner. Upon the examination, however, of these containers and the enclosed cotton neither formalin nor carbolic acid could be detected by odor and the bacteriologic findings demonstrated their inefficiency. It is unnecessary to say that the customary habit of simply

rinsing a thermometer in water and wiping the instrument on a towel or handkerchief affords no protection.

A series of experiments have been made for the purpose of determining so far as possible in a small number of cases the probabilities of infection by means of a thermometer.

The method pursued was (1) to obtain the diagnosis of the case in which the thermometer was last used; (2) the time that had elapsed since the instrument was used; (3) how the thermometer was cleansed after using.

Technic of Examination.—Having obtained the information indicated in the foregoing, the next step was to infect melted agar from which plates were made. The method of making plates was as follows:

A petri dish was sterilized and half a tube of melted agar poured upon the bottom dish. With a sterilized glass brush (made sterile by passing directly through the Bunsen flame) the degree marks were thoroughly brushed upon the agar spread in the dish. The lid was lifted carefully and quickly, and as quickly replaced. In the remaining half of the melted agar in the tube, the thermometer was rotated for a few minutes, then withdrawn, the tube agitated, and its contents poured into the dish containing the first part of the agar, and the lid replaced. The plate was then allowed to set.

Inoculations were also made in bouillon by rotating the thermometer in the medium which was then set aside for 24 or 36 hours, and when cloudiness appeared, plates of agar were made. The results obtained by this method were used only for the purpose of establishing the character of the organisms present, being controls to the agar plates made as already described.

The next procedure was to observe how many colonies developed in the agar plates and what bacteria were present. The following is a detailed list of some of the examinations made and the results:

A thermometer used in a case of bronchopneumonia in a child was washed in cold water, dried with a handkerchief, and examined 2 hours later. In 48 hours, 46 colonies had developed; 17 of these were *Staphylococcus pyogenes albus*; 2 colonies were *Staphylococcus pyogenes aureus*; the remaining were sarcinae and yeasts.

A thermometer used in a case of diphtheria was washed with cold water, dried with a handkerchief, and examined 48 hours later. The plate yielded 12 colonies; 7 of these were *Staphylococci* (*pyogenes albus* and *aureus*), and the remainder were sarcinae.

A thermometer used in a case of tuberculosis (pulmonary) was cleansed as were the foregoing, and examined 48 hours later. The plate developed 1 colony of the *Staphylococcus pyogenes albus* and 2 colonies composed of sarcinae. The physician from whom the thermometer was obtained used carbolic acid in the thermometer case.

From a thermometer that had not been used for 42 days, and where the physician had forgotten the diagnosis of the case in which the instrument was last applied, there developed 6 colonies. Of these, 2 were *Staphylococci*, 1 was evidently a member of the colon group, and 3 were sarcinae.

A thermometer used in a case of rheumatism and immediately washed in a 5% solution of carbolic acid was examined 72 hours later, and yielded at the end of 48 hours' cultivation, 12 colonies; 3 were *Staphylococcus pyogenes albus*; 5 sarcinae; 1 *Bacillus subtilis*, and 3 of a chromogenic (pink) diplococcus.

A thermometer used in a case of pulmonary tuber-

culosis was washed in cold water, dried with a handkerchief, and examined 56 days later. In 48 hours 15 colonies developed; 4 of these were Staphylococci; 6 were sarcinae; 3 Bacillus subtilis; 2 chromogenic (pink) diplococcus.

A thermometer used during the puerperium was washed with cold water, dried with a handkerchief, and examined 24 hours after the last time it was used. Plates contained 2 colonies of the Staphylococcus; 4 Bacillus subtilis; 6 of the sarcinae, and 4 of the chromogenic (pink) diplococcus.

A thermometer was obtained from a physician who had used the instrument in a case of diphtheria, washed it in water, and later took his own temperature, again cleansing the instrument as in the first instance. I examined the thermometer 24 hours later. The cultures yielded 24 colonies; 6 of Staphylococcus pyogenes albus; 1 of a bacillus which I was inclined to regard as the pseudodiphtheria bacillus, and 17 colonies of sarcinae.

Without going further into the details of the examination in various cases, the following tables are submitted:

Table I is the result of the examination of thermometers used in the mouth, and Table II of thermometers used in the axilla.

TABLE I.

Cases.	Length of time after using.	No. of Colonies.	Bacteria found.
Bronchopneumonia	56 days	46	Staphylococci, 19 colonies Sarcinae, 27 "
Diphtheria	48 hrs.	12	Staphylococci, 7 " Sarcinae, 5 "
Tuberculosis	48 hrs.	3	Staphylococci, 1 " Sarcinae, 2 "
Rheumatism	72 hrs.	12	Staphylococci, 3 " Sarcinae, 5 " Diplococcus (pink), 3 col. B. subtilis, 1 colony
Tuberculosis	46 days	15	Staphylococci, 4 " Sarcinae, 6 " B. subtilis, 3 "
Puerperium	24 hrs.	16	Diplococcus (pink), 2 col. Staphylococci, 2 colonies Sarcinae, 6 " Diplococcus (pink), 4 col. B. subtilis, 4 colonies
Diphtheria	48 hrs.	24	Staphylococci, 6 " Pseudodiphtheria bacillus, 1 colony Sarcinae, 17 colonies
Not given	42 days	6	Staphylococci, 2 " Sarcinae, 3 " B. coli communis, 1 col.

An examination of the results yielded by this investigation would satisfy the most skeptical that thermometers can readily transmit the bacterial flora found in the oral cavity. The writer is aware that for the satisfactory completion of this inquiry it would have been necessary to examine the secretions in the mouths of the patients upon whom the thermometers were used, and to have satisfied himself as to the character of the bacteria that they contained. There is another source of danger into which the inquiry did not extend, infectivity of thermometer cases, but as the case would only be a carrier, the essential danger, if any exist, must be in the thermometer. In order to determine how readily thermometers could be disinfected the writer made 9 experiments, using the following technic:—

Immediately after removal from the mouth the thermometer was washed in water, immersed in corrosive sublimate for 2 minutes, removed from the antiseptic, dried in the air, and replaced in the case. Later the instruments were examined, using the same technic as detailed above.

TABLE II.

Cases.	Length of time after using.	No. of Colonies.	Bacteria found.
Chronic indigestion	24 hrs.	4	Staphylococci, 3 colonies Sarcinae lutea, 1 "
Chronic indigestion	3 hrs.	14	Staphylococci, 10 " Yeast fungi, 3 " B. subtilis, 1 "
Chronic indigestion	12 hrs.	12	Staphylococci, 11 " Yeast fungi, 1 "
Chronic interstitial nephritis	24 hrs.	6	Staphylococci, 2 " B. subtilis, 4 "
Gout	48 hrs.	4	B. subtilis, 4 "
Measles	24 hrs.	20	Staphylococci, 11 " B. subtilis, 5 " Unidentified bacilli, 4 "
Measles	48 hrs.	6	Staphylococci, 5 " B. subtilis, 1 "
Measles	8 hrs.	26	Staphylococci, 22 " Sarcinae lutea, 4 "
Scarlet fever	12 hrs.	24	Staphylococci, 18 " Sarcinae lutea, 4 " B. subtilis, 2 "
Scarlet fever	24 hrs.	18	Staphylococci, 12 " Sarcinae lutea, 4 " B. subtilis, 2 "
Tuberculosis	36 hrs.	6	Staphylococci, 4 " Sarcinae lutea, 2 "
Tuberculosis	24 hrs.	16	Staphylococci, 6 " B. subtilis, 4 " Sarcinae lutea, 6 "
Tuberculosis	72 hrs.	2	Staphylococci, 2 "
Tuberculosis	48 hrs.	6	Staphylococci, 4 " Sarcinae lutea, 2 "
Tuberculosis	8 hrs.	22	Staphylococci, 12 " B. subtilis, 8 " Sarcinae, 2 "
Diphtheria	24 hrs.	4	Streptococci, 1 " B. subtilis, 3 "
Bronchitis	72 hrs.	6	Staphylococci, 4 " B. subtilis, 2 "
Bronchitis	24 hrs.	12	Staphylococci, 8 " Yeast fungi, 4 "
Bronchitis	12 hrs.	28	Staphylococci, 12 " Sarcinae lutea, 10 " B. subtilis, 6 "

The results of these experiments are given in Table III.

TABLE III.

Cases.	Length of time after using.	Result.
Rheumatism	1 hour	Sterile
Chronic interstitial nephritis	2 hours	"
Croupous pneumonia	1 hour	"
Enteric fever	3 hours	"
Bronchitis	2 hours	"
Chronic indigestion	1 hour	"
Influenza	2 hours	"
Influenza	2 hours	"
Acute parenchymatous nephritis	1 hour	"

CONCLUSIONS.

1. It is possible for the thermometer to be laden with the usual flora of the oral cavity.
2. Such bacteria may retain their capability of growth for an indefinite time, at least 2 months, as shown by the above experiments.
3. Many pathogenic bacteria possess similar capabilities, and it is not unreasonable to assume, although the above experiments are not conclusive upon this point, that transmission of bacterial disease by the thermometer is possible.
4. Thermometers are easily disinfected.
5. Where possible each patient should be possessed of a thermometer, as much his own property, and as sacred to his own use as his toothbrush.
6. Where for reasons of economy or otherwise it is impossible to carry out the recommendations expressed

in conclusion 5, the thermometer should be disinfected before and after using.

7. The custom now prevalent in the hospitals of keeping thermometers in disinfecting solutions is to be commended.

ATYPICAL PNEUMONIA AND PULMONARY TUBERCULOSIS.

BY

W. H. BERGTOLD, M.D.,

of Denver, Colo.

Current medical science and effort can aspire to nothing higher than the endeavor to lessen and eradicate tuberculosis; there are many factors in this aim, as the profession works at it today, worthy of our unceasing attention. Everything done to enlighten the public as to methods insuring better personal and communal hygiene, and tending to make clear the dangers of tuberculosis, is to be encouraged and assisted. On our side we must not forget to remind each other that as we desire the public's cooperation in such an all-important matter, we owe to it our best endeavors to strengthen our efforts and perfect the methods used in hastening suppression of the disease.

One of the chief aims in the struggle against tuberculosis is to make an *early diagnosis*; *ceteris paribus*, the sooner a case of tuberculosis is detected the better are the patient's chances of recovery, and the earlier can he be taught to conduct himself so as to be of the least danger to himself and the community. It is therefore one of the first duties of the medical man to improve constantly every method and to systematize all knowledge leading to an early diagnosis of pulmonary tuberculosis; and it follows that anything bearing on the early diagnosis of this disease, or leading to a suspicion of its presence, is timely and important.

A certain symptom-complex gradually impresses us as a given disease, to which we apply a name. No two cases of any disease have ever been exactly alike, and we do not expect any given cases of the same malady to agree with other in all details; often the conventional limits of a disease-picture are not fully realized, and we say that such a case is not typical, or that we are dealing with one of two diseases, similar superficially, but essentially different. It is of great moment, at times, to be positive as to which one of two diseases is present, not only because of treatment, but also upon account of the needs of prognosis and quarantine. Thus, while it makes a great deal of difference in the treatment and general management whether a given case be streptococcus or diphtheric angina, it also makes an important difference, both as regards treatment and prognosis, whether a case be true croupous pneumonia or acute pneumonic tuberculosis.

Croupous pneumonia, of all acute diseases, in a large proportion of the cases, follows closely a pretty clear type; but is at times subject to variations, having unusual onset, course, and termination, though these forms are certainly in the minority.

Is there any reason why we should be more than usually watchful of an atypical case of what seems croupous pneumonia? Any cursory study of a considerable number of histories covering cases of pulmonary tuberculosis would lead us to answer in the affirmative. By atypical pneumonia I mean an inflammation of the lungs simulating croupous pneumonia but lacking one or more of the latter's cardinal features, and especially showing anomalies of duration, temperature curve and termination. Many cases of tuberculosis have croupous pneumonia as a terminal infection; on the other hand there is plenty of evidence to prove that many cases

beginning apparently as croupous pneumonia, later on show patent indications of pulmonary tuberculosis, and succumb to it.

In studying my cases of pulmonary tuberculosis I have taken particular care to secure facts relative to the possibility of previous pneumonias, together with full details concerning the true character of the attack as evidenced by symptoms, course, etc. In one series of 193 cases of pulmonary tuberculosis, 26, or 13%, gave a history of previous "so-called" pneumonia, (or pneumonias), all of suspicious type, varying from one showing no signs or symptoms of croupous pneumonia except fever and consolidation, to others atypical only in one or two ways, *i. e.*, altogether without expectoration, or long continued with no crisis.

Croupous pneumonia is the most common of acute diseases, and in fact seems to stand next in frequency to tuberculosis; the ratio of deaths of tuberculosis as against pneumonia being as 100 to 76, according to the U. S. Census Report of 1890. It is probable that this large death-rate in pneumonia stands for only about 25% of those attacked, showing enormous frequency of the disease in this country alone; but we must also bear in mind that there are probably thousands of deaths reported as pneumonia, where the diagnosis was vague, and that among them are probably a variety of lung inflammations not all croupous.

If 13% of cases of pulmonary tuberculosis show previous pneumonias, all more or less closely related to the onset of the tuberculosis, it is reasonable to suspect that many cases of croupous pneumonia end in pulmonary tuberculosis. Nevertheless Osler says, "Ordinary fibrinous pneumonia never terminates in tuberculosis." In this apparent contradiction lies the point of these remarks. It indicates a discrepancy somewhere: either the assumed infrequency of croupous pneumonia terminating in tuberculosis, or the observation that 13% of my tuberculous cases show in their histories previous pneumonias, or the diagnosis of antecedent pneumonia, is incorrect. I believe that the so-called pneumonias were mostly incorrectly diagnosed, and that these acute attacks were, in fact, acute onsets or outbreaks of previously existing pulmonary tuberculosis. Long after all indications of a true croupous pneumonia should have ceased, these cases, through this error, remained with the true nature of the cough undetected; meanwhile the persistent cough continues, the patient is unknowingly a disseminating focus of tuberculosis, and remains so until attention is compelled to the true malady by more obvious signs; moreover, valuable time is lost, marked physical deterioration may ensue, and the chances of an early arrest, with minimum damage to the lungs, grow less and less.

If I read these facts aright, they seem to point out but one duty—that whenever we see a case of what is apparently croupous pneumonia, very atypical in onset or course, or having subsequent persistent cough, it behooves us to bring to our aid as early as possible every diagnostic method to detect or exclude the presence of tuberculosis. It is common for tuberculosis to announce itself by an onset superficially simulating croupous pneumonia. The following cases will illustrate:

J. G., aged 28, family history clear, except that father, still living, had been alcoholic, and a brother had died a year previously of pulmonary and laryngeal tuberculosis. He had always been well up to the date of present illness, which came on with a chill, sharp pain in the side, shortness of breath, high fever, and signs of consolidation of the left lower lobe in its upper portion; there was a slight mucopurulent expectoration from the beginning.

Careful questioning elicited the fact that the expectation had been present for nearly 6 months before the illness, which together with the family history, and the anomalous expectoration, cast suspicion upon the apparent nature of the malady. An immediate examination of the sputum showed many tubercle bacilli, proving

that we had to deal with tuberculosis and not with true croupous pneumonia of an atypical character.

My experience leads me to believe that there are many such cases occurring every day, being diagnosed pneumonia, and recognized as tuberculosis only when the malady declares itself so plainly that even a layman could determine its presence.

Though it is probably true that few cases of croupous pneumonia culminate in tuberculosis, still we must not forget that it is possible to have a mixed infection, wherein the pneumococcus may cause a goodly share of the first changes, and the tubercle bacillus bring in its characteristic effects later.

During the past year the following case, illustrating the above-mentioned fact, came under observation:

S., aged 36, always well up to 1899; from 1896 to 1899 worked unduly hard, doing much traveling with little rest. In 1899 he had an attack of croupous pneumonia which was atypical in that there was no chill, no side pain, and no rusty expectoration. In the slightly tenacious mucous expectorations pneumococci were found; the expectoration persisted after convalescence was well established, and tubercle bacilli were found in it 3 weeks after the pneumonia had ceased.

It is quite possible that this case may have been one of tuberculosis engrafted on a resolving pneumonia as a secondary infection; but I believe that so rapid an infection must be exceedingly rare. In my histories, one record says, among other things:

March, 1899, had an atypical pneumonia in Pueblo, Colorado. This man was, when I first saw him nearly a year thereafter, the picture of health, weighing 196 pounds; yet notwithstanding, had a tuberculous infiltration in the right lung, with slight softening, and tubercle bacilli in the sputum. One suspicious fact about his history, which should be most carefully considered, was that during the 3 years previous to 1899, he had been more or less constantly with, and caring for, his wife, who had pulmonary tuberculosis. No attention was paid to his slight, persistent cough and the expectoration that continued after the pneumonia, until some months later, when its failure to disappear resulted in an examination for tubercle bacilli with a positive result. I take it that the primary attack was a tuberculous bronchopneumonia, the true nature of which, and the subsequent cough, should have been recognized earlier.

In many cases encountered during the past 3 years, during which time I have given this topic most careful attention, I have observed tuberculosis develop in the same lobe in which there had been a previous attack (in some cases attacks) of pneumonia; this is more than a coincidence, as careful inquiry showed such pneumonia-like seizures to have been atypical. These facts, it seems to the writer, warrant the conviction that under such circumstances we had to deal with the histories, not of true croupous pneumonia, but of tuberculosis, having an acute, severe onset.

This is, perhaps, all well known; nevertheless, every one of the cases under consideration, was not correctly diagnosed until a considerable time had elapsed, some remaining unrecognized as tuberculous even for several months. It is not the purpose of this paper to dwell on differential diagnosis between croupous pneumonia and pulmonary tuberculosis, nor on the self-evident need of accuracy in nomenclature; it is desired rather to emphasize this point: *Be suspicious of an atypical pneumonia.* Let it be understood that I by no means consider all cases of unusual pneumonia to be tuberculous, but I do believe that every such case should be suspected and put under surveillance until proved not tuberculous. It is my belief that a large percentage of cases of atypical pneumonia would prove tuberculous, exhibiting the tuberculous deposit in the same area previously attacked by pneumonia, if watched beyond convalescence.

Happily we have today sufficient diagnostic resources at our command to enable us to make an early, correct diagnosis in the class of cases under consideration. A careful blood-count at almost the onset might enable us to suspect the nature of a pneumonia-like attack, possibly even at once excluding completely a croupous pneumonia; moreover, we should always examine for

pneumococci or tubercle bacilli, and later on, if need be, give a diagnostic injection of tuberculin, as in the early stages we may fail to find any characteristic organism in the sputa. We must concern ourselves also with the previous history of a case; if it shows a tuberculous tendency in the family, or evident channel of infection, and if there is an atypical pneumonia, the case should be watched with especial care. We must also not forget the intrinsic tendency of pulmonary tuberculosis to heal, or be kept in abeyance, even under very unfavorable circumstances, by a strong reactive tendency in certain individuals; such a one may have a so-called pneumonia, and have had a slight cough preceding it for several weeks or months, with perhaps a slight hemoptysis, and recover, remaining unrecognized as a case of tuberculosis.

Further and more amplified examination of clinical histories and literature would show a larger percentage of patients having had atypical pneumonia previous to tuberculosis, than is indicated by my percentage. Let it be understood that all these 26 cases remained undiagnosed as tuberculous for a considerable period after the acute pneumonic attack; 7 gave a history of more or less persistent cough for varying periods before the pneumonia, for in 1 case 8 years; 17 had marked cough remaining after the pneumonia, with mucopurulent expectoration; 7 developed the tuberculous deposit in the same lobe that had been previously solidified by an atypical pneumonia; 4 had repeated attacks of pneumonias, at intervals, all distinctly atypical in history and course; 8 had unusually severe pleurisies with the pneumonias. Surely such histories carry an ominous stamp from the onset.

With our present numerous and advanced methods of diagnosis, including examination of the blood and of the sputum for tubercle bacilli and pneumococci, the biologic and tuberculin tests, and the ordinary methods of chest examination, there is indeed little excuse for allowing similar cases to go many weeks, even days, unrecognized.

ELECTROLYSIS IN DISEASES OF THE SKIN.

BY

F. E. WISECUP, M.D.,

of Cincinnati, O.

In my cases I prefer the wet galvanic battery. A constant current is necessary. The current being made we have alkalies liberated at positive pole while at negative acid forms. At the negative pole we see bubbles of hydrogen gas forming caused by the potassium and sodium set free uniting with the oxygen causing the decomposition of water in the tissue. The same chemical action produces caustic soda and potash, and thus destroys animal tissue, as if applied in the usual way. At the positive pole the tissue becomes oxidized and charred by the oxygen and chlorine which is produced. If a steel needle is used on positive pole it will become oxidized. The results obtained are far more satisfactory when the needle is used on negative pole. When the needle is attached to negative pole the destruction or dissolution is immediate, the needle remains clear and is easily withdrawn; while with the needle on the positive pole a dark center is formed, the puncture remains hard, and the needle has a tendency to stick and become oxidized.

The more simple in construction the battery the better. A constant current, and sufficient knowledge to use the proper amount must be gained by experience. The milliamperemeter is used by a great many, but with a proper amount of experience I believe one can do the work as well without it. I depend entirely upon observing the formation of hydrogen gas around the needle, thus indicating sufficient destruction. As to the num-

ber of cells to be used, or the time to leave a needle inserted in the hair follicle, there is no rule that can be invariably relied upon. Each individual differs, some being good conductors, and others bad. Atmospheric conditions make a difference also. A thin, moist skin is a good conductor, while a dry, thick skin conducts very poorly. The amount of current used cannot be uniform. I have frequently removed a hair with 4 cells, leaving the needle inserted in the hair follicle half a minute before destruction was sufficient, while with the next hair it was necessary to remove the needle almost instantly. A hair requires a certain degree of destruction, regardless of the time required or the current used. Therefore, the milliamperemeter is of but little value. A very good rule to follow is to insert the needle about $\frac{1}{4}$ inch into the average hair follicle, but a much less distance for smaller hairs. Aim to have the point come in contact with the hair bulb. One may tell when the needle reaches the hair bulb by the slight resistance met. A puncture of the sheath of the hair follicle will be recognized by a slight jerk as the needle passes through the mesh of the subcutaneous tissue. Leave the needle inserted until the white froth bubbles from around it, but there is great danger in leaving a needle inserted too long. When a scar forms a small scar follows, and when hairs are closely situated, a large scar will sometimes be the result; this may be avoided by using a straight steel needle. Never use one with a bulbous point, as it is not only painful to insert, but in order to destroy the papilla, one must use a stronger current. The neck of the needle being smallest at the surface we have our strongest current here. Consequently the greater destruction is at the surface instead of at the root of the hair. Use a perfectly straight needle, and as small as possible. The end must be blunt, not sharp, thus rendering it less liable to puncture the sheath. I prefer jewelers' brooches, Nos. 3 to 7.

Most physicians who do this special work recommend the use of the sponge electrode, but I am unable to get a uniform current by this method. The operation being painful, the moment a stinging sensation begins the patient grasps the sponge harder, producing a stronger current. I always place a small bowl of water in the patient's lap, place one end of the conducting cord attached to the positive pole into the bowl, and allow the patient to dip 2 or 3 fingers of one hand into the water, thus making the circuit. To lessen the pain I have the patient remove the fingers from the water while inserting or removing the needle; destruction having been sufficient, I remove the hair with epilating forceps.

When hairs are extremely large, I reinsert the needle, that I may be absolutely sure of the destruction. I remove about 250 hairs in 1 hour, and have worked 6 hours in a day upon one patient without the slightest skin injury. The operation produces slight redness, which disappears in a day or two. I always dip the needle before using in a carbolic solution and bathe the parts with an antiseptic solution, and when the work is completed apply zinc oxide or a preparation of cold cream. I have never met any complication directly due to the operation, nor have I ever produced scars. Superfluous hairs can be permanently eradicated, but the operation being tedious, it requires great endurance on the part of the patient. It is absolutely impossible to remove the hairs permanently with one insertion, as a small number of hairs will return, usually 10% to 15%, depending entirely upon the ability of the operator. A number of fine hairs will develop after the removal of the coarser ones. This is not due to stimulation produced by removing the coarser ones, but these are hairs which have not yet reached their normal size, and they will grow regardless of treatment. The most satisfactory patients are women past middle life when all lanugo hairs have developed; in young women it may be years before the development is complete.

All forms of nevus may be successfully treated by electrolysis. The common birthmark or "port wine mark" is the most unsatisfactory under this head. In treatment, first observe the small capillaries by stretching the skin tightly, then a small needle attached to the negative pole is passed into each capillary, following its course so far as possible, allowing the needle to remain until destruction has been sufficient. Repeat the operation in the above manner endeavoring to destroy the vascular supply. The result, though tardy, will be very satisfactory, and very little, if any, scarring will result if one is careful. If it should be impossible to follow each capillary, then insert the needle at an angle into the meshwork of fine capillaries. Make a series of punctures, not too close together and in parallel lines across the mark. With each puncture the needle should go into the subcutaneous tissue. Great care must be taken not to produce a great, white scar.

Moles are destroyed by passing a small needle through the base in several directions. A strong current is required, however, and the mole should be almost cut away by the needle. One operation is sufficient in such cases. A scab will form and should not be removed, but let fall off of its own accord. In most cases no scar will result, but should one form it would be very insignificant and scarcely noticeable. Hairs should be removed several days before attempting removal of a nevus. In removing the hairs the nevus is frequently reduced and in some cases entirely removed.

Cavernous nevus, when not too large, can be cured by electrolysis. In this operation a small needle must be passed through and beneath the growth, making several passes parallel. Then repeat it in the opposite direction, or you may radiate the needle from the one point of entrance. No hemorrhage will result and the operation may be but a short one.

Dilated vessels can be destroyed by passing a No. 3 or No. 5 needle perpendicularly into the vessel. As the destruction takes place small bubbles of gas can be seen coursing in all directions. It may be necessary to repeat the operation. A current of from 4 to 6 cells is necessary.

Cicatricial scar tissue can by this treatment be successfully removed also. I use the No. 3 needle, with just enough current to produce a stimulating effect; puncture the scar, allowing the needle to penetrate the subcutaneous tissue; leave the needle inserted a few seconds and then make the punctures very close together, covering the entire surface. In about 3 days, at the seat of each puncture a small branny scale will form: These are removed and the operation repeated. The cicatricial tissue will grow thinner after each operation and a pinkish hue appear. Not only does this operation apply to scar tissue, but the unsightly skin graft, with its shiny, white surface, improves. In the removal of fibroma, warts and fibrous nevi I use a flat needle or knife, sharpened on either side, tapering gradually to a very fine point. I push it through the growth in several directions, cutting it almost entirely off. A minute white scar can be substituted for powder marks or tattoo-marks by passing a small needle into the discoloration, as in removing superfluous hairs. Gradually the discoloration disappears, leaving a shiny white spot which is hardly perceptible. The cicatricial tissue can be afterwards treated in the manner described, leaving a pinkish surface.

Xanthoma readily succumbs to electrolysis by simply passing the flat needle through, and gently pressing it to either side, or, if unusually large, by making several punctures in opposite directions, each puncture requiring about a half-minute.

Enlarged pores, commonly called blackheads, are treated by inserting a small needle into them, and rotating it around and around to destroy the walls; healing causes the gland to close entirely. A minute white scar will sometimes result, but often no trace whatever is perceptible.

SPECIAL ARTICLE

THE NERVOUS EXHAUSTION DUE TO WEST POINT TRAINING.

BY

DR. CHARLES E. WOODRUFF,

of Fort Riley, Kansas.

Surgeon, United States Army.

In about three-fourths of the Congressional districts, selections to West Point cadetships are made by competitive examinations; generally there are a large number of competitors, and the successful candidates must be very able and well trained in their studies. Every year there are thus sent to the academy a very intelligent set of men, the pick of the United States. It is reasonable to expect that a large proportion of them should become famous or at least men of some note and success in life. The fact is the very reverse occurs, for it seems as though the best way to extinguish a man is to send him to West Point. Of the hundreds of able men admitted, so few are ever heard of again that civilians constantly ask, "What becomes of all these picked men if they are the choice of the United States?" "What is it the academy does to them to snuff out their abilities or keep their lights under a bushel?" Of those who enter the academy about one-half graduate, so that the weeding out should leave a remarkably picked set of men who should accomplish much in their life-work.

We must assume that the methods of selection really secure brainy men, but we can positively deny that such examinations secure the best, for it is a fact that intellectual traits like quickness and memory, by means of which boys compete in their studies, are not those upon which success in life depends. The real basis for success is mental energy combined with a good balance of faculties resulting in correct judgments. Great men not infrequently are noted as having been poor students at college. The quickness and brightness so necessary at West Point are really undesirable qualities, for they are apt to make the mind act too quickly for correct reasoning, and they are the leading characteristics of a large class of men who have little staying powers. The nerve-tissue is flabby, easily fatigued, and wears out in a few years. Some of these men are wonderfully brilliant and capable of considerable mental effort, but only for a few years. Finally, quickness and brilliancy may exist in degenerate minds of a very low order, and boys of this class can enter the academy, but they never stay long. So we are perfectly justified in denying that the candidates are all of the proper material for success in life, though we cannot deny their generally high average of ability. Many graduates of West Point have occupied the highest positions, have proved to be great men and have reflected great honor on their school. They have been great leaders in statesmanship, business, war, art and literature, and the roll of honor is a long one, of which every graduate is justly proud. The point in question is that the roll of prominent names shows too small a percentage. Did the present methods secure the best men, the Engineer Corps, receiving only the cadets of the highest standing, should have at least 90% of noted men. Edward Everett Hale said: "If you should take 12 prize medal men from Harvard and put them in a sinking ship they would all drown through inability to construct a raft." They are mental sponges capable of great absorption but not able to produce. They are generally outstripped by others, as in the famous Yale class of 1837.

Educators give many reasons for the alleged poor results of West Point training. Among others may be mentioned the fact that military students do not work voluntarily, but are forced to it to secure the prized com-

mission in the army. They cannot do otherwise than consider the curriculum a necessary evil when they see those who fail at the academy and who through political influence secure civil appointments to the army, subsequently succeed in their profession as well as graduates. In civil schools the student wants the course of instruction by means of which he is to succeed in life.

It is an error to rate scholarship as military ability. Some successful military leaders have been noted for their ignorance of general topics and hatred of books. Nevertheless it takes so much study to master the details of military science that the majority of its great professors have, like Napoleon and von Moltke, been hard students.

In the late war there was a remarkable absence of West Pointers among the ranking officers, but in this there is no reflection on the academy, as it was due to an unavoidable circumstance. After the civil war a large number of young volunteers who had the requisite influence were given commissions in the army, as there were not enough graduates for more than a small number of the vacancies. These volunteers had by gradual promotion just reached the upper grades, so that nearly all the field officers and the higher officers in the staff were of this class. West Pointers who graduated after 1865 were therefore in subordinate positions.

The training of the cadet in subordination and obedience must also be taken into account, for this dwarfs and even stifles the mental faculties needed in aggressive initiative. Great military leaders, full of energy and new ideas, are, as a rule, undisciplined and insubordinate in the lower grades. Too much training in blind obedience unfits for independent command and excellent subordinates are apt to become moral cowards when thrown on their resources. West Pointers explain that their training fits them only for subordinate positions where, as good soldiers, they should have no ideas beyond the intelligent execution of orders. This is why civilians and outsiders, who have never been subjected to the mentally destructive effects of discipline, occasionally spring to the front and take the lead where well-trained soldiers fail.

There are two other reasons for the absence of expected achievements on the part of West Point graduates. In the first place, promotion falls to those who live longest, whether they are fit for higher duties or not. There is no incentive to work, and neither civilian nor military officer will work unless he can secure the rewards of work. In the second place, men with new ideas who suggest changes in existing things, are quite apt to be insubordinate and sooner or later get into trouble. They may be considered even pestiferous and it takes them but a short time to learn that they are more comfortable if they make no suggestions.

A critical review of the methods of study and of the life of the cadet, leaves no doubt in the mind of the physician skilled in such matters, that many of the failures we have mentioned are due to nervous exhaustion caused by the unwholesome high pressure of their four years of toil. This matter of school routine has occupied the attention of physicians and educators for many years, and the discussions have crystallized the opinion that former methods have been of great harm, and that modern schools must ease up the strain on the delicate nervous system in childhood and youth. A few years ago, Dr. E. Stuver, of Fort Collins, Col., addressed queries to many physicians and educators, and his paper is a basis for argument for it gives the opinions of practical educators who see the harm done and of practical physicians who are called upon to treat the minds and nerves wrecked by the teachers.

The nervous system of a child is an exceedingly delicate mechanism which is easily disordered. He requires wholesome, easily digested food, plenty of fresh air and sunshine, frequent opportunities for unrestrained exercise, frequent periods of relaxation for rest, frequent

changes in work and plenty of sleep. It is known that the nervous system retains its infantile traits until the twenty-fifth year, at which time we are accustomed to call it stable. West Point cadets are all under the age of stability and the rules governing the training of young children apply to them with equal force, though of course in modified form. It is safe to apply to West Point the consensus of opinion of educators in the lower grades to determine the faults of that system.

The answers to Dr. Stuver's questions brought out at the very start the different points of view of the two classes of men—the teachers who do the damage and the physicians who recognize it. To the question, "Do you think our comprehensive course of study is best calculated to develop the highest physical and intellectual powers of the child?" 29 educators said no, 18 were doubtful, and 15 said yes, but of the 35 physicians who answered, 32 said no, only 1 was doubtful, and but 2 said yes. We will probably find the same differences of opinion between line officers and surgeons as to the damage done by the West Point course.

In the answers to Dr. Stuver's questions there were differences of opinion as to the proper length of time which could be safely devoted to any one recitation, but the tendency was to limit them to 10 or 20 minutes in the primary grades and to 20 or 30 minutes in the grammar grades, teachers varying greatly in their ability to interest the scholars and postpone fatigue. When a child tires it is time to stop, for further effort only injures the brain, as it is accomplished at greater expenditure of force and the impressions are very evanescent. For West Point, therefore, the extreme limit of safety is 1 hour, and the extra half hour is not only wasted but actually injurious, and they would accomplish more with half the recitations. To keep a child of 14 or less, 2 hours on a single recitation is said to be a heartless violation of all mental laws, and we can assert the same of the long recitations at West Point. In addition, the cadet, when through his work at the blackboard, must face about and stand at the military attitude of "attention," which is such an unwholesome strain that they now and then feel faint and have been known to go to hospitals as a result of this exhaustion.

The child's normal nervous force must have an outlet in motion. When this restlessness was considered wickedness, repression was resorted to and the destruction of the minds of children was not uncommon. There is still much unwholesome restraint, and one has only to watch children as they are dismissed from school to be convinced of the pressure they have been under, for they all seem to explode as soon as they are outdoors, running, screaming, tumbling, and going through their various antics. It is now known that they cannot keep quiet without an effort of the will, which is extremely exhausting, and that unrelieved nerve-pressure causes considerable destruction of nerve-tissue. Hence, in answer to the question as to how often there should be recesses or periods of relaxation, the majority said every hour, one saying every 45 minutes. It is a matter of experience that more work is done with less fatigue, if there is an opportunity every hour for the students to blow off surplus steam by unrestrained childish motion, and the more noise they make the greater the apparent relief. "Children must have their halters taken off, the bars let down, and be turned loose like young colts."

There is a partial compensation at West Point, in that the recitations alternate with periods of study in the rooms. Here there is a relaxation from the rigid attitude of attention of the class-room and the restraints of the instructor's presence, but there is still confinement, necessity of quiet, and a repression which are just as wearing in the long run. Except for a half hour after each meal and a trifle longer on Sundays, the cadet is constantly under an unwholesome, unscientific and exhausting restraint.

Calisthenics and drills require an effort of the will

and increase exhaustion instead of relieving it. Teachers and physicians alike recommend frequent relaxation in the open air free of all restraints. What a mistake, it is, then, to consider the daily rigid military drills of the cadet a wholesome exercise for boys whose will power has already been strained beyond the safety point. As a daily drill is necessary, it should be considered work, for which there should be periods of relaxation to compensate.

In all colleges there are explosions of nerve force in which the students seem to go "off the handle." They are normal, natural, noisy ways of "blowing off steam," and have more to do with keeping the students healthy than any other college habit. These outbreaks have been notably lessened by the introduction of gymnasiums and athletic sports, normal, voluntary and unrestrained methods of relieving nervous tension. All these reliefs are reduced to an unwholesome minimum at West Point and the repression has the result of more exhaustion. It can be denied that the frolic needed in the cadet life will destroy discipline, for it would be just as absurd to claim that the screaming, yelling, howling mob of school children at recess is ruining the public school discipline. The wholesome taste for sport is so starved in the cadet that his mania for extracting fun out of everything is really piteous.

The unwholesome nervous strain of cadet life, with its violation of mental laws, is very ably stated by Lieutenant W. E. Ellis, Fourth U. S. Artillery, in a recent article written in praise of the school. "The amount of work performed by the cadet is prodigious. Scarcely a moment is wasted. Under the rigorous discipline, which taxes mental and physical capacity to the utmost for six days in every week, with only a slight loosening up on the seventh, the West Point cadet is always, barring accident, in perfect physical condition. Many a baseball victory has been won with hardly an hour's preliminary practice during the week, and preparation for the most terrific football struggle has been confined to an occasional hour under the electric light in the riding hall, in addition to brief practice on the plain before breakfast and after drill. From 5.30 in the morning throughout summer, and from 6 in winter, during the whole 4 years' course, with only a single vacation midway in the course, the unceasing work goes on, until taps sound at 10 in the evening. To illustrate, the astronomical course to which most colleges devote a year's study is covered at West Point in 2½ months, and it is done thoroughly, too, as is proven by the rigid examinations which every cadet must pass to maintain his position in the class."

As "training" is unnatural, exhausting and harmful in many ways, and is the principal factor in shortening the lives of professional athletes, who by the way are notoriously shortlived, we can appreciate the harm done to the cadet by this system. It is surprising to what extremes of unwholesome existence a healthy boy may be subjected without killing him. It is on this account and also by reason of the exceptionally good physique of the cadet at the start, that the damage is hidden. Strains which break the adult only bend the youth.

The above quotation shows that the educational system is one of intense cramming, for the whole course covers 3 times as much ground as any brain can healthfully absorb. In addition the cadets become expert in memorizing for short periods. They can read over certain lessons so intently that they can recite them if asked within an hour, but so soon as they leave the class room, they feel the knowledge oozing out and by the next day have forgotten much of it. The length of the daily lessons is so inordinate that no human brain can learn them properly in the required time. This method of using a superficial memory is the best the cadet can do, and it is vicious in every respect.

Of many schools it is said, "Unfortunately, under our cramming, high-pressure methods of education, with the

frequent examinations and grand-stand plays for public show and approval, children are spurred on and incited to cram and memorize, regardless of the permanent effects of such a course. This sort of work keeps the child in a constant state of worry, anxiety and excitement; the brain is irritated, the vitality lowered and the mind weakened. Under such a system even the brightest and best pupils will lie awake nights and worry over their grades, their examinations and promotions, when never a thought of care on such matters should disturb them."

Graduates of West Point have told me that while at the Academy their nights brought distressing nightmares more often than absolute oblivion. They seemed to have problems floating before them, and they struggled in dreams with work. This means that the overexcited brain-cells refuse to quiet down and that the bloodvessels are still dilated instead of being contracted as in normal sleep, and though parts of the brain may sleep other parts are just as active as when the cadet is awake. No wonder then that they sometimes get up in an exhausted condition as when they retired.

The question of the amount of sleep is an important one, for brain nutrition takes place during this time. Deprivation of sleep is far more destructive of brain tissue than is starvation. At the age of 16, there should be 8½ hours' sleep for mechanics, but brainworkers must have at least 10 hours. These periods are lessened as we grow older, so that at 24 years of age the minimum is 7¼ hours and the maximum 9¼. Taking an average of all these ages we can affirm without fear of contradiction that the cadet should have 9 hours' sleep, and that some of them should have 10. Yet according to the regulations it is impossible for them to get more than 8 in winter and 7½ in summer. Cadets, no matter how exhausted, are not allowed to go to bed until after the evening study hours, a barbarous custom which compels many of them to sleep in their chairs on occasions when they are too exhausted to study at night.

Some students drink large quantities of coffee to keep them awake. They are spurring on by this stimulant a tired nervous system at the very time the opposite class of drugs is imperatively needed. Sedatives must be used to contract the dilated bloodvessels and to quiet and soothe the irritated nerve-cells into recuperative sleep. It would be a good plan to keep these useless stimulants from the cadet supper-table, and indeed, as such drugs may be very harmful if used in excess before the age of stability, there is scientific reason for keeping them even from the breakfast table. Very little coffee is allowed the German cadet.

It is known that mental energy decreases from the moment of awakening and that the machine seems to run down about the middle of the afternoon, and this is the reason for the siesta of middle life and old age. After a short sleep or "nooning" there is a rise of energy. "Mental work is injurious after dinner," so the greatest damage at West Point probably takes place in the afternoons, when the sufferings of the cadets in their efforts to keep awake are sometimes acute. The Germans are much more humane, for their cadets have a 2 o'clock dinner, after which they are free until 4.30.

It is stated that "nature will not permit a forced brain to sleep;" therefore nightwork is more harmful than any other, for a considerable interval should elapse between study-hour and bedtime, to allow the dilated bloodvessels to contract and the excited brain-cells to quiet down. In certain schools for boys, where night study-hours were abolished, it was found that the boys slept better and somnambulism ceased. The quality of nightwork is also very poor. The majority of errors made by bank clerks are in the afternoons, and it is found to be an economy to shorten the afternoon work. Experiments in California have been so decisive that home work by the public school pupils is to be abolished by law.

The exact amount of work which a growing brain

can do before it becomes exhausted, varies with age and the personal equation. "Sir Edwin Chadwick, from a large number of observations extending over 50 years, came to the conclusion that the limit of effective class teaching was inside of 3 hours, and furthermore, that those children who attended school ¾ of the day, and worked at some manual occupation the balance of the time—the half-timers, as they are called—acquired a superior mental activity and outstripped those who devoted their whole time to the regular course of study." Dr. Clement Dukes, physician to Rugby School, estimates the maximum hours of mental work per week which can profitably be expected from a growing brain, as 6 hours at 5 or 6 years of age, gradually increasing to 40 hours at 16 or 17, 45 at 17 to 18, and 50 at 18 or 19. For the West Point cadet an average of 52 hours per week is a very low estimate, and a majority of them put in between 60 and 65 hours, exclusive of the 20 hours or more in which the nervous system is on a strain at rigid drills and other formations. Dr. Duke says that such overstrain results in arrested progress and even in retrogression, "in weakened brain, body and interest," and that the growing brain is actually checked in growth. Many a cadet finds to his dismay that the pace is too rapid, and the academy thus yearly turns out as failures some of its very best material. How much more scientific and sensible is the slower German method in which the cadet's recitations cease at 1 p. m., and where there is freedom from all work after the 2 p. m. dinner until 4.30, after which the drills, a light lunch at 5 and a heavier supper later take up much of the time until the 9.30 bed-hour.

Another cause of exhausting strain is the dread of failure, due to the feeling that there is a special disgrace in this failure. Hundreds of successful civilians would not hide their West Point failure if they knew that the best men are sometimes rejected. The Sandhurst cadet is not nagged thus, for he is not dismissed until he fails twice in the examinations. The dread of hazing also causes as much, if not more, exhaustion than the actual hazing itself, which usually consists of the pranks boys play upon one another the world over.

A brain used to its utmost 8 hours a day should have a half-holiday twice a week, or a complete change all day long once a week, an extra change every 2 months, and every 6 months a long rest of several weeks. No such ideal being possible at West Point, it is necessary to relax the deadening and exhausting monotony. A British cadet gets 16 weeks' holiday in his course of 18 months; the West Pointer gets 16 weeks in 48 months.

Variety in the work is of as much importance as frequent interruptions, for sameness soon palls and then work can be accomplished only at greater expense. Distasteful work is still worse and the modern educator makes it his business to render work pleasant. The conditions at West Point are unfavorable for such modern ideas, for no one cares whether the cadet is pleased or not. If he fails he goes home and there are hundreds waiting to take his place. In civil schools, where the income depends upon the success in teaching, the aim is to get as good results as the material permits, and but few fail.

Now let us consider the known results of the unwholesome high pressure at West Point to prove that it is one of the causes for the extinction of many a graduate. We have already mentioned the difficulty of keeping awake in the evening as one of the symptoms of exhaustion. During afternoon recitations it is generally a struggle for the cadet is not actively occupied, and a dry lecture of a half hour will put most of them to sleep. A student who can not keep awake during a dry lecture of 45 minutes is unfit for study and only damaged by the effort. At the end of the scholastic year those who go into camp literally spend the summer in sleep. Every spare hour is given to slumber and every afternoon will find all asleep who have no duties. Officers, ignorant of nerv-

ous diseases, do not appreciate this disgraceful state of affairs, for the least desire to sleep in daylight is not healthy and is actually repugnant to the healthy nervous system of youth. In the furlough at the end of 2 years the exhaustion is worse and instead of getting the much needed recreation the average cadet spends the time mostly in sleep. They may be said to average 12 to 15 hours in bed throughout the summer. After the 4 years matters are still worse, another furlough is spent in sleep and it is fully 2 years before the average cadet is rested up, and for many years a few need a siesta upon any unusual exertion. During the academic year not a few cadets are admitted to the hospital for no other reason than exhaustion. It is safe to say that upon graduation fully $\frac{1}{10}$ of the cadets are in a condition of profound exhaustion, mentally and physically, so severe indeed that some are unable to join their regiments for several months.

The academy is noted for its excellent discipline, a matter of great pride to its alumni; yet it is safe to say that unless the cadets were kept in this nervous torpor of partial exhaustion, the restraints would be wholly impossible. As a rule they are in a species of mental torpor at drills, going through the exercises in a purely automatic manner. As before mentioned there are remarkable "breaking out" experiences in all institutions for the young where there is restraint and monotony. In the deadly monotony of West Point there is not enough physical exercise to prevent these explosions, except on rare occasions, and this is proof that there is too much exhaustion of nerve-tissue to permit nerve-force to collect in its natural motor-channels. The average cadet finally sinks into a deplorable condition of mental apathy, with an ever-present fear of failure, closely resembling the first stages of melancholia. The longing to be freed of all restraints and never look into a book again, amounts almost to a mania. Not a few are so broken as to be identically the same as the cases of neurasthenia found after the fortieth year. In youth it is difficult for exertion to be so excessive that repair is wholly impossible, for the will-power is not strong enough. After a certain stage of fatigue, boys simply sleep with their eyes open, partly oblivious to their surroundings. The strong mature will-power may take a man to the breaking point. Yet I have had cases to treat among officers suffering severely from the dozens of symptoms due to the exhaustion of their training; and some scandals have been caused by men of this type.

It is exceedingly rare for a graduate to be able to do any mental work in the first year after graduation, a few can work after 2 or 4 years of rest, but the majority never regain their full mental powers. Few if any are uninjured. The defects of the sufferers are not noticed, for hard mental work is rarely required with the troops, the work being merely routine. I have known the exhaustion mistaken for laziness and the young officer begin his career with a bad reputation. As a rule, the graduates, who after a few years return to West Point as instructors, are completely exhausted by 2 hours' work in the class room. Dr. Duke calls attention to the premature exhaustion of forced brains, and says that "greater staying power and less training is better than excessive training with diminution of vigor."

A dreadful symptom in most graduates is the intense hatred of books—a bibliophobia so intense that the mere mention of study will raise loud protests. Cadets who on entering the school are enthusiastic students are completely weaned of the desires which all other schools seek to cultivate. Knowledge is of such enormous extent, that the students in civil schools are taught that their graduation is the beginning of their work, but the West Pointer looks upon his graduation as the end.

The condition of many graduates is best described as "burnt out" which is scientifically correct, for the oxidations due to exertion are not repaired. When we recol-

lect that mathematical labor causes a greater excretion of wastes than any other, we can appreciate the rapidity of the burning out in a course essentially mathematical. These studies are the chief culprits, for they take up more time than any other 2 or 3 combined. The waste of invaluable nerve tissue is inexcusable, because nine-tenths of the graduates never have use for more mathematics than what they knew before they became cadets. The course could be cut to one-third its present extent, indeed the St. Cyr cadet trained for infantry or cavalry has no mathematics whatever. A famous Professor of mathematics said to his class, before a course of lectures, "Gentlemen, to my mind, the most interesting thing about the subject is that I do not see how under any circumstances it can ever be put to any practical use." The same may be said of much of that at West Point.

In their exhausted state, the graduates are in proper condition to contract any infection. If they were as strong as they are supposed to be, so many of them would not fall victims of disease so soon after they go home. They are ripe for alcoholism, which is but a symptom of exhaustion, and a few succumb though nearly all recover before they have become chronics. None of them are fit for tropical service upon graduation for that climate causes increased exhaustion, a condition not appreciated by those who have never served there.

A writer has stated that "tradition and precedent are the 2 divinities of the military academy, hence it comes that while the world makes giant strides, the military academy is the same yesterday, today and forever." In its methods it is just one century behind the times. It was organized at a time when universities gave courses of instruction of which the modern high school would be ashamed. Its entrance-examination, fixed by law, is about what was needed for a first-class university at a time when there was no public school system. The present candidates, with few exceptions, must brush up in studies which they had dropped several years before. The faculty complain bitterly of the law and demand a higher standard, as at St. Cyr, so they might omit the more elementary studies of the first year or two. They would then introduce subjects taught at the service schools, institutions started by the way, to finish what West Point fails to do. The state of affairs would then be as bad as it is at present.

The real fault is a system which demands of the human brain 3 times as much as it can do. Instead of trying to crowd more into the course a new course is needed. The last century has seen such a tremendous advance in knowledge that one brain can not possibly absorb more than one little specialty of one profession, and universities now have 20 courses of study where one sufficed a century ago. Likewise military science has grown far beyond the limit of a single brain, and modern armies are composed of specialists, none of whom can possibly learn all the duties of the others. In Europe this is all recognized and their military schools are technical institutions giving a training in the specialties of the science and art of war. We go on after the old method of trying to run all the specialists through the same mould, and the academy fails of being either a preparatory or a technical school along modern lines. Yale has already taken a modern step by reducing the course so that the students can obtain a degree in 3 years. Life is too short for the old methods.

It seems remarkable also to see officers rushed back to West Point as teachers when they have not the least idea of any of the laws of the science of pedagogy. Without training, it is as useless to expect them to do good teaching as to expect them to do good surgical work, and in addition the old system is perpetuated and its evil intensified. Some of the instructors are so ignorant of methods of teaching that they insist upon verbatim recitations, a method now considered a crime. These faults at conservative West Point are to be expected, for until a decade or so ago, but little time had been given to the

scientific study of the growing brain. Pedagogy is a new science, but its laws can not be applied to the academy too soon.

The academy has been of more importance than the people generally recognize, for its graduates have been the backbone of our armies in every crisis of our history and Washington knew that they would be. It is then intemperate to argue that it had better be abolished. Its enemies sometimes say that unless it can be remodeled on modern lines, it bids fair to do more harm than good, and that college graduates who have not been "burnt out" and mentally warped, have a better chance of becoming able leaders than the West Pointer too exhausted to take up advanced work. It must be sorrowfully confessed that the history of modern warfare gives some basis for such an opinion. All military science originates in Europe. America is a follower and never has been a leader, except for a short time. Europe does all this with inferior schools, which do not compare with West Point. All foreign visitors are enthusiastic in their praise of the American school. European officers do all this with an education essentially that of a high school, and their subsequent work is evidence that they are more able than Americans. The contrast is the more remarkable because in all other sciences, with a few minor exceptions, American invention leads the world. Indeed, American civilians who make military inventions, sometimes go abroad to have their ideas recognized and adopted. We demand of our cadets 3 times as much as any other nation in the world, Sandhurst and Woolwich cadets even leading "a life of luxurious ease compared with that of the West Pointer," and by this overpressure we defeat the very object desired—prolonged usefulness.

The friends of West Point, and every patriot should be its friend, should insist upon the uprooting of evils and modernizing its methods. The first step is to reduce the course to such a point that a fairly good brain can absorb it properly, and this can be done by eliminating the preliminary or elementary studies and the useless advanced ones. The entrance examination will have to cover more ground, and that can be safely done, as the public school system is now competent to prepare the candidates. The academy will then be a technical school and nothing else. All students could follow the same course for 2 years in such branches as are needed in every army position. They should then be commissioned as second lieutenants before they take up their specialties, a system adopted, so it is said, by Russia. This would be only a modification of what we sometimes do after the 4 years' course. There is even no objection to sending some of these 2-year men to medical schools, as they do in the German Army in a modified way. Ordnance, engineer, and artillery lieutenants could then be given 2 years of instruction which would be of no earthly use to the line lieutenants. The latter could be given a short course—say of 8 months—and then sent to their regiments. It has even been suggested to limit appointments to college graduates, but to give them as prizes for scholarship would bring a worse class of neurotics than the present method.

To commission cadets as second lieutenants after 2 years work would remove very much of the nervous strain of the present course, providing they had a good vacation each summer, and more holidays. It also would correct one of the most ridiculous conditions in our service. A soldier can obtain his commission after 2 years of easy work, but the cadet must wait 4 years and do a hundred times the work exacted of the soldier. No nation in the world makes it so easy for the soldier and at the same time so difficult for the cadet to enter the commissioned ranks. Very many other advantages would result from a reduced course, but they do not concern us here, though we might mention the increase in the number of graduates, a practical matter of much importance, now that the enlarged army calls for so

many more technically trained men than it ever has before. It would be quite practicable to send the infantry and cavalry graduates to their separate technical schools where they should be joined by the officers appointed from the ranks or civil life. By these means the capacity of the school would be doubled, its graduates as well educated as they are at present, and the scientific corps supplied with better men, and all the graduates would have greater staying powers than they now have. The best military schools in the world are those of Russia, for they are based upon modern scientific mental laws. Every means is taken to avoid mental and physical fatigue, and the methods of mental and physical culture are superb. Their great aim is to turn into the army, officers of great endurance. We do the very opposite at present, and we can afford to take a lesson from this great, virile, and newest of world powers.

The academy must abolish the mistaken system of rejecting the cadets, who, though very able, are not possessed of the unwholesome and abnormal qualities of quickness and brightness. It is stupid to argue that all of that half who cannot keep the pace would not make good officers—they are selected with too much care for such a supposition. These rejects, by the way, are better fitted for tropical service than the more neurotic who succeed at West Point. By retaining them and by the above system of shorter courses of study, the academy could supply 3 times the number of officers it now does, there would be no need for an increase in the cadet corps and Congressmen would make appointments every 2 years instead of every 4. Another reason for this increase in the output of graduates lies in the fact that 2 years is the extreme limit for tropical service, unless the officer does duty in a cool building and is never exposed to the climate by service in the field. Regiments which stay there longer than this limit will require surplus officers to take the place of those recuperating at home—a system used by foreign armies, much needed by us already, and one which we will have to adopt or the troops will be perpetually short of officers.

In European armies paresis was formerly called a military disease on account of its frequency among professional soldiers. The causes were undoubtedly the rapid pace at which they lived and the awful nervous strains of frequent warfare. Drunkenness has disappeared in great part from our service and field duty was not common until recently, so that paresis has not been common in America, but unfortunately its place has been taken by neurasthenia, which now ranks as a military disease and is probably more common than in brain-workers in civil life. It is the real cause for quite numerous retirements under other diagnosis. The causes are partly idleness and the nagging of military discipline, so intensely irritating in certain commands, as well as the strains of the cadet life. How important, then, it is for us to so manage our cadets that their nervous systems are strengthened to be able to stand this strain and develop great staying powers, even if they know less of the mathematics of wave motions.

The International Sunshine Society, which has for its object the rendering of aid to the shut-in and sick, has nearly 100 members in Baltimore.

Milk Depot.—A movement to establish a central milk depot in Atlanta, Ga., under the direct supervision of the Board of Health, is assuming definite shape.

New Hospital.—Work has begun on the hospital to be erected by the Franciscan Sisters at Louisville, Kentucky. The building will be built of brick and stone and will be 3 stories in height. The cost will \$50,000.

Sanitarium at Crab Orchard.—The Southeastern Kentucky Medical Association has purchased a tract of land at Crab Orchard, on which is located the celebrated chalybeate well, and, it is said, will shortly build a sanitarium there.

8. Note on the Value of Experiments in the Question of Food Preservatives. A. S. GRÜNBAUM.

1.—Briefly, devoting especial attention to Weismann's theory, Adami criticizes adversely many of this author's contentions, and he formulates a side-chain theory of structure somewhat akin to that laid down by Ehrlich in his now well known theory of the nature of immunity. This **side-chain theory of inheritance of acquired characteristics in man** is elaborated and attention is devoted seriatim to inheritance in unicellular forms, sexual conjugation and inheritance, inheritance in multicellular forms, and atavism. With reference to the question, Can acquired defects be transmitted? he considers the noninheritance of acquired mutilations, the indirect inheritance of acquired diathesis, and the direct inheritance of acquired constitutional states. [A.O.J.K.]

2.—Watson, writing of the **pathogenesis of tubercles and allied conditions in the cord**, holds that tubercles is not a "nervous" disease in the sense usually apprehended, and that the lesions in and around the vessels are of primary importance, the lesions of the neurons being determined by local interference with the blood-supply. This does not exclude the consideration of a varying vitality of neurons as an important factor in the disease. Further, he states that there is good ground for the belief that the condition is dependent on a chronic auto-intoxication, the vascular lesions being to some extent general, but tending to be more advanced locally, and that the more advanced local changes determine a failure of nutrition in the adjacent nerve elements. If these views are correct he believes that the condition ought to be curable in the early stages, and that the present tendency to differentiate tubercles sharply from many other diseases in which there is a well-marked lesion of the cord of an allied character is to be deprecated. He believes that we should rather investigate the nature of different toxins and the conditions that have brought about variations in the results of their action. [A.O.J.K.]

2.—Shaw reports a case of **sarcoma of the root of the left lung**, producing stenosis of the bronchus and vessels, and associated with pneumonia, probably due to the septic organisms present. The latter named condition much resembled tuberculosis macroscopically, but examination revealed only streptococci, staphylococci, and a few slender bacilli—no tubercle bacilli, giant cells, or tuberculous granuloma systems. Reference is made to a number of similar cases reported in the literature. [A.O.J.K.]

4.—Buzzard reports the sequel to a case of **pulmonary hypertrophic osteoarthropathy**, first reported by Walters in the *British Medical Journal*, February 8, 1896. The patient had serious disease of the lungs, with the expectation of considerable quantities of thick, purulent sputum, kyphosis, and paralysis of the legs. He died October 9, 1899. At the necropsy, among the interesting findings were extensive excavations of the lungs, one of the cavities being in direct communication with the space between the third and fourth dorsal vertebrae; absence of conclusive evidence of tuberculosis in the lungs and the bronchial glands; thickening of the ends of the radius and

the ulna, the increase in thickness affecting the dense bone more than the cancellous. The end of 1 finger being examined showed no appreciable alteration in the bones or joint; there was, however, an excess of fat in the pulpy end of the finger, whence its bulbous shape. [A.O.J.K.]

5.—Campbell, in a note on the **pulse-rate in pulmonary tuberculosis**, states that allowing for the possibility of over-exertion, excitability under examination, and the presence of mitral stenosis, all of which accelerate the pulse-rate, the frequency of the pulse is a useful aid in prognosis. Making these allowances, a patient with a pulse-rate of over 100 is not likely to make any approach to recovery from pulmonary tuberculosis during 6 months (which should be the ordinary limit of residence in a sanatorium). Cases in which a tuberculous area in the lung has been cleared out by excavation, followed by a period of quiescence, during which the cardiac pulsations may not exceed 84 per minute, are suitable for treatment, as there is likelihood that life will be prolonged considerably by 6 months residence in a sanatorium; so that a consideration of the pulse-rate may point to a more hopeful outlook than would at first sight be suggested by somewhat advanced physical signs. A pulse of 100 or more will usually be found to accompany an evening temperature reaching or exceeding 101°, and these 2 signs, of grave import, being persistently present in a case in which absolute rest has been enforced for some time, give little hope of treatment proving of any avail. An acceleration of the pulse is found at the onset of the pulmonary affection, so a gradual fall will be found to take place if a case is making progress toward recovery, a difference of from several to 16 beats per minute having been noted in the rate on admission and at the end of 6 months' treatment. [A.O.J.K.]

6.—Syers expresses his conviction that the **murmur of aortic insufficiency** is most clearly audible in the second left interspace rather than in the second right interspace, as usually taught. The point at which the murmur is loudest is almost invariably the middle of the sternum, and it is frequently very loudly audible just above the xiphoid cartilage. The mistake relative to the point of maximum intensity and clearness of the murmur he believes has arisen from the statements in the textbooks being accepted in a slavish fashion without inquiry and from the growing tendency to employ the binaural stethoscope, "one of the most serious dangers that has ever threatened the practice of auscultation," and one which if persisted in, he believes, will lead very rapidly to the decline and fall of diagnosis of chest disease. [A.O.J.K.]

7.—Low describes some experiments regarding the **development of *Filaria nocturna* in different species of mosquito** in St. Lucia. Experiments with *Culex taeniatus*, a very bloodthirsty animal, revealed that it is not an efficient host for the filaria. Though the embryos migrate to the thorax and undergo some development, yet none ever reach maturity, and therefore never pass to the proboscis. On the other hand, in *Culex fatigans* the embryos of the filaria develop with marked rapidity and by the eleventh or twelfth day mature forms may be seen in the head, neck and proboscis, and more rarely in the abdominal cavity of the mosquito. The facts of the case are summed up as follows: Some mosquitoes are inefficient hosts for the filaria, the embryos never migrating from the stomach; some are partially efficient, the embryos reaching the muscles, where they undergo partial development, and then become absorbed; while others are properly efficient, the time taken for complete metamorphosis varying with the temperature and other climatic influences of the place in which the experiments are conducted. It may be as short as 8 days, as originally suggested by Manson. Experiments were also undertaken to determine the intermediate host of *Filaria demarquai*—*Anopheles albipes*, *Culex taeniatus* and *Culex fatigans* being used. So far the experiments have been entirely negative—these mosquitoes not acting as efficient hosts. [A.O.J.K.]

8.—Grünbaum, in a Note on the **value of experiments in the question of food preservatives**, criticizes adversely certain experiments undertaken by Rosenheim and Tunncliffe, whose paper, according to Grünbaum, seems to suggest that they find nothing to condemn in the use of preservatives in milk. [A.O.J.K.]

3.—The literature of the subject is reviewed. In syphilitic affections of the testes and epididymis the spermatic cord is seldom involved and less frequently still as an independent manifestation, as in the case reported. [H.M.]

4.—Shock is a sudden depression of the whole of the functions of the body. The symptoms vary from profound collapse to mere temporary impairment. The pathology is obscure. One theory ascribes the phenomena to suspension of nervous power, resulting in paralysis of heart and abdominal vessels and the vasomotor system, causing stagnation of blood and insufficient oxygenation of the heart muscles which are thus unable to force the small amount of blood through the empty vessels. The better theory is that shock is due to peripheral irritation of the sensory and sympathetic nerves and functional paralysis of the nerve centers which causes arrest or enfeeblement of cardiac and respiratory action. Cases of torpid and of erethistic shock, or prostration with excitement, are described. From uncomplicated shock recovery is usually complete, occasionally permanent impairment follows, a case of change of disposition being reported. In so-called secondary or delayed shock some other explanation must be sought. The cause of death may be found in pulmonary edema, renal congestion, concealed hemorrhage, septic collapse, or fatty embolism from minute drops which have been set free by the accident. In the latter case the measures suitable for true shock are the most valuable. When injury of large bones has occurred the limb should be immobilized as soon as possible so that absorption of fat cells from the marrow may be prevented. [H.M.]

5.—All indications are fulfilled when fragments of bone are in apposition and at rest. Healing is more rapid with unimpeded circulation. The so-called Hodgen's splint can be made in a few minutes by means of an iron rod properly bent, a few safety pins, a piece of cloth to make suspension for the leg, and a cord for attachment to the ceiling. It can be used in all cases of leg and thigh fracture by varying the adjustment by bending the rod at the knee and the amount of extension by moving the bed. For the arm a trough or other nonconstrictive dressing can be applied. In clavicle fractures all indications are fulfilled by requiring the patient to lie on his back on a firm, smooth mattress. Plaster-of-paris should never be used for a primary dressing, but only during convalescence, in order to give the patient his freedom. Every surgeon ought to be able to dress his case of fracture with what he can find on the spot. [H.M.]

7.—Sitophobia is used by Einhorn to describe the fear on the part of mentally sound persons of taking food on account of resultant bad consequences. In 2 cases reported it developed as a sequel of constipation, the patients fearing to tax the intestinal tract any further, and in others it followed chronic diarrhea. Similar cases are of daily occurrence. The constipation is more

aggravated by the abstinence, and in the diarrheal cases the deficient nutrition undermines the constitution. The symptoms are those of general anemia, anemia of the brain, dizziness, dryness in the throat, extreme fatigue, insomnia, etc. The treatment consists in increasing the food taken. Sometimes this must be done gradually, administering bromids in nervous, and codein in painful conditions. [H.M.]

8.—Besides the continuity of membranous tissue existing between the nasal cavities and conjunctiva, there is equally intimate association through the nerve, arterial and venous supply. This is described in detail. While nerve reflex will explain the majority of disturbances of the conjunctiva, venous stasis due to nasal hypertrophies holds a prominent place. The latter will explain the aggravation of symptoms after a night's sleep, the horizontal position favoring sluggishness of the circulation. [H.M.]

9.—The Alexander-Kellogg operation for anchorage makes no provision for liberating the adherent uterus. Intrapertoneal shortening is defective on account of the slender distal extremity of the sound ligament, and the Kelly ventrosuspension render the uterus practically immobile, if of permanent advantage; or, failing this, it gradually sinks into its former abnormal position. It often leads to serious embarrassment in pregnancy. The sound ligament grows with the development of the uterus. Theoretically, the same change occurs when it is implanted in the abdominal wall. The idea originated with Ferguson, but his operation has been modified by the author. An abdominal incision is made at the usual site, the adhesions are broken up, the uterus brought forward, the round ligament seized and a silk thread carried under, $\frac{1}{2}$ inches from the uterus, and held by forceps. The fascia, muscle and peritoneum are grasped by a volsellum 1 inch from the lower angle of the wound, and during traction, perforating forceps are thrust through, seizing the thread which holds the ligament. The clamp is removed from the thread, which is drawn through the perforation, bringing a loop of round ligament after it. The latter is fastened into the perforated wand by a catgut suture. Inclosing the abdominal incision the projecting loops are caught en route by the running suture which closes the fascia, and drawn to the middle line. The chances of incarceration of the bowel are exceedingly remote. Scrupulous asepsis is necessary. [H.M.]

10.—The ordinary methods of extracting superficially embedded foreign bodies is described. If deeply located in the cornea, the overlying tissue is cut and a strong electro-magnet applied. As a rule it is easy to remove pieces of iron from the sclera. In penetrating wounds, with retention of the magnetic body, after determining the visual acuity and field, and examining with focal illuminations and ophthalmoscope, the sideroscope should be used. That of Hirschberg is described. Frequently it is necessary to use the x-rays for diagnosis. The area of the eye can be outlined previously by fuse wire, fastened to temples and lids by court plaster. The history of the magnet in eye surgery is briefly reviewed and a short description of the Haab and Hirschberg magnets is given. For extraction, the site which will cause least injury to the eye is chosen. For diagnosis, the magnet should be applied only when all other means have failed. The method of applying is described. [H.M.]

11.—Tubercle bacilli are not always easy to demonstrate, even though present in large numbers. Fuchsin solutions are variable. Those which give the best results, together with other tubercle bacilli stains, are mentioned. Carbolic acid is the preferred mordant. Cobb's modification of the Berlin method of preparing specimens is described, as is also the best method of cleaning slides. Bacilli from different patients and from the same patient at different times will not invariably stain by one method. In some undoubted cases none can be shown by any method, though there are bodies which may be involution forms. Some will stain only after 18 or 24 hours' exposure. Difference in size is observed. Though they cannot be demonstrated they are believed to be constantly present in the sputum of well-marked cases. Other bacilli retaining anilin dyes are named and differential diagnosis in regard to them and scratch marks is considered. Resistance to destaining acids is probably due to the 22% of fat in normal tubercle bacilli. Variations may be due to smaller percentages or to the

production of an antitoxin or to mixed infection. Death may be due to loss of function or intoxication. In the latter, mixed infection probably plays an important role. Staphylococci are most in evidence. Streptococci are the most resistant. The antagonism of smallpox and syphilis with tuberculousis is touched upon. [H.M.]

14.—Since 1898 the movement for the establishment of medical departments in public libraries has spread rapidly owing to the passage of favorable resolutions by the American Medical Association and American Library Association. After 3 years 1 voice is raised in protest against "spending the money of the people for books benefiting only one class." Ninety-five percent of the reading of the public consists of novels. Are not the 5% readers of "solid literature" the real public for whom books are written, published and preserved? Ought public libraries exclude books on agriculture because this would be catering to farmers, books on chemistry because they supply the wants of chemists? Dr. Wire asks why physicians should be favored over lawyers at the public expense. There are about 10 medical departments of libraries supported by the State, whereas every state or territorial library is *eo ipso* a law library, and therefore the number of supported law libraries amounts to more than 60. [H.M.]

Boston Medical and Surgical Journal.

June 13, 1901. [Vol. CXLIV, No. 24.]

1. Some Observations on Chronic Seminal Vesiculitis. ARTHUR L. CHUTE.
2. Iodophilia. THEODORE DUNHAM.

1.—Chute and O'Neil, in some observations on chronic seminal vesiculitis, state that the disease generally occurs with urethral disease and that it is much more frequent than it is generally supposed to be. The writers found 60 cases among 540 out-patients presenting various sorts of genitourinary disease. Neurasthenic symptoms, combined with irregularities of erection, are almost pathognomonic of this disease, but the only way in which an absolute diagnosis can be made is by rectal examination. Such an examination is strongly advised in all cases of urethral disease, recent or of long duration, in which the disease is not progressing favorably. The treatment said to be of the greatest benefit and apparently curative, so far at least as subjective symptoms go, is the mechanical emptying of the diseased vesicles and ducts. [C. A. O.]

2.—Iodophilia is of distinct value in diagnosing certain doubtful conditions. The staining solution is made with 3 parts of potassium iodid, 1 part of iodine and 100 parts of water, thickened to syrupy consistency with gum arabic. The blood smear, which need not be fresh, is mounted in 1 drop of this and studied with an oil-immersion lens. In certain conditions the protoplasm of a certain proportion of the polymorphonuclear neutrophiles takes on a reddish-brown coloration. In some it is a diffuse stain, in others is confined to refractive granules and varies from light pink to dark red. It is always present in progressive suppurations and pneumonias. The intensity of the reaction is said to be closely related to the intensity of the process. It is found in pneumonia before the physical signs are specially suggestive. The only diseases which must be eliminated from the diagnosis are certain grave anemias, advanced pernicious anemia and leukemia. [H.M.]

Medical Record.

June 15, 1901. [Vol. 59, No. 24.]

1. A Note on the Spread of Yellow Fever in Houses. Extrinsic Incubation. H. R. CARTER.
2. On the Origin of Cancer: What Remains to be Demonstrated. SAMUEL W. BANDLER.
3. The Redundancy of the Preinsula in the Brains of Distinguished Educated Men. EDWARD A. SPITZKA.

1.—The history of a large number of cases of yellow fever occurring in Mississippi in 1897 and 1898 is traced in detail in

order to show that a certain time from the development of the infecting case passes before the property of communicating the disease to others is attained by the infected place. This time is named the **period of extrinsic incubation**. As bearing out this theory it is noted that cases of yellow fever which occur aboard ship after disinfection at maritime quarantine have not been followed by others among the crew; that cases in houses which were disinfected soon after were not followed by others among the inmates; that cases which occurred in houses vacated soon after have not been followed by others among those leaving, but cases have occurred among those who remained in the house or in the neighborhood; that secondary cases do not occur among those exposed seen after the occurrence of the primary case, but do occur among these exposed later. By deducting the period of incubation and the period of exposure of the secondary cases from the interval between them and the primary case the period of extrinsic incubation is estimated as generally not less than 10 days. The practical application to quarantine is pointed out and attention is called to the correspondence of these observations with those of Reed in regard to the time that must elapse after the infection of the mosquito before it can communicate the disease to man. [H.M.]

2.—Cullen has pointed out that in Gaylord's preliminary communication there is no conclusive evidence that a pure culture was in any instance employed or that the organism was recovered from the growth produced. The observations of various investigators as to the relation of yeasts to new growths, etc., is reviewed, including the production of adenocarcinoma by Sanfelice with the blastomycetes of fruit juices. The investigations of Leopold are described in detail and the degree in which they correspond to Koch's 4 postulates is pointed out. The presence of yeast in the carcinomatous tissues was proved by the formation of alcohol when pieces were put in grape-sugar solution, and also microscopically; pure cultures were made; growths were produced by inoculating the organism into another body, and the same organism was recovered from these growths. The growths, however, were not carcinomatous, but their structure was that of giant-celled sarcoma. Since **cancer cells have produced real carcinoma** in animals, we must demand the same result on injection of the causal microorganism, and this Leopold has not obtained. Gaylord has obtained true carcinomatous tissue from his inoculations, but the presence of cancer cells cannot be excluded from the peritoneal fluid which he used. The causal relation of blastomycetes to the growths produced in animals by Leopold must be granted. The decision concerning the character of these neoplasms and their actual relation to carcinoma and sarcoma is to be the controversial point. [H.M.]

3.—The anatomic features of the human insula are of fundamental importance in the interpretation of mental states. Charcot and others regarded this as the cortical center of speech and it was claimed this lobe was largest and most complex in the human brain. E. C. Spitzka showed that it was larger and more complex in the porpoise, his final conclusions being that the greater development of the caudal portion was due to its being commensurate with the amplitude of the cortical field of the eighth pair, the functions transmitted by which—equilibrium and audition—are highly developed in the cetacea. The insula of the porpoise is narrow and pointed cephalad. The reverse is true in the human insula. Would it be rash to propose that the postinsula shares in its development that of the auditory sense center while the growth of the preinsula is more in consonance with that of the true speech center? At the present time the insula is regarded as the middle association center of the auditory perceptive and the emissary centers. The left insula of deaf mutes has been shown to be defective. Writers generally agree that exposure of the insula indicates defective brain development. In the brains of both Seguin's the left preinsula is exposed. This is attributed to excessive development, while exposure in the defective is due to deficient development of the opercula and in such cases the insula itself is of inferior development. In the Seguin's there is **redundancy of the polar region of the left preinsula**. The fissures are deeper, with complementary fullness of the gyrus. The effect of paternal influence is discussed. [H.M.]

1. Decortication of the Lung for Chronic Empyema. GEORGE RYERSON FOWLER.
2. A Study of Some Complications and Sequels of Typhoid Fever. H. A. HARE and H. R. M. LANDIS.
3. "The Porro-cesarean Operation" with Report of 2 Successful Cases. JAMES H. GLASS.
4. The Treatment of Scarlatinal Nephritis. CHARLES GILMORE KERLEY.

1.—Fowler reviews 41 cases of decortication of the lungs, and reports his last case because of its operative interest, although it is too recent to judge of its functional result. Total pleurectomy was performed under spinal cocainization. The operation lasted 1½ hours, and was absolutely painless, except the insertion of the last 3 sutures. The indications and contraindications for operation, or for the employment of the various methods, except those relating to the condition of the chest organs discoverable by physical signs, can hardly be stated before opening the chest. The thickened pleura may be impossible of detachment in some cases. A study of 30 of the 41 cases, shows that tuberculous disease was responsible for all the deaths (3), at least half the failures to cure the empyema, and a majority of the failures to procure complete restoration of the function of the lung. Fowler concludes that decortication is adapted to all old cases of empyema where extensive tuberculous lesions are not present; that it may be substituted for Estlander's operation in the majority of cases where it has been considered as indicated, and that it should replace Schede's operation in all cases. The operation of choice is the extirpation of the visceral, cortical, and diaphragmatic portions of the diseased pleural membrane. Respiratory exercises are an essential part of the aftertreatment. [A.G.E.]

2.—The literature of the complications and sequels of typhoid has almost equaled in the past 2 years that of the previous 20 years. There has been an uninterrupted decrease in mortality, probably due to improved sanitation. The causes of abortion during its course are considered, and cases are reported showing that the pregnancy may be uninterrupted. Literature shows that typhoid is frequently found in the newborn. In these, intestinal lesions are absent, owing to absence of intestinal function, and to infection having occurred through the circulation. The disease is unusual under 2 years. In children a sudden onset is not infrequent, perforation and hemorrhage are rare, the temperature may be extremely irregular. Except under 2 years, the mortality is lower than in adults, and complications and sequels less frequent. In advanced life typhoid is uncommon and exceedingly dangerous. Cases with mildness of onset, and those marked by intercurrent disease, are next considered, and those with abrupt onset, chills, septicemic types, and those complicated with malaria. Abortive types are described. The replacement of the formerly typical diarrhea by constipation in half the cases in recent years is noted, as is also the difficulty sometimes of differentiating from appendicitis, peritonitis, and enteritis, when abdominal pain is severe. Bronchitis and pneumonia may be present at the onset from localization of the bacillus. Nervous symptoms, including simulated meningitis, neuralgia, aphasia, oculomotor paralysis, mania, and melancholia, are described. [H.M.]

3.—Glass, in view of the practically common mortality in well done Sanger and Porro-cesarean operations, has reached the opinion (1) that tubal excision without hysterectomy for the purpose of sterilization and interference with future pregnancy is unwarrantable, since the first should presume the second step, as the organ left is rendered functionless and can only become a source of possible trouble or evil; (2) that we should have a well-defined plan of ovarian conservatism and that in all cases possible an ovary or its fraction should be left in situ, since recent study so conclusively shows the value of its secretion in general nutrition, and its preventative influence in the nervous disturbance incident to the early and artificial menopause. He reports 2 cases of Porro-cesarean operation, in the first of which delivery per vias naturales was prevented by a carcinoma springing from the cervical canal and invading the

vaginal wall posteriorly. The patient recovered from the operation, but died 1 year later from a recurrence of the cancer in the trigone of the bladder, which caused a fatal nephritis. In the second case, examination after several days of labor showed a sloughing funis presented, implying of course a dead child and presumably septic uterus. The necessary Porro-cesarean operation was performed, with complete recovery of the patient. [W.K.]

4.—Every scarlet fever patient should be kept in bed 3 weeks, in a room at 68° to 72° F. When nephritis develops there is danger of over-treatment. Milk broths and thin gruels only should be given. The bowels should be kept open with calomel. Aconit in minute doses may be used for diaphoresis, and hot-air baths may be given under the bedclothes. If this is not sufficient, a bath in water at 108° F. should be substituted. The bed should be heated before returning the child to it. The best remedy of all is hot water flushings of the colon, 1 to 1½ pints of saline solution at 110° F. being used every 6 to 8 hours, the rectal tube being inserted 10 inches. [H.M.]

1. The Topical Treatment of Focal and Jacksonian Epilepsy. J. WILLIAM WHITE.
2. Theoretical and Practical Considerations on the Treatment of Jacksonian Epilepsy by Operation; With the Report of 5 Cases. JAMES JACKSON PUTNAM.
3. What I Have Learned from 161 Operations for the Relief of Senile Hypertrophy of the Prostate Gland. ORVILLE HORWITZ.
4. The Value of the Combined Medical and Surgical Clinic to the Student. ROBERT G. LeCONTE.
5. A Case of Abdominal Pregnancy. AUGUSTUS C. BEHLE.
6. Speicalism and Some of Its Relations to the General Practice of Medicine. HENRY WALLACE.

1.—White states that the essential cause of epilepsy, exclusive of demonstrable sources of brain irritation, is unknown, but that areas of the cerebral cortex seem to be in an unstable equilibrium. In trying to account for the apparently beneficial effect of various operations on epileptics, he finds but 4 possible explanations: (1) anesthesia; (2) psychic influence or so-called mental impression; (3) relief of tension; (4) reflex action, or the "reaction of traumatism." Anesthesia has been discarded after a series of observations on epileptics. The effect of psychic influence must be admitted to be possible. Relief of tension can hardly be considered a factor, and reflex action is of vague influence. White then considers the question of giving patients the benefit of both operative interference and sedation of the affected brain area. To this end he has employed the following method in 2 cases: The affected center is exposed by a small trephine opening and 30 minims of a 2% encain solution injected into the brain substance. This injection is repeated at intervals, and is fortified by the administration of bromids for 1 to 2 days. In CASE I a needle-like pain in arm was relieved, and the convulsions were diminished in frequency and severity. Injections were made at intervals between March 11, 1899, and December 1, 1900. CASE II was operated upon January 23, 1901, after several injections during 1900. Nausea and numbness soon followed, and 1½ hours afterward the most severe attack ever experienced by the patient came on. Patient was discharged next day, and has not been heard from since. White offers the method conservatively, because of its possibilities, stating that the results are not noticeably better than those following miscellaneous operations, while the result in CASE II throws some doubt on the entire safety of the procedure. [A.G.E.]

4.—See AMERICAN MEDICINE, Vol. 1, No. 6, page 234.

5.—Behle reports a case of abdominal pregnancy seen in St. Mark's Hospital, Salt Lake City. An incision was made through the sac which passed through part of the placenta. The knee of the fetus was then felt; the head somewhat extended and lying in the right iliac fossa, the dorsum toward the right. The cord was severed and the child delivered. The fetus showed slight signs of maceration. About a pint of thick amniotic fluid was in the sac. The fetus was a male child, very

large, weighing 6½ pounds, plump and well-developed; no deformity being noticed. It was 53 cm. in length and 43 cm. around the shoulders. The woman made an uneventful recovery. [W.K.]

5. The Pathology and Therapy of Cleitricial Contraction of the Bladder. DESIDER RÁSKAI.

2.—In an article on the **hydropathic treatment of incipient tuberculosis**, Meffert describes in detail a very simple home procedure extensively used in the hydropathic institute of the University of Berlin. It consists of "dry packing, cold sponging and rain-douche," repeated twice a day, and has been found of use not only in cases of incipient tuberculosis, but in later stages of the disease as well as in chlorosis. [H.H.C.]

3.—In the conclusion of his article on the **serum diagnosis of tuberculosis**, Romberg, as a result of his experiments, states that, as in the case of Von Behring's investigations on animals, the blood-serum of tubercular patients agglutinates Von Behring's emulsions of the tubercle bacilli, and that the reaction is very similar to that described by Arloing and Courmont as resulting from the mixture of their serum and pure cultures of living bacilli. He believes that a positive reaction of agglutination is a certain indication of the presence of an active tuberculous process in the body, and that a negative result indicates either an entire absence of tuberculosis, a healed in or inactive condition, or a rapid florid stage of advanced disease. [H.H.C.]

5.—Ráskai reports a case of contracted bladder following gonorrhoea, and discusses the treatment of the condition. [H.H.C.]

1. The Morphology of Bacteria and their Relation to Virulence. G. ASCOLI.
2. Occult Hemorrhages of the Stomach. I. BOAS.
3. A Simple Gas-Volumetric Method of Estimating Sugar. E. RIEGLER.
4. The Magnet-Operation Room. J. HIRSCHBERG.
5. Industrial (Methemoglobin) Poisoning and Treatment with Oxygen Inhalation. H. BRAT.

1.—Careful investigation has led Ascoli to the conclusions that (1) the existence of nuclei in bacteria, or structures corresponding to nuclei, cannot be proven; (2) the granulations so often seen in bacteria, which neither represent undeveloped spores nor nuclei, are, in spite of chemical differences, homologous structures; (3) a general relation between the granules and the vitality or virulence of the bacteria does not exist. [H.H.C.]

2.—Boas believes that **hidden gastric hemorrhage** is of very frequent occurrence, not only in gastric ulcer, gastric neurosis, etc., but more especially in carcinoma of the stomach, in which the patient often "bleeds to death, as it were, by drops," without the knowledge of the physician. He recommends a very careful analysis of the feces and gastric contents in cases where there is the least cause for suspicion. [H.H.C.]

3.—Riegler describes a very simple and effective process of **estimating the quantity of sugar present in urine**, basing his procedure on the principle that cuprous oxid, heated with hydrazin sulfate in the presence of a base (tartrate of potash and soda is the salt used), results in a reduction of the copper salt to metallic copper, while the nitrogen is set free. The apparatus used is the same as that employed by Riegler in his quantitative analysis of urea, and the estimation is simplified by the use of a table prepared by Riegler himself, giving the quantity

of sugar corresponding to each milligram of nitrogen produced during the reaction. [H.H.C.]

5.—His experimental investigation on **methemoglobin poisoning** and its treatment with oxygen inhalations leads Brat to the following conclusions: (1) Pflüger's law, that increase of oxygen-pressure leads to no greater activity of the vital processes is correct; (2) the complete saturation of the unchanged hemoglobin with oxygen, together with the oxygen absorbed in the serum, are capable of sustaining life, even when the quantity of intact hemoglobin present is less than the minimum ordinarily necessary to sustain life; (3) bleeding is conducive to an increase in the alkaliescence of the blood; (4) by increase in the pressure of the oxygen it is possible, in sufficiently alkaline blood, to change the methemoglobin into a modified compound or combination capable of sustaining life. [H.H.C.]

3. Pathology and Therapy of Prolapsus of the Female Urethra. A. PINKUSS.
4. New Experimental Investigation of the Curative Action of Anthrax Serums. A. SCLAVO.
5. Nervous Tachypnea. RECKZEH.
6. The Determination of Small Quantities of Free Fluid in the Peritoneal Cavity. V. CRIEGERN.

1.—Lucae contributes a short review of the progress made in the diagnosis and treatment of **aural diseases** up to the present time, giving to the English and French the credit for the advancement in aural technic during the first half of the nineteenth century and to the Germans for the latter half. [H.H.C.]

2.—After repeated attempts to demonstrate the existence of **gallstones** by means of the Röntgen apparatus, Beck, of New York, has succeeded in obtaining excellent results in at least 2 cases. In general he finds that the longer the exposure to the x-rays, the more prominent the liver outlines and the less distinct the gallstones. He therefore advises repeated experimental exposures, or at least 2 of 5 and 10 minutes respectively. Only such tubes as can stand a high voltage and are not so hard are permissible. As a standard he recommends a tube which, with a spark-length of 40 cm., will throw a gray-black shadow of the carpal extremity of the experimenter's radius, the adjacent soft parts being scarcely visible. Further, the intestinal tract should be thoroughly purged and the patient placed on his abdomen with shoulders and left side raised, the rays being allowed to act from the *side* rather than from above. In conclusion, Beck enumerates the different varieties of gallstones with their skiagraphic peculiarities, and reports 2 cases of cholelithiasis in which he was successful in obtaining good skiagraphs. [H.H.C.]

4.—Sclavo, in reporting the results of experiments with his new **anthrax serum** on sheep material, claims to have found a specific cure for the disease. He substantiates the claim by citing cases in which his serum has been successfully used on human beings afflicted with the disease. [H.H.C.]

5.—Reckzeh concludes his article on **tachypnea** with statistics of the cases coming under his observation and of those on the records of the Second University Medical Hospital at Berlin, discussing the etiology, symptoms, complications, prognosis and treatment of the conditions, which in most cases he found to be a manifestation of hysteria. [H.H.C.]

6.—von Criegern claims that even very small quantities of **free fluid in the abdominal cavity** may be diagnosed by inserting the forefinger as far as possible into the inguinal canal of the patient while in the erect position and percussing gently the abdominal wall, thus causing wave movements which can be felt by the operator's finger-tip. [H.H.C.]

9. A Case of Senile Chorea. BISCHOFF.

1.—An experimental investigation into the behavior of the leukocytes of the blood in counterirritation applied to the skin. The forms of irritation investigated were iodine, mustard plaster, and Baunscheidt's application, consisting in the use of perforators and the subsequent inunction of croton oil. The experiments indicated that the beneficial effect of such irritation is not in any marked degree dependent upon leukocytosis. There is, indeed, barring the eosinophiles, usually a reduction in the white cells. Blisters and Baunscheidt's application at times produced a considerable leukocytosis, but not constantly. Iodine sometimes gave rise to a relative increase in the eosinophiles. As there is some analogy between the condition produced by counterirritation and local inflammatory processes of an infectious nature, the author thinks that the general leukocytosis of the latter is not an especially favorable reaction of the organism against the local inflammation, but is the result of a flooding of the entire circulation with chemotactic toxins. As regards local inflammation, only the local accumulation of leukocytes is of importance, although it is possible that the general leukocytosis may assist the leukocytes acting locally. This, however, is not proved. The therapeutic basis of counterirritation, therefore, is not the movements of the leukocytes, but is what the author, adopting a cumbersome word of Sahli's, calls a **phlogogetic action**; that is, one guiding the circulation of the inflamed parts into favorable channels—a rather unsatisfactory explanation. [D.R.]

2.—The existence of potassium sulfocyanid in the human saliva was discovered by Treviranus in the beginning of the nineteenth century. The substance may also be found in the urine and in the nasal and conjunctival secretions; but in all these places it seems to be derived from the saliva. It is probably not a decomposition product formed in the mouth, but is secreted by the salivary glands, and is formed out of cyanogen compounds as a disintegration product of the proteids. The sulphur of the latter, uniting with the toxic cyanogen, this is converted into the less active sulfocyanid (rhodan compound). The quantity of sulfocyanid in the saliva varies in different individuals. That first secreted gives the reaction more intensely than that secreted afterwards. The saliva of smokers seems to contain a good deal more than that of nonsmokers, although Grober was unable to detect any definite influence of nicotine. He examined 100 persons suffering from different ailments, using the following method:—2 cc. of saliva were acidulated with a drop of acetic acid, and to this 3 drops of a dilute, watery solution of iron chlorid (1 in 10) were added. Upon shaking, the characteristic red color of potassium sulfocyanid developed. For quantitative purposes, he prepared 3 standard solutions, with which the color in the test was compared. His conclusions are as follows: (1) Potassium sulfocyanid occurs only in the saliva of human beings; (2) it is not produced by decomposition of the saliva; (3) the amount secreted diminishes with the duration of the secretion; (4) change in food has no influence upon the quantitative relations of the secretion of potassium sulfocyanid; nor has the use of tobacco in nonsmokers any influence. The ingestion of minute quantities of hydrocyanic acid, however, increases the secretion; (5) the elimination of potassium sulfocyanid is

possibly dependent upon the state of proteid consumption and proteid decomposition in the organism. As this consumption and decomposition is greatly lessened in cachectic individuals, the latter eliminate less potassium sulfocyanid, or none at all. The author found, for example, that in carcinoma of the digestive tract the secretion was entirely suspended. [D.R.]

3.—Berliner reports a case of **perforation of the abdominal wall** in a patient with cirrhosis of the liver. The perforation occurred at the umbilicus. At the autopsy cirrhosis of the liver and acute miliary tuberculosis of the peritoneum were found. Microscopic examination of the fistulous canal showed that its walls were the seat of tubercles. The question arose whether the tuberculosis had antedated the perforation and had prepared the way for it, or whether it was a simple instance of inoculation tuberculosis in an already existing tract. The latter is more likely, but the possibility of the first must be kept in mind. [D.R.]

4.—An exhaustive clinical study of the organs of circulation in 288 patients in the early stages of syphilis. In $\frac{2}{3}$ of the cases the function of the heart was disturbed in the secondary stage. The disturbances varied from trivial anomalies to pronounced cardiac insufficiency; arrhythmia and abnormal rhythm, either acceleration or retardation, were common. In addition to bradycardia and tachycardia, disturbance of the nutrition of the heart muscle was frequent, and manifested itself subjectively by palpitation, objectively by signs of insufficiency of the myocardium. In 40% of the cases murmurs were heard. If present, dilation usually affected the right side of the heart. In a small proportion of cases there was an increased resistance in the peripheral arteries, even in persons who were young; but factors besides syphilis play a part here. Aortic insufficiency or signs of aortic aneurysm were not observed in any case. The blood-pressure was lowered in nearly all patients to a greater or less degree. The hemoglobin was almost invariably reduced. But the changes in the heart cannot be explained by the chlorotic state of the blood, nor as the result of the action of the mercury, since they are observed before this drug is administered. The cardiac disturbance must, therefore, be ascribed to the syphilitic infection as such. [D.R.]

5.—The author reviews the literature of **general infection produced by gonorrhoea**. In such infections the following structures may be involved: The joints, the heart (myocardium, endocardium, and pericardium), the tendon sheaths and synovial bursas, the pleura, the eye, the nervous system, and the muscles. Five cases are then cited in which gonorrhoea seemed to be the primary cause of a general infection. The first was a man of 57, in whom the clinical diagnosis was **cryptogenic septicemia**. It was found that an old gonorrhoea had given rise to a prostatic abscess, which in turn had led to septic thrombosis of the prostatic plexus. This was the starting point of a pyemia that ended fatally in 10 days. The existence of the gonorrhoea and of the prostatic abscess had been entirely overlooked during life. In the second patient there was a **general infection resembling typhoid fever**. The autopsy showed a prostatic abscess due to staphylococci as the primary cause. Although the urethra was normal, there was no other view tenable than that a former gonorrhoea had caused the prostatic abscess. The third patient, a man of 52, presented symptoms of **pyemia**, with intermittent fever and a periosteal abscess. The primary cause of the pyemia was again an abscess of the prostate. In the fourth patient, a man of 55, the diagnosis was **purulent cystitis and malignant tumor of the prostate, with pyemia**. The autopsy showed suppuration in the prostatic and perivesical tissue. Whether gonorrhoea had been the starting point was not known, but was considered likely. These cases show the importance of **carefully examining the prostate in septicemia in men**, even when the external genitalia present nothing abnormal. The fifth patient was 26 years of age; he developed a **septicemia secondary to gonorrhoea**. The first symptoms were a polyarthritis 6 weeks after the gonorrhoeal infection. The joint disease finally localized itself in the left hip, and resisted all treatment. A left-sided sciatica, a tenosynovitis of the right hand, and finally a malignant endocarditis of the aortic valve, developed. The bacterial cause was

not discovered. The gonococcus was not found in any of the cases as the cause of the general infection; only the first and second cases, however, were bacteriologically studied, and in them staphylococci were found in the metastatic foci. [D.R.]

6.—A splendid hematologic study of a remarkable case of acute pernicious anemia with a leukemic state of the blood, previously reported by v. Leube. The patient was a boy of 10, who entered the hospital May 6 and died May 9, 1900. He was healthy until April 22. From April 22 until April 29, he remained home from school. He vomited twice but was not very ill. On May 1 he again went to school, but on the fifth was dismissed on account of his pallor. Four days before death nosebleed and yellowish discoloration of the skin, with pains in the neck, teeth, and epigastrium, developed. The boy became apathetic, and finally, completely unconscious. The temperature was between 39° and 40° C. The blood showed 256,000 red corpuscles, 10,600 white, and 10% of hemoglobin. **Macrocytes**, **microcytes**, and **polychromatophilic red corpuscles** were found. There was also **poikilocytosis**. The blood-platelets seemed to be increased and large numbers of **nucleated red corpuscles** were present. These were of various types, and represented all the embryonic stages of red blood-cell formation. Regarding the leukocytes, the most interesting observation was the discovery of **polymorphonuclear, nongranular leukocytes**, the existence of which in the blood has been recorded only 4 times. **Myelocytes** of both the neutrophilic and the eosinophilic type were present. The lymphocytes were greatly increased. Large mononuclear and transitional forms were present in normal proportion. Studies were also made of the bone marrow, the splenic pulp and the lymph-glands. As for the bone marrow, poikilocytes, macrocytes and cells with anemic degeneration (polychromatophilic cells), as well as nucleated red cells of different types, were seen; there were also some cells which were so peculiar that it was difficult to determine whether they were megaloblasts or leukocytes. The author considers them to belong to an intermediate type termed by Ehrlich the **irritation form** (Reizungsform). Polynuclear leukocytes, neutrophile and eosinophile myelocytes, large and small lymphocytes, and large mononuclear and transitional cells, were also found. The article is beautifully illustrated with plates prepared by the author. [D.R.]

7.—Gidonsen has used **hetol** (sodium cinamate) advocated by Landerer, in 12 cases of **pulmonary and laryngeal tuberculosis**. He comes to the conclusion that the drug has no advantage; indeed there is a loss in body weight. [D.R.]

8.—An experimental study of the influence of **sodium cinamate** (**hetol**) on rabbits in which an ocular tuberculosis had been produced, convinced Fraenkel that the drug had no influence. [D.R.]

9.—A case of **senile hemichorea** in a woman of 73, ending fatally, after lasting 5 years. Examination of the nervous system was practically negative. There was a tuberculous caries of the vertebrae; but this developed later than the chorea. The author has continued the table of the recorded cases prepared by Riesman, the sum total in the literature now being 69. [D.R.]

1.—Two cases are reported in which exclusion of the intestine from the fecal circulation was accomplished by **enteroanastomosis**. The operation was performed on a man of 40 because of pyostercoral fistula in the right iliac fossa following tuberculous appendicitis. Ileocolostomy was performed, thus excluding a large segment of the small intestine. In a second

case the operation was performed upon a man of 20 for a similar condition, but the anastomosis was made between the lower end of the ileum and the sigmoid flexure. From their experience and a study of the literature De Lora and Patel conclude that this method of treatment is accompanied by slight danger and is often very efficacious. In fistula of the small intestine the fecal material often accumulates in the lower segment of the small intestine and the fistula persists. In fistulas of the large intestine the results are more definite and often curative. If the fistula is situated in the region of the ileocecal valve, anastomosis of the ileum with the sigmoid flexure is advocated. If it is in the terminal portion of the small intestine not involving the cecum the anastomosis may be between the ascending colon and the ileum. Unilateral exclusion may even be employed in case of tuberculosis of the cecum without fistula as a curative measure and for the prevention of fistula. [M.B.T.]

2.—Tillaux and Riche have collected from the literature 12 cases in which ligation of the abdominal aorta has been performed and they report an additional case. From experience and a study of these cases they conclude that **ligation of the abdominal aorta** in man is never followed by gangrene, that congestive phenomena in the head are rare and unimportant, that paraplegia is inconstant, variable and usually transitory, and that the fatal results cannot be directly attributed to the operation itself. The case reported is that of a man of 56 who had a large tumor in the left inguinal region which had been at an earlier date taken for a hernia and a truss had been applied. Marked pulsation appeared later on, however, with evident signs of aneurysm and the tumor increased to the size of an adult head. As extirpation of the sac would have been impossible the only treatment seemed to be ligation and the abdomen was opened by a median incision and a silk ligature was applied high up about what was taken to be the common iliac artery. The arteries were quite atheromatous as the patient was an alcoholic. The circulation was immediately arrested in the aneurysm and there was no pulsation or bruit. There was not the least disturbance of the vitality of the lower extremity; no peculiar sensations or paralysis nor anesthesia following the operation. Edema of the lower left extremity developed, however, and later, urination became difficult. At the end of 2 weeks after the operation the condition became gradually worse, delirium set in, and death occurred. At the necropsy a diffuse aneurysmal sac was found which occupied the left side of the abdomen. The ligature was found to have been applied not on the common iliac artery as was supposed but to the aorta just above its bifurcation. The internal and middle coats were not ruptured. There was no clot formation above the ligature and it was possible to pass a groove director into the calibre of the artery at the point of ligature. The external iliac vein was thrombosed and the symptoms of edema probably resulted from this. [M.B.T.]

4.—Chopart's amputation is compared with other amputations of the foot, and its merits and disadvantages discussed. Lapointe believes that this operation could continue to hold a place among the amputations at this region, and if the soft parts do not permit covering the bones of the tarsus he advises resection of the astragalus to permit joining the flaps. [M.B.T.]

5.—Baudet and Duval discuss the various operations which have been proposed for the **total extirpation of the seminal vesicles** and the genital tract. From an anatomic study they find that the vesicles are located in the aponeurotic space, from which they are easily enucleated. There is only a single vascular pedicle located externally. This aponeurotic cavity may be opened from above and the vesicles readily removed after tying the vascular pedicle. Inguinal incision is considered the most favorable. The incision is continued a greater or less distance below the pubic spine, depending upon whether simple vasectomy or castration is necessary. It is continued upward along the inguinal canal to within 2 fingers' breadth of the anterior superior spine. The skin and muscles are divided, opening the canal, and the aponeurosis of the transversalis is lifted up together with the peritonium. The iliac fossa is freed by blunt dissection, to avoid tearing through the fascia which covers the great vessels. Caution is advised not to exert too great tension

on the vas so as to rupture it. After freeing the vas and vesicle from all sides it is cut free from the prostate with curved scissors and the bleeding surface is touched with the thermo-cautery. The technic of this operation was practised on 10 eadavers, and complete extirpation of the entire genital tract was found possible in all these cases. Two cases are reported in which the operation was practised on the living subject. A child 2½ years old was affected with tuberculosis of the left testicle. The family history was not known on the father's side, but the mother was quite well. The child was bottle-fed and poorly nourished. No pulmonary complication followed the attack of whooping-cough, but bronchopneumonia occurred during convalescence from measles. One year previously the mother had noticed that the testicle was affected. The serotum was enlarged, the skin was reddened, there was considerable pain. An abscess was incised and evacuated. Six months later a fistula persisted from which yellowish fluid escaped. The testicle was about twice the size of the one on the opposite side; there were no areas of softening, there was slight nodulation. The lungs were negative. The operation described was performed without any difficulty, and the child remains in excellent condition 3 months later. Pathologic study showed that the tuberculous process was far advanced. In a second case a man of 20 for 6 months had swelling of the left testicle and for 2 weeks a fistula had been discharging. The left seminal vesicle was enlarged, nodular and hard. The operation was performed as described, and 2 months later the man is in good condition, and though there is still fistula in the inguinal region he seems to be on the road to certain recovery. [M.B.T.]

1. Opium Poisoning Treated with Permanganate of Potassium. EUSTORJIO CALDERON. (Pacific Medical Journal, March, 1901.)
2. Some Suggestions in Using Bromids in Epilepsy. L. PIERCE CLARK. (Indiana Medical Journal, March, 1901.)
3. Schnetter's Placenta Forceps. E. J. KEMPF. (St. Louis Medical Review, May, 1901.)
4. Koplik's Spots; Their Value in the Diagnosis of Measles, Particularly in Private Practice. JOHN ZAHORSKY. (Maryland Medical Journal, April, 1901.)

1.—Calderon cites a case of **opium poisoning** which he treated with complete success by the use of potassium permanganate. He first used the stomach pump, then washed out the stomach with a 1 to 5,000 solution of the permanganate until the water came out rose-colored, using in all about a gallon of the solution. Next he injected hypodermically a full syringe of a 1 to 20 solution in water. After this he left 150 grams of a 1% solution to be taken in tablespoonful doses every hour. The permanganate oxydizes the morphin which is contained in the stomach, causing it to become inert. The resulting mangandioxide is insoluble and therefore harmless. If the amount of morphin taken is known, the proportion of 5 parts of permanganate should be given as the antidote; if however the amount of morphin is unknown, 1 tablespoonful of a 1% solution should be given every hour. In laudanum poisoning 0.4 grams of permanganate per os neutralizes 30 grams of laudanum. [H.R.C.]

2.—In his paper on the use of the bromids in the treatment of epilepsy, Clark states that the first aim must be the suppression or at least the alleviation of the spasms. This he accomplishes by the use of the following mixture:

℞
Potass. bromid,
Ammon. bromid,
Sodii bromid, ññ 5 grains,
Elixir simplex, q. s. ad 1 dram.
M.

He begins by giving 1 teaspoonful a day for about a week, then gradually increases the dose until either the attacks cease or 1 ounce of the salt has been given. During this time care must be taken lest the patient develop bromid intoxication. Hot and cold baths, massage and electricity should be given, the bowels watched, the diet prescribed, and high rectal saline douches administered once or twice a week. After the dosage

has been established permanently the physician must endeavor by building up the general system of the patient to effectually cure the disease. Clark is also a strong advocate of the hypochlorization or salt-starvation method as an adjunct to the bromid treatment, which consists in reducing the amount of sodium chlorid consumed by the patient to ¼ the usual amount. This is accomplished by placing the patient on the following diet: Breakfast, milk, 1 pint; lunch, 2 cakes made of eggs, farina, milk and sugar, coffee; dinner, bouillon, unsalted, boiled beef, unsalted, potatoes; supper, porridge made with farina, sugar, boiling milk, etc. In cases which do not tolerate the bromid treatment he finds that a 10% solution of bromid will yield very satisfactory results. [H.R.C.]

3.—Kempf, in his paper on Schnetter's placenta forceps, tells of his own experience with the instrument, and of the good results which he has obtained from its use. He believes that it fills a want of the busy practitioner, and from its simplicity and usefulness, should highly recommend itself. [H.R.C.]

4.—Zahorsky found Koplik's spots in 18 out of 26 cases of measles. In speaking of the sign he says that: (1) Occasionally the spots are entirely absent; (2) the patient may not be seen at the proper stage of the disease (the spots appear from 1 to 3 days before the eruption on the skin, and they persist for a few hours to several days); (3) the white spots may be entirely removed; (4) the light may be imperfect. He also says that there can be no question of the value of Koplik's sign when present; but when absent, all the symptoms and signs with the history of the case, must be considered before measles can be excluded. [H.R.C.]

Münchener medicinische Wochenschrift.

April 16, 1901. [48 Jahrg., No. 16.]

1. Acute Serous Meningitis. HEGENER.
2. The Treatment of Tuberculosis. KLEBS.
3. The Theory of the Process of Fermentation. OPPENHEIMER.
4. The Treatment of Rachitis with Suprarenal Extract. HÖNIGSBERGER.
5. Addison's Disease. HINSMANS.
6. Stomach Lavage in Children. STEINHARDT.
7. Treatment of Gout with Quinic Acid. SALFELD.
8. The Statistic Report of the Pediatric Polyclinic of the Royal University at Reisingerlanum for 1900. SEITZ.
9. Treatment of Fibrinous Pneumonia. HORNUNG.

1.—Hegener gives the histories of 2 patients; one, a man of 32, and the other of 24, in whom, following **middle-ear disease**, symptoms of cerebral disturbance developed. This was characterized by a slowing of the pulse, headache, and optic neuritis. In the first patient there was also a subnormal temperature, vertigo, and tenderness of the skull on percussion. A radical operation was undertaken in the belief that there was an abscess, but none was found. Some serous fluid escaped, and afterwards, for days, the dressings were soaked with cerebrospinal fluid. The patient made a good recovery. In the second case, the mastoid was opened and a cholesteatoma removed. There was temporary improvement, but 5 days later the symptoms became more marked; the patient was drowsy, his pulse slow, and the temperature slightly elevated; there was also a spasm in the right face and arm, with unconsciousness. In the diagnosis, abscess, octogenic meningitis, and extradural abscess, were considered. A large bony flap was cut with an electric saw, and on inserting a knife into the brain, considerable serous fluid escaped. No pus was found. The dressings afterwards became soaked with cerebrospinal fluid; the man made a good recovery. The author considers these cases examples of **serous meningitis**. Unfortunately, no bacteriologic examination of the cerebrospinal fluid was made. [D.R.]

2.—Klebs emphasizes the important role played by the **toxins of the tubercle bacillus** in the production of **intestinal tuberculosis**. These toxins are probably responsible for the digestive disturbances which antedate the appearance of tuberculous lesions in the alimentary tract. He believes that **butter** containing tubercle bacilli is harmful, not alone by reason of these bacilli, the virulence of which is not great, but also on

account of the presence of tuberculotoxins. The popular opinion prevailing in some parts of Europe, that the use of butter in large quantities brings about skin eruptions—furunculosis, eczema, etc.—is well founded, as the butter probably contains tuberculous toxins. He himself has had an interesting experience with skin affections. Ten years ago he had a severe eczema of the hands, which resisted treatment for 2 years. Eventually, it was cured. On returning to Europe from Chicago, last year, he spent the summer in a Swiss village. An old leg ulcer broke out again, and the eczema reappeared on his hands. He thought that irritant substances in the butter, of which he had consumed 5 kilograms (10 lbs.) in the course of 100 days, might be responsible; but although he abandoned the use of butter, he did not grow any better. He then took internally, and applied locally, **tuberculoïdin**, with the result that he was very quickly cured. On injecting animals with an extract of melted butter, he found a marked depression of temperature, such as is produced by tuberculotoxins; and he concluded that **butter toxins and tuberculotoxins are identical**. The butter toxins are probably attached to the casein particles. Klobb advises purification of butter or its substitution by other fats, such as goose fat. Many of the symptoms of tuberculosis, he believes, are due to the tuberculous toxins, and can be counteracted by his tuberculoïdin. [D.R.]

3.—By electrolysis, Breiding obtained a pure and stable form of metals (so-called Metallsole), which had an extraordinary **catalytic action** upon peroxid of hydrogen, and was capable of decomposing it, just like organic matter and enzymes. He called these colloid metals **inorganic ferments**, and considered them identical with organic ferments. Oppenheimer, however, takes issue with him, and considers that the term inorganic ferments is a contradiction in terms, as ferments are of necessity organic. Ferment action consists of 2 phases. The second phase, that of the actual decomposition, may be identical with the catalytic action of metallic substances; but before this catalysis is possible, the ferment probably forms a compound with the body upon which it acts; this is the first phase. The ferment is specific and selective, and acts only upon certain substances. Thus the **precipitins, hemolysins, and bacteriolysins** are strictly specific, and their action is best explained on Ehrlich's lateral chain theory. It is also possible to produce antiferments, the lab-ferment and egg-albumin, fibrin, and even peptone; but antipepsins and antidiastases have not been obtained. Oppenheimer's conclusions are: First, that the catalytic action of organic substances can be separated from their specific ferment action; that fermentative processes do not strictly obey the laws of catalysis. The most important feature differentiating ferments from inorganic catalytic substances is that the former enter into actual combination with the specific substratum upon which they act. [D.R.]

4.—The author obtained no encouraging results from the action of **suprarenal gland** in the treatment of rickets. [D.R.]

5.—Attention is called to the importance of **accessory suprarenals** in connection with Addison's disease, and to the fact that the patients suffering from this disease present in the terminal stages the symptoms of profound intoxication. [D.R.]

6.—Steinhardt recommends **lavage** in the treatment of **digestive disturbances in children**. He introduces a catheter through the nose, and has found that children do not resist this method, and would be quiet while the stomach was being washed out. He uses plain water for the purpose. [D.R.]

7.—Salfeld has employed quinic acid in the form of **sional**, which is a combination of the acid with piperazin, in the treatment of **gout**. It was given in doses of 1 gram (15 grains) 5 or 6 times a day. The results were very good. Upon articular rheumatism, however, the drug had no beneficial effect. [D.R.]

8.—A criticism of an article on the treatment of **fibrinous pneumonia** by Pässler, in which Hornung especially inveighs against the use of alcohol in pneumonia and other infectious diseases. He considers alcohol a powerful vasomotor depressant; and as the infectious toxin has a similar action, he thinks that we but multiply poisons when we give alcohol. He recommends digitalis and campher, and has also seen good effects from caffeine. [D.R.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended June 15, 1901:

SMALLPOX—UNITED STATES AND INSULAR.			Cases	Deaths
Alaska:	Douglas City.....	May 25.....	5	
California:	San Francisco.....	May 25-June 1 ...	4

Changes in the Medical Corps of the U. S. Navy for the week ended June 15, 1901:

WENTWORTH, A. R., surgeon, detached from the Solace and ordered to the Albany.
HARRIS, H. N. T., surgeon, detached from the Albany and ordered to the Monocacy.
EVANS, S. G., passed assistant surgeon, detached from the Monocacy and ordered to the Solace.
MEYERS, G. M., assistant surgeon, appointed assistant surgeon from June 1, 1901.
MURPHY, J. F., assistant surgeon, ordered to the Naval Academy, June 15.
BACKUS, J. W., assistant surgeon, ordered to the Vermont, June 17.
ASSERSON, F. A., assistant surgeon, ordered to the naval hospital, New York, June 17.
MAYERS, G. M., assistant surgeon, ordered to the Pensacola Navy Yard, June 18.

Changes in the Medical Corps of the U. S. Marine-Hospital Service for the 14 days ended June 13, 1901:

WHITE, J. H., surgeon, to report at Washington, D. C., for conference, June 7, 1901.
WILLIAMS, L. L., surgeon, granted leave of absence for 3 days, from June 6—June 6, 1901. Granted 2 days extension of leave of absence, June 8, 1901.
PRETTUS, W. J., surgeon, granted leave of absence for 3 days from June 13, 1901—June 11, 1901.
NYDEGGER, J. A., passed assistant surgeon, granted leave of absence for 30 days from June 8, 1901—June 8, 1901.

SPRAGUE, E. K., passed assistant surgeon, granted leave of absence for 30 days from May 30—May 31, 1901.
 WICKES, H. W., passed assistant surgeon, granted leave of absence for 4 days from June 3—May 31, 1901.
 DECKEL, C. E., assistant surgeon, granted leave of absence for 10 days, on account of sickness—June 6, 1901.
 KING, W. W., assistant surgeon, granted leave of absence for 4 days—June 11, 1901.
 BREADY, J. E., acting assistant surgeon, granted leave of absence for 1 day, June 19—June 11, 1901.
 ECROYD, HENRY, acting assistant surgeon, granted leave of absence for 10 days from June 8—June 6, 1901.
 MASON, W. C., acting assistant surgeon, granted leave of absence for 6 days from June 2—June 10, 1901.
 SMYTH, F. R., acting assistant surgeon. Leave of absence for 3 days granted Acting Assistant Surgeon Smyth by Bureau telegram of May 31, 1901, revoked—June 10, 1901.
 STANTON, J. G., acting assistant surgeon, granted leave of absence for 15 days from June 3—June 6, 1901.

Board Convened.

Board convened to meet at Washington, D. C., on June 7, 1901, for the physical examination of an applicant for cadetship in the U. S. Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon H. D. Geddings, Chairman; Assistant Surgeon B. S. Warren, Recorder.

Changes in the Medical Corps of the U. S. Army, for week ended June 15, 1901:

Orders of May 31, which relate to Captain Charles R. Gill, assistant surgeon, are revoked, and Captain Gill will proceed to Fort Totten in time to accompany the 2d battalion of engineers from that post to San Francisco, Cal.

HALLOCK, Captain HARRY M., assistant surgeon, is relieved from duty at Fort McPherson, to take effect upon the expiration of the leave granted him May 11, and will then proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

SARGENT, E. H., contract surgeon, is assigned for duty at Vancouver Barracks.

Leave for 1 month, to take effect on or about June 30, is granted Contract Surgeon Halsey L. Wood.

The following named hospital stewards, appointed June 1, are assigned to duty at their present stations: Benjamin L. Jacobson, San Juan, P. R.; Arthur Eutroppe, Fort Baker; Charles M. Hunter, Fort Niobrara; August A. Bemtgen, Army general hospital, Washington Barracks; Andrew S. Donnan, Fort Banks; Edwin A. Searson, Fort Howard; Arthur M. Fiske, Fort Terry; Frederick Thomas, Army general hospital, Washington Barracks; LeGare J. LaMar, Fort Ephan Allen; Mathew Galvin, general hospital, Fort Bayard; Richard A. Wood, Fort Stevens; John L. Gerlach, Fort Porter; John R. Sands, Fort Clark; Rowland D. Laws, muster-out camp, Presidio; Charles L. Keeler, Army general hospital, Presidio; Thomas G. Bristow, Alcatraz Island, Cal.; John J. Walker, Fort Walla Walla; Samuel S. Snarr, Key West Barracks.

EDWARDS, WILLIAM, hospital steward, general hospital, Fort Bayard, is transferred to Frankford Arsenal, Pa., for duty to relieve Hospital Steward Max Werner. Steward Werner will be sent to San Francisco, Cal., and report for assignment to duty at Honolulu.

BAIGENT, JOHN, hospital surgeon, hospital corps, appointed June 1, Hamilton Barracks, Matanzas, Cuba, will report by letter to the commanding general, department of Cuba, Havana, Cuba, for assignment to duty.

MINOR, FREDERICK L., hospital steward, appointed June 1, Columbia Barracks, Havana, Cuba, will report to the commanding general, department of Cuba, for assignment to duty.

WALLS, HENRY J., and KRAUSE, HENRY C., hospital stewards, appointed June 1, headquarters, department of Cuba, Havana, Cuba, will report to the commanding general, department of Cuba, for assignment to duty.

NAYLOR, WILLIAM S., hospital steward, appointed June 1, Holguin, Cuba, will report by letter to the commanding general, department of Cuba, Havana, Cuba, for assignment to duty.

HERRMANN, CHRISTOPHER, hospital steward, appointed June 1, Presidio, will report for transportation to Manila, P. I. Upon arrival at Manila he will report for assignment to duty.

COLLINS, JOHN L., hospital steward, appointed June 1, Plattsburg Barracks, will be sent to Fort Williams, for duty.

CLEVELAND, DELANCEY, Jr., hospital steward, appointed June 1, Hamilton Barracks, Matanzas, Cuba, will report by letter to the commanding general, department of Cuba, Havana, Cuba, for assignment to duty.

SCHUMANN, THEODORE, hospital steward, appointed June 1, Vancouver Barracks, will be sent to San Francisco, Cal., and report for transportation to Manila, P. I. Upon arrival at Manila he will report for assignment to duty.

ABELE, JOHN G., hospital steward, appointed June 1, Fort Egbert, Alaska, will be sent to Fort Davis, Alaska, for duty.

SCULL, JAMES A., hospital steward, appointed June 1, now en route from China to Manila, will report upon his arrival at Manila, for assignment to duty.

LOEBENSTEIN, CHARLES T., hospital steward, appointed June 1, Fort Adams, will be sent to Fort Greble, for duty.

The following changes in the stations and duties of officers are ordered: Captain Francis A. Winter, assistant surgeon, is relieved from duty at Fort Sheridan, to take effect upon the expiration of the leave granted him May 23, and will then proceed to Jefferson Barracks, for duty, to relieve Major Marshall W. Wood, surgeon. Major Wood will proceed to St. Louis, Mo., and assume charge of the medical supply depot in that city, to relieve Lieutenant-Colonel Joseph Girard, D. S. G. Lieutenant-Colonel Girard will proceed to Vancouver Barracks and report to the commanding general, department of the Columbia, for duty as chief surgeon of that department, and will also report to the commanding officer, Vancouver Barracks, for duty as surgeon at that post.

ASHBURN, PERCY M., first lieutenant, assistant surgeon, upon his arrival at San Francisco, Cal., will proceed to Fort Sheridan, and report for duty.

AISENMAN, WOLF, hospital steward, Fort Hamilton, is relieved from further duty at that post and will report on the Army transport Ingalls, for duty aboard that vessel during its voyage to Manila, P. I. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

HERNST, WILLIAM, hospital steward, hospital corps, now at Honolulu H. T., is transferred to the general hospital, Fort Bayard, for duty. ERWIN, Captain JAMES J., assistant surgeon, is honorably discharged, to take effect June 30. Captain Erwin will proceed to his home. Leave for 1 month is granted Contract Surgeon S. A. Greenwell. Leave for 21 days, from June 14, is granted Major W. Fitzhugh Carter, surgeon.

Leave granted Contract Surgeon H. E. Menage, May 2, is extended 1 month.

BAKER, WALTER S., hospital steward, appointed June 5, San Francisco, Cal., will report to the commanding general, department of California, for assignment to duty.

GRISWOLD, Major RICHARD S., surgeon, recently appointed, now in New York City, will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

The following changes in the stations and duties of officers are ordered: So much of par. 24, S. O. 53, March 12, this office, as assigns Major John S. Kulp, surgeon, to duty at Fort Hancock, is amended so as to direct him to proceed to New York City, for duty as attending surgeon and examiner of recruits and as medical superintendent of the Army transport service in that city, to relieve Major William D. Crosby, surgeon. Major Kulp will report by letter to the commanding general, department of the East. Major Crosby will proceed to Fort McPherson, for duty.

The following changes in the stations and duties of officers are ordered: So much of par. 12, S. O. 131, June 6, this office, as directs First Lieutenant Basil H. Duteber, assistant surgeon, to proceed to Fort Totten, for duty, is amended so as to direct him to proceed to Fort Hancock, for duty, to relieve Captain Deane C. Howard, assistant surgeon. So much of par. 7, S. O. 2, January 3, this office, as relates to Captain Deane C. Howard, assistant surgeon, is amended so as to direct Captain Howard to proceed to Havana, Cuba, and report for assignment to duty.

BAMBERGER, RAYMOND S., hospital steward, now at San Juan, P. R., is transferred to the Army general hospital, Washington Barracks, for duty with the hospital corps.

STEWART, LYELL R., hospital steward, now in Washington, D. C., having relinquished the unexpired term of furlough granted him, is relieved from further duty in the department of Cuba. He will be sent to New York City and report for transportation to Manila, P. I., on the Army transport Ingalls. Upon arrival at Manila he will report for assignment to a station.

AMERICAN MEDICINE

1321 Walnut Street

Philadelphia

Cable Address—AMMEDIC, Philadelphia

Subscription Price - - - - Four Dollars a Year in Advance

Postage in the United States and Canada, Mexico, Hawaii, Guam, Porto Rico, and the Philippines, free; foreign postage, \$2.50. Subscriptions may begin at any time. Volumes end with the last issues of June and of December.

News.—Our readers are requested to send us items of news of a medical nature, also marked copies of local newspapers containing matters of interest to members of the medical profession. We shall be glad to know the name of the sender in every instance.

Original Papers.—Articles are accepted for publication with the understanding that they are contributed solely to this journal.

Correspondence on all matters of clinical interest, particularly with reference to therapeutics, will be welcomed. Unobjectionable questions concerning formulas, treatment, etc., will receive attention in the department of Practical Therapeutics.

Copyright.—Matter appearing in AMERICAN MEDICINE is covered by copyright, but usually no objection will be made to the reproduction of anything appearing in its columns if the author's consent is obtained and proper credit is given.

Illustrations, such as half-tones, zinc etchings, etc., as in the judgment of the editor are necessary to illustrate articles, will be furnished when photographs or drawings are supplied by the author.

Reprints (250) of Original Papers will be furnished gratis to authors making the request. Covers to these and extra reprints will be furnished at net cost.

Advertisements.—Advertising forms go to press 8 days in advance of the date of issue. Therefore, in sending in copy, time should be allowed for setting up advertisements and for the sending and return of proofs. The advertising-rate is one dollar per page per thousand of issue. Double prices for preferred positions.

Change of Address.—In ordering a change of address it is important that both the old and new addresses be given.

Remittances.—Remittances should be made by check, draft, registered letter, money or express order. Currency should not be sent, unless registered. Stamps in amounts under one dollar are acceptable. Make all checks, etc., payable to American-Medicine Publishing Company. Address all correspondence to 1321 Walnut Street, Philadelphia.

VOL. I, No. 13.

JUNE 29, 1901

\$4.00 PER ANNUM.

To lessen the spread of disease by insects, the Marine-Hospital Service enjoins upon its medical officers every precaution to prevent the access of flies, mosquitos, and fleas to hospitals and quarantine stations under their charge. Fumigation by sulfur is considered the best method for destruction of these pests, since formaldehyd is uncertain, and pyrethrum powder merely stupefies and does not kill. If, failing the sulfur, pyrethrum is used, insects must be gathered directly after the use of the powder and burned. Petroleum must be used on all pools of water accessible to stations of the service, and containers of drinking-water should be carefully covered. All patients should be carefully protected by netting, those suffering from communicable disease to prevent the carrying of contagion, others to prevent their being infected. Special attention must be given to water casks, etc., on ships coming from regions where malaria and yellow fever prevail. These orders constitute an advance in sanitary science of a kind too often unmarked. The adoption of such measures by the Government make them the natural and familiar thing, to neglect which will in time be recognized to be as inimical to public safety as to neglect vaccination or permit a mad dog to roam at large. But, when the day of comparative immunity from plague, yellow fever, typhoid and malaria has come, popular antiscience will doubtless soon forget to whom it owes such freedom, and use this, as it has so many past steps in the elimination of disease, in some curiously distorted manner for the vilification of those who spend their lives for the betterment of the race.

Plundering and Corruption in the Name of Charity would be the fitting designation of some of the work of the Pennsylvania Legislature in its recent appropriations or refusals of appropriations to private and semipublic institution. To read the reports of the proceedings one blushes at the revelations, and wonders whither "Americanism" is tending. There is hardly a pretence of principle or fair play, and only payment of corrupt political "deals," with general pauperization of our charitable institutions, or obedience to "influence," is visible in the results of the balloting. Why such an institution as the University of Pennsylvania should be denied help while others are freely endowed, why a little charity that loudly demands gets what it wishes, while a great one like the Pennsylvania Hospital, which asks for nothing, is not considered at all, is essentially

inexplicable and thoroughly disgusting. The present methods and injustices of appropriation by this State are so flagitiously evil that they harm and debauch both the giver and the receiver. Such exhibitions of debasement have the one merit that the present plan is seen to be far worse than that of no appropriations whatever. Either reform or abrogation is imperatively demanded.

The Fourth-of-July Battles since the Revolutionary war have perhaps been more fatal, in deaths and injuries than was that war itself. The stupidity and disgrace of our modern "celebrations" are unpatriotic to a shameless degree. Our newspapers succeeded in learning of 59 deaths and 2,767 injuries resulting from last year's "celebration," and Dr. Reynolds, of Chicago, is quoted as finding a total of at least 47 deaths in his city in the past. In Philadelphia last year 10 were killed and 311 injured. The profession should bring its influence to bear to stop the reckless folly. There is at least one Mayor in the United States alive to his duty. Mayor Harrison, of Chicago, has declared that:

"Discharges of fireworks, firecrackers, gunpowder, or other explosives in any alley, back yard, or other confined space is hereby positively prohibited.

"The discharge of cannons, guns, pistols, revolvers, dynamite or cannon crackers, or other firearms is hereby absolutely prohibited under penalty of \$25 for each offense.

"The placing upon the car tracks of any railway, or upon the rails of any railroad within the limits of the city of Chicago any torpedo, bomb, or other thing containing any substance of an explosive nature is hereby absolutely prohibited under penalty of a fine of \$10 for each offense.

"The sale or gift of toy pistols or metal caps to children is hereby absolutely prohibited. Any violation of this provision will subject the offender to arrest and a fine of \$10."

A Uniform Examination for License to Practise Medicine or Reciprocity.—Ever since the introduction of the much-needed State laws for license to practise medicine there has been the disagreeable necessity for nearly every physician who has changed his place of residence to take another examination for license to practise. This has given rise to a good deal of dissatisfaction and discussion as to the best way of avoiding this hardship. The conditions in different States at present are so different that uniformity in the examination for license to practise will be impossible for some time to come. In some of the sparsely settled Western and Southern States where the inducements to settle are not great, it cannot be expected that the best trained

and most highly educated practitioners will desire to practise and it would not be right to demand so severe an examination for license to practise in such States as in more favored districts. However, a uniform requirement is quite possible in many of the older States where the conditions of education are more settled. In replying to a toast on "Medical Education" at the annual banquet of the Surgical Section of the American Medical Association, Dr. W. L. Rodman suggested a solution of the problem which seems more feasible than reciprocity in medical licensure. Dr. Rodman suggested that examination papers should be prepared under the direction of the medical officers of the army, navy and marine-hospital service, these boards working in cooperation with members from the boards of different States. Examination papers prepared in this way should be sent once a year to some central city or cities in the different States where the examination could be conducted by the local officers. The papers could then be returned to the central board for correction. This would, of course, involve an enormous amount of labor for such a board, but it would make possible a perfectly uniform examination and probably few would complain of the justice of the questions asked or of partiality in marking. At a little extra expense a few extra officers could be taken by the government service and could be assigned to this duty and it seems to us the most reasonable method which has thus far been suggested of obtaining a uniform standard. Of course, such a method of examination would have to be approved and accepted by each of the local State boards, as the United States Government has no right to dictate to the States in such matters. There seems to be no real reason why half the States of the Union should not have this uniform requirement for admission to the practice of medicine and surgery. Such a central board would be more economical than numerous large State boards and it would do away with a great deal of undignified wrangling of candidates with examiners and between different boards as to whether their examinations are of equivalent value.

Stagnation in the Navy Medical Department is a complaint that comes from many sources. The incorrectness of the methods of the complainants is as suggestive as the facts themselves. What are naval surgeons doing for the progress of the corps or of medical science? We hear answers which charge that no opportunities are offered whereby good work can be done. There are no hospital or Red Cross ships in the Orient, the "ambulance" ship with her formalin sterilizers having been dismantled for a navy transport. There is not, it is said, an x-ray apparatus on any ship outside of the United States, and the literature furnished, or not furnished, by the government is ridiculously insufficient in quantity and quality. All this, too, while appropriations are being turned back into the treasury. The hospital at Yokohama has only two medical men in attendance, while the appointment of new acting assistant surgeons is unaccountably postponed. Why, also, should not the medical officers have graduated retirement as have those of the army and of the line, after 30 or 40 years of service and at their own request, to make

a specified number of vacancies? Even in the English service the time is 20 years. Does anybody in authority care for either professional or governmental efficiency and advance? Original work and utilization of great opportunities seem to be positively discouraged. Upon whom rests the responsibility?

The London Polyclinic and English Medical Progress, or rather the lack of progress were contrasted at a "Festival Dinner," London, on May 22, presided over by Mr. A. J. Balfour, and attended by 500 representative medical men. Donations in aid of the Polyclinic amounting to \$8,500, were announced. The Polyclinic said the chairman had three functions, that of medical charity; that of giving postgraduate instruction; but more important, that of medical research and discovery. There followed some quite plain truth-telling by Mr. Balfour, who said:

After making all allowances for the great claims on the gratitude of the world which the British medical profession undoubtedly had, it remained true, he believed, that in comparison with Germany, France, or Italy, England had not done all that it might as pioneer of medical discovery. In England they were proud to say that they left to private enterprise and benevolence duties which in other less fortunate countries were entrusted to the government, but if that policy was to be successful, they must have the private enterprise and the private benevolence—(cheers)—and he questioned whether they had shown the possession of those great qualities to the extent that they ought to have done. "We have not done sufficient," continued the right honorable gentleman: "we lag behind: We, the richest country in the world, lag behind Germany, France, Switzerland, and Italy. Is it not disgraceful? Are we too poor, or are we too stupid? Do we lack the imagination required to show what these apparently remote and abstract studies do for the service of mankind? I greatly fear that we lack the imagination, and that we have allowed ourselves to lag in the glorious race run by the civilized countries in pursuit of knowledge, and that we have permitted ourselves by far too large an extent to depend upon others for those additions to our knowledge, which surely we might have made for ourselves. Let us not be backward in this great international competition, which may be merely said in some sense to balance that more costly and more destructive competition in armaments, and it may be in commerce. Here, at all events, the interests of all nations are as one; here, at all events, there should be no undue rivalry, or, if any rivalry at all, it should be only as to which nation shall add the most to that scientific knowledge upon which depends, more than the efforts of statesmen, politicians, soldiers, and sailors, the future happiness and progress of mankind."

We heartily wish the desired success to the London Polyclinic, and to every other similar institution having the same objects. We could have wished that the chairman had seen fit in his comparisons to cast his eye westward. The United States has, in truth, as strikingly outrun England in the race for medical discovery and progress as any of the nations he mentions. A strange lethargy seems to have palsied the English profession.

Philanthropy in School Work.—Chicago has the distinction of being the first city in the world to furnish free transportation for crippled children of school age to a school of their own. The superintendent of compulsory education of that city in investigating many cases of absence found that a number of children remained from the school sessions both on account of sensitive

ness because of their deformity, and because, in many instances, they were unable to reach the school without an attendant, an impossibility in families all the members of which had to be breadwinners. The community had provided for the schooling of these unfortunates, but the cost of transportation fell mainly upon the parents and guardians, except when private charity furnished the means. In a building in the stockyard district where the larger proportion of these children live, a large room has been set apart for them in order that they may not be annoyed and jostled by their healthy and boisterous mates. A smooth-running omnibus with an attendant plies daily between the school and the homes of the children, and eighteen crippled and comparatively helpless children constitute the first class. Similar schools are contemplated in other parts of the city. That the school boards of other cities will turn their attention from the jobbery in books and the traffic in positions of which they are too often accused, and enter into a noble emulation in the humanities with Chicago is devoutly to be hoped, even though their efforts should be crippled by the bartering of school and hospital appropriations in political corruption.

Leprosy in the United States.—A circular letter, 8,000 copies, sent from Washington to every city and county physician, every health officer and every responsible head of a hospital in the country, has brought in 2,000 replies, from which information has been gathered that an alarming number of cases of leprosy exists in the United States, chiefly among foreigners. An act for the suppression and prevention of leprosy has been presented to Congress through Hon. Irving P. Wanger, of Pennsylvania, endorsed by the Philadelphia and Pennsylvania State Boards of Health. This bill, which was first submitted to the State Boards of Health of Maine, Massachusetts, Ohio, Minnesota, Louisiana and other States, and which was approved by most of them, proposes to remove the care of lepers from the State Boards of Health, and includes the appointment of a single commissioner on leprosy and emigration laws especially against countries known to be leprosy. By its provisions every State Board is privileged—not compelled—to turn over its lepers to the National Commission. The mixed isolation law of Dr. Hansen, of Bergen, Norway, which allows some lepers to remain in their homes, has been adopted by Wisconsin and Minnesota, but this could not be done with impunity in other States where the climate is not so antagonistic to the bacillus. It will be compulsory with every State Board of Health, and its only duty will be to take direct supervision of every reported leper residing within the State limits, and to maintain absolute and continuous isolation. Sending lepers to the National Asylum is preferred to the State asylums as recommended in the bill, but this is left to the option of the States. The proposition to set apart a farm of a mile square in Yellowstone Park for a National Leper Home is also included. Leprosy is found in its worst types on the coast, and the question of its transmission, whether by fish or mosquitos, will be studied this summer by an expert of the fish expedition to Hawaii. Dr. Isadore Dyer, who has made a careful study of the disease, in connection with the interest

aroused by the difficulty in selecting a site for the lepers' home near New Orleans, reviews the history of leprosy in Louisiana, and urgently appeals to the press and public-spirited citizens to take action for the control and eradication of this disease, as the results following the Berlin Conference of 1897, composed of delegates of all the powers met to discuss the terror and evil of leprosy and its prevention, show conclusively the wisdom of legislation, sanitary precaution, segregation and systematic medical treatment. National measures, not those of different States, must be the most effective, since thus alone would there be concerted action.

The New Specific Test for Blood.—By far the most important and suggestive results of experimental research during very recent times are those that relate to certain specific biologic reactions. Of these, possibly the most important, at least in a diagnostic and medico-legal sense, is the specific test for blood. Recently it was ascertained that the injection of the blood of an animal into an animal of another species results in the production of a certain substance or substances destructive of the blood of the first mentioned animal. The demonstration of this fact opened a field of research almost unlimited in its extent. It was soon ascertained that similar specific results were achieved when tissues other than the blood were employed in the experiments. In this connection, Nuttall and Dinkelspiel present in abstract in the *British Medical Journal* of May 11, the results of a series of experiments that they were led to undertake in view of the recent discovery of specific precipitins that act upon various bacterial products—milks, peptone, egg albumin, and different kinds of blood. Having injected rabbits intraperitoneally with horse-serum, dog-serum, ox-serum, sheep-serum and human serum, they were able to observe the formation of specific precipitins in their blood. The antisera from these animals were tried on twenty-four different bloods with uniformly negative results, if one excepts the slight reaction exerted by the antiserum for human blood upon the blood of two species of monkey. In addition, a slight clouding was produced by the antiserum for ox-blood when added to sheep's serum and vice versa. Some animals gave an effective serum after the third injection. Bloods that had been dried for two months and preserved at room temperature, either in the dark or exposed to diffuse daylight, or in the dark at 37° C., as also such as had been exposed for a week to the action of sunlight, as also serum from a blister, the result of a burn, all gave a positive reaction when tested with their particular antiserum. Some human blood that had undergone putrefaction for two months, when diluted 1. in 100 with normal salt solution, gave a marked reaction with the antiserum for human blood, which it did not do on the addition of other blood serums. A rabbit that was treated with some old antidiphtherial horse serum preserved with trikresol in a corked bottle for 2 years and 7 months, yielded a specific precipitin for horse serum. Positive results also were obtained by treating a rabbit with a pleuritic fluid that had been kept in the laboratory for 5 or 6 months, and preserved

by the addition of chloroform. A slight but distinct reaction was obtained with human nasal and lacrimal secretion. Dilutions of human blood (1 in 100) mixed with an equal volume of dilutions of blood of the ox, sheep, dog and horse and tested for human blood, all gave a positive reaction and vice versa. Control experiments with normal rabbit serum, as also with non-homologous antisera, gave negative results. Nuttall and Dinkelspiel state that their investigations confirm and extend the observations of others with regard to the formation of specific precipitins in the blood serum of animals treated with various serums. They conclude that these precipitins are specific, although they may produce a slight reaction with the serums of allied animals. They believe also that the substance in the serum that brings about the formation of the precipitin, as also the precipitin itself, are remarkably resistant. Finally they believe that this specific test is the most delicate means hitherto discovered of detecting and differentiating bloods, and they hope that it may be put to forensic use. This phase of the subject has also been commented upon by a number of other writers, among whom may be mentioned Bordet, Uhlenhuth, Wasserman and Schültze, Deutsch, Nolf and others. Details of the investigations of Nuttall and Dinkelspiel are promised in the forthcoming number of the *Journal of Hygiene*.

Cesarean Section for Placenta Prævia.—The recent advocacy of this radical treatment for placenta prævia demands a word of comment and caution, and, possibly, a word of condemnation. The one argument in its favor is that it reduces the fearful fetal mortality in these cases. But the question is, whether an increased maternal mortality will not ensue if such a procedure is extensively adopted. The splendid results attained by Fry, of Washington, who employed bipolar version, thus saving fourteen mothers and five children in fourteen cases of placenta prævia, and by DeLee, of Chicago, in the use of the tampon in a series of twenty-five cases without maternal mortality, show pretty conclusively that, if proper care is taken, the maternal deathrate may be very satisfactory. This condition is rarely recognized until labor is in progress. It is usually diagnosed and treated by the general practitioner, and he is generally better equipped for the treatment of this complication by version, and other conservative methods, than by cesarean section; and if such radical teaching should be disseminated and be adopted we believe the maternal and fetal mortality would be increased. It is unfair to apply to these cases of ectopic placenta the admirable statistics of Zweifel, Olshausen, Reynolds and others, who have reduced the mortality of the cesarean operation to 3% in elective cases for contracted pelvis. The pathologic condition is essentially different, the choice of time for operation, and often the diagnosis of lesion, radically different, and the results will vary materially. Cesarean section for placenta prævia will, probably, always be a dramatic maternity-hospital operation, only applicable occasionally, and never generally adopted by the rank and file of medical men for the relief of this dangerous complication of gestation.

The Model Tenement Houses are likely to increase in numbers it seems; for, according to the report of the City and Suburban Homes Company, of New York, the venture is a business success. This corporation is dealing with the tenement house problem, combining business with philanthropy, and its success is attested by a 4% dividend on the company's capital, which amounts to about \$2,000,000 in Manhattan. The *New York Evening Post* is authority for the statement that this company will spend \$1,250,000 more next year, chiefly on model tenements for colored people on the west side. The success of this movement exposes the falsity of the view that wretched tenement house conditions are inevitable, that model tenements will not pay, and that the poor prefer filth to cleanliness. Such opinions come from those who make 15% out of the tenements as they are now managed, and from indolent people who want to wash their hands of the entire problem. Many such corporations are urgently needed in every city in the United States. It is useless to expect that people who are obliged to live in dirty, poorly ventilated houses, without baths or other proper sanitary arrangements, can develop sound, healthy bodies. The wretched tenement houses of the large cities have always been the hotbeds of all kinds of disease, and will continue to be so until the poorer classes have an opportunity to get better quarters at an outlay which is within the limits of their means.

The Origin of Gallstones.—For many years speculation has been rife regarding the origin of gallstones, but not until animal experiments were made was definite light thrown upon the method of their formation. The old theory of a gallstone diathesis, maintained by Bouchard, Chauffard, and others, has been abandoned, since it is in reality not an explanation. The theory of a change in the composition of the bile, a change purely chemical in nature and origin, is also not satisfactory. At present the view that best meets the requirements of the case is certainly the one that attributes the formation of gallstones to a microbial influence. Naunyn was the first to advocate this, and numerous experiments have since corroborated it. Gilbert, Mignot, and Fournier in France, were able to produce gallstones by the injection of the colon bacillus or the typhoid bacillus into the gall bladder, and Mark W. Richardson and Harvey Cushing, in this country, were equally successful.

It is important in such experiments that the bacterium employed should not be too virulent. It may be injected into the gallbladder directly or intravenously. Cushing's experiments showed that the presence of bacteria in the bile was not alone sufficient to produce gallstones; it was necessary to injure the gallbladder so as to bring about a catarrhal process. This gives support to Naunyn's view that, in addition to a bacterial cause, a catarrhal inflammation ("lithogenous catarrh") of the gallbladder is an essential element. That the bacteria form the nucleus of gallstones after having been previously agglutinated in the bile, is a plausible hypothesis, but has not yet been proved. The microbial theory of gallstone formation is also strengthened by the discovery of bacteria, at times living, in the interior

of naturally formed gallstones. Thus, Fournier found bacteria in 23 out of 70 calculi examined, and Mignet discovered the colon bacillus in 3 out of 5 cases of gallstones. In recent experiments reported from Durante's clinic in Rome, Italia used *Bacillus coli* and the typhoid bacillus for the production of gallstone. Dogs and rabbits were employed, and the injections were made directly into the gallbladder, the cystic duct being previously ligated. When virulent organisms were used, the animals invariably died without any concretions having been formed; but when the bacteria had been attenuated, they seemed to bring about a change in the reaction of the bile (an acidification) which led to a precipitation of the cholesterol. The crystals of the latter became cemented together by the mucus from the inflamed mucous membrane, and assumed the characteristics of gallstones. Whether dead bacteria are capable of producing gallstones was not determined.

Newspaper Medical Advertisements.—We commend the policy of the new management of *The Philadelphia Times* to exclude "hideous advertisements." It says:

"It is not hard to draw the line. *The Philadelphia Times* has drawn a line that it never allows to be passed. It refuses to insert, at any price, though they are repeatedly offered, all advertisements of "diseases of men," "female remedies," "guaranteed cures," and such like indecencies, and of massage, clairvoyance and other cloaks for vice. It equally refuses advertisements which promise something for nothing, that guarantee big dividends or otherwise lure the reader to questionable investments. And it absolutely rejects all objectionable displays and the huge illustrations in advertisements that are offensive to good taste and to common decency."

It has always been incomprehensible to us why 100,000 medical men take and read newspapers offending every decent sentiment of the profession in the way characterized by the *Times*. If we refused to buy such journals or sanction such journalism, and if we let the editors and publishers know of our refusal, we could largely or entirely stop the abuse. It is our plainest duty to support such newspapers as thus sacrifice a temporary gain in the cause of decency. We hope that physicians will buy the *Times* in preference to other papers which have no honor or principle in such things. Are there, indeed, others that adopt the same standards and rules? If so every medical journal in the United States should know of the fact and tell its readers of the good news.

In the work of the Medical Department United States Army proving that the infection of yellow fever is conveyed by the mosquito, there was also incidental demonstration of the greatest abstract love, that which leads a man to lay down his life, not merely for his friend, but for his race. When the investigation reached the point that further progress depended upon human experiment, the brave physicians attached to the Service offered themselves in the cause of humanity, fully recognizing the danger attached to the demonstration they believed would, and which did, follow. To this love of humanity and of pure science Jesse W. Lazear fell a victim; but through his sacrifice and that of others was established a discovery characterized as great in import-

ance to the race as any save those of vaccination and anesthetization. It is well that there should be commemoration of the heroism of this action, and we are heartily in accord with the movement for raising funds for a lasting memorial to Dr. Lazear, now in hand by his friends and associates. Dr. Stewart Paton, of Johns Hopkins Hospital, has been appointed to receive subscriptions.

Physicians should have some adequate means of redress for the injury and mortification inflicted upon them through the use of their names in flamboyant and unethical exploitations of the unscience popularly known as newspaper medicine. The latest victim of these outrageous methods is Dr. DeForest Willard of this city, who after the usual unavailing personal visit to the offending paper, requests us to say that "the unwarranted and unwarrantable use of his name in connection with a recent Sunday newspaper article, very justly arouses his disgust and disapprobation."

The *Lancet* contends that cigarets are less harmful than either cigars or the pipe. We regret the indirect advice. The evil of cigaret smoking consists in the excess and continuousness of the smoking habit it seems to encourage, and in the fact that the apparent cheapness of the cigaret also adds to the addiction. Worse than all is the morbid devotion of youths and even children to the noxious habit. If the *Lancet's* contention be admitted, the cigaret habit is at least harmful and disgusting to others!

Mrs. Eddy recently characterized homeopathy as a stepping stone from allopathy to "Unchristian Unscience." We have no knowledge of the school called allopathy, but we are quite certain that she is in error as to homeopathy. At their recent convention in Richfield Springs, N. Y., the homeopaths put themselves on record that they would have nothing to do with such nonsense, and one woman physician denied that Eddyism was spreading among homeopathic women.

There is great dissatisfaction in many cases running to anger at the lack of arrangements on the part of the railways for the return tickets of members of the American Medical Association from St. Paul. Many gave up the attempt to secure such tickets; the red tape in some cases was beyond the power of railway officials to overcome or understand. Another year the "Community of Interests," so far as physicians are concerned, will be broken, if better plans are not made.

The excursion of the American Medical Association delegates to Yellowstone National Park was a little marred by insufficient hotel accommodations, but every one's enjoyment was increased by the railway company's agent in charge of the party. Mr. Sweet became so popular that a subscription was secured for a gift to be made to him. The park is a veritable wonderland, and many physicians will henceforth have a new interest in some problems of geology.

BOOK REVIEWS

Atlas of Ophthalmoscopy, by Professor O. Haab, of Zürich. Translated from the third German edition and edited by G. E. De Schweinitz, M.D., Professor of Ophthalmology, Jefferson Medical College. 152 colored lithographic illustrations and 82 pages of text. Philadelphia: 1901. \$3.00. Saunders' Hand-Atlas Series.

It is of tremendous advantage to the American ophthalmic student that this hand-atlas of internal diseases of the eye by Dr. Haab has been brought over into our language. The 82 pages of text are of great value in leading up to and elucidating the illustrations. Next to study of the eyeground in the human subject comes study of good pictures of the more important and frequent pathologic conditions seen in the consulting room and clinic. To have side by side with the ophthalmoscopic pictures such splendid plates of the microscopic lesions adds tenfold to the value of the work. The American editor has done much to aid in making this a *vade mecum* to the ophthalmoscopist.

A Few Essentials of the Diseases of Children Arranged in the Form of Questions and Answers, by William M. Powell, M.D. Third Edition. Thoroughly Revised by Alfred Hand, Jr., A.B., M.D. Philadelphia and London: W. B. Saunders & Co., 1901. Pp. 259.

While the use of the so-called "quiz compend" must be deprecated, it cannot be denied that the undergraduate is in need of some handy volume in which he can study the elementary principles of a given topic; and not rarely the practitioner also finds it convenient to have a small book in which he can at a glance get the gist of a subject. When it comes to pediatrics, the little work before us can be recommended. The book has been revised by Dr. Alfred Hand, Jr., with due attention to the progress in the field of children's diseases. The addition of a chapter on infant feeding enhances the value of the book.

Cancer of the Uterus, its Pathology, Symptomatology, Diagnosis and Treatment; also the Pathology of Diseases of the Endometrium. By THOMAS STEVEN CULLEN, M.B. (Toronto), Associate Professor of Gynecology in the Johns Hopkins University. With 11 lithographic plates and over 300 colored and black illustrations in the text by Max Broedel and Hermann Becker. New York: D. Appleton & Co., 1900.

The size of this book, which covers 693 pages, divided into 27 chapters and an appendix, in discussing carcinoma of the uterus, is not out of proportion to the importance of the subject. The bulk of the book is devoted to a discussion of the various forms of carcinoma of the uterus, special attention being given to the pathology and diagnosis, but there are also adequate chapters on normal anatomy, the removal and examination of tissues for diagnosis, methods of operating and prognosis. Important points are brought out by reports of cases which are usually given in detail and by numerous beautiful illustrations. The space given to pathology and diagnosis, with illustrative cases, is out of proportion to the remaining topics discussed, but these questions are of specially great importance, because less thoroughly understood by the general practitioner. Some idea of the exhaustive way in which the subject is treated may be gained when we state that 44 pages, the largest chapter in the work, are devoted to adenocarcinoma of the uterus. The complete reports of cases cover so much space that probably the average reader will not find time to read many of them, but a brief summary of each case is given before the detailed report, so that the reader can gather from this whether the case is likely to be of special interest to him. In discussing the prognosis of carcinoma the entire series of cases is tabulated and the results are given in concise form. This chapter will prove one of the most interesting for the average reader. Out of 61 cases of squamous cell carcinoma of the cervix, operative removal was found impossible in 4 cases; 31 patients of the remaining number who were operated upon have died or given unmistakable evidences of return of the growth. Thus, there are only 13 living and well. Some patients died shortly after leaving the hospital; others have remained well for months or years. In 6 cases the uterus was removed per vagi-

nam; in 5 by the abdominal route, and in the remaining 2 the combined method was used. Although the number of successful cases is small, Cullen believes that the surgeon should not be discouraged, and that with earlier diagnosis and improved methods of operating the percentage of recoveries will be greatly increased. Of 12 cases of adenocarcinoma of the cervix 2 are living and well; of 30 cases of adenocarcinoma of the body of the uterus, 3 died as a result of the operation; 6 from local recurrences from 5 months to 2 years and 7 months after operation, and 1 could not be located. The remaining 20 are still free from carcinoma. This is certainly encouraging, and because of the favorable results which have been obtained, a proportionately large amount of space is devoted to the discussion of adenocarcinoma of the body of the uterus.

In summarizing the theories as to etiology from an analysis of the cases which form the basis for this book, Cullen expresses his belief that heredity has little influence; trauma as produced by parturition apparently bears a causal relation to carcinoma of the cervix but not to that of the body of the uterus. Cohnheim's theory as to the origin of carcinoma from embryonic inclusion of epithelial elements, Ribbert's theory and the parasitic theory are not thought to offer satisfactory explanation. He concludes that the results of many investigations, while giving an increased knowledge concerning the histologic structure of carcinoma, have still left its etiology an unsettled question. As to methods of operation, Werder's method of combining the advantages of vaginal and abdominal methods is preferred. Vaginal hysterectomy, Cullen believes, should be avoided whenever possible. He uses the vaginal method only in patients with very thick abdominal walls in whom an abdominal operation would be fraught with much difficulty, and for elderly patients who cannot stand prolonged operation, or for weak patients. The disadvantages of the operation are that the operator can form no accurate idea of the extent of the growth, that many ligatures must be placed by touch, and it is impossible to remove infected glands satisfactorily.

The preparation of such a work as this involves an enormous amount of labor, extensive, thoroughly-studied clinical material, carefully-taken histories, thoroughness in pathologic study, and much trouble in following the patients to learn the later results of operation. Cullen speaks of the large number of cases of carcinoma that come too late for operation and every surgeon knows how appallingly large this number is. Any book which directs the general practitioner to the importance of the study of malignant disease and aids him in its early recognition, cannot fail to be of great value. Unfortunately, there are few hospitals in which the records are so carefully kept, and the pathologic material so carefully studied, that the results can be utilized for the benefit of the profession, and for the surgeon the book will be indispensable. As an example of book-making nothing finer can be found. The importance of such accurate and beautiful cuts and engravings as illustrate this book can hardly be overestimated, and the artists certainly should share the credit with the author for having produced a monograph which is unexcelled in medical literature.

Clinical Examination of the Urine and Urinary Diagnosis.

—A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery, by J. BERGEN OGDEN, M.D., Instructor in Chemistry, Harvard University Medical School; Assistant in Clinical Pathology, Boston City Hospital; Medical Chemist to the Carney Hospital; Visiting Chemist to the Long Island Hospital, Boston.

The subject matter is fully and comprehensively discussed, and the book is well adapted to the needs of the student and the practitioner. The author has added an improvement over the older books by discussing the subject under 2 headings. Part I deals with the chemistry and microscopic findings in the normal and pathologic urine. This portion is fully abreast of the latest teaching in a subject which is yearly attracting more attention. It contains numerous instructive illustrations, and comprises the entire ground usually covered by the older works on this subject. In Part II a new and valuable feature is introduced, viz., the subject of diagnosis, with especial reference to the urinary findings in the various diseases. The author takes up the numerous diseases of the urinary tract and gives the

urinary findings in each disorder; then the various diseases outside of the urinary tract and the resulting influence which each disorder has upon the quantity and quality of urine. Part II is valuable in that it gives in brief under each separate disease the information with reference to the urine which is found in works on practice and diagnosis only after extensive search and inquiry. We feel that this work can be safely recommended to those desiring a succinct and complete discussion of the clinical significance of the urine.

Gallstone Disease, with Special Attention to the Differential Diagnosis of the Separate Forms, based on an Experience Gained from 433 Laparotomies upon Gallstones, by Professor HANS KEHR, of Halberstadt. Authorized translation by WILLIAM WOTKYNs SEYMOUR, A.B., M.D. Formerly Professor of Gynecology in the University of Vermont. Philadelphia: P. Blakiston's Son & Co. Cloth, \$2.50.

Part I is made up of a series of 4 lectures on the Pathology, Anamnesis and Examination, special diagnosis, and treatment of cholelithiasis. Part II consists of the detailed history of 100 operative cases. The great merit of the book depends on the fact that it is a review of the author's rich and practical experience. Special attention is given to the differential diagnosis based on a knowledge of the pathologic anatomy of the various forms of gallstone disease. The importance of early operation is emphasized, the attendant dangers being no comparison to the disastrous results which may attend protracted palliative treatment to which, however, in suitable cases a place is accorded. The thoughtful reading of the work, which is eminently practical, cannot fail to give to the reader a more intelligent idea of the conditions which may exist in gallstone disease as well as the measures which should be instituted for their relief.

Anatomical Atlas of Obstetrics, with special reference to Diagnosis and Treatment. By Dr. OSKAR SCHAEFFER, Privatdocent in Obstetrics and Gynecology in the University of Heidelberg. Authorized translation from the second revised German edition. Edited by J. Clifton Edgar, Professor of Obstetrics, etc., Cornell University, New York, with 122 figures on 56 lithographic plates and 68 other illustrations. Philadelphia and London; W. B. Saunders & Co., 1901. Price \$3.00, net.

This volume is one of Saunders' well known series of hand atlases and therefore needs little comment. Every year the medical teacher realizes more and more fully the value of the stereopticon and the biograph as teaching adjuncts, and next in value to these appliances ranks a well illustrated book. A good illustration or diagram will often convey more information to the mind of the student than many pages of descriptive text, and the pages of this atlas are replete with splendid illustrations. The work is divided into 2 parts. The first treats of the physiology and diathetics of pregnancy, labor, and the puerperium; the second deals with the pathology and treatment of pregnancy, labor and the puerperium. The volume will be found of special value as a book of reference to be used in connection with the larger treatises on obstetrics. The type, paper, binding and lithographic plates are excellent.

Pulmonary Tuberculosis, Pneumonia, and Allied Diseases of the Lungs: Their Etiology, Pathology and Treatment, with a Chapter on Physical Diagnosis. By Thomas J. Mays, A. M., M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic; Visiting Physician to the Rush Hospital for Consumptives. Illustrated. New York: E. B. Treat & Co., 241-3 West Twenty-third Street, 1901. \$3.00 net.

Dr. Mays regards pulmonary tuberculosis as a disease dependent on some lesion of the central nervous system or pneumogastric—in other words, the consequence of a neurosis. He even regards the lung diseases other than tuberculous as so manifestations of a localized neurosis. Acting upon this theory he recommends as treatment for tuberculosis only such remedies as operate through the central nervous system. The treatment of the subject matter is both interesting and lucid, while the chapter on physical diagnosis with its differential tables is a valuable adjunct.

AMERICAN NEWS AND NOTES.

GENERAL.

Famine Sufferers of China.—The sum of \$20,000 for the relief of the famine sufferers has been cabled to Reverend Arthur Smith, of Tientsin, Chairman of the Missionary Relief Committee.

The American Medico-Psychologic Association held its fifty-seventh annual meeting in Milwaukee, Wis., June 11-14 inclusive. It is the oldest national association in this country. The annual address was by Dr. Warren P. Lombard, of the University of Michigan.

The Dentists of the Army are being very well equipped with the instruments of their profession. They were allowed to select what they believed were required in their work in the field, the selection, of course, to be within certain bounds governed by the known necessities of each case.

The Board of Pension Examining Surgeons has been completed by the appointment of Dr. P. W. Falls. Dr. Falls received his commission from Washington June 5, and is the third member required on the board, Dr. Joseph Scott and Dr. A. G. Maylie having received their commission last week.

American Orthopedic Association.—At the meeting held at Niagara Falls May 11, 12, 13, 1901, the following officers were elected: President, H. Augustus Wilson; first vice-president, William J. Taylor; second vice-president, G. G. Davis, of Philadelphia; secretary, John Riddlon, of Chicago; treasurer, E. G. Brackett, of Boston. Philadelphia was chosen as the place for the next meeting in May, 1902.

Support of Physicians.—Each physician in the United States has 655 persons to look to for his support, according to the latest Governmental statistics. California stands at the bottom, or top, depending on the view, of the list, for there are only 416 actual and prospective patients for each physician, while in Alaska 2,349 persons have to depend on 1 doctor. New York is near the average, with 603 persons for each physician, Pennsylvania has 662, and New Jersey has 856.

London Tuberculosis Congress.—A fund of over \$15,000 has been subscribed to defray the cost of making the Congress which will be held in London July 23-26 a success. An excursion party of physicians from the United States will leave New York, July 10 on the steamer Zealand, and land at Cherbourg for a few days in Paris before the Congress opens. The return will be made from Liverpool August 1 by the New England for Boston or by the Umbria for New York August 3.

Cornered Opium Market.—Advices have been received from Smyrna to the effect that rain has seriously impaired the Turkish opium crop and that American buyers have realized handsome profits. Just before the rain, brokers representing an American drug syndicate purchased nearly 80,000 pounds of opium, practically cornering the visible supply. Their operations, together with the prospective shortage, have sent up the price of opium in the London market 18 cents per pound.

Obituary.—ROBERT J. MARTIN, of Augusta, Me., June 16.—MAURICE B. PERKINS, of Union College, June 18, aged 65.—WILLIAM L. SMITH, of Pleasant Hill, Ky., June 18.—W. A. MEYER, of Cincinnati, Ohio, June 19, aged 30.—WILLIAM IRVING, of St. Mary's, Ontario, June 19.—LEE WOODS, of Abbeville, La., June 14.—J. W. SMITH, of Dover, Tenn., June 17, aged 84. MARY BARTON, of Washington, June 19, aged 55.—J. HOWARD ATHEY, of Holly Springs, Miss., June 20, aged 69.—JOSIAH C. ORR, of Athens, Ga., June 13.—WILLIAM J. CAMPBELL, of Worcester, Mass., June 14.—E. E. WAITE, of New Bedford, Mass., June 20, aged 43.

Yellow Fever.—Surgeon-General Wyman has under advisement the question of raising the quarantine on passengers from Cuba destined for points north of the Southern Maryland boundary line. A recommendation that the quarantine be raised is made in an official cablegram received yesterday from Surgeon Glennan, in charge at Havana. The reports from throughout the island are satisfactory and show a general absence of yellow fever. The Louisiana State Board of Health, however has taken a firm stand against relaxing the restrictions, and has demanded the disinfection of all baggage received there from Cuban points. Nonimmune passengers from Cuba now are held at quarantine at New York a sufficient period to make a total of 5 days from Cuba. Surgeon Glennan proposes to discontinue this detention of usually a day and a half in quarantine.

EASTERN STATES.

The Massachusetts State Board of Health has been ordered by the Legislature to make a scientific and thorough physiologic investigation of the healthfulness of baking powders, making such tests as will demonstrate whether or not the

brands on sale are injurious to health, and to determine whether the introduction into food of an article in small quantities, ordinarily harmless, would, when taken by a person in feeble health or dietetically disordered, eventually undermine the system. The results of these investigations are to be reported at the next General Court.

NEW YORK.

St. Vincent's Hospital will receive \$2,500 by the will of Mrs. Matilda B. Brown.

Elmira Reformatory.—Dr. Frank L. Christian, formerly a house physician at Bellevue Hospital, and more lately medical officer of the Eastern District Reformatory, has been appointed medical superintendent. He has resigned from the Eastern District Reformatory.

Court Criticises Chiropody Law.—A barber was convicted in Special Sessions recently for practising as a chiropodist without a license. The law makes this a misdemeanor, punishable by a fine of not less than \$50. Justice Jerome suspended sentence and said that the measure was wrong.

Sanatorium Burned.—The Mountain House, near Cornwall, N. Y., was destroyed by fire recently. The building was being prepared for use as a sanatorium for tuberculous individuals. To such a use the people of Cornwall objected, and had arranged to hold a mass meeting to make a public protest.

Charged with Neglect of Duty.—Dr. Obed L. Lusk, assistant sanitary superintendent of the borough of Queen's, has been indicted by the grand jury. The charge is neglect of duty in allowing a man with smallpox to remain in his home in a crowded tenement and in not removing the body until 2 days after death. The conduct was severely criticized by the jury.

Damages for Injuries.—A verdict for \$17,500 was awarded in the Supreme Court of Brooklyn, recently, to Miss Julia C. Bennett, in her suit against the Brooklyn Heights Railroad Company, to recover \$50,000 damages for personal injuries. Mrs. Kate V. Hoey recovered \$12,500 damages from the Metropolitan Street Railway Company for the death of her husband, who died of tuberculosis 9 months after an injury.

A Census of the Tuberculous.—Dr. Daniel Lewis, Commissioner of the State Board of Health, is going to take a census of the tuberculous individuals of New York State. The names will not be mentioned in any use that may be made of the results of the inquiry, which will comprise first, the extent to which tuberculosis exists, then the effect of the climate, the locations chiefly affected, and the possible origins. The census will be carried on by means of the physicians, who number 10,000 in the State.

Medical Society of the State of New York.—Dr. Henry L. Elsner, President, announces the appointment of his Business Committee for the ensuing year, consisting of Dr. Nathan Jacobson, Chairman, 430 South Salina Street, Syracuse, N. Y.; Dr. George Ryerson Fowler and Dr. William C. Krauss. All letters and inquiries pertaining to papers and scientific communications for the semiannual meeting, to be held in New York City, October 15 and 16, 1901, and the annual meeting, to be held in Albany, January, 1902, should be addressed to the Chairman.

A National Locomotor Ataxia League has been organized in New York. The object is to erect and maintain a sanatorium for the care and treatment of those so afflicted, with the hope that the special opportunities for investigation to be found at this sanatorium will make possible the discovery of a cure. It is reported that a reward of \$10,000 has been offered for the first permanent and guaranteed cure. The applicants must bear the cost of the experiments, which must be upon 2 cases in the advanced stage and under the surveillance of the league. It is said that 300 persons have joined the league, and that there are between 18,000 and 20,000 cases in the United States. The officers and directors are all sufferers, as the Constitution provides.

PHILADELPHIA, PENNSYLVANIA, ETC.

St. Joseph's Hospital.—Dr. Charles F. Nassau has been appointed surgeon in place of Dr. J. Chalmers DaCosta, resigned.

The Philadelphia Flower, Fruit and Ice Mission recently distributed 2,200 bouquets among the various hospitals, homes and missions. In addition to this money was sent to the different diet kitchens to provide the worthy poor with ice.

Typhoid Diminishing.—The Philadelphia health report for the week ended June 22 shows the number of deaths to have been 410. The condition in West Philadelphia is much improved so far as typhoid fever is concerned. A total of 61 cases

is reported with 7 deaths; scarlet fever 79 cases with 5 deaths, and 73 cases of diphtheria with 11 deaths.

An Antituberculosis League Dispensary is to be established at Atlantic City by the local Ministerial Union. The proposition is to maintain the dispensary for the benefit of residents suffering with tuberculosis who are too poor to have regular medical attention. It is designed to secure a portion of a city lot on which to erect the building.

Medical Department of the University of Pennsylvania.—The Class of 1881 celebrated its twentieth anniversary with a dinner at the Hotel Bellevue, June 12, 1901. A permanent organization was established with the following officers: President, Dr. G. E. deSchweinitz; vice-president, Dr. W. Easterly Ashton; secretary and treasurer, Dr. Daniel W. Nead.

Woman's Medical College.—A report from the obstetric department shows 303 cases attended from May 1, 1900, to May 1, 1901; number of children born, 303; no maternal deaths and 20 fetal deaths. The number of after-visits made by physicians and students was 5,017. The report of the maternity shows 110 cases delivered, no maternal deaths and 7 fetal deaths.

The Hygienic Committee of the Board of Education of Philadelphia recently decided that the eyes of all pupils attending the elementary schools at the commencement of the term must be examined.

The question of excluding teachers suffering from any contagious disease, including pulmonary tuberculosis, was discussed and will be taken up at the next meeting.

Medico-Chirurgical Hospital.—It is reported that a petition has been filed asking that important amendments be made in the charter of the corporation. The principal change is in the Board of Trustees. As now constituted, this body consists of 16 members, 6 members of the Medico-Chirurgical College Faculty, 2 appointed by the Governor, 2 elected by the corporation and the remainder by the contributors to the hospital. All, with the exception of the Faculty members, serve for 1 year. Under the amendment the Board consists of 12 members, who shall serve until their successors are elected. The first Board is to be elected by members of the corporation, and thereafter the Board is to fill vacancies which may occur among its members.

SOUTHERN STATES.

Maryland University Hospital.—Dr. George H. Stewart has succeeded Dr. S. Peachy Latare as medical superintendent.

Blind Crows.—A disease, resembling cataract, has developed among the crows of Arlington, Va., blinding hundreds of them.

Leprosy.—The certified death of a leper is reported from San Antonio, Texas, and there are 2 other cases of leprosy in the city.

Knoxville (Tenn.) Hospital.—The City Council has decided to borrow \$16,000 to complete the city hospital. The total cost will be \$48,000.

Frederick City (Md.) Hospital.—The erection of the building has begun and will be pushed rapidly. The present estimated cost is \$7,910.40.

Providence Hospital, in Washington, is to have additions and improvements to cost \$200,000. In the same yard will be erected a power house and nurses' home, at a cost of \$50,000.

The Maryland School for the Deaf and Dumb, at Frederick, closed June 12, after a season marked by the largest attendance in the history of the institution, 106 pupils having been enrolled.

Dallas Medical College, which was recently made the medical department of Trinity University, had its commencement exercises June 18. There were 8 graduates in medicine and 2 in pharmacy.

Charlotte Williams Hospital.—A gift of \$10,000 to this institution from J. W. Middendorf, of Baltimore. The hospital is in Richmond, Va., and was founded as a memorial by a gift of \$100,000 from the Williams family of that city.

Surgeon at Every Fire.—The Commissioners of the District of Columbia have unanimously approved the recommendation of the chief engineer of the fire department, that 1 member of the board of police and fire surgeons, if no more, shall be present at every large fire.

The Baltimore County Medical Association met June 20, at Towson. Many new members were elected. Dr. Richard Grady read a paper on "The Preservation of the Health of

Teeth," and Dr. T. C. Peebles one on "Twenty-six cases of Typhoid Fever in Private Practice, with one Death."

Unsanitary Towns in Maryland.—Dr. John S. Fulton, of the State Board of Health, on a recent visit with Health Officer Dr. Howard Bratton of Cecil county, to Port Deposit, found the sanitary condition of that town very poor, but is reported to have said that it is no worse than Baltimore and most other Maryland towns.

The Child-Labor Act, passed by the recent Legislature of Tennessee, prohibiting the employment of children under 14 years of age in shops, mines, and factories, has gone into effect. The factory superintendents say that it does not interfere with them, but will seriously embarrass poor families who are partly dependent on the work of the children.

Child Labor.—An agreement has been signed by 88 Georgia mills not to employ children under 10 years after September 1, 1901, and not to employ children under 12 at night, except when widowed mothers need their help. This is a voluntary movement on the part of the manufacturers. It is said that they defeated legislation on the subject but public opinion and the agitation of labor organizations against child-work have had much to do with bringing about this action.

Army Medical School Faculty.—The following-named officers of the medical department have been detailed as members of the faculty of the Army Medical School in Washington, D. C.: Colonel William H. Forwood, president of the faculty; Colonel Calvin De Witt, professor of military medicine; Major John Van R. Hoff, lecturer on the duties of medical officers in war and peace; Major William C. Borden, professor of military surgery; Major Frederick P. Reynolds, instructor in hospital corps drill and first aid to the wounded.

WESTERN STATES.

A Crematory will be built in Kalamazoo, Mich., at a cost of \$1,800.

South Dakota State Guards.—Dr. Weimer, of Yankton, has been made Surgeon-General, and Dr. O. H. Gerdes, of Enreka, Medical Surveyor.

The Barker Divorce Bill, prohibiting the marriage within a year, except by permission of court, of persons divorced, has passed both Houses in Wisconsin.

The New Hospital at La Crosse, Wis., was opened on May 14. The building has complete appointments in every detail, and has accommodations for 50 patients.

Dr. Christian Fenger, of Chicago, in recognition of his contributions to surgical knowledge has been decorated with the Crose of Danneborg by Christian IX of Denmark.

Dr. Nicholas Senn Honored.—At the recent annual commencement of Rush Medical College, the honorary title of Master of Surgery was conferred upon Dr. Nicholas Senn.

A compulsory vaccination law passed in Wisconsin is rendered valueless by the fact that persons having religious scruples against inoculation can be exempted on an appeal to court.

St. Mary's Sanatorium.—The Boyle Memorial, of Fond du Lac, Wis., will cost, when completed, \$50,000. The sanatorium is the gift of John T. Boyle in memory of his mother, after whom it is named.

A Private Hotel and Sanatorium at a cost of \$400,000 is to be built by 5 of the foremost physicians and surgeons of Chicago. It is to be provided with an ample staff of attending physicians as well as with a corps of nurses.

Chief Kenawashi, between 90 and 100 years old, the oldest medicine man of the Yakima Indian tribe, was shot and killed recently because he failed to cure several cases of smallpox on the Yakima reservation, in Washington, last winter.

The Western Reserve University is to receive gifts from prominent persons in Cleveland amounting to \$100,000. A chair will be added in the Medical College, endowed by H. M. Hanna, in memory of his father, the late Dr. Leonard Hanna.

Fire in Army Hospital.—A fire in the General Military Hospital at the Presidio, San Francisco, Cal., June 10, destroyed 3 wards, kitchen, diningroom, and medical supplyroom. None of the patients were injured. The loss is estimated at \$25,000.

The New Wesley Hospital, the only Methodist institution of its kind in Chicago, was recently opened. The institution will be dedicated when the indebtedness of \$25,000 has been paid. The building is 6 stories high, contains 250 rooms, and cost \$210,000.

Bequests to Hospitals.—The will of the late Dr. W. S. Caldwell provides that Providence Hospital of Chicago shall receive the residue of his estate, estimated at \$50,000. St. Francis Hospital and the Orphans' Home, of Freeport, Ill., receive \$10,000 each.

Chicago's Impure Water.—The following bulletin has been issued by the health department: "All of the city water is suspicious, and is not entirely safe to use for drinking purposes unless it is boiled or filtered. The water should be boiled at least 20 minutes."

Free Vaccination and Free Virus is the proposition of the Indiana State Board of Health, the expense, estimated at \$16,000, to be drawn from the contingent fund by the governor. The board proposes to furnish absolutely pure virus, and have the vaccination done in each county by its own agent.

Northwestern University, Woman's Medical School.—The alumnae association at the twenty-first annual meeting elected the following officers: President, Annie White Sage; first vice-president, Vira Brockway; second vice-president, Catherine Angell Warthern; secretary, Eliza H. Root; assistant secretary, Mary Gilruth McEwen; treasurer, Mary Hollister.

Trade Interests was the subject of a paper read at the recent meeting of the Illinois Pharmaceutical Association by Thomas V. Wooten. The claim was set forth that there exists a growing disposition on the part of physicians, encouraged by the manufacturers of tablets, etc., to dispense with the writing of prescriptions to druggists and instead provide their own prescriptions, much to the detriment of the legitimate pharmacist.

Tuberculosis in Colorado.—The discussion of tuberculosis was the feature of the recent opening session of the Colorado State Medical Society. Dr. Henry Sewall reported for a committee on the subject Tuberculosis in Colorado. He said that in 16 months to May 1, 1901, 1,674 deaths from tuberculosis were reported. In 970 cases the disease originated outside of Colorado. In 480 cases the origin was not given. In 224 cases, or 13.32%, the disease originated in Colorado.

Extending an Operation Without Consent.—Judge Kavanagh, of Chicago, recently ruled that when a surgeon is performing an operation on a person under the influence of an anesthetic, and finds that another operation, not contemplated before, is necessary, he has the legal right to perform the second operation without waiting to get the consent of the patient. This ruling was made when he directed a verdict of not guilty in the suit of Mrs. Agnes Mulhern against the Post-graduate Medical School and Hospital. Mrs. Mulhern was operated on by Dr. Franklin H. Martin, June 7, 1897. After the surgeon had made the incision, he found that other internal organs were diseased besides those for which the patient was taking treatment. Both operations were performed, and the patient is now in good general health.

CANADA.

McGill University has been chosen as one of the institutions to carry on original research work under the supervision of the newly incorporated Rockefeller Institute of Medical Research. It is understood that Professor Adami, of the pathologic department, will be in charge.

New Canadian Society.—The graduates of Queen's University (Kingston, Ontario) in New York have organized a society, to be known as the New York Society of Graduates and Alumni of Queen's University. The society will act conjointly with the New York Society of McGill University and the Canadian Society of that city in sending a representative to present an address to the Duke of Cornwall and York on the occasion of his visit to this country.

Ontario Medical Association.—The twenty-first annual meeting was held in Toronto, June 19. The first paper was by Dr. William Oldright, subject, Three Recent Gallstone Cases. Dr. Herbert A. Bruce read a paper on Excision of the Upper Jaw for Sarcoma, and a patient on whom he operated was shown. Hernia was discussed by Dr. Angus McKay, and Ectopic Gestation by Dr. Garrett. Problems of Vaccination was the subject of an earnest address by Dr. P. H. Bryce, the Provincial Medical Health Officer. He says physicians, as well as the laity, underestimate the value of vaccination. The Medical Aspect of Empyema was discussed by Dr. R. Ferguson, and the Surgical Aspect by Dr. J. L. Turnbull. The evening address by Dr. George H. Carveth, on the Open Air Treatment of Disease, was well illustrated. Dr. Ryerson said, in the discussion which followed, that typhoid patients in South Africa made more rapid and better recoveries when treated in tents than in hospitals. Drs. Elliott, of Gravenhurst, Freel and Bryce spoke strongly in favor of it, the latter recommending it for smallpox cases.

FOREIGN NEWS AND NOTES

GENERAL.

The Naval Hospital at Yokohama is about completed, and a letter to Surgeon-General Van Reypen, of the navy, states that the building is greatly admired, occupying a commanding location on one of the bluffs and looking from a distance like the Capitol at Washington. The Japanese Government has given a lease in perpetuity for the site occupied by the hospital.

European Hospitals in Cairo.—The European Hospital, which was governed by the various consuls, has now been closed, as being no longer necessary, for the leading nationalities have all found themselves in a position to erect a hospital of their own. The Germans and Austrians have for some years each had a hospital, while the Greeks and Italians are now about to build one. The French have just opened a very good hospital of 30 beds in the desert outside Cairo.

Infectious Disease Hospital.—Near the city of Melbourne, Australia, a large building has been erected, which is to be used as an infectious disease hospital. It is stated that something like £10,000, will still be required to complete the internal arrangements. So far the total cost has been £20,000 which has been contributed by public subscription and Government donation. The Government declines to assume any further responsibilities in the matter, inasmuch as it has gone to a large expense in equipping a plague hospital on Coode Island.

Mortality in Concentrated Camps.—It is reported that the mortality in the Johannesburg camp, up to May 31, was 6 men, 6 women, and 63 children; and in the Transvaal camps, up to the same date, 39 men, 47 women and 318 children. The authorities are arranging for the release of the women and children who have friends to receive them, but the government cannot undertake to feed them in isolated positions. There are 40,229 persons in the concentrated camps of the Transvaal and Orange River colonies. The high death rate among the children is accounted for by an epidemic of measles.

Obituary.—FRANCIS WILLIAM WARRINGTON of Congleton, Cheshire, Eng., June 7, aged 62. JOHN PHILIP TOPPING of Goodmayes, Ilford, Eng., June 2, aged 42. THOMAS BOND of Westminster Hospital, London, June 6, aged 60. THOMAS CAYZER, at Mayfield near Liverpool, Eng., May 29, aged 67. WILLIAM CHARLES BLAND at Arranmore, Eastbourne, Eng., June 4, aged 53. EDWARD JOHNSON HARDY Booth of Huddersfield, Eng., May 31, aged 55. CHARLES A. CLARK at North Sidney, N.S.W., June 5, aged 45. JAMES ALEXANDER DUNBAR, Inspector-General of Hospital, Bengal army, June 6, aged 86. ALEXANDER G. MELVILLE, late professor Queen's College, Galway, aged 82.

Cremation.—The annual report of the French Society for the Propagation of Incineration, shows that there are 40 cremation societies in Germany with a total membership of 12,000. There are 25 crematories in the United States and 22 in Italy. In Sweden cremation is becoming more frequent and in Copenhagen 70 cremations were carried out in 1890. In Austria, Holland, Belgium and Spain great efforts are being made for the introduction of cremation. In Paris in 1900 there were 297 incinerations at the request of the family of the deceased; from hospitals, theaters, etc., 2,752; embryos, 2,776; total, 5,825. In addition to the crematory built in 1879 by the Cremation Society there are now crematories in Manchester, Liverpool and Glasgow. At Hull, Birmingham and near London, new crematories are in the course of erection. At Woking 1,824 cremations had taken place down to the end of 1900; at Manchester, since 1892, 475; at Liverpool, since 1896, 102; and at Glasgow, since 1894, 75.

Bubonic Plague.—Since the beginning of the outbreak until June 8, 700 cases of plague have occurred at Capetown, of which number 326 have proved fatal. At Port Elizabeth, up to June 1, 7 cases of plague occurred. Though there are many Chinese in Capetown, only 1 Chinaman has succumbed to plague. This fact is to be taken into consideration along with the fact that Europeans readily contract the disease, and of which many die. In Southern China the European is comparatively exempt, whereas the Chinese falls a ready victim. The Malays are also wonderfully free from plague in Capetown, but in no Malay State or Country has plague as yet prevailed to any extent. The plague returns for all India during the week ended May 18, show 1,918 deaths from the disease, against 2,592 during the week preceding. In Bombay City 295 deaths occurred from plague during the week ended May 18. In the Bombay districts the registered deaths from plague amounted to 457 during the week ended May 18, against 338 during the previous week. The continuance of plague at Zagazig, Egypt, has caused a panic amongst the inhabitants of the city, who are fleeing to the surrounding country. In consequence of this exodus the disease is reported to have broken out in several of the neighboring villages. Officially, some 18 cases of plague are all that have been reported. During the week ended June 8 there were 161 cases and 155 deaths from plague in Hong Kong.

GREAT BRITAIN.

A New Hospital for Tuberculous Individuals is to be built near Aberdeen, which will be supported entirely by voluntary contributions. Every facility according to the best continental models will be afforded for open air treatment.

London Open-air Sanatorium.—The treatment of tuberculosis at Pinewood, Wokingham, will be opened for the reception of patients August 1, 1901. The sanatorium is situated in 85 acres of pine forest, on sandy soil, and with a southern aspect. The cases suitable for admission to this sanatorium are those in the early stages of tuberculosis.

Cutlery for Lunatics was recently advertised for by the British Admiralty office, and it brought to light some unusual cutlery that, while made regularly in Sheffield for the past 20 years or more, is but little known. The knives are perfectly dull, round blades, with a small cutting area about an inch long, situated in such a way that it cannot be used except for the purpose intended. The fork terminates in a small round ball, on which there are 3 prongs about an inch long.

The British Congress on Tuberculosis will be held in London, July 22 to 27. On the evening of Monday, July 22, the opening day of the Congress, a reception will be held by the Organizing Committee in the Queen's Hall. July 23, Professor Koch will address a public meeting in St. James's Hall, and in the evening a reception will be held by the Lord Mayor in the Mansion House. July 24, Professor Brouardel, of Paris, will address a public meeting in St. James's Hall. On July 26, excursions will be arranged to sanatoriums and other places of interest. During the period of the Congress some of the largest private houses in London with interesting collections of pictures will be thrown open to visitors.

CONTINENTAL EUROPE.

Ernst Haeckel of Jena has just begun his eighty-first semester of lectures on Embryology and Zoology. His students decorated the lecture hall and held an informal celebration in honor of the occasion.

Therapeutic Serums.—A State Institute for the manufacture of therapeutic serums has been established in Copenhagen. It is proposed to supply the Danish Colonies as well as Denmark from this source.

Dr. Fohlgemut, a Berlin surgeon, is credited with the invention of an apparatus by which chloroform may be inhaled with a mixture of oxygen which secures anesthesia and frees the use of chloroform from danger.

Medical Attendants of the French Senate.—Dr. Depasse has just been promoted to the position of physician in succession to Dr. Chavanne, retired, and Dr. Maurice has been appointed assistant physician.

Water Pollution.—A royal Prussian commission is studying the subject of keeping the rivers pure, and effective legislation will be established regarding the influx of sewers and impure water from factories, mining operations, etc.

A Society for the Study of the History of Medicine and the Natural Sciences has recently been founded in Germany. The organizing committee consists of Prof. G. W. A. Kahlbaum, of Basel; Prof. J. Pagel, of Berlin, and Dr. Sudhoff, of Hochdohle.

Sanatorium for Tuberculous Children.—The birth of the new Italian Princess has been made the occasion for a handsome donation by the King of 200,000 lire (£8,000) to the Commune of Rome toward the erection of a sanatorium for tuberculous children.

University for Women.—The Russian Government has authorized the establishment of a university for women, having the faculties of natural science, pure science, and medicine. A Moscow merchant has donated 3,000,000 roubles toward its foundation.

An Institute of Colonial Medicine.—An active campaign is being waged at present with a view to the creation in Paris of a school of colonial medicine. Professor Raphael Blanchard is at the head of the movement, and a public subscription has been started for the inauguration and endowment of the new institute. Already nearly 250,000 francs have been subscribed.

Specialists in Germany.—Of 27,374 medical men in Germany, 3,431 described themselves as specialists. There is 1 medical man to every 2,014 of the population of the empire and 1 specialist to every 16,066 of the population. In Saxony there are no less than 370 specialists among 2,048 medical men. The majority of the specialists, of course, resided in the large towns with more than 100,000 inhabitants, the number being 2,068, or 60.3% of all the specialists; in the towns of medium size, with from 45,000 to 100,000 inhabitants, there are 512, or 14.9% of the whole, and in small towns with less than 45,000 inhabitants there were 851, or 24.8%.

SOCIETY REPORTS

NINTH CONGRESS OF THE GERMAN GYNECOLOGICAL SOCIETY.

May 29-31, 1901.

[Specially reported for AMERICAN MEDICINE by J. EDWIN SWEET.]

[Concluded from page 527.]

WYDER (Zürich) discusses the **Symptoms, Diagnosis, Prognosis and Therapy of Puerperal Eclampsia**. In regard to the symptoms and diagnosis, Wyder brings nothing new. He considers that the prognosis under all circumstances, whether it is a case of eclampsia ante, inter or post partum, must be placed as *valde dubia*. In regard to the therapy it is hardly to be expected that obstetricians will agree as long as we have no certain knowledge of the etiology of the disease. A rational treatment must be based on the following principles: (1) The woman must be confined by the most rapid method possible, at the same time as carefully as possible, without any too great consideration for the life of the child; (2) all obstetric manipulations should be performed in narcosis on account of the heightened reflex irritability; (3) painful attention to anti-septic and aseptic precautions; (4) the most careful study of the individual when using those drugs known as heart poisons—chloroform, chloral hydrate, morphin, veratrum viride—and to restrict their use as much as possible; (5) careful stimulation of the secretory activity of the kidneys, the skin, the bowels, to further the excretion of the toxins; (6) a removal of at least a part of the poisonous substances coursing in the circulation, or a dilution of the same, by bleeding in suitable cases, and subcutaneous, intravenous, or rectal salt infusions; (7) increased oxidation of the blood by means of oxygen inhalations, a method which has been but little tried in Germany; (8) in case of threatened heart collapse, excitants, such as camphor, ether, caffeine. In cases with albumin in the urine, etc., Wyder recommends prophylactic treatment—milk diet, etc., and if the prodromal symptoms of eclampsia appear, vomiting, pain in the stomach and head, he does not hesitate to induce premature confinement.

Speaking before the congress, FEHLING adds to his paper some facts gathered since its publication, notably the results of Schmori; Fehling still holds that we have no constant pathologic anatomic findings in eclampsia. Treatment would be based on the supposition that the disease is caused by the fetus, and should consist in rapid and careful confinement. Dührssen's incision is too brusque for general practice, of use possibly in clinics in trained hands. A natural confinement, where one could have hastened matters, is to be considered a mistake. He uses salt infusion, eventually following bleeding. The narcotics should be restricted to the examination and to the attack. Fehling thinks he has seen cases where death was due alone to the use of morphin. He has had 30 cases, with 11% mortality.

WYDER considers the disease an intoxication, not an infection, which does not continue after the birth of the child. In those cases where the attack occurs but once, and where it occurs days after confinement, it is hard to recognize the fetal influence. The idea that eclampsia is a form of uremia modified by the pregnancy, is not entirely without justification. He considers the disease the expression of influences of different kinds. He thinks further study will disclose more subtle changes in the brain, and that we should examine the children more carefully.

SÖHLEIN (Giessen) calls attention to the fact that the prognosis is gradually becoming better. He has had 26 cases in Hesse, with no deaths. Ten years ago Söhlein found a mortality of 20% in the German clinics, which has now fallen to 15% and 10%. He thinks this due to improved therapy, especially to the metrenrhyster.

SCHMORL (Dresden), as guest of the Society, reports on the pathologic findings in 73 cases of eclampsia. In every case but he found the same changes in the secretory epithelium of the kidneys, parenchymatous, and fatty degeneration; in 3 cases, hemoglobin infarcts; in 71 cases hemorrhagic and anemic necroses of the liver, changes which begin at the periphery of the acini; in the other 2 cases he found total thrombosis of the portal vein. The changes in the liver have no relation to the severity of the convulsions. In 10 cases, icterus was present; in 3 he found similarity to acute yellow atrophy of the liver. He thinks that bile salts are still more often present in the circulation, but that the time is too short to permit of the coloring of the skin. In 66 cases he found thrombi and hemorrhages in the lungs. In 58 of 65 cases he found capillary hemorrhages in the brain, often localized in the nucleus caudatus. In 42 cases, hemorrhages in the heart-muscle with necrosis and parenchymatous and fatty degeneration. In several cases pathologic conditions of the suprarenals and the pancreas were noted. The emboli, composed of cells from the placenta and of liver cells are always secondary, and play no pathognomonic role. Schmori has examined 8 children; in 5 he found the

characteristic changes in the kidneys; in 3, those of the liver. The result of these studies is that eclampsia is characterized by definite pathologic findings, consisting of the degenerative changes in the secretory epithelium of the kidneys, hemorrhages, and thrombosis of the liver, thrombosis, hemorrhages, and softening of the brain, and the changes in the heart muscle. Schmori believes this picture more constant than the findings in cases of sepsis, poisoning, etc., where the pathologic picture may vary greatly, and yet pathology considers the picture pathognomonic. In no other disease does the same complex occur. Schmori believes, therefore, that eclampsia is an identical disease in all cases, not a complex of symptoms. When the toxin is produced is not known, possibly the new teaching of the lysins will clear up the question.

KRÖNIG and FÜTH (Leipzig) have experimented to determine the **Etiology of Eclampsia**. Authors have studied the freezing point of the blood and its viscosity, and conclude: (1) The fact that an osmotic pressure exists between fetus and mother makes it probable that the disease is an intoxication of fetal origin. A change in the blood of eclamptic patients is not to be determined, neither by a determination of the viscosity, nor of the specific weight. (2) The pulse tension is increased, yet this is doubtless not due to an increase of the viscosity of the blood.

SCHUMACHER (Strassburg), as guest, reports **Experiments Relating to Eclampsia**. He has injected urine into the circulation of animals and endeavored to ascertain its toxicity. He finds it very difficult to ascertain the toxic equivalent of normal urine. A certain relation exists between toxic effect and specific weight—the more concentrated, the greater toxic effect. Neither urine nor amniotic fluid is more toxic in cases of eclampsia than in normal cases. The blood serum has likewise the same effect in eclampsia and in normal cases. The serum of the fetus is no more toxic than that of the mother, contrary to what Tarnier claims. Schumacher explains the false results of former authors by assuming that they neglected the specific weight of the urine.

BLUMREICH and ZUNTZ, as guests: **Experimental Additions to the Pathogenesis of Eclampsia**, have experimented on animals by determining the reaction of the cortex of the brain to toxins which produce convulsions; they find that the brain of pregnant animals reacts to smaller doses of creatin than does the brain of nonpregnant animals.

DIENST (Breslau), as guest: **Anatomic Findings and Examinations of the Blood and Urine of Eclamptic Mothers and their Children**.

SCHRÖDER (Bonn) on the **Determination of the Pulse Tension and the Freezing Point in Eclampsia** finds that the pulse tension is higher in pregnancy. An increase of pulse tension in eclampsia occurs only in those cases where nephritis is present. Pulse tension is dependent upon the amount of urine excreted—large amount of urine, tension lowered, and the reverse. He thinks he has found the freezing point lowered in 8 cases.

STRASSMANN (Berlin): **The Dividing Point of the Aorta in Pregnant Women and its Relation to Eclampsia**. He believes that when the aorta divides at a higher or lower point than normal, the ureters cross the psoas in such a way that they are more readily exposed to pressure. His theory is not supported by his own statistics.

KNAPP (Prague) on **The Teaching in Regard to Uremia**. GLOCKNER (Leipzig) on **The Relation Between Puerperal Eclampsia and Epilepsy**, reports 5 cases where he thinks a relation existed; in 2 cases epilepsy appeared after an attack of eclampsia and has continued.

The fourth session continues the **Discussion on Carcinoma Uteri**.

MARTIN (Greifswald) emphasizes the difficulty of deciding, even at operation, whether the lymph-glands are affected or not. He considers Schuchard's incision of great value. He has also tried the method devised by Döderlein (Tübingen), and described at the last Surgical Congress in Berlin, and finds it a great aid and astonishingly easy. He favors Schuchard's incision, followed by Döderlein's method.

JORDAN (Heidelberg) takes the field for the vaginal route. He points out that the results with the vaginal method are at worst much better than the results of cancer operations on other organs, and holds that in view of these results we have no right to expose patients to the fivefold risks of the abdominal operation. As regards analogy with other cancer operations, Jordan claims that we cannot compare cases of breast and lip cancer with cancer of the womb; we must compare with cancer of the other organs of the abdomen, and in these cases surgeons do not attempt to extirpate the lymph-glands. He points out further that Wertheim lost 3 cases from the gland extirpation. A radical operation is impossible at best. He favors Schuchard's incision.

VEIT (Leiden) does not expect much from statistics—the only way to find out how cancer spreads is the anatomic. One can doubtless cure cancer of the uterus without extirpating the lymph-glands. Veit considers the abdominal route the better, more comfortable for the operator, etc. We need not fear sepsis. He operates either from above or combined. All of his cases where he had to remove the glands died.

HOLZAPFEL (Kiel) has performed a radical operation in 96 cases, 79 by the vaginal route.

FRITSCH (Bonn) considers the result of the discussion—the

must begin again from the beginning. We have 3 methods—high portio amputation, vaginal extirpation and the abdominal route. His results with the vaginal route are better than in other cancer operations. He has 10% lasting cures, and is satisfied with that. In the abdominal method he advises tamponade, not the closing of the wound toward the vagina. He has performed total extirpation in 395 cases, with 26 losses; he has seen ileus in 2 cases.

DÖDERLEIN (Tübingen) demonstrates on charts his new method of vaginal total extirpation, which he has tried in 50 cases with no death; 1 case operated by an assistant died. He first incises the posterior cervix lip, generally opening the Douglas with this first incision; then he continues the incision along the median line of the posterior uterus wall to the fundus; drawing down the corpus, he continues down along the median line of the anterior uterus wall, continually drawing the uterus away from the bladder, and operating in the vesicovaginal space. Finally he severs the anterior cervix lip, and has the organ in halves; then he proceeds to the adnexa. Hemorrhage is slight during the dividing of the uterus, and any slight bleeding is easily controlled. He claims for his operation that it is easily performed, there is practically no danger of operative injury to bladder and ureters, and hemorrhage is slight.

WERTHELM (Vienna) defends his method, which he thinks the best, although not enthusiastic for it, because he can overlook the field of operation to better advantage.

SCHATZ (Rostock) has operated 120 cases. He has 6 cases, operated by the old method, alive after 10 years or more; 9 cases alive after 5 years or more. He mentions 3 cases in which cancer existed simultaneously in some other organ, *i. e.*, not as a metastasis.

DÖDERLEIN (Giessen) calls attention to the fact that the number of operable cases is increasing.

FREUND and WINTER closed the discussion. Freund concludes from the discussion that the larger number of those present prefer the vaginal route. He could never attain such good results as those reported by Fritsch; could show but 7-8% lasting cures, and therefore chose the abdominal route. Winter concludes: the earlier the operation, the better. No method for the prevention of implantations has been suggested. Schuchardt's incision is in general approbation. Winter himself considers the method valuable because one can operate cleaner and better. The hope of the future is in an abdominal method which gives a smaller primary mortality. Studies of the lymph-glands are greatly needed. We must differentiate between the different forms of cancer; in the future we will say, "This form of cancer I operate by the vaginal, that form by the abdominal route."

The congress then proceeded to the discussion of eclampsia.

HERZFELD (Vienna) On Eclampsia, has studied the protocols of the Pathologic Institute in Vienna, and has found 81 cases recorded. All cases had in common pathologic changes in the kidneys, edema of the brain and the lungs. In a number of cases changes in the liver. Remarkably frequent were osteophytes of the skull. In 18 cases he found compression of the ureters recorded, and gives it as his opinion that eclampsia is an intoxication caused by fetal products, which under normal conditions are excreted by the kidneys, but which, in cases of compression of the ureters, can cause eclampsia.

VEIT (Leyden) has seen but 14 cases in Leyden, with 1 death. He advises morphin and rupture of the membranes. He mentions some cases where he thinks the same toxin was at work, but was not concentrated enough to produce convulsions. He does not think we should always use forced confinement.

NAGEL (Berlin) has had a mortality of 27%, which varies in different years; in 1895-1896, 12% mortality, in 1896-1897, 39%. Altus' treatment was the same in both years; 183 children were born alive, 103 dead. Nagel calls attention to the fact that the disease often occurs in groups and suggests that it may possibly depend upon the weather. He has never seen a case of direct infection.

The fifth session began with demonstrations. Of especial interest were the preparations demonstrated by ASCH (Breslau), who found in one case that a bougie which had been sterilized in formalin produced a necrosis, not only of the mucosa, but also of the muscularis.

KRETSCHMAR (Wiesbaden) shows a rare small cystic tumor—a folliculoma malignum ovarianum gottschalk.

KRÖNIG (Leipzig) describes a method of controlling the manufacturers of catgut sterilized according to his method; he places in the tube or box containing the catgut, a substance which melts at the required temperature, 160° C.

FREUND, junior (Strassburg), shows several preparations from cases which clinically, and at operation, resembled extrauterine pregnancy; serial sections showed, however, that there was no pregnancy, but that the hematoma of the Douglas, came from other sources, as in 1 case from a burst bloodvessel of an engiomatous tube.

The Congress then proceeded to the discussion on eclampsia.

ALBERT (Dresden) thinks the disease due to a latent inflammation of the decidua. He claims to have found microbes—in microscopic preparations—in 2 cases. He thinks there is no specific germ, but that the disease is caused by the resorption of the toxins of different germs.

SCHATZ (Rostock) misses in the discussion those cases of eclampsia when the attacks appear in groups; he has seen as many as 3 distinct groupings. He further mentions those cases where the patients have a marked nervous disposition, but these cases are generally less severe. In regard to bleeding, Schatz considers the idea that the bleeding lets out a greater or less amount of the specific poison too mechanical to be plausible; venesection is of advantage because it lowers the pulse tension. He reports 1 case where the attacks were very severe following a cesarean section, but the convulsions ceased immediately upon removal of the tampons. He has also studied the influence of the weather, and finds that in Mecklenburg, the influence of the weather is directly opposed to that claimed for Berlin; in Berlin the cases are more frequent in winter, in Mecklenburg in summer.

OLEHAUSEN (Berlin) has always held that the disease is an intoxication; he has found it hard to believe that the toxins are of fetal origin; has always believed more in the influence of the pressure of the pregnant uterus. He denies the claim advanced by Harzfeld that edema of the brain is a constant pathologic finding. In a number of the 104 autopsies he has seen there was no edema of the brain, and in 1 severe case the brain was fairly sclerotic. He uses morphin less than formerly, and thinks he obtains better results. Rupture of the membranes is used in his clinic very often. He has used venesection in 84 cases with the idea that the concentration of the poison is lessened; he uses salt infusions either with or without bleeding. His latest statistics show 400 cases with 17% mortality. The disease is on the increase; in the last year he has had 83 cases, against 50 of the year before, and less in the preceding years. The disease is also more severe; he measures the severity by averaging the number of attacks for each case; for the 83 cases of the last year this average was 94. He considers cesarean section indicated and less dangerous than the deep cervix incision of Dührssen.

DÖDERLEIN (Tübingen) reports on the Frequency of Eclampsia in Würtemberg; in this province it is very rare, for example about 20 times as rare as in Russia. He does not know how to explain it—possibly because the conditions of life are better than in some other provinces. Nephritis is also relatively rare in Würtemberg.

HALBAN (Vienna) has obtained negative results in his experiments on the freezing point.

KÜSTNER (Breslau) thinks the discussion shows unity of opinion in regard to the therapy, careful and rapid confinement. He has performed cesarean section in 6 cases, all of which died; he did not gain the impression that the operation had any effect on the course of the disease.

P. MÜLLER (Berne) asks what shall be done in those cases where albumin, edema, etc., are present? Are we justified in inducing eventual abortion?

GESSNER calls attention to the many cases where the attacks cease hours before labor is completed, and which are nevertheless enrolled in the statistics as cured by confinement; he thinks there is no proof that these cases would not have cured of themselves. He uses morphin and chloral hydrate.

FRIESCH (Bonn) thinks prophylaxis would yield good results, especially in those cases where the woman has previously suffered from eclampsia.

L. MAYER (Copenhagen) has had good results in 49 cases of eclampsia with the nonelastic metreurythner.

EVERKE (Bochum) reports 52 cases from his practice. In 34 cases he used Dührssen's incision, 4 died without regaining consciousness, 3 died of sepsis; in 7 cases he performed cesarean section, of which 5 died.

BRESMER reports 4 cases from his practice in Weisbaden. All 4 died. He thinks one fault in general practice is that the physician is called too late.

SÖHLEIN does not think that the toxin is always produced by the fetus; he mentions a case in an old woman of carbolic acid poisoning which produced eclamptic symptoms.

FEHLING, closing the discussion, calls attention to the fact that eclampsia is very rare south of the river Main; the most cases occur in the large cities to the north of the Main, notably Berlin, Dresden and Leipzig; osteomalacia is, on the contrary, hardly known to the north of the Main. He uses morphin, but has given up the large doses first advised by Gustav Veit. Eclampsia occurs in but 5% of the cases of nephritis gravidarum; therefore forced confinement is indicated only in those cases in which the eclamptic symptoms have already appeared. The incision has shown unity in regard to the treatment; the theories of the etiology are still widely at variance.

The sixth session was devoted to the papers on different subjects. The session opened with the paper by KOSSMANN (Berlin) *The Identity of the Synectium with the Epithelium of the Uterus*, who demonstrates enlarged photographs of sections of the ova of rabbits which prove, as he thinks, his standpoint that the synectial cells can only arise from the epithelium of the uterus, never from the ectodium of the blastula. He thinks that the nuclei of the epithelial cells increase in number by simple division until we have the synectial cell. PFAUNTIEL (Breslau) takes the opposite standpoint, and holds that we cannot conclude from the rabbit as to the conditions in man.

NYHOFF (Groningen) read a paper on *Why does the Placenta first loosen itself, under normal conditions, after the birth of the child?*

KÜSTNER (Breslau) has endeavored to find why the danger of laparotomy is so great. He thinks many cases of shock are due to the most acute form of sepsis. He then began by using rubber gloves for his assistants, then for his left hand, and now he uses rubber gloves for both hands, and to lessen the expense of long gloves, he uses rubber cuffs; he further handles the peritoneum as exclusively as possible with instruments. He also sews sterile rubber flaps to the wound before opening the peritoneum. To improve the cosmetics of the operation he makes a suprapubic cross incision within the hair boundary. Colpotomy is less dangerous than laparotomy.

PFAUNENGTIEL (Breslau): Further Experience with the Suprasympphysic Fascia Incision. He has operated in 113 cases with his incision, which he devised to avoid postoperative hernia. He does not think it necessary to improve the cosmetics of the operation, and makes an incision above the hair boundary, parallel to the pubic bones, then the aponeurosis, then he dissects the fascia from the recti and opens the peritoneum by a vertical incision between the recti. He has had no cases of hernia following his method. A disadvantage is that the dissection of the aponeurosis from the muscles gives a better opportunity for infection. He has had some cases of wound infection, but fewer as his technic has improved. He considers the ordinary incision better for tumors.

WINTERNITZ (Tübingen): The Diagnostic and Therapeutic Value of Bacteriologic Examination of the Uterus Cavity in Cases of Fever Following Labor. He considers the bacteriologic examination the only method of determining whether the fever is caused by infection or by mastitis, etc.

ALBERT (Dresden): On the Germs Found in the Pregnant Uterus. He claims to have found cocci and rod-shaped organisms in sections of the fetal incubances. Microscopic findings in stained sections without cultures as proof of "latent inflammation" are not convincing to say the least.

ZIEGENSPECK (Munich): On the Insignificance of Douglas' Fold as to the Position of the Uterus.

VON FRANQUÉ (Würzburg): On the Formation of Metastases in the Uterus in Malignant Diseases of the Tube. He advises the removal of the whole genital system in malignant tumors of the tube, since one often finds metastases in the uterus at an early stage, a suggestion first made by Sänger.

QUEISUER (Bronberg) discusses the city care of confinement cases and the control of the women who nurse such cases after the midwife has left.

HALBAN (Vienna) has experimented on a species of ape to solve the question of menstruation. He has removed the ovaries and implanted them under the skin, and as a result of such experiments avers that Pfüger's theory of the cause of menstruation is false—menstruation is caused by some metabolic product of the ovary which can act after the organ has been removed from its normal connections.

The Congress of 1903 will meet at Würzburg under the presidency of **HOFMEIER**. The first main topic for discussion will be **Extrauterine Pregnancy**; the second, **Operations for Prolapse**, with Especial Consideration of the Lasting Results.

NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.

ELEVENTH ANNUAL MEETING, HELD IN ST. PAUL, JUNE 3, 1901.

Dr. EMIL AMBERG read the Report of the Committee on Interstate Reciprocity and Uniform Medical Legislation: He said that the first step toward interstate reciprocity and uniform medical legislation must be established in the various political divisions by forming the medical laws so that interstate reciprocity is allowed. The second step consists in establishing the standard for physicians who are permitted to practise. The third step consists in an arrangement by which the findings of one Board may be accepted by another Board.

The committee reported with satisfaction that the progress along all lines mentioned had been satisfactory during the last year. In regard to the first point the committee reported that the law permitted reciprocity in the following political divisions: District of Columbia, Delaware, Illinois, Indiana, Kansas, Maryland, Michigan, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Virginia, Washington and Wisconsin. Concerning the second point the committee noted with satisfaction, progress in Indiana and Washington. With reference to the third point, the New England States showed that the division into groups is practicable and desirable. The demand for uniformity of medical education is apparent. The establishment of uniformity is possible. It can be established through the Examining Boards, aided by the profession and by the public. The committee came to the following conclusions:

1. The acceptance by the weaker divisions without examination of applicants from States having higher requirements without demanding reciprocal recognition and the discrimination of Medical Boards against inferior schools in their own rates reveals a commendable spirit.

2. As a step toward interstate reciprocity, the Committee commended the action already begun of reciprocal arrangements and agreements between the Boards of the several States having laws which provide for reciprocity and whose requirements are similar. This will result in the formation of groups of States with established reciprocity.

It is recommended that the members of the Confederation from States in which the standard of requirements is not yet sufficiently high, use faithfully the argument that interstate reciprocity can be obtained for the practitioners of that State only upon the basis of such legislation as will bring the standard up to that required in the States with which they intend to establish reciprocity. The 3 principal points considered were: (1) That the law in any political division should require or authorize the examination of all applicants for license by a competent Examining Board; (2) that to be eligible to examination the applicant should be required to furnish to the Examining Board evidence of having graduated from a reputable medical college in good standing with the Board in the State in which said college is located and with the Board to which application is made; (3) examinations should be uniform throughout the States as to subjects or branches upon which examination is required. The Committee believes that it would be well for the Confederation to agree upon the branches upon which applicants should be examined, to the end that uniformity of requirements by the various Boards may be attained, and that the percentage required in each subject and the manner of conducting the examinations, together with the rules to be enforced in each examination, should all be uniform. The Committee urgently recommended that reciprocity between the Examining Boards of the country on all questions pertaining to the welfare of the public and the elevation of the profession be maintained. To this end there should be the fullest and freest communication between the Boards, which should not be limited to their official reports.

Dr. HARVEY B. DALE followed with a paper entitled **Some Vulnerable Points in Medical Legislation**. He stated that the ultimate intent of medical legislation is unquestionably good. Its motive is a laudable one. It aims to directly benefit suffering humanity, not to establish a doctors' trust, nor to stifle competition, nor to strangle any practical new idea or system of treatment in its infancy. Enforced unification of standards on the part of medical colleges would simplify matters. It would result in a diploma being generally recognized for what it purports to be—a certificate of actual fitness to practise medicine. It would enable the recognized graduate in one State to move into another at his own will. It would remove all injustice and hardship now endured, not always patiently, by qualified physicians. It would strike the Upas tree at its root instead of lopping off its branches. It would do away with the manifest injustice to really qualified and honest college faculties, now inflicted by postmortem dissections of their deliberate decisions. In a word, it would reduce the present complicated legislative machinery to a very simple and effective mechanism. Given a concise, yet comprehensive, definition of what constitutes the practice of medicine, a uniform requirement that all who engage in such practice should have a medical diploma, and a legislative guarantee based upon actual information that such diploma says what it means, and means what it says, quackery would find life a burden in this country. The qualified physician of one State would be a qualified physician everywhere. The pretender might travel from Maine to California, and from California to Maine again, looking in vain for a chance to plunder the people.

Dr. HENRY BEATES, Jr., read a paper entitled: **How Should the Practice of Medicine be Legally Defined.**

He presented the following definitions for consideration: To practise medicine. Definition: For any one, excepting those carrying out the directions of the attending physician, to engage directly or indirectly, habitually or occasionally, gratuitously, or for pecuniary or other compensation, in the care, management or treatment, by any means whatsoever, either material or immaterial, for the prevention, relief or cure of any or all diseases, accidents or disability to which human or animal life is exposed, threatened or afflicted.

Practitioner of Medicine: Any one, excepting those carrying out the directions of the attending physician, who engages directly or indirectly, habitually or occasionally, gratuitously, etc., as above.

The Practice of Medicine: The engaging by any one, except those carrying out the directions of the attending physician, directly or indirectly, habitually or occasionally, gratuitously, etc., as above.

The above definitions were only offered in the nature of suggestions. During a lengthy discussion the definitions were criticized, several modifications suggested, but no action taken by the confederation committing it to any particular definition.

The following officers were elected for the ensuing year: President, **Dr. N. R. Coleman**, Columbus, Ohio; first vice-president, **Dr. Henry Beates, Jr.**, Philadelphia; second vice-president, **Dr. James A. Egan**, Springfield, Illinois; secretary-treasurer, **Dr. A. Walter Suiter**, Herkimer, New York; Executive council, **Dr. William S. Foster**, Pittsburg; **Dr. Joseph M. Matthews**, Louisville; **Dr. William A. Spurgeon**, Muncie, Ind.; **Dr. William Warren Potter**, Buffalo, and **Dr. Augustus Korndorfer**, Philadelphia.

CORRESPONDENCE

ANTIVIVISECTION IN MASSACHUSETTS.

BY

HAROLD C. ERNST, M.D.,
of Boston, Mass.

A paragraph in AMERICAN MEDICINE, page 282, of the issue of May 18, 1901, I think is unfortunate because it may mislead. It is the last part of the statement in regard to antivivisection, in which the lines run as follows: "while the Massachusetts laws guard against this point by the admission of any authorized agent of an incorporated society, to any place registered under the law for the practice of vivisection." This, of course, implies that there is a distinct law in Massachusetts against vivisection, which is not the case. There is a law against vivisection in the public schools, but no other. The practice of animal experimentation in Massachusetts is covered by the general laws against cruelty to animals, which are of the most severe kind and the existence of which has made it possible to prevent the passage of the annoying restrictive measures that have been attempted 3 times in the last 5 years.

CORRECTION.

To the Editor of AMERICAN MEDICINE:—Your reporter for the neurologic section of the American Medical Association evidently confused me with someone else. He represents me as endorsing the special pleading of Dr. Lambert Ott for the railroad claim agent. I was not present at the reading of the paper; had I been I should have strongly emphasized the position taken by Drs. Moyer and Craft.

JAS. G. KIERNAN, M.D.,
Chicago, Ill.

CONGRESS ON TUBERCULOSIS.

To the Editor of AMERICAN MEDICINE:—I would like, through your journal, to call the attention of members of the profession to the important Congress on Tuberculosis, which will be held in London from July 23 to 26. It is much to be desired that a large contingent from the United States should participate in the work. Many prominent physicians have signified their intention of joining the Congress. Members of the profession wishing to do so should send their names, enclosing \$5, to Dr. St. Clair Thomson, 20 Hanover Square, London, W., England.

W. OSLER,
Baltimore, Md.

PAY HOSPITAL FOR CONTAGIOUS DISEASES.

BY

J. MADISON TAYLOR, M.D.,
of Philadelphia.

The managers of the proposed Pay Hospital for Contagious Diseases have secured by purchase an excellent site just out the city limits, near Narbeth, on the Pennsylvania Railroad. The lot is bought and paid for, and the buildings will be erected as soon as possible. There is likely to be local opposition on the ground of supposed danger of infection, but the plans are made by Mr. Herman Miller, an architect who has distinguished himself already by his originality and practicality in hospital construction, and includes a novel method of ventilation by which all the air from the pavilions, etc., is carried by pipes directly to the smoke shaft of the furnace and acts as draught to the fires, which are kept going night and day—nothing escaping into the surrounding atmosphere. This will guarantee absolute disinfection and immunity, hence there will be no safer place to live than in the immediate vicinity of this hospital. A copy of their plans will be published at an early date in this journal.

The hospital is a most imperative need for all physicians who enjoy equally full privileges of attending their own patients, and for all people of such means that they prefer to,

and are able to pay for accommodations, and thus escape being sent to the Municipal Hospital.

The success of this most invaluable institution will depend upon the consistent support of the physicians themselves. It is particularly important that they support the management at this time, while organized opposition is arrayed against the projectors.

A SUCCESSFUL PORROCESAREAN SECTION

BY

JOHN R. COOK, M.D.,
of Fairmount, West Virginia.

Mrs. H. C., aged 24, Welsh, was admitted to my private hospital, February 20, at 2 p. m., sent by Dr. F. W. Hill, who had been called to attend her. At the time of admission she had been in labor 48 hours. The water had broken and os was considerably dilated, but the head could not enter the superior strait because of a pelvis deformed through an injury received when the patient was 6 years old.

On examination, the conjugate diameter was found to be 2½ inches, and the os patulous, well dilated. In fact it was difficult through the narrowed canal to reach the head of the child. It seemed more dangerous to attempt craniotomy than to open the uterus from above. As soon as the patient was thoroughly cleansed, with the assistance of Drs. Hill and Howard, I made an incision 7 inches long—3 inches above and 4 inches below the umbilicus—delivered the uterus, packed gauze around the abdominal incision, and opened the uterus by a longitudinal incision. I then took hold of the feet and removed an 8 pound male child. I lost no time in removing the afterbirth, but clamped the cord. Leaving the placenta in the uterus, I proceeded to remove the organ, which was amputated at the cervix. I pushed a piece of gauze through the cervix into the vagina to give more thorough drainage and, turning the stump in, walled off the abdominal cavity, washed out the clots, and closed the abdomen with silkwormgut. The patient was removed from the table with a pulse of 100, but with infusions of salt-solution rallied, and has made an excellent recovery.

It has been just 3 weeks since the operation, and the mother is sitting up, and has sufficient milk for her child.

GONORRHEAL OPHTHALMIA IN THE NEWBORN.

BY

H. A. BRAV, M.D.,
of Philadelphia,

Clinical Assistant in the Polyclinic Hospital of Philadelphia.

In the latter part of December, 1900, N. A., an Arabian, residing in the southern section of this city, came to my office suffering from an acute attack of specific urethritis. According to the usual method of treatment, I prohibited sexual intercourse; when he told me that he had had connection twice with his wife before consulting me, he not having been aware of the contagious nature of the disease. His wife was at that time in the sixth month of pregnancy, and knew nothing of her husband's malady. I warned him of the danger to the child, especially when delivered by a midwife, and advised him to engage a doctor for the confinement, but both husband and wife refused to have a man attendant on religious grounds. In the beginning of April, 1901, about 2 weeks after the birth of the child, they sent for me. I quickly responded, having been told by the messenger what the nature of the illness was; and I found a baby, well-developed for its age and evidently in good health, suffering with ophthalmia neonatorum of the most virulent form. There was great swelling of the mucous membrane, edema of the lids, and free secretion of thick, creamy pus. Although I knew the history of the case I made a microscopic examination and found the gonococci of Neisser in abundance.

I was told that the disease started when the child was 3 days old, but as the midwife said it was harmless and would disappear in a few days, they neglected to send for me. I ordered cold-compresses to the edematous lids, and an antiseptic eyewash to be used every 15 minutes. Once a day I touched the swollen mucous membrane of the everted lids with a solution of silver nitrate, 10 grains to the ounce. This treatment was continued for 2 successive weeks, and also the instillation of a weak solution of atropin at great intervals. At the end of the second week the grave symptoms subsided, but a slight discharge continued which lasted for a few days. At the end of the third week the child was perfectly well. I therefore stopped the nitrate of silver applications but ordered the mother to use the eyewash every 2 hours for 3 more weeks.

The interesting features of this case in my estimation are the escape of the mother from symptoms of gonorrhoea and the comparatively short time it took for the disease to yield to treatment.

THE TREATMENT OF ABDOMINAL AORTIC ANEURYSM BY A PRELIMINARY EXPLORATORY CELIOTOMY AND PERITONEAL EXCLUSION OF THE SAC, FOLLOWED AT A LATER SITTING BY WIRING AND ELECTROLYSIS, WITH THE REPORT OF 2 HITHERTO UNPUBLISHED CASES.¹

BY

RUDOLPH MATAS, M.D.,

of New Orleans, La.

[Concluded from page 546.]

In attempting to establish the limitations of the Moore-Corradi method let us first briefly consider the conditions that are usually met in practice. It is of prime importance that we should first recognize that the cure of aneurysm does not rest solely upon the successful coagulation of the blood or the arrest of the blood-current in the sac. Such a result, it is true, may mean the cure of the aneurysm itself; but, in abdominal aneurysm, the result, even when most successfully obtained, may precipitate an untimely end and the patient may die *because his aneurysm is cured*. This conclusion, paradoxical as it may seem, will be readily understood when we reflect that some of the most important visceral arteries—*e. g.*, those given by the celiac axis, the superior and inferior mesenteric branches, and the renals—often take their origin from the aneurysmal portion of the artery. Hence it is obvious that if the circulation in the sac is arrested and the openings leading into these branches are blocked by the aneurysmal thrombus, the viscera supplied by them—in view of the absence of a sufficient collateral supply—will necessarily starve and undergo fatal necrotic changes. That this is not an idle or theoretic fear is well and abundantly shown by the fatal results of coagulation caused by other non-aneurysmal conditions in which the intestinal arterial supply is blocked by thrombosis of the mesenteric vessels. A few reported cases of abdominal aneurysm in which this fatal form of mortification has been brought about by the sudden obstruction of the large visceral branches given off from the aneurysmal sac will suffice for illustrative purposes. The case reported by Lunn and Benham in the *Medico-Chirurgical Transactions*, London, 1885, vol. lxxviii (*British Medical Journal*, April 18, 1885, vol. i, p. 783) is particularly interesting:

An abdominal aortic aneurysm in a male patient, aged 30 years, could be felt in the epigastric region. The dimensions of the tumor were 6 to 7 inches from side to side and 5 to 6 inches from above downward, and extended anteroposteriorly from the vertebral column to the anterior abdominal wall. On October 31 distal compression was applied to the aorta with Corte's compressor for 4½ hours, under chloroform and ether alternately. The following morning all the physical signs of aneurysm were less marked. The tumor was smaller, harder, and pulsation less marked. The patient continued to improve for 7 days. On the eighth day, however, persistent vomiting set in, and on the twelfth day he died, with marked peritoneal symptoms. *At the necropsy the aneurysm was found to be cured, but there was gangrene of 2 feet of the jejunum.* The superior mesenteric artery which originated in the sac was completely blocked. In the discussion that followed the report of this case, Mr. Bryant stated that he believed that in one of his cases of abdominal aneurysm in which he had applied distal compression, death had occurred from the same cause.

By inquiring into the records of the 15 cases of abdominal aneurysm treated by wiring and electrolysis, I find only a few which furnish clearly defined evidence bearing on this point, but these few are sufficiently sig-

nificant when we consider that in many others death followed too quickly after the operation to exhibit this distinctive mode of termination.

In 12 fatal cases out of the total 15 reported, the causes of death are stated as follows: In Loreta's case death occurred on the ninety-second day, from rupture of the aorta below the coagulated and cured sac; Lange's patient died on the twelfth day after wiring, from pneumonia and exhaustion; the aneurysm had partially ruptured before the operation and had remained active, and was uninfluenced by this procedure; Stevenson's patient (superior mesenteric artery involved) lived only 27 hours after the operation, death being caused by direct hemorrhage following the operation; Stewart's abdomino-thoracic case (No. 1) was fatal in 9 days, from rupture of the sac; Stewart's second abdominal case terminated fatally on the fifth day, from hemorrhage and other complications resulting from perforation of the aorta with wire; Parham's patient died 45 days after the operation, from exhaustion, hemorrhage, and the effects of penetration of the wire into the thoracic aorta and left ventricle of the heart; Reeve's case ended in death 24 hours after the operation, from interference with the circulation caused by penetration of wire into the thoracic aorta up to the aortic valves; my patient died 19 days after wiring and coagulation of the sac, from rupture of a secondary diverticulum or pouch in the sac, which yielded after the main cavity had been filled with clot. The remaining 3 fatal cases (Halsted's, Finney's first abdominal case, and Pringle-Morris's) have points directly bearing upon the influence of the topography of the aneurysm and the origin of visceral branches from the sac, in its relation to the prognosis of abdominal aneurysm.

In Halsted's patient celiotomy was performed and the tumor exposed; 17 inches of No. 27 silver wire was first introduced and a galvanic current applied for 12 minutes; then a larger canula was introduced, and 38 inches of No. 25 silver wire was also introduced; to this the anode of a galvanic current was applied and a current of varying strength from 30 to 100 milliampères was passed and continued for 85 minutes. The patient lived 40 hours after the operation, and died with symptoms of sudden internal hemorrhage. The autopsy showed that a tumor extended from the diaphragm to the renal veins. An opening was formed in the dome of the sac leading into the pleura, which contained an immense quantity of blood. The aneurysmal opening leading to the aorta was very large—almost as large as the vertical diameter of the sac itself. "The chief abdominal vessels were found to arise from the lower portion of the sac, the celiac axis and superior mesenteric coming off within the sac, while the renal arteries sprang from the dilated aorta just at the mouth of the sac." In this case, as Dr. Hunner remarks, "when we consider the position of the origin of the celiac and the superior mesenteric vessels from the wall of the sac there can be no doubt that the patient's death would have been even more precipitous had there been a formation of an obliterating clot during the operation."

Finney's first abdominal case is also instructive on this point. This patient died on the twentieth day, from hemorrhage and exhaustion. Five feet of silver wire was passed through a fine insulated aspirator needle. The wire was alloyed with 0.0075 of copper and drawn from No. 8 to No. 27. The galvanic current was begun at 30 milliampères and increased 10 milliampères each 5 minutes until 70 milliampères was reached, where the current was kept 1 hour. The effect upon the tumor was marked. The thrill ceased, no expansile pulsation could be determined, the sac was firm and decidedly smaller. After closing the abdomen nothing but a communicated pulsation as of a solid tumor lying on the aorta, could be made out. The success of the operation seemed assured; but, on his recovery from ether, the patient complained of excruciating pain which increased until, within a few days, morphin was being given in ½ grain doses every 2 or 4 hours. Pulsation in the sac returned on the fifth day, and continued to increase until death. On the nineteenth day there was bleeding of about 300 cc. of bright red blood in the wound. He died on the twentieth day, 7 hours after the hemorrhage from the external wound.

At the autopsy, upon dissecting the aneurysm, it was found, among other very interesting conditions, that the celiac axis originated from the upper border of the sac. It was also found that the aneurysmal orifice corresponded with the origin of the superior mesenteric artery, of which artery the aneurysm was a dilation. It was evident that the wire had entered this portion of the sac and that blood had coagulated within the sac and almost filled it with solid antemortem clot. In connection with this involvement of the superior mesenteric and celiac axis it is interesting to note that at about the transverse portion of the duodenum there was an irregular area measuring 4.5 by 6.5

¹ Condensed from complete paper which is published with appendix containing report of published cases in Transactions of the Southern Surgical and Gynecological Association, for the meeting held in November, 1900.

cms., over which the mucosa was exceedingly hemorrhagic and partially necrotic. The jejunum, as well as the duodenum and upper portion of the ileum, was of a dead chocolate color, and on being opened these were found to contain considerable bloody fluid. In the light of these postmortem findings it would appear that in this case, as in Dr. Halsted's, the almost complete obliteration of the aneurysmal portion of the superior mesentery was largely responsible for the necrosis of the bowel.

In Pringle and Morris's case, in which death took place on the fifth day from traumatic delirium and asthenia, the post-mortem findings explain to us how it happens that in some cases of aortic aneurysm which involve the celiac axis recovery is possible after coagulation and obliteration of the sac without bad consequences as regards the visceral and intestinal circulation. In the necropsy of this patient the aneurysm, which was seated in the celiac area, was undergoing coagulation and was apparently in process of cure. It was noticeable, however, that the opening leading into the sac was situated in the posterior and lateral wall of the artery opposite the origin of the celiac axis. This sufficiently accounts for the absence of untoward results, as it was possible, under these conditions, for the aneurysm to consolidate without affecting the circulation in the celiac branches.

Stevenson's patient, in whom the aneurysm was found at the necropsy to have involved the superior mesenteric artery, would, no doubt, have shared the same fate had he survived longer the effects of the hemorrhage from the puncture. The patient died 24 hours after the introduction of 2 yards of "the finest steel wire."

In the 3 cured cases (Morse, Langton and Noble) the evidence bearing upon the exact relationship of the important visceral branches to the sac is, for obvious reasons, difficult to determine with any degree of accuracy, and consequently is not specified. In Morse's case, no information can be obtained as to the exact location of the tumor except that it occupied the upper epigastric region; therefore, presumably, the celiac area was involved. In Langton's case, it is distinctly stated that the aneurysm was situated in the front of the aorta below the superior mesenteric artery. Consequently it was situated in the second division of the aorta, which would account for the success of intervention. In Noble's case, it is stated that the sac was adherent to the lower border of the stomach and to the transverse colon, and this would suggest, with other facts, that the tumor originated below the celiac axis and the superior mesenteric artery. The comparatively low origin in these 2 cases would, therefore, tend to bear out the conclusion that aneurysms which originate low down on the abdominal aortic tract, especially below the superior mesenteric, all other conditions being equal, are much more favorable for attack by this method than those seated higher up in the celiac area.

* * * * *

In accordance with these facts we may classify the sacculated aneurysms of the aorta into 3 categories. The first group includes all the aneurysms which originate in the infradiaphragmatic portions of the aorta, extending from the diaphragm to and including the origin of the renal arteries; this is the most important anatomic division of the artery, because it gives birth to the celiac axis, with its gastric, hepatic and splenic branches, the superior mesenteric and renal arteries. It is the most important pathologic section of the abdominal aorta, because it is the most frequent seat of aneurysm. Lebert demonstrated long ago that 50% of abdominal aneurysms originated in this part of the aortic tract—(52 out of 92 cases). It is also unfortunate that this division of the artery is comparatively short—scarcely more than 2 to 3 inches—the entire length of the abdominal aorta from the diaphragm to the bifurcation being only 15 cm., or about 6 inches. Therefore it is almost impossible for an aneurysm to develop in any part of this division without involving the origin of one of these all-important visceral branches; unless, as in Pringle and Morris's case, which must be a very rare occurrence,—the aneurysm begins in the posterior or lateral aspects of the aortic circumference. Consequently, from the prognostic point of view, aneurysms of the first or celiac division are of the gravest and most forbidding character.

The second division extends from the origin of the renals to and including the origin of the inferior mesenteric; this division includes only 1 vessel of great importance, the inferior mesenteric, but as this anastomoses very freely with the superior mesenteric and the inferior hemorrhoidal, it is probable that the occlusion of the vessel at its origin would not be followed by gangrene of the colon to which it is distributed; aneurysms in this division are much less frequent, but should they origi-

nate here their prognosis is better than in the first division.

The third division of the abdominal aorta extends from the inferior mesenteric to the bifurcation of the aorta. It is the longest division of the artery, and as it gives birth to no branches of visceral importance (lumbar and sacra media), it is the safest of all the divisions in a topographic and prognostic sense. Aneurysms here, unfortunately, are the most infrequent, and for this reason the comparatively favorable disposition of the artery at this level is of little help practically, except in the very few cases in which aneurysms originate within its boundaries.

It is also most unfortunate for both surgeon and patient that a knowledge of these divisions, which are of great pathologic interest, is of little avail practically, because it is impossible for the operator to determine, with any degree of precision, the exact site of the aneurysmal orifice, no matter how freely he may explore the abdomen. The tumor in all cases overlaps the point of origin of the sac; the peritoneal investment and overlying viscera, which are usually adherent to the sac, make all efforts at precise exploration futile and impracticable. It is therefore only by approximation and guessing that the relative position of the aneurysmal sac can be made out or even suspected.

In view of our powerlessness to make an accurate diagnosis of the site of the aneurysmal orifice, and also of the practical certainty that all aneurysms involving the first or celiac portion of the abdominal aorta involve one or more visceral branches of vital importance; and in view, also, that 50% of the aneurysms of the abdominal aortic tract are seated in this division of the artery, we must conclude that in all such cases it will be wise to abstain from attacking such aneurysms by the Moore-Corradi or any other method which aims at cure by coagulation. While it is not denied that an occasional cure can be effected even in aneurysms of the celiac region by this method, it is evident that a favorable termination will be the result of a happy chance, a mere accident due probably to posterior position of the orifice of the sac, which is extremely rare and which the surgeon has no logical or reasonable means of recognizing or anticipating.

* * * * *

If we eliminate the aneurysms of the upper or celiac division of the aorta as distinctly unfavorable to the mode of treatment under discussion, we will find its field of application restricted to a very small number of selected cases in the middle and lower divisions of the aortic tract; but even in these, when the anatomic objections are removed, there are other serious dangers to be considered which must imperil the life of the patient and militate against the success of the operation.

Foremost among these dangers is the possible rupture of the sac in multilocular aneurysms from unequal distribution of the clot during the process of coagulation. The danger is well illustrated in my case, in which, after apparently arresting the circulation in the main sac, a secondary diverticulum developed rapidly a few days after the operation, leading to its final and fatal rupture on the nineteenth day. That this accident will occur in spite of a good technic, applied under the most favorable conditions and after the success of the operation has been apparently secured, is amply demonstrated by several well-recorded thoracic and abdominal cases.¹

¹ Dr. Hunner, in his paper, l. c., p. 276, calls attention to this grave danger in the following paragraph:

"One of the greatest dangers in this procedure, particularly in the large multilocular aneurysms, is the development and rupture of a secondary sac due to the rapid filling of the main sac by coagulum and the shunting of the blood-stream against a portion not receiving a special strain before. Apparently, this occurred in the cases of Donnellville, Cayley, Ransohoff, Hulke, Barwell and in Stewart's first case." [Thoracic cases.]

"Loreta's unique case of rupture of the aorta at its junction with the base of the former aneurysm was probably caused, as he suggests, by the lack of nutrition to the wall due to changes in the circulation brought about by contraction of the organizing sac. General arterosclerosis would weigh against the operation."

Another unavoidable but rare accident is that which results from extension and detachment of clot from the aneurysmal orifice into the main trunk, leading to embolism and thrombosis of the aorta, with gangrene of the lower extremities. This possibility is well shown in a case reported by H. Morris to the Medico-Chirurgical Society of London, April 14, 1885 (*British Medical Journal*, 1885, vol. i, p. 784), in which an aneurysm of the subdiaphragmatic portion of the aorta had undergone spontaneous cure, with the formation of a clot which extended to the bifurcation of the artery, blocking up the iliacs.

Another danger inherent to the wiring process is the escape of a wire through a large aneurysmal orifice into the aorta, from which it may sometimes migrate to the heart itself. This accident is likely to occur whenever the orifice of the sac communicating with the artery is large. It necessarily follows in all cases in which a fusiform aneurysm is mistaken for a saciform formation. In the latter case it is avoidable, at least in abdominal cases, but as no one can positively diagnose the size of the aneurysmal orifice, *intra vitam*, it is evident that such accident is unavoidable when conditions favoring its occurrence exist.

The following case, kindly communicated to me by our Fellow, Dr. F. W. Parham, is worthy of special attention in this connection. The operation was performed in 1896, in the Charity Hospital of New Orleans, and I copy the observation in full as written by Dr. Parham:

History of a Case of Abdominal Aneurysm; Exposure of the Sac by Opening of the Peritoneal Cavity in the Median Line; Introduction of 26 Feet of Fine Steel Wire Through a Canula; Death in 45 Days; Wire Found Extending Along the Abdominal and Thoracic Aorta Even Into the Ventricle of the Heart.—James B., white, male, aged 46 years, was admitted into Ward 19, Charity Hospital, service of Dr. J. H. Bemiss, March 30, 1896. Patient was a man of very dissolute habits, being addicted to drinking immoderately for many years. At the age of 19 he contracted syphilis which, he says, manifested itself in the form of eruptions at various times. There is no family history bearing upon his present disease.

In July, 1895, while pursuing his occupation as fireman, he suddenly felt an intense pain in the lumbar region of the back, which gradually extended until it spread across the back. For about 2 weeks this kept him from working, and when he did go back he attended to his work with great difficulty, feeling very weak and complaining often of dizziness. He lost weight, and after December, 1895, was compelled to give up his work. When admitted to the hospital he was able to lie comfortably only on the right side with his left leg drawn up. If he lies for any length of time on his back he suffers intense pain, and he is almost unable to lie on the left side at all.

Physical examination by Dr. Bemiss showed lungs normal, as likewise the heart, except that the apex-beat was slightly displaced to the left. A distinct pulsation was observed, synchronous with the first sound of the heart, just below the ensiform cartilage, very close to median line. Palpation showed marked thrill, and expansion of the mass was made out. Auscultation revealed 2 sounds at the site of pulsation, the first being very prolonged, the second shorter. Liver-dullness was normal. The urine was not examined at this time.

The treatment pursued was potassium iodid in gradually increasing doses up to toleration in conjunction with sulfate of morphin when required to relieve pain.

He was admitted to my service on April 21, the conditions being practically unchanged. The medical treatment having failed, he was admitted to the surgical service with the hope that surgical interference might accomplish something.

Accordingly, on April 23, 1896, under chloroform, I opened the abdomen in the middle line, the incision about 5 inches in length, lying entirely above the umbilicus. The sac was easily found and uncovered of overlying tissues. It was an aneurysm of the abdominal aorta about the size of the fist, lying just above the umbilicus. A small trocar was inserted and the canula withdrawn. Some little difficulty was experienced in managing the canula, which was too short for the purpose, the adhesions preventing the tumor from being appreciably lifted from its bed. Some blood was lost from the canula, but a gauze pack being placed around it there was no further serious difficulty on this account. Very small steel wire, very resilient, so springy, indeed, that when it was once loosed from its spool it would fly off with a sudden jerk into space; about 26 feet were introduced in 2 sections.

The wound was only partially sutured, being left open, with gauze pack about the aneurysm. The patient was returned to the ward very much depressed, but nothing striking had occurred during the operation.

For 3 days strychnin and digitalis were given at frequent intervals, with an occasional dose of morphin to relieve severe pain, of which he complained. This pain was referred to the lower region of the thorax. After the third day no further stimulation was required, and the last dose of morphin was given on the fourth day. The diet consisted of hot water in small quantities until the afternoon of the second day, when he was allowed peptonized milk to which was added panopeptone on the next day. These were gradually increased in quantity. On May 5 pure milk was given, and this was alternated with panopeptone. May 11 he was allowed soft boiled eggs and soda cracker. After this he seemed to be doing well, and only occasional notes are recorded.

Later I find the following notes in the clinical record:

May 14, complains of slight pain in the lower part of chest, left side; is very restless.

May 15, rested well, but sleeps very little.

June 5, suffering from slight pain in lower part of chest and upper region of abdomen; nauseated. The pain passed off during the afternoon.

June 6, p. m., feels very well, but complains of a pressure in the chest and cannot bear the weight of any cover.

June 7, a. m., passed a very good night, sleeping a little, but complains of nausea, and of pain in both sides; feels very much depressed; 9 a. m., vomited; taken with a violent pain in the center of thorax, over region of the heart. At 9.45 a. m. tried to get out of bed, and while being restrained fell into collapse, losing consciousness, covered with a cold perspiration; pulse very weak. 12.30 a. m., resting and seems better; vomited. 12.50 p. m., taken with a severe pain; again collapsed, with loss of consciousness.

He died June 7, 1896.

The temperature and pulse records are of especial interest, and are here appended for study in connection with the post-mortem findings.

TEMPERATURE AND PULSE RECORD.

April 23, 1896, returned from the operating room at 12.45 p. m.

April	Hour.	Temp.	Pulse.	Respiration.
23	1 p. m.	99½	80	.
"	23 5 p. m.	100½	100	.
"	24 8 a. m.	102½	123	33
"	24 5 p. m.	101	.	30
"	25 5 a. m.	101	106	22
"	25 1 p. m.	100	107	26
"	25 5 p. m.	99½	93	23
"	26 5 a. m.	99½	80	20
"	26 5 p. m.	99	80	19
"	27 8 a. m.	98	79	18
"	30 6 a. m.	98	80	18
May	2 6 p. m.	98	70	18

Findings at the Autopsy.—The abdominal wound had completely healed, the site of the operation being marked by cicatrix. There was some difficulty in reaching the cavity owing to the adhesions. The parts about the wound were firmly matted together, but there was no evidence anywhere of pus. The liver was adherent to the abdominal wall at the median line; on its convex surface a bloody serum was observed. There was edema about the aneurysmal sac, and there was extravasation in the omentum. Some clots were found in the pelvic cavity, but nowhere below the level of the umbilicus was there any sign of any inflammatory exudate. On the superior wall of the stomach was a large adherent clot. The pancreas was adherent to the duodenum. There was a general matting together of the tissues in the neighborhood of the aneurysmal sac. There was no hemorrhage in the pleural cavity. The organs weighed as follows:

Kidneys, left, 6½ ounces; right, 5½ ounces.

Spleen, 9½ ounces; *liver*, 3 pounds, 1 ounce.

Lungs, left, 9½ ounces; right, 10½ ounces.

The aneurysmal sac was of the size of the fist and apparently as soft as at the time of the operation. The wire could be felt plainly coiled in the sac, but, strange to say, it could be traced up the aorta throughout its whole length until some of the strands could be found entering the heart itself, where some could be actually seen in the ventricle of the heart. The aneurysmal opening, situated in the anterior aortic wall opposite the seat of puncture, was large enough to admit the tip of the index finger. A point of wire could be felt protruding through the wall of the descending aorta just below the arch. There was also a solution of continuity of the wall of the sac at its lower part to the left and slightly behind. The wire had apparently undergone no change in the sac, and the aneurysm was not visibly affected by its presence. The aorta where the wire came through seemed practically unchanged, and the impression was that it had only recently pushed its way through. The wire in the heart also seemed to have caused little disturbance. The specimen was not more closely examined at this time, but was removed for further study and was subsequently exhibited before the Orleans Parish Medical Society. I thought at first that the wire might have been pushed up in the manipulations of the autopsy, but careful examination did not confirm this suspicion, and the general opinion of those present was that the migration of the wire was entirely ante-mortem. Unfortunately, the specimen was subsequently lost by decomposition, and the more minute changes could not be further investigated.

Dr. Parham's case is certainly very remarkable in this respect: The long survival (45 days after the migration of the sac into the aorta and heart), and in spite of the actual perforation of the aorta in one place, is certainly a revelation. It is still a question, however, whether the wire actually migrated out of the sac into the aorta and ventricle at the time of the operation or whether this happened subsequently; and that death only occurred later when, owing to the elastic spring of the steel wire, it escaped out of the aneurysmal orifice and suddenly reached the heart. The fact that the aorta was practically unchanged and that there was no thrombus, supports the impression produced at the time that the wire had only pushed its way through shortly before death. Whatever the interpretation of this occurrence, the case is another most striking illustration of the remarkable tolerance of foreign bodies by the aorta as well as of the dangers of the method. Of the other cases in which this migration of wire out of the sac, has occurred only 2 (Reeve's and Stewart's) are abdominal cases, Ransohoff's and White and Gould's being thoracic. In Reeve's case a silver-plated, soft, copper wire, 0.016 inch in diameter, was used and 7 feet introduced. As shown at the autopsy, the wire, irregularly twisted, occupied the center of the sac; one end, together with a double loop of wire, passed up the aorta, the looped part reaching about 10 inches, and the single strand quite up to the aortic valves of the heart, where it left a spot of ecchymosis. Yet in this case, as in Parham's, the conditions were the best calculated to prevent such an accident, as the aneurysm was distinctly sacculated, "the opening from the aorta into the sac being not over 1 inch in diameter."

In Stewart's case "fine silver wire (10 feet) was used. It was passed into a sacciform aneurysm and thence into the dilated aorta." In Ransohoff's case (aneurysm of ascending arch) 8 feet of flexible wire was passed through a canula. Nearly fatal syncope occurred after the introduction of the first 4 feet. At the autopsy (1 month after operation) it was found that 1 loop had passed through the aortic opening and rested just above and in close contact with one of the lunules of the aortic valves.

It is evident from the occurrence of this very serious accident in at least 3 out of 15 reported abdominal cases (20%) that it is not an insignificant element of danger, no matter how much the use of fine, properly drawn and snarled silver wire may have diminished this danger, which is especially inherent to coiled steel wire.¹

Rupture of the sac by penetration of its walls with a stiff wire is another accident which is recorded; rupture of a thin sac by overdistention with too much and too stiff wire has been the cause of failure in a few instances; this can be usually avoided by following Stewart's instructions and not wiring with more than 10 feet of very fine, highly drawn wire. There is a risk of cauterization and ulceration of the sac by applying too strong a galvanic current, and, finally, there is the risk of sepsis and shock, which are less likely to occur if the operation is performed in 2 sittings, as in the writer's case.

To summarize, then, the objections to the Moore-Corradi method:

1. The cure of the aneurysm may lead to the death of the patient by obliterating the orifice of important visceral arteries; this is most likely to occur in dealing with aneurysms of the upper or celiac division of the abdominal aortic tract—*i.e.*, in about 50% of the cases.

2. Secondary rupture of the sac from the strain put upon weak portions of the sac in multilocular aneurysms, after partial coagulation of the contents has taken place,

¹Hunner in referring to this dangerous migration of the wire, speaks also of White and Gould's case of fusiform aneurysm of the ascending arch in which the wire (22 feet of fine steel wire) escaped out of a more superficial sacular aneurysm into a second fusiform dilatation of the aorta. The great danger of the escape of wire from an external sacular secondary aneurysm through a large opening into a primary fusiform aneurysm of the aorta is certainly not to be overlooked in thoracic aneurysm.

(particularly likely to occur in subjects of general endarteritis with atheroma).

3. Escape of wire through a large aneurysmal orifice into the lumen of the aorta, with migration upward into the heart leading to perforation, traumatic endarteritis, endocarditis, with the formation of secondary thrombi and emboli.

4. Danger of perforating the sac by stiff wire or by overcrowding the sac with too much wire.

5. Danger of extension of clot from the coagulum in the aneurysm to the main artery, leading to fatal blockade at the bifurcation, with gangrene of the lower extremities.

6. Danger of rupture of sac from sudden withdrawal of abdominal support and displacement of adherent organs in the course of the exploratory laparotomy.

7. Danger of mistaking a fusiform for a sacciform aneurysm.

8. Danger from emboli and thrombi following incomplete coagulation of the blood in the sac (a very rare and practically unknown occurrence in abdominal cases).

9. Danger of shock.

10. Danger of sepsis.

In the presence of this formidable array of dangers which beset the application of this method we ask ourselves what are the conditions, if any, which are favorable to its successful application? Theoretically possible, but clinically rare, are the following conditions: (1) The aneurysm should be saccular; (2) it should be unilocular; (3) it should be provided with fairly strong, resisting walls; (4) the patient should be young or middle aged, fairly healthy, and free from general endarteritis and atheroma; (5) the aneurysmal orifice communicating the sac with the lumen of the parent artery should be small; (6) the aneurysmal sac should spring from the lower, inframesenteric division of the artery, preferably between the origin of the superior mesenteric and the bifurcation; (7) if given off from the celiac region the orifice should be situated on the posterior or lateral wall of the aorta.

With these ideal conditions, and with a perfect technique, the chances of permanent cure would be immensely increased and the operation could be undertaken with great probability, almost certainty, of success. But as the most important of these conditions can never be ascertained *intra vitam*, and we are thus unable to differentiate clinically between the favorable and the unfavorable cases, we are forced to conclude that the Moore-Corradi method as at present applied, and in spite of the undoubted improvements that have been made in its technique, is a most dangerous procedure, essentially lacking in the elements of that scientific precision and knowledge of avoidable perils which are necessary to elevate it out of the plane of empiricism and surgical experimentation. Its chief recommendation now rests upon the naked fact that in 3 out of 15 recorded cases (20%) it has actually arrested the progress of aneurysms and saved life. Apart from this clinical fact, it can claim but little else in its favor except that in the presence of almost certain death from the disease when allowed to follow its natural evolution, even a remote possibility of survival by operation is better than no chance at all.

In studying this subject purely from the point of view of results, we should bear in mind that the facts upon which we have based our conclusions are only those furnished by published cases, and that in this connection, as in so many others in medical literature, there are probably many failures with the method which are never recorded. It is more likely that the successful cases have found their way to the press, but we doubt that this is true of the failures. Were all the cases published so as to make them available it is more than probable that the preponderance of fatalities would be even greater than is at present recorded.

Returning to the question with which we began our inquiry—*viz.*, to what extent have the advances made

in the purely technical phases of this procedure improved the patient's prospects of relief and his chances of survival?—we would say that, after analyzing this question from every point of view, we are compelled reluctantly to admit that little if any advantage has been gained in the statistical results. Thus we find that in 15 abdominal cases 7 were treated by wiring alone, and of these 2 recovered (Morse, Langton) or 28 $\frac{1}{2}$ %; 8 were treated by the combined method of wiring and electrolysis (Moore-Corradi method), viz., Stewart, 2; Reeves, 1; Halsted, 1; Noble, 1; Matas, 1; Finney, 2. Of these only 1 was permanently cured (Noble's case), or 12.50%. If we were to add Finney's second patient, who was subjectively improved and was probably living when the case was reported, we would have 25% of recoveries by this method, but in this case the aneurysm was active when the patient was discharged.

In conclusion, I would state that in the light of present experience we should restrict our recommendation of the combined method to that small group of comparatively favorable cases in which the aneurysms are confined to the inframesenteric portion of the aorta, and then only after other safer methods of treatment had been tried and failed. In aneurysms situated in the upper part of the aortic tract, the boundaries of which cannot be even approximately determined, I would regard this procedure in the light of a pure experiment—a veritable surgical adventure—which would be justified solely by the imminent danger of death from rapid progress of the disease with threatened rupture of the sac, and associated with great suffering. Even then the operation could not be recommended, but should be undertaken solely at the urgent solicitation of the patient after a thorough understanding that the chances would be no less than 70% against his recovery from the operation.¹

PERSISTENCE OF THE THYROGLOSSAL DUCT.²

BY

DAVID RIESMAN, M.D.,

of Philadelphia.

Professor of Clinical Medicine, Philadelphia Polyclinic; Instructor in Clinical Medicine, University of Pennsylvania; Visiting Physician to the Philadelphia Hospital.

The patient whom I have the honor of showing to you this evening is a Scotchman, aged 56, married, a mason by occupation. He came to the Dispensary of the University Hospital in the beginning of February of this year, complaining of peculiar pains radiating from the nuchal region to the front of the head. In the course of my examination I found a moist dimple in the median line of the neck, concerning which he gave the following history:

Thirty-eight years ago (he remembers the date exactly; it was 2 days before the wedding of the Prince of Wales, now the King of England), while playing with another boy, he struck the front of his neck against the other boy's knee. There was no bruise-mark; but on the same day a swelling developed, which opened and discharged a week later. Caustic was applied several times, but the opening never closed from that day to this.

There is more or less constant discharge of fluid, which is usually thin and whitish or milky; sometimes, however, it is thick. He has to wipe the area continually to remove the drop

¹Dr. Hunner in his careful compilation of the reported cases (i. e., by combining the statistics of the thoracic and abdominal cases, has collected 14 in which Moore's method of wiring alone was followed; of these 14 cases, 8 were thoracic and 6 abdominal. Two of these, abdominal cases, resulted in cure—14 per cent. of recoveries.

With the combined method (Moore-Corradi) there have been 23 cases, 17 thoracic and 6 abdominal. Four of these, or 17%, recovered, 3 thoracic (Rosenstein, Stewart, Kerr) and 1 abdominal (Noble).

By combining the statistics of the 2 methods, and adding to Hunner's list 2 recent thoracic cases, one of which was cured and the other improved, reported by Freeman (Denver), and the 2 fatal abdominal cases reported in this paper (Parham and Matas), we make up a total of 41 cases of aortic aneurysm thus treated, with 8 recoveries (2 abdominal and 6 thoracic) or 19 $\frac{1}{2}$ % total recoveries.

Hunner also refers to 9 cases, or 3% in which there was an amelioration of symptoms and prolongation of life. He very properly cautions that "we must not be too sanguine on this point, for in any given case we cannot prophesy as to the patient's length of days or degree of suffering if there be no operative interference."

²Read before the University of Pennsylvania Medical Society, April 13, 1901.

of fluid, which, as a rule, is the size of a pinhead; occasionally, especially when he catches cold, it becomes larger, and may then be as big as a pea. As I have said, the discharge continues all day long, but during the night a crust forms at the bottom of the cavity. The depression is funnel-shaped; 5 mm. transversely and 8 mm. vertically. It is situated in the median line of the neck, above the thyroid gland, and corresponds to the middle of the hyoid bone. The bottom of the cavity is red and moist, and is covered with a mucopurulent discharge, which on microscopic examination consists of fat-drops, a few granular cells, and some epidermal scales. There appears to be a single small opening, into which, however, I was unable to introduce a probe for any distance. The cavity is surrounded by a firm infiltration, measuring 15 mm. in all directions. At the bottom, the depression is attached to the deeper structures; it can be pulled sideways to a limited extent, but cannot be drawn forward, as the skin of the neck and chin can be normally. That the tissues of the depression are adherent to the hyoid bone, is most clearly realized when the patient swallows; the funnel is then seen to deepen markedly, and the surrounding structures are sucked in and drawn up with the hyoid bone, so that the integument below the chin form a transverse fold over the top of the deepened funnel. During swallowing the depression is nearly 3 cm. in width. There is no pain, and no tenderness to ordinary pressure, but when I picked up the dense tissues around the depression with the forceps and tried to draw them forward, the patient experienced considerable pain. I applied some strychnin to the bottom of the cavity, thinking that the fistula might communicate with the mouth or the pharynx: but the patient did not taste the drug.

The continued discharge, lasting incessantly for 38 years, suggests that we are dealing with a minute fistula, of the length of which we can form no definite idea. It seems, however, that it extends as far as the hyoid bone.

This is the second case of the kind that I have seen. A few years ago there was a student in one of my classes in the laboratory (he is now a practising physician in Pittsburgh) who had a fistula similarly placed. It had been cauterized and incised without any benefit, as it would always recur. Eventually, it was, I think, removed. I have not heard whether there has been any return of the discharge.

There can be but little doubt that in our patient the traumatism produced by the blow against the neck was only an incidental cause of the fistula. We may confidently assume that a blind tract of congenital origin existed, the distal end of which was near the surface of the skin. The blow merely served to remove the slender partition-wall that separated this tract from the exterior.

The embryologic studies of His have shown that fistulas in the median line of the neck are usually the remains of the thyroglossal duct of the embryo. The formation of this duct, and the fistula to which it gives rise, can be better understood by a brief account of the development of the thyroid gland. In nearly all vertebrate animals this organ is formed from a central, unpaired rudiment or *Anlage*, and 2 lateral rudiments. The former appears first, and is an outgrowth from the endodermic epithelium of the ventral wall of the primitive pharynx, in the neighborhood of the visceral arches. It is surrounded by the ridges that are destined to form the base of the tongue, and in its descent remains for some time connected with the root of that organ by a canal, called the thyroglossal duct or canal of His. After its descent it unites with the lateral thyroid masses, which are primarily hollow outgrowths from the endodermic lining of the fourth visceral furrows. The thyroglossal duct begins to undergo atrophy at the fifth week, and by the eighth, is entirely obliterated, its upper extremity being, however, permanently indicated by the foramen cecum, on the dorsum of the tongue.

In some cases the primitive canal does not entirely disappear, and then various anomalies may result. Thus, the canal from the root of the tongue to the hyoid bone—the so-called ductus lingualis—may remain, and may reach a length of 2 $\frac{1}{2}$ cm.; or there may be a persistence of the lower portion—the ductus thyroideus—which then extends as an epithelium-lined canal from the thyroid gland to the hyoid bone. In that case, the gland is usually possessed of a middle horn, from the apex of which the ductus thyroideus arises. This horn may not

be situated in the median line, but in every instance the upper extremity of the duct has a mesial position. In the case studied by His, the 2 ducts, although approaching closely to each other (within 5 mm.), were not united, the hyoepiglottic and thyrohyoid ligaments acting as a partition-wall. According to some authors, the thyroglossal duct bifurcates at its lower extremity; this explains the presence, in some cases of thyroglossal fistula, of a double opening on the front of the neck. This was true in 2 instances reported by Durham.

The thyroglossal fistulas are lined with ciliated columnar epithelium, which is replaced by squamous as the lingual portion of the duct is reached. The opening may be anywhere, from a little above the hyoid bone to the level of the sternum; but in every case the aperture is strictly in the median line. Fistulas opening laterally, or fistulas with median apertures and lateral tracts, are probably to be considered as of branchial origin. They have recently been studied in an exhaustive manner by Coplin.

Thyroglossal fistulas move, as in our patient, with the hyoid bone on deglutition, having, therefore, the same characters in this respect as tumors of the thyroid gland. Sometimes the fistula is permeable to injections up to the foramen cecum; this, however, is rare in the adult, since, as already indicated, the continuity of the duct is interrupted at the thyrohyoid membrane. Thyroid-gland follicles, and even accessory thyroids, are often intimately connected with the duct. Accessory thyroid glands may, however, be found independently of a persistent canal; and may be situated above, in front of, behind, below, or even within the hyoid bone. Sometimes the upper portion of the thyroglossal duct persists and is transformed into a tumor composed of true thyroid tissue, springing from the base of the tongue. About 2 years ago, Dr. H. L. Williams showed me a section of a growth that had been removed from the root of the tongue. On examination I found it to be composed of typical thyroid follicles. Dr. Williams subsequently reported it in conjunction with another case of the same kind.

There is another possible source of cervical fistula, as pointed out by Durham: This is a persistence of the sinus praecervicalis—a cleft formed by the sinking in of the lowermost arches, and disappearing in later embryonal life by a coalescence of its ridges. Its persistence gives rise to fistulas lined with squamous epithelium. A distinction between these 2 forms of fistula, in the present stage of our knowledge, is to be considered as a refinement; although it is a point of importance that these latter fistulas sometimes communicate with the esophagus.

There are other interesting congenital anomalies associated with vestigial remains of the thyroglossal duct, such as mucoid and dermoid cysts; but it is unnecessary to discuss them at this time.

Regarding the treatment of thyroglossal fistula, it is evident that only a complete extirpation of the canal with its epithelial lining can bring about a permanent cure.

Ice for the Poor.—The Baltimore Association for the Improvement of the Condition of the Poor is distributing free ice to the sick and aged poor. The sick diet, consisting of milk and eggs, which the association furnishes to the sick poor, makes the furnishing of free ice a necessity in order that the milk may be kept sweet and fresh until used. Physicians are requested to report cases known to be in need.

MYOMECTOMY OF 9 MYOMAS DURING PREGNANCY AND DELIVERY AT TERM.¹

BY

JOHN DUNCAN EMMET, M.D.,

of New York.

Visiting Gynecologist, St. Vincent's Hospital.

Pregnancy in the myomatous uterus is always an interesting subject, because it is of sufficiently frequent occurrence to come within the range of each of us, and because its indications are various and involve the life or death of the fetus and sometimes of the mother as well.

Gutierrez, quoted by Delagènière, maintains that of 295 myomatous women, 51 become pregnant. If these statistics are accurate, it would represent the proportion of about 17 pregnancies in every hundred cases of myomas. Durkee, quoted by Howard Kelly, makes this proportion only 2.03%. Fortunately, however, no such proportion even as this latter one presents practical difficulties to the gynecologist or obstetrician, for it is an established fact that many myomatous uteri carry their pregnancies to term and through delivery without difficulty. The myomas in these cases are either pedunculated at the time of conception or become so during the pregnancy, as a rule, but a number of cases are on record of subperitoneal, sessile tumors in or near the fundus which have presented no serious difficulty at term.

All authorities—prominently among these Howard Kelly, of Baltimore; Delagènière and Dolèris, of Paris, give the following general rules regarding the indications of the various forms of this condition: Small myomas and those situated at or about the fundus, or even lower in the body of the uterus frequently, do not interfere with normal pregnancy and delivery, if these tumors are pedunculated. Sessile tumors are likely to cause abortions, but if situated at or near the fundus they need not do so. When myomas are situated at the junction of the uterus and its cervix, or in its lower third, myomectomy is justifiable and indicated, because these tumors will probably interfere with the descent of the uterus into the pelvis and present a serious obstacle to delivery.

These data divide myomas of the pregnant uterus into 3 classes, both in regard to prognosis and in regard to indications. The first division consists of pedunculated myomas which are not likely to interfere with normal pregnancy and delivery, unless they block the pelvis from their size or situation, and do not call for surgical interference, per se. The second class, embracing subperitoneal and interstitial tumors of the body, frequently prevents the completion of pregnancy, but, on account of the liability of abortion to follow their removal, surgical interference is not indicated as an elective measure. The third class embraces sessile or partially pedunculated or completely pedunculated tumors so situated that they will interfere with the descent of the uterus and with delivery, and thus necessitate either cesarean section or the death of the fetus, and possibly that of the mother, from attempted delivery through the natural passages. During pregnancy, subperitoneal and interstitial tumors are likely to increase very rapidly, owing to the greater supply of uterine blood, while the pedunculated do not share, to anything like the same extent, in this increased nutriment.

The form of surgical interference always indicated—where surgical procedure is indicated at all—is, I think, without question, myomectomy. The excuse in these cases for hysterectomy, which has been largely practised, is founded on the erroneous belief that myomectomy, owing to the violence done the organ and the consequent uterine contractions, is nearly always followed by

¹Read before the American Gynecological Society, June 1, 1901, Chicago, Ill., and published synchronously by courtesy of the American Gynecological and Obstetrical Journal.

abortion. Reliable statistics, extending over more than 20 years, or from the dawn of aseptic surgery to the present day, give no foundation for this current belief, and my own experience testifies to what extensive use myomectomy, when employed with adequate precautions against undue violence, may be applied without loss of the fetus.

R. H. Turner, of Paris, in a monograph published in that city in 1900, gives the following statistics of myomectomy during pregnancy: Between the years 1874 and 1890, 33 of these operations were reported, with 61% of fetal mortality and 36% of maternal mortality, but between the years 1890 and 1900 the reported operations are 44, with only 21% of fetal mortality and 9% of maternal mortality. Of the 79% of pregnancies in the latter series, or 34 children which survived the operation, 25 went to term; 2 went to 8½ months; 2, 7½ months, 3 are reported as having "continued,"² and the result in the 2 cases is uncertain.

From the year 1900 to April, 1901, I can find but 5 cases of successful myomectomy during pregnancy, including the one am now about to report. Dolèris reports a large pedunculated myoma removed, but though he reports recovery without abortion, he does not state time of delivery. Lewis reports removal of a subperitoneal tumor followed by normal delivery. Muir Evans reports removal of pedunculated myoma. The patient was in her eighth month and doing well when reported. My patient was operated upon April 24, 1900, and was delivered at term. Gemmel reports removal of 3 myomas in early pregnancy with delivery at full term.³ In the case which I am about to report I removed 9 myomas, all sessile, and 1 of which was deeply interstitial. This case presented the following history:

Mrs. T., aged 30; twice married; first marriage, 3 years ago; second marriage about 2 years ago. American born; occupation until 2 years ago that of a saleswoman. Admitted to the Woman's Hospital in the State of New York, April 16, 1900. She first menstruated at 15; has always been somewhat irregular, period usually occurring every 5 weeks, flow scanty, duration 3 days, with severe pain on first day. No previous pregnancies. Last menstruation January 17, 1900. Previous history otherwise, as well as family history, negative. On admission she complained of almost continual backache; bowels constipated; breasts somewhat enlarged with darkened areola; slight nausea in the morning for the past month. Vaginal examination showed a large uterus filling the pelvis and os retroverted. Several myomas can be felt in the body of the organ. No distinct objective symptoms of pregnancy, owing to presence of tumors. A diagnosis of multiple myomas with probable pregnancy was made.

Operation.—On April 24, 1900, with the assistance of Drs. Sweeney, Barfield and Spalter, internes at the Woman's Hospital, I opened the abdomen by a large median incision. The patient was put in Trendelenberg's posture and the intestines covered and pushed up with a large flat sea-sponge. The uterus was grasped with the hand and brought upward out of the pelvis and was found to be studded with myomas varying in size from that of a hen's egg to that of a pea. The majority were situated in the neighborhood of the fundus and more were pedunculated, though several were subperitoneal for ¾ of their caliber. Two of the largest and most prominent of these were situated just above the cervix, 1 in front and the other at the back of the uterus. The position and size of these 2 myomas decided me to perform myomectomy, even at the risk of abortion, for I was convinced that these tumors, largely increased in size as they would be at term, would make normal delivery impossible. It seemed to me also that it gave the woman a better chance and would not materially increase the immediate risk of interrupting the pregnancy if I removed all the myomas which the uterus contained, for if I succeeded in accomplishing this it would contract evenly. I was not aware how many myomas the organ contained until I had removed the most prominent ones, and then I was able to discover several more imbedded in the body of the uterus and not distinguishable at the first examination. One of these was quite large and could not be felt from the surface of the organ; I discovered it only after the removal of a prominent one lying in its immediate

neighborhood. Two small myomas I removed through the same incision in the peritoneum, breaking down a thin layer of interstitial tissue which separated them. I continued to remove the tumors until I had obtained 9, closing each peritoneal incision with continuous catgut ligature. In several instances my suture was carried deep down into the interstitial tissue. Having carefully examined the uterus, I was convinced by its symmetric shape and decrease in size that I had at last found and removed every tumor which it contained. Nine tumors had then been removed through 8 incisions. Bleeding had been inconsiderable during the operation, and finding that the slight oozing which followed the closure of each incision had practically ceased, I dusted aristol powder freely over the site of each line of sutures to prevent the formation of adhesions with the intestines, removed a few small blood-clots from the *culdesac* behind the uterus, allowed the intestines to fall down and fill the pelvis behind the uterus, and then closed the abdominal incision with through-and-through interrupted sutures of silver wire.

The patient bore the operation well, and beyond a small abscess in the connective tissue of the abdominal wall at the lower angle of the wound, which was drained and carefully dressed as soon as discovered, her convalescence was uneventful. During the first 3 or 4 days after the operation the patient received 2 opium suppositories (U. S. P.) daily to obviate, so far as they might, any tendency to uterine muscular contraction.

The most important points, I think, in the technic of this operation, were, first, that the uterus was supported and held steadily by the hand of my assistant grasping it posteriorly, great care being used to avoid jerking or handling the uterus unnecessarily; secondly, that in enucleating each myoma I avoided drawing the tumor up out of its bed, but, holding it in situ, pushed back the peritoneal and interstitial tissue which enclosed it, either with my fingernail or the handle of the scalpel, until I had reached the bed of the tumor and freed it. This method was slow, but it reduced excitation of the uterine muscle to a minimum and allowed very slow and gradual contraction of the bed of the tumor. Bleeding was reduced to a minimum and the lines of suture greatly shortened. I am convinced I owe it to this consistent effort to avoid, by every possible means, excitation of the uterus, that abortion was obviated.

The great lesson to be learned from this case is, in my opinion, the fact that hysterectomy may and should be avoided in all cases of myomas complicating pregnancy. If pregnancy can continue after so prolonged and irritating an operation as a 9-fold myomectomy, I cannot believe that myomectomy may not always be practised with equally as careful technic as was exhibited in this case. If the statistics which I have here collected and the history of my case shall save a proportion of fetal lives, by showing that we should not hesitate to give the patient and her child the chance which myomectomy offers, great good will have been accomplished.

I have searched all records most carefully for all the cases of this condition which have been reported up to date, beginning with Turner's report in 1874 and ending my researches with the month of April, 1901. As Turner's monograph is an elaborate and evidently carefully compiled work, and is acknowledged as trustworthy by all who have written upon the subject in question I have accepted his statements as correct, but from 1900, when his statistics end, until April of this year, I have searched and verified myself the reference to all cases reported.

LABOR AND SUBSEQUENT HISTORY.

After convalescence the patient returned home and remained remarkably free from all pain and nausea. Owing to the great kindness and appreciation of the authorities of the Woman's Hospital, to whom I represented the very unusual importance and scientific interest of this case, and that she was unable to provide for herself fittingly at home, I was enabled to place this patient in the hospital for her accouchement. Although a free patient, she was given a private room and special nurses and she and her baby were most carefully tended until I judged her fit to return home. I cannot say too much in appreciation of this action of the Visiting Committee of the Board of Governors and of the superin-

² Howard Kelly, in his "Operative Gynecology," states that he has had 3 myomectomies during pregnancy which continued to term, and gives the details of 1 case, but 1 of the other 2 has evidently not been reported, because I can find reference to but 2, either in Turner's statistics or in the subsequent literature.

³ Ford, of Utica, reports 5 cases of uterine fibroids complicating pregnancy. In 1 case he reports spontaneous delivery of intrauterine fibroid 6 months after delivery, but in none of these cases does he report myomectomy followed by delivery at full term.

tendent through whom I urged my request. All rules and precedent of the hospital were suspended and this labor case was ungrudgingly admitted, not on grounds personal to me, but solely from a generous interest in the success of a case of unusual importance.

Several days passed beyond the date of her expected confinement with no symptoms of labor, until about 1 a. m., on November 2, the patient awoke with a violent pain of long duration, followed almost immediately by a second, and with this pain the head was born with great force. The entire duration of the labor, from the time the head engaged until the birth, was 20 minutes. In the course of a half-hour the placenta and secundines came away spontaneously and intact and the uterus contracted firmly. There was no hemorrhage, but owing to the rapidity and force of the uterine contractions the cervix was deeply lacerated and the posterior vaginal wall was torn extensively, almost down to the sphincter ani. I had been notified at my house, a mile away, by messenger, on the occurrence of the first pain, and arrived at the hospital 45 minutes later. The patient was so exhausted then that I determined to put off any attempt at repair until later in the day. When I then placed her under anesthesia and thoroughly examined the lacerated posterior vaginal wall—I did not intend to operate on the cervix—I found that it was so contused, edematous and friable, that I judged it best for the patient not to attempt operative repair but to endeavor, by strict asepsis and approximation of the parts, to obtain the best results possible. To this end her legs were kept tied together and hot creolin douches with a Davidson syringe were given, by an experienced nurse, every 3 hours. Milk appeared on the third day abundantly. I kept the patient in bed for 3 weeks. At the end of that time normal involution had taken place in the uterus and cervix and the posterior wall had healed and lay well up in contact with the anterior. She left the hospital with her baby, a well-developed, healthy girl, on November 27, 1900, feeling entirely well.

Her convalescence from her labor was uneventful and when I last examined her, before she left, the abdominal wall was firm. A month ago she came to my office to report and I found a small abdominal hernia at the lower angle of the wound where the abscess had been. She confessed that as soon as she left the hospital she began to do heavy housework, including the family washing, and about a month thereafter she became conscious of a "weakening" at the lower angle of the wound. The uterus now is less than 3 inches in length, freely movable, and in normal position, while the cervix is cleft but is small, not everted and soft. There is no pathologic laceration there. The fascial tension of the floor of the pelvis is apparently intact, for the patient is entirely free from all subjective symptoms referable to this cause.

Shortly after my return to New York I shall operate upon the abdominal hernia, in my service at St. Vincent's Hospital, and expect to find no difficulty in effecting a cure.

University of Pennsylvania.—The 1876 class of the Department of Medicine held its first annual banquet at the University Club, Philadelphia, at 7 p. m. on Alumni Day, June 11, and effected a permanent organization for the benefit of its Alma Mater. The following officers were elected: President, Charles A. Oliver, A.M., M.D.; vice-president, William H. Klapp, A.M., M.D.; secretary, Francis M. Perkins, A.M., M.D.; treasurer, Benjamin F. Baer, M.D., with an executive committee of 12 members, who will meet at the call of the president.

American Climatologic Association.—The following delegates have been appointed to represent the American Climatologic Association at the British Congress on Tuberculosis: Dr. Edward O. Otis, Boston; Dr. Judson Daland, Philadelphia; Dr. Henry L. Elsner, Syracuse, N. Y.; Dr. Charles E. McGahan, Aiken, S. C.; Dr. Thomas D. Coleman, Augusta, Ga.; Dr. Carroll E. Edson, Denver. Dr. Guy Hinsdale, Philadelphia, has received a notice of his appointment as honorary member of the Congress.

SUBTROCHANTERIC OSTEOTOMY FOR THE DEFORMITY FOLLOWING HIP DISEASE.¹

BY

E. H. BRADFORD,

of Boston, Mass.

The natural cure of hip disease, if untreated, inevitably results in a characteristic crippling deformity, with marked flexion and abduction. Even in the treated cases, if neglected during the convalescent stage, this deformity frequently results.

It is not necessary to give in detail the history of the development of the operation for the correction of the deformity as the facts are well known, and Gant's operation is an accepted procedure. The object of this paper is not to present what is new, but to call attention to some of the practical details of an operation which is most satisfactory in its result, not difficult of execution, but, unfortunately, not as generally employed by the surgical profession as is desirable. The following case will serve as a type.

A young man of 18 suffered from hip disease when a boy of 4. The usual course of abscesses and sinuses followed, but after a number of years all finally healed and he was left with a right angle deformity of the thigh with severe adduction. He was able to walk with 1 crutch, but was unable to place the whole foot upon the ground. There were many cicatrices of old sinuses about the hip, subluxation, and an actual shortening of 1½ inches. Subtrochanteric osteotomy was performed and the limb corrected in the manner hereafter described. The recovery was uneventful; the correction of the deformity has been maintained without recurrence for 12 years until the present time. He is now able to walk with perfect freedom without crutch or cane, with no practical shortening of the affected limb.

It is unnecessary to give the histories of similar cases varying but little in detail. It may be, however, of interest to consider the best manner of conducting the operation and after-treatment.

The subject for convenience may be limited by describing the procedure only in its application to the deformity following hip disease, where there is ankylosis at the hip, either osseous or firmly fibrous, with or without subluxation. Osteotomy for coxa vara will not be considered here. There are various methods suggested for the division of the bone, but only 3 need to be mentioned, transverse osteotomy, oblique osteotomy and wedge-shaped section. Of these, transverse osteotomy will be found satisfactory in the cases of flexion without adduction, and is readily performed. In ordinary cases no preliminary incision through the skin is necessary, as the osteotome can be driven to the bone through the skin with a slight blow of the mallet. The place for the entrance of the osteotome is at the level of the lesser trochanter, or slightly below this, that is, below the insertion of the psoas and iliacus tendons. It is evident that where osseous ankylosis has taken place there is little danger of recontraction whether the insertion of the tendon of the psoas and iliacus is below or above the break, but even under these circumstances the point of election for the division of the bone will be found just below the lesser trochanter, on account of the greater ease of the division of the bone at this point, narrower here than higher up on the femur.

The osteotome is driven directly to the bone through the skin with the broad axis of the osteotome parallel with the axis of the thigh. When the bone is reached, the osteotome is turned in the hand of the operator and driven directly through the outer layer of the bone to the medullary layer. After the osteotome is well engaged in the bone, the direction should at each blow

¹Read before the American Surgical Association, at Baltimore, May 7, 8, 9, 1901.

be turned to the right and left, so that it will cut in an excursion wider than the width of the osteotome and to diminish the danger of the hemorrhage. The division of the bone is continued, working from the cortical layer to the medullary layer, the difference being recognized by the difference in the resistance to the blows of the mallet. The femur should be divided from $\frac{1}{2}$ to $\frac{3}{4}$ of its thickness, and the rest of the division performed by the fracture. It will be found to be easier to fracture the remaining portion of the femur by first moving the femur by adduction and flexion rather than by abduction and extension, though after the bone is fractured the limb should be moved in the direction of abduction and extension to stretch the contracted soft parts.

The width of the osteotome is a question of judgment, some operators preferring a narrow osteotome and others a wider one. The corners of the osteotome should be rounded to prevent any sharp projection, and if carefully used the operation is without danger of hemorrhages.

In some instances it will be necessary to perform tenotomy or open incision of contracted tissues, but usually, especially in children and adolescents, these tissues can be readily stretched. It is manifestly a neater operation if the osteotome should not be reinserted, but that all the cutting by the osteotome be performed while it is still in the wound; but a reinsertion of the osteotome can be easily made if a sufficient amount of the bone has not been divided to make the fracture easy. It is manifestly an advantage to leave a certain amount of the bone uncut to be fractured, as the uncut periosteum helps in the needed subsequent union of the fragments.

OBLIQUE OSTEOTOMY.

In place of transverse osteotomy the bone may be divided obliquely, entering the osteotome slightly below the greater trochanter directed to below the lesser trochanter, from without inwards and from above downwards. This is advised for the purpose of increasing the length of the limb, employing forcible traction for the purpose at the time of the operation or during after-treatment. The amount of lengthening gained in this way is, however, limited by the fascia and shortened muscles which can be stretched, and by the lack of elasticity of the uncut periosteum. If the periosteum were entirely severed, firm union is apt to be delayed or interfered with, a complication to be avoided.

Oblique osteotomy has, over linear osteotomy, the advantage of furnishing, in the obliquity of the fragments, an obstacle to the slipping inward of the lower fragments if the limb is thoroughly abducted. Experience enables the surgeon to determine by the sense of touch the correct position of the edge of the instrument, and with ordinary care there is no danger of hemorrhage or undue injury to the adjacent tissues. Wedge-shaped resection of the femur near the trochanter has no practical advantage over oblique osteotomy, and though mechanically correct, is surgically unnecessary.

POSITION OF THE OSTEOTOMIZED LIMB.

In cases with adduction or where there is much subluxation, oblique osteotomy is preferable to linear, but after either has been performed the question of the position in which the limb is to be placed is of the greatest importance, as the success of the operation naturally depends upon the position in which the fragments of the bone are placed for reunion. If the periosteum is but little injured, it is well known that union of broken bones takes place finally, even if the axis of the fragment differs greatly from that of the original bone.

Nature's fault in the union of neglected fractures serves as a precedent in the correction of the deformity. In the simplest cases the contractions of the soft parts are readily overcome after the osteotomy by manual

effort. If the deformity is not great and that chiefly of flexion without much actual shortening, all that is necessary is to place the limb in a position nearly parallel to the normal bone, and allow union to take place. If flexion is severe the fragments do not remain in contact after correction, in their whole cut surface, but this in no way prevents a firm union with the upper or lower fragments, forming an angle instead of a straight line, the callus giving sufficient solidity for future use.

Whether the limb is to be placed in a position in a plane with the long axis of the trunk or slightly flexed will depend upon the amount of flexibility in the lumbar spinal column. If the latter is rigid, the patient will find difficulty subsequently in sitting comfortably if the flexion is completely corrected. Ordinarily, however, especially in adolescents and children, an exaggerated amount of flexibility has been developed in cases of this sort, and this can be relied upon to give sufficient amount of change in the position of the thigh relative to the axis of the trunk, for the different positions incident to sitting, standing and walking. To avoid the danger of this it is, however, desirable in older patients to place the thigh in a position of slight flexion; not more than 15° will be required for this. Where the limb is adducted, as well as flexed, it is necessary to place the limb in an abducted as well as a straightened position, the amount of the abduction depending upon circumstances, especially the amount of actual shortening of the limb. It is to be borne in mind that in cases of severe distortion after hip disease with flexion and adduction, tilting of the pelvis takes place, the affected side being abnormally raised. This adds a practical shortening of the limb, measuring from the umbilicus to that given by the flexion of the limb, and to the actual shortening from subluxation. If this abnormal tilting of the pelvis is corrected, the practical shortening is diminished, and if this tilting of the pelvis is over-corrected, so that the pelvis is tilted in the direction opposite to its former position, a practical lengthening can be secured. The amount of this practical lengthening depends upon the amount of possible tilting of the pelvis in the corrected direction. This again is dependent upon the lateral flexibility of the spinal column. In adolescent cases, a practical lengthening of from 2 to 3 inches can be frequently secured in this way, which is frequently enough to overcome the shortening from subluxation and also from arrest of growth, unless this is unusually great.

The operation (if done without preliminary incision down to the bone) is practically a subcutaneous one, and the dressing required is small if proper aseptic precautions are observed. It is usually unnecessary to disturb the wound until several weeks after the operation.

In selecting the means of fixing the limb after osteotomy, the decision is influenced by the ease with which the correction has been obtained. Where there are few contractions of the soft part and the fractured limb can be placed easily in the desired position, it will be found most serviceable to place the patient in a plaster-of-paris spica, with the affected limb strongly abducted, if the previous adduction has been great. The sinking of the mattress at the buttock is usually sufficient to allow for a slight amount of flexion, which is ordinarily desirable. The advantages in a plaster-of-paris bandage consist in the fact that the patient is placed in a position which he cannot escape from. There is less danger of misplacement of the fragments in changing the patient's position. The disadvantages of plaster-of-paris bandages lie in the discomfort caused if imperfectly applied, and in the fact that the position of the limbs cannot be readily changed. Where complete correction is not possible, and it is desirable to stretch the contraction of the soft parts, a traction appliance can be used, the ordinary weight of the pulley being the most convenient.

The amount of abduction to be given the limb varies with the amount of practical lengthening desired. An

abduction of 45° will be found not excessive in cases of severe distortion, and will be of advantage in securing practical lengthening.

It is evident that where the limb is placed in an overcorrected position after severe deformity, it will be necessary to allow considerable time before expecting complete solidification, and under these conditions some retentive apparatus is advisable. Plaster-of-paris furnishes a suitable support for this purpose, but as a substitute a stiffened leather splint laced upon the trunk and thigh will answer. It is not safe ordinarily to allow the patient to bear weight upon the limb until 10 weeks after the operation, and in larger patients where the deformity is great 3 months of protection is preferred. Locomotion by aid of crutches should be permitted after 8 weeks.

It is evident that where the ossification is not rapid danger of relapse exists. This should be prevented by obliging the patient to wear retentive apparatus for a long period, even after locomotion with crutches is allowed. The amount of time that is necessary for retentive treatment depends upon conditions not easily defined, and is a matter of judgment.

It is desirable that the operation should not be done on too young or on rapidly-growing patients. The yielding character of growing bone, and its inability to resist deforming pressure in sitting and standing, may cause a recurrence of the deformity—a danger which does not exist in older patients. An unusual complication may be mentioned—namely, the coexistence of severe knock-knee, with severe adduction and the flexion of the thigh, following hip disease, requiring after the operation at the hip a second osteotomy at the knee, but with a successful result in the end.

In fine, the operation may be considered as most satisfactory to both patient and surgeon, correcting the deformity and diminishing a humiliating disability, with but little discomfort to the patient and no greater risk than that following a fracture. The demand upon the surgeon consists simply in the exercise of skill and judgment easily acquired.

THE HALLUCINATIONS OF DIGITALIS.—DOES DIGITALIS CAUSE HALLUCINATIONS, DELIRIUM OR INSANITY UNDER CERTAIN CONDITIONS?

BY

HARRY ORVILLE HALL, M.D.,

of Washington, D. C.

Reading Room, Library Surgeon-General's Office, U. S. Army.

The physiologic action and so-called cumulative effects of digitalis are subjects which have engaged the attention of many of our great medical writers from time to time. The fact that in the textbooks on therapeutics scarcely any mention whatever is made of hallucinations or delirium as physiologic effects of the administration of digitalis, even in toxic doses, would lead one to conclude that these effects were not attendant upon the use of that drug. Dr. Hare,¹ in speaking of the effect of digitalis on the nervous system, says:

"The action of digitalis upon the nervous system is only manifested when poisonous doses are used. Small toxic doses decrease reflex activity by stimulating Setschenow's reflex inhibitory centers in the medulla, and finally by depressing the spinal cord. Convulsions are sometimes seen as a result of the action of decomposition products of digitalis—namely, toxiresin and digitalresin. Finally, the motor nerve-trunks themselves are depressed and the muscles are paralyzed."

Dr. Butler² on the same subject says: "No effect is produced by medicinal doses of digitalis on the nervous system. Immoderate doses, however, occasion headache and vertigo, together with lessened reflex activity,

by stimulating Setschenow's inhibitory center, and depressing the motor nerves. The muscles themselves may be paralyzed, the sensory nerves being unaffected."

It is possible that only in rare instances has this effect been noticed or been attributed, if noticed, to the use of digitalis, and yet is it not also possible that where delirium or hallucinations have occurred in connection with the administration of digitalis, these symptoms have been attributed to the disease from which the patient was suffering, and not to the medicine prescribed? In other words, are the symptoms which manifest themselves during treatment always attributed to the right cause? May they not frequently arise from the medication employed and not from the disease?

Dr. E. G. Janeway,³ in his discussion of the valuable paper read by Dr. H. A. Hare before the Association of American Physicians, on the subject of the cumulative action of digitalis, used these words: "Do we always attribute sudden death, even when disease is present, to the right cause? I have had cases come to autopsy without finding a satisfactory cause of death, unless we investigated the medication as well as the disease with which the patient was afflicted. In certain cases where patients have dropped dead suddenly on going to the closet, it was ascertained that for some time these patients had taken large doses of digitalis. So that, failing to find a satisfactory explanation of the sudden death as a result of the conditions of disease present, we must ascribe it to the associated medication."

The nature of the disease for which digitalis is usually prescribed being one in which sudden death is likely to occur more or less frequently, it naturally would prevent the attending physician from looking elsewhere for the cause of death. Possibly if digitalis were the remedy usually prescribed for disease of some less vital organ than the heart, sudden death or unusual symptoms, such as delirium, occurring during its administration, might lead to closer investigation. It was in following out this line of reasoning that I was led to inquire as to the medication in the case referred to below.

If it were possible, it would be exceedingly interesting to have before us the clinical history of a large number of patients treated by digitalis in order that we might observe what proportion of them were, during the administration of the drug, subject to hallucinations or delirium. So far as I have observed, the French writers are the only ones who have called particular attention to the above symptoms as physiologic effects of repeated doses of digitalis. Trousscau has pointed out that full doses produce hallucinations, delirium, and a slow pulse of 32, and in this statement he is endorsed by Peter.⁴

But the one author who seems to have made a careful study of digitalis as a cause of delirium is Dr. P. Duroziez. In a lengthy article by him published in 1874, he gives a list of 20 cases in which delirium or death accompanied the administration of digitalis and, as he believed, was caused thereby.

Before giving a review of these cases reported by Duroziez, I may say that I was led into an examination of the physiologic effects of digitalis, in connection with and as a result of the illness and subsequent death of a friend who for several weeks prior to death was subject to strange hallucinations, which finally terminated in acute mania. The most expert neurologists who were called in consultation, among them the late Dr. Godding, were unable to explain the cause of the mental disturbance. The patient was a woman between 30 and 40 years of age, the mother of 4 living children. She was of robust build, and of a happy and cheerful disposition, unusually so, and had never had any serious illness. The sickness from which she was suffering on this occasion was attributed to some derangement of the liver, and she was treated for congestion. I am unable to speak with any degree of certainty of the earlier stages of her illness or symptoms, as I was not made acquainted with the

clinical history of the case. It ran along in the usual course for several weeks, and then it began to be reported that she was "out of her mind" at times. At these times she would have strange hallucinations. For example, she would say to the nurse, "I am now going to die," and then she would compose her limbs, close her eyes, and begin to breathe slowly and more slowly, and finally appear to cease breathing altogether, until the attendants would almost believe she had actually died. She would remain in this cataleptic state a short time, and then come to and report what she saw while "dead." Sometimes she would say she had been to heaven, at other times to hades, and would minutely describe the persons she saw there. She would frequently spring from the bed and attack the nurse and try to drive her from the room. These attacks gradually grew more frequent and violent, and after consultation with Dr. Godding and other neurologists, it was decided that she must be removed to an asylum, but before any move could be made she grew rapidly worse with acute mania, and soon died from exhaustion.

The whole course of her illness was so singular and unaccountable to those who had known her from childhood, that I was led to suspect that possibly some drug might lie at the bottom of her trouble. Her physician, a very dear friend of mine, and one of the best and most expert and honored practitioners, of large practice, was very much perplexed over the case. He had known his patient from infancy, and he was unable to attribute any cause for her singular mental disturbance. He called in experts in mental diseases to assist him in diagnosing the case, but they were unable to find any apparent cause for the strange hallucinations and violent delirium. She had not yet reached the climacteric, and none of her medical attendants, so far as I know, attempted to explain her peculiar mental condition by attributing it to uterine changes or disease.

Having, in the absence of other satisfactory explanation, entertained the suspicion that some drug might have produced the strange symptoms, I at once made inquiries as to her treatment, and was informed that several weeks prior to the onset of the mental disturbance, some heart complications had set in, and for some considerable time she had been taking digitalis daily. What the dose was, or how often administered, I was unable to learn. At that time, and until her condition became dangerous and alarming, no nurse had been employed, and the administration of the medicines was entrusted to her children, or whoever happened to be present at the time. Knowing something of the nature of digitalis, I concluded that it might be the offender, and at once began a research through the literature of the subject in the Library of the Surgeon General's office, with a view of ascertaining if any writers on the subject spoke of delirium or hallucination as physiologic effects of repeated doses of this drug. I examined hundreds of articles on the subject of the physiologic effects of digitalis, and of the bad effects of accumulated or toxic doses, but no one mentioned delirium as one of the effects of the drug until I came across the paper by Duroziez, "Du délire et du coma digitaliques,"* which confirmed me in my suspicion that in the case referred to above, the hallucinations and delirium were possibly the result of accumulated doses of digitalis. Of course I may be mistaken, but the fact that no satisfactory explanation of the mental derangement could be arrived at by her expert medical attendants, added to the fact that one at least of the learned writers on the subject had observed no less than 20 cases where delirium followed the administration of digitalis, it would naturally be supposed that I had some foundation for my suspicions. The very first sentence of Dr. Duroziez's paper is this: "Digitalis, does it produce delirium oftener than is supposed? We think so." He then goes on to say that "the delirium either passes unobserved or is attributed

to the disease. We believe, at least, that the question cannot be disposed of immediately, and that there is enough doubt to warrant a further study of the subject. Digitalis is not an indifferent drug. You must take account of its action. In the first cases which follow it was certainly to blame for the trouble. Error is impossible." The following cases are then given in detail:

CASE I.—An asthmatic patient, 72 years old. July 2, pulse 80-84, regular and fairly strong; feeble respiration; exaggerated vocal resonance; loud, sibilant râles. Gave alcoholic extract digitalis 5 gr. July 3, pulse 84, regular; gave alcoholic extract digitalis, 5 gr. July 4, pulse 84; gave extract digitalis, 5 gr. (30 centigr.) July 5, pulse 84, regular; gave extract digitalis, 5 gr. July 6, no digitalis given. July 7, pulse 80, regular; gave alcoholic extract digitalis, 40 centigr. July 8, pulse 80, regular; gave 40 centigr. alcoholic extract digitalis. July 9, pulse 88, regular, fluctuating and moderately strong, great pressure; delirium during night; no digitalis. July 11, pulse 80, regular, fairly strong; 40 centigr. of alcoholic extract of digitalis. July 12, pulse 84, regular, fairly strong; gave 40 centigr. digitalis. July 13, delirium during the night. July 14, pulse 84, vibrating, regular and strong. July 15, pulse 90, weaker, but regular; delirium during night. July 16, pulse 84; delirium during night. July 17, delirium ceased. July 24, pulse 84 and some colic. August 2, pulse regular and strong.

CASE II.—B., aged 65, entered hospital July 13, left August 31. Aortic insufficiency; abdominal and general dropsy. From July 19 to August 5, took 20 and 30 centigrams of powdered digitalis in infusion; sweats and faintness. August 5, in evening, pulse regular, fairly strong; had to sit up to breathe; very weak; no nausea; urinated frequently, but small quantity; gave alcoholic extract of digitalis, 30 centigrams. August 6, more agitated last night than at any other time; jumped out of bed crying "fire," but in the morning is calmer. Have stopped digitalis; in the evening, pulse 88 and regular; feels better. August 8, pulse 76, normal.

CASE III.—Age 71, entered hospital May 24, died August 20. Dilatation of aorta and mitral insufficiency; took 4 and 5 granules of digitalin and 30 centigrams of powdered digitalis during the month. On June 25 had been out of his head for 3 days; pulse 36 and dicrotic. Stopped the digitalis June 26; dry tongue and dicrotic pulse. June 28, mind does not wander so much; no more hallucinations, but he sees dead people standing about him; later on gave 30 and 40 centigrams of digitalis. He died 2 days after the medicine was stopped.

As it would take too much space to give the full details of the 20 cases, I will summarize them in the form of a table, giving merely the form of the drug, the dose, the length of time administered, and result:

No. of Case.	Form of Drug.	Dose.	No. of Doses.	Result.
1	Alcoholic ext. of digitalis.	30 to 40 centigr.	6 doses.	Delirium.
		40 "	2 "	" and death.
2	Alcoholic ext. of digitalis in susp.	20 to 30 "	18 "	"
3	Digitalin.	4 to 5 milligr.	1 month.	"
	Powder of dig.	30 centigr.	1 "	"
4	" "	30 to 40 centigr.	1 "	Death.
5	Dig. in maceration	20 "	42 days.	Delirium and death.
6	" "	1 gram.	4 "	"
7	" "	1 "	1 day.	"
8	" "	1 "	2 days.	Death.
9	" "	1 "	4 doses.	Hallucination.
10	Alcoholic tincture	1, 2, 3 and 4 grams.	20 "	Death.
11	" "	40 grams.	4 days.	Delirium.
12	Wine of Trousseau.	27 "	9 "	" and death.
13	Dig. in maceration	15, 50 and 60 centigr.	17 "	"
14	" " soup.	1 gr. and 1 gr., 50 "	4 "	Death.
15	" "	20, 40 and 60 "	3 "	Delirium and death.
16	" "	40, 60 and 30 "	3 "	" " "
17	" "	60 and 80 "	4 "	" " "
18	" "	1 gram; 1 gram.	1 "	Death.
19	" "	1 "	1 "	Sudden death.
20	" "	30, 40 and 50 centigr.	10 days.	Death.
21	" "	1 gram.	5 "	Delirium and death.
22	" "	15 and 20 centigr.	13 "	" " "
23	Digitalin & wine of Trousseau.	1 gram and 50 centigr.	1 "	Death.

In 3 cases of cirrhosis of the liver, digitalis caused delirium and death, and the author states that "digitalis is especially dangerous in albuminuria, in aortic insufficiency, in cirrhosis and in anemia. And if my interpretation is just, which I do not undertake to affirm, moderate doses of the drug have produced death."

I shall be amply repaid for the trouble I have taken in preparing this paper, and my object will have been

accomplished, if its publication may lead to a more careful observation of the symptoms, particularly of a mental or nervous character, attendant upon the administration for a protracted period, of this most valuable drug. If any members of the medical profession have observed in their practice symptoms of delirium or hallucination, however slight, in connection with or during the administration of digitalis, I shall be glad if they will make it known through the columns of your Journal. In fact, if all physicians who meet with idiosyncrasies in the use of any drug would make it known to the profession at large, the result would be beneficial.

THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIPJOINT.

BY

LEONARD W. ELY, M.D.,

of New York City.

Until within recent years a hopeless deformity, increasing with the age of the patient, and condemning her to the life of a cripple, congenital dislocation has now been stripped of most of its terrors, and yields to treatment as few other serious deformities do. The improvements in treatment are of recent date, and it is most important that the general practitioner should know what they are, for he is the one who sees the patient during the only time that complete recovery is possible. If he consult his textbooks he will probably make up his mind that little can be done,¹ but if he has had the opportunity to observe the results of proper treatment, it will seem highly reprehensible to allow these cases to go untreated.

I shall in this paper presuppose a thorough knowledge of the morbid anatomy of the deformity, and shall merely mention the important fact that we have to deal with an acetabulum that is often little more than a shallow indentation, and with a femur head that is more or less altered, depending on the age of the patient.

Three methods of treatment are before us: (1) The closed method, that is, without the aid of the knife; (2) the open method with slitting of the capsule and reposition of the head in the acetabulum; (3) the open method with opening of the capsule and deepening of the acetabulum. The first is generally known as the Lorenz method, and of the third the most ardent champion is probably Hoffa, of Würzburg. Of the 3 the best operation is the first, but it is applicable only to young children, and requires an accurate technic for its successful performance. Probably many of the adverse criticisms which have been made upon it are due to an ignorance of this fact. In the opinion of this or that operator some point seems unessential, and he ventures to introduce an "improvement" of his own, thereby upsetting the entire operation. Again, a difference in method may exist not from intention but from ignorance.

The Lorenz method, briefly, is: To put the head of the femur where it belongs and to keep it there in such a way that the weight of the body and the constant mus-

cular tension may press it into the socket. Lorenz calls it the Belastungsmethode, or "loading method." The first item is often quite easy of performance. Anyone who has ever tried the reduction under ether in a young child will bear out the truth of this statement. The crux of the treatment is keeping the head where it belongs and "loading" the body upon it. There are those who deny that this will deepen the acetabulum, and, until a sufficient number of cases be brought to the autopsy table, they cannot be proved wrong. We know that the dislocated head often makes for itself one or two shallow sockets on the dorsum of the ilium, and, reasoning from analogy, it would seem that the acetabulum should be deepened by the constant pressure of the head against it, though perhaps never reaching its normal size. However, those who have seen Lorenz's results are willing to leave theory to others and content themselves by adopting his methods. How convince a man that a thing is impracticable when he has seen it done?

In the first place, it is necessary to state that the age of the patient has an important bearing on this operation. In single luxation the chances are good up to 10 years, and then grow rapidly unfavorable. In double dislocation we cannot look for good results much after the seventh year. It is well not to attempt the operation in either case before the end of the second year.

No preparatory treatment is necessary in very young children, but, as we near the age limit, it becomes more advisable to subject the patient to a preliminary extension, or to a tenotomy or several of them followed by extension. No hard-and-fast rule can be laid down for these procedures. If the soft parts are yielding, and if by manipulation the head can be brought down to the region of the acetabulum, we may omit preliminary treatment.

The treatment of single dislocation in a young child, that is, a case in which reduction is comparatively easy, receives first attention. Two assistants are necessary besides the anesthetist, and one or two others are advisable if they can be procured. The first maneuver is the breaking down all resistance in the adductor group of muscles, and this is accomplished in two ways, *i. e.*, by forcible abduction intermittently applied, and by a species of massage with the ulnar border of the hand upon the adductors close to their insertion to the pelvis—a sawing motion, back and forth. Too much stress cannot be laid upon the thorough execution of these procedures, for on them depend, not only the comfort of the patient after the operation, but also in great measure the success of the operation itself. They are usually only half done.

The next step is the forcible extension, after the perineum has been well protected from harm. One assistant grasps the leg, and 2 others prepare to make counter-extension, one with his hands on the perineum, the other steadying the trunk. Traction is then rhythmically done, and often the hand of the surgeon, held during this maneuver upon the trochanter, feels the head slip in and out of the socket.

Having overcome the resistance of the extensors the operator turns his attention to replacing the head over the posterior border of the acetabulum. Grasping the thigh, flexed at right angles to the trunk and rotated slightly inward, just above the knee, with one hand (the left leg with the right hand, let us say for example), and placing the thumb of the other hand upon the trochanter, the fingers on the vulva, the surgeon makes strong traction with the right hand in the direction of the thigh, that is, at right angles to the body, at the same time abducting the thigh forcibly and pressing the trochanter inward with the left thumb. This is repeated until the reduction takes place, as it usually will in a young child with decided, palpable shock as the head slips in.

Should this not succeed, we place a cushioned wedge under the trochanter, and, with the pelvis held firmly in place by an assistant, we slowly and forcibly abduct

¹ "Of the reduction of such a dislocation, in the usual sense of the term, there can, of course, be no question [*sic*] for the normal structure of the joint does not exist, and the most that can be attained is to diminish the deformity and functional disability."—American Textbook of Surgery 1899. "A number of different methods of treatment have been recommended, but none of them have been entirely satisfactory."—Morris, Orthopedic Surgery, 1898. Other authorities give various opinions, some favoring operation, some discountenancing it.

the thigh flexed at right angles to the body. This abduction, applied intermittently, is carried just beyond the plane of the body, and, in order to avoid fracture of the neck, the greatest care is requisite in its execution. It is not as satisfactory a way of reduction as the first, because not nearly as safe; but often, in children over 4 years of age, it is the only practicable method. If this also fails we may try forcible abduction of the extremely flexed thigh, also on the cushioned wedge. If again we do not succeed, we must have recourse to the knife, of which more later.

Let us suppose that in one of these ways the head has been replaced. In traumatic dislocation our work would then be about ended. Not so in congenital luxation; this is merely the beginning. The next problem which confronts us is to keep the head where it belongs, and we do this first by repeatedly pressing the head of the femur into the acetabulum, the thigh being in extreme abduction, accompanying this motion by an outward rotation—a boring motion repeated again and again. We shall probably find then that we have in this way increased the stability of the joint, and that it will not be so easily relaxed when brought to the most unfavorable position, namely, flexion and adduction.

The position in which we shall now put up the limb will be that in which relaxation backward is least apt to occur, and that will be, in the ordinary case, where the stability is not exceptionally great, extreme abduction carried slightly behind the plane of the body. It will be retained there by a plaster-of-paris spica, and if we are wise we will apply this spica as Lorenz directs. The writer has seen many spicas, but until he saw Lorenz apply one he never knew what a spica should be. The main points are these: It reaches from just above the iliac crests to just above the knee. It is snugly molded on the crests and allows free motion in the knee. It is applied over a carefully-made padding, under which is a layer of shirting, and inside this again are 1 or 2 strips of bandage with which to scratch the skin during the long time the spica will be on. The bridge across the pubes is narrow—about 3 inches—but very thick—about 1 inch. The finger is inserted under the plaster after it has been trimmed out, and the edges bent slightly out over the spines of the ilia, in order to avoid undue pressure. The child is then put to bed, and the first stage of the treatment is over.

During the next few days the child may be more or less restless, and may have some pain, but except perhaps to bandage the leg if edema exists, nothing need probably be done. After this period the patient should be encouraged to go about and use the leg. It is astonishing to see with what success this will soon be done. Children learn to walk, and even to hop and move rapidly about. At first the leg is held in flexion, and any extension is resisted as painful. By persistence the patient learns to extend it, except in rare instances of paralysis of the anterior crural nerve; and, in case of her refusal to make the necessary effort, the surgeon must himself do passive motion as gently and as slowly as possible. In this way alone can succeeding contractures be avoided. The sole of the shoe on the affected side should be raised 2 or 3 inches.

Thus encased, the little patient spends the necessary 4 or 5 months of the first plaster spica quite comfortably. She may be taken home, and only one thing is required from the parents, namely, the most scrupulous cleanliness. If the spica has been properly applied, excoriations are hardly to be expected, but if they do occur, the plaster may be slit up a little and pressure in this way relieved.

At the end of this first period of fixation, which varies in duration, inversely as the stability of the primary reduction, between 3 and 6 months, the plaster is removed and the skin carefully cleansed.

Now comes a procedure in which the greatest skill is necessary, the correction of the extreme posture and the

securing of one characterized by moderate abduction and slight flexion. The danger of a relaxation backward is small, but of one forward and upward, very real. No force is to be used. The patient should herself make as much of the correction as she can, and should be assisted very gently by the hand of the operator. Another spica, similar to the first is then applied. It will be found that with this the raised sole on the affected side will not need be as high as with the first, or may not be needed at all. Indeed, if the abduction has been pretty well corrected, the tilting of the pelvis and consequent apparent lengthening of that leg will necessitate a raised sole on the sound side.

With this spica the child is even more at ease than with the first. It should usually be left on 5 or 6 months, or 1 or 2 months longer than the first. After it has been removed the joint is treated by massage and active and passive movements, especial care being given to secure good abduction and extension. The foot at first will be in extreme outward rotation, but this will, to a great extent, disappear, and in the meantime the deformity is usually compensated by a rotation of the pelvis, a pushing forward of the affected side.

This is in brief, the Lorenz method for single dislocation. In double luxation the joints may be replaced at the same time or separately, and the technic in either case is so similar to that of single dislocation that it needs no separate description.

In case of failure with the bloodless method our next choice is the open operation with slitting of the capsule. This will be necessary not only in those cases which have passed the age limit for the bloodless operation, but also in some cases within the limit where contraction of the capsule presents an insuperable obstacle to reduction by this method.

This operation is performed by various operators in somewhat different ways. Perhaps the best is the following: The thigh must first be so loosened in respect to the pelvis that the head of the femur can be brought down to the level of the acetabulum or near to it. Some operators say that the long muscles resist this, and cut their tendons, others cut those of the short ones, but it will probably be necessary to divide the adductors. These tenotomies may be done some weeks before the operation and be followed by systematic daily extension in bed. Sometimes prolonged extension will be sufficient, and the tenotomies may be omitted. At the time of the operation a final thorough extension may be done with a sheet on the perineum.

The incision may be from the anterior superior spine downward and backward along the outer border of the tensor vaginae femoris (Lorenz), or from the trochanter directly downward (Hoffa). It is continued down to the capsule, and care is exercised to avoid cutting muscular tissue, by retracting the tensor vaginae femoris and the gluteus. If the iliopsoas lies upon the front of the capsule it also is drawn aside. The capsule is then slit longitudinally, and the finger of the operator in this opening feels for any constricting bands. These must be cut, and forcible traction on the limb by one or two assistants is then begun, counterextension being afforded by a sheet over the perineum. As traction is thus made, the pelvis tilts down on the affected side, and so the limb is brought into extension and abduction. As the head nears the acetabulum other tense bands of the capsule will be felt and must be divided, the finger being all this time kept in the wound, and the traction being intermitted in order to guard against injury to the perineum. The head should finally slip in with a snap, and often may be helped over the ridge of the acetabulum by the pressure of the other hand of the operator, exerted on the trochanter. Instead of dividing the constricted portions of the capsule, Whitman inserts a dilator and stretches them.

The wound is then closed or left with drainage, according to the operator's confidence in his asepsis, and

the limb is put up in plaster in extension, moderate abduction and marked inward rotation. This last element in the attitude is secured by including the slightly flexed knee in the spica; that is, by running the plaster to the ankle.

The after treatment is similar to that of the closed method, but less care need be taken in returning the limb to the "indifferent" or normal attitude, for the position in which it is put up is much nearer it.

If the surgeon is not convinced of the stability of his reposition, he has recourse to the third method. This differs from the preceding in that after the capsule has been opened, the acetabulum is deepened by means of a scoop. Inasmuch as considerable oozing is to be expected, provision must be made for drainage. The great disadvantage of this method is that it requires long, persistent, and very tedious after-treatment. Passive motion must be practised daily in order to prevent ankylosis in a flexed and adducted posture. If this deformity occur, the last state of the patient is perhaps worse than the first. Gentleness must be combined with force in every manipulation, and, in addition to the passive abduction and extension done by the surgeon, the child should be encouraged to practise these motions voluntarily. Massage will also be of assistance.

Such are in brief the 3 operations. None of them presents anything startling, and all of them are based on sound common sense. Everything is to be gained, and little can be lost. It is a curious fact, already pointed out by Lorenz, that these patients are, as a rule, unusually beautiful and attractive children. The sex is, in the great majority of cases, female. What the untreated deformity means to them need not be emphasized.

PREVENTION OF DISEASE INFECTION BY MICRO-ORGANISMS THROUGH THE MOUTH AND NASAL CAVITIES.¹

BY

ROBERT REYBURN, M.D.,

of Washington, D.C.

Professor of Physiology in Howard University.

The study of the life-history of microorganisms has thrown great light on the causes of many of our infective diseases and their proper treatment; many of them are composed of small particles of germinal matter, or protoplasm, without either the nuclei, cell walls, or cell contents, that are found in what are ordinarily known as cells, in living organisms. Before our eyes and on the stages of our microscopes, we can study them to our heart's content. We can watch them multiply either by the development of ova (or eggs), by gemination (or budding), by fission (or division), or by the production of alternate or successive generations.

The first question to be answered concerning these microscopic organisms is the natural query: Whence came they? To this question we can give no answer.

Just as impassable as it was before the invention of the microscope, is the yawning gulf that divides living protoplasm from dead matter. We can start on our argument today with the axiom, *Omne vivum ex ova* (every living thing comes out of an egg), with just as much assurance of its truth as when it was first enunciated by the great philosopher. Yea, even more so, for time and increased knowledge have only accumulated evidence of its truth.

When the biologist of today makes a pure culture of a living organism, and places it with the proper precautions, in a pure medium or soil fitted for its growth, he invariably finds, and expects to find, the same organism growing under his eyes, or on the stage

of his microscope. He no more finds, or expects to find, a different organism resulting than a horticulturist would expect to find grapes growing upon an apple tree, or thistles upon a plum tree. In regard to the theory of spontaneous generation, or the spontaneous formation of living organisms, from dead matter, it is only necessary here to say, that it is almost universally abandoned by all biologists of any eminence. This theory has been destroyed by the labors and investigations of many scientists, more especially by the elaborate and long-continued experiments of Professor Tyndall, of England, Professor Pasteur, and others.

The life-history of microorganisms when considered with regard to their rapidity of multiplication, presents an interesting field of study. It is very probable, and indeed very certain, that the study of a bacterium and its progeny for a few days gives us a series of generations more numerous than have existed among the higher classes of animals since the earth was fitted for their habitation. The rapidity of the growth and multiplication of bacteria is as far beyond the capacity of the human mind to conceive as it is to attempt to measure the distances of the stars in the heavens or to count their numbers.

Professor Buckner, of Germany, states that the time usually required for one microbe or germ to become two, by the process of division, is 15 minutes. At this rate it is computed that a single microbe would produce in 24 hours a million times the present human population of the earth. Professor Law estimates that a single bacterium dividing and redividing would produce in 48 hours, if undisturbed, 281,900,000,000, which in bulk would fill a half-pint measure,—all produced in 2 days from a single germ measuring the $\frac{1}{1500000}$ part of an inch.

Pathologic bacilli are just as numerous when found, and divide as rapidly. Professor Böllinger states that a cubic centimeter (about $\frac{1}{4}$ of a fluid dram) of tuberculous sputum (from a case of pulmonary tuberculosis) contains from 810,000 to 960,000 tubercle bacilli.

In an ordinarily copious expectoration the tuberculous patient deposits nearly 1,000,000 bacilli into his cup, and on an average in one day he throws 30,000,000 or 40,000,000 of these microorganisms into the world. Thus at a low estimate, 10,000 tuberculous patients now living in New York City, daily expectorate some 300,000,000,000 tubercle bacilli.

The bacilli which cause diseases therefore exist in every breath of air we draw, in the articles of food we consume, and in much of the water we drink. Uncounted myriads of them are to be found in the digestive apparatus of persons who seem to be in all respects perfectly healthy. How then do we escape the attacks continually made upon us by these destructive bacilli and bacteria?

It must be perfectly apparent that the fluids or tissues of the body must have the power to destroy and render inert these poisonous microorganisms; otherwise none of us could live. Where does this power reside? Metchnikoff thought he had discovered where when he elaborated the doctrine of phagocytosis, or the destruction of bacteria and other microorganisms by the leukocytes or white corpuscles of the blood. Nutall, Buckner, Lubarsch, and in this country, T. Mitchell Pruden and many others, have shown conclusively, however, that the power of destroying the bacteria, etc., resides not only in the leukocytes, but in the blood serum. This preservative power of blood serum explains why it is that the human body is able to resist the destructive action of the innumerable poisonous microorganisms which continually surround us. There exists, however, two conditions which have a most powerful effect in increasing or diminishing the power of the blood serum to destroy these poisonous microorganisms. The first of these here to be mentioned is the high or low condition of the health of the individual at the time of receiving the infection. If the individual is in a high state of health, his blood serum is then capable of destroying an

¹ Read before the Medical Society, Washington, D.C., April 17, 1901.

immense number of these pathogenic organisms, and he is thus rendered immune to the disease.

Any condition, however, which impoverishes the condition of the blood and tissues of the body, impairs this protective power. Thus anemia or any malnutrition existing in children from improper diet or bad hygiene, renders them an easy prey to the onset of infecting microorganisms.

The indiscriminate and too abundant use of candies and cakes by children cannot be too greatly deprecated. We all know that pure sugar, moderately used, is not only harmless but wholesome as an article of food. But when mixed with injurious and sometimes poisonous coloring matters, such as are found in colored candies, its use should be absolutely prohibited to children. The admixture of glucose with the sugar used in candies is also indirectly an element of danger on account of the possibility of its producing arsenic poisoning. Of course no arsenic is ever intentionally mixed with glucose, but it has been found to exist as an impurity in the sulphuric acid which has been employed in the manufacture of glucose.

Probably all of our readers are aware of the large number of deaths which have lately occurred in England, and which have been found to be cases of undoubted arsenic poisoning, due to the contamination of the glucose used in that country in the manufacture of beer.

Pure sugar is perfectly harmless to the teeth of children, but when given to them in the form of candies it produces an acid condition of the fluids of the mouth which rapidly produces decay of the teeth. A mouth filled with decayed teeth is always in a septic condition. These septic fluids of the mouth have not only lost their bactericidal power, but are continually being swallowed and passed into the stomach and aid in infecting the stomach and intestinal canal. Many cases of chronic dyspepsia and gastrointestinal catarrh are due to the chronic infective condition of these organs thus produced.

All of us are familiar with the horrible odor of the breath of persons who have a mouth full of decayed teeth. These persons come to us suffering from aggravated forms of dyspepsia or gastrointestinal catarrh. We often cure them not so much by medication as by sending them to seek the aid of a dentist. After the dentist has extracted the roots and furnished properly fitting teeth, the cure of the patient is generally credited to the improvement in his mastication. It is not so much due, however, to that cause as it is to the destroying of the flow of microorganisms which have been poisoning the stomach and intestinal canal.

The second condition which greatly influences the fatality of every infectious disease due to the presence of poisonous microorganisms, is that the deadly effects produced depend upon the number and kind of bacilli introduced into the body at the time of receiving the infection. Experiments upon animals with many varieties of poisonous bacilli show a very close analogy to the phenomena produced by other poisons; such, for instance, as opium, etc. If the dose of the poisonous bacilli is large, the animal dies; if it is small, his blood serum may destroy this limited number, and he may recover. How, then, can we diminish the number of these bacilli in our patient and thus prevent him taking into his system a deadly dose of these poisonous germs? It becomes, then, self-evident that if we wish to minimize the danger of infection, the first thing to be done is to procure and preserve a healthy condition of the mouth and nasal cavities, through which these germs enter the body. It should be remembered that this bactericidal property (or power of destroying poisonous microorganisms) is only found in the fluids of the body when healthy. For instance, it has been shown by Wurtz, Lemoyez and others that a large number of microorganisms are found at the external orifice of the nose, and are entangled and retained by the vibrissae (or the thick hairs which line the nostrils). Farther up the nostrils

the number diminishes, and in the upper part of the nasal cavities they are entirely absent, for the healthy nasal mucus is sterile and does not contain any microorganisms. If, however, we have any acute or chronic inflammation of the nasal cavities, whether due to catarrh or the presence of polypi, adenoid tumors, or other morbid growths, this power of destroying microorganisms possessed by the nasal mucus is lost, and the system is left in a condition which renders it an easy prey to the attacking organisms.

This fact is a weighty argument to be added to the long list that might be adduced in favor of breathing through the nose. Mouth breathing in fact is always a symptom of disease, and shows that there is in the nasal passages some obstruction to the free entrance of air into the lungs. One of the most frequent causes of mouth breathing is chronic enlargement of the tonsils. When these are enlarged it shows that they are diseased, their protective power has been destroyed, and their crypts and follicles afford resting places for the lodgment of pathogenic bacteria, and bacilli, and the distribution of their poisonous products of the system.

Chronic enlargement of the tonsils therefore requires prompt and thorough treatment, and in most cases demands their removal. Another evil effect of this condition is the imperfect development of the chest, which is produced by their interference with the process of respiration. Patients afflicted with enlarged tonsils are compelled during sleep to breathe with their mouths open. This produces unhealthy dryness of the mouth, favors the entrance of infecting microorganisms, and produces a nasal snuffling tone of voice, which is quite characteristic.

Adenoid and polynoid growths in the posterior nasal spaces, and pharynx, also produce the same effects and should always be promptly removed. The epithelial cells of the mouth, the saliva and fluids of the mouth, also possess bactericidal power, though in a much less degree than the nasal mucus. In regard to the proper method of keeping the mouth and nasal cavities in a clean and sanitary condition, it is scarcely necessary to dwell here at length.

The use of the tooth brush and cleansing the teeth with some mildly antiseptic solution three times a day should be enjoined upon our patients. If they object to this, urge them to cleanse them at least twice a day, in the morning and before going to bed. It seems scarcely necessary here to give formulas for this purpose, but a dilute solution containing glycerol of carbolic acid, listerin, or camphophenique will do what is required. For a tooth powder there is nothing so good as precipitated chalk, which moreover is perfectly harmless and cannot injure the teeth as some of the more active tooth powders do.

It is the opinion of many eminent men of our profession that the regular and systematic cleansing of the teeth of children with some mild antiseptic solution or dentifrice, would not only prevent decay of the teeth but would greatly diminish the number of cases of scarlet fever, diphtheria, measles, tuberculosis, typhoid fever, and in fact all the other infective diseases which kill so many of our children every year.

Dr. Jacobi¹ in a paper read before the New York Academy of Medicine says: "The bronchopneumonia of children is often caused by *Bacterium coli communis*, which has been conveyed to the mouth from soiled and dirty fingers. He says further that if the respiratory organs are healthy there is no ill effect produced, but if catarrh of the respiratory passage exists, then the bronchopneumonia (which is so fatal to young children) is developed."

Dr. William Hunter² says: "The condition of the mouth associated with the presence of decayed teeth and rotten fangs, is one of profound sepsis or poisoning, differing from ordinary sepsis in that all the pus organisms are continually being swallowed. It is also a sepsis con-

nected with diseased bone. The gastric juice has fortunately a great capacity for killing poisonous microorganisms, but this capacity is not complete in the intervals between the taking of food. It should be remembered that when the stomach is empty, little or no gastric juice is secreted, and hence the bactericidal power of the stomach, which chiefly lies in the gastric juice, is for the time almost entirely lost."

Cases of gastric catarrh are liable to become septic catarrh; septic absorption from the decayed teeth and gums must be considerable, and there is also the danger of infecting the tonsils, with the consequent farther danger of tonsillitic, pharyngeal and eustachian tubes infection. The treatment Dr. Hunter recommends³ in these cases consists in the removal of all diseased stumps and roots, or if that be not possible, in the direct application to each diseased tooth of carbolic acid, 1 in 20, or 1 in 40, rubbed in by means of a camel's hair-brush, or a piece of cotton wool. In the *New Surgery*, 1897, edited by Dr. Roswell Park, we find on page 312, the following, of interest to the dental surgeon: "The study of the bacteria of the mouth is of great interest to the surgeon. The relationship between mouth bacteria and local lesions of the teeth and jaws and mucous membranes, of secondary gastric disturbances and the study of the mouth as a first point of infection for both local and general diseases, is a wide subject. Suffice it to say, that, normally, the mouth contains scores of varieties of bacteria—saprophytic usually, but including also common pathogenic forms, which may be found as normal inhabitants of the mouth without injury to the individual—but if the vitality of the tissues is lowered to a sufficient degree, these pathogenic germs may find a favorable breeding-ground for the production of disease. The mouth furnishes a point of infection for most pathogenic germs, *e. g.*, those of diphtheria, erysipelas, actinomycosis, the oidium albicans of thrush, tubercle bacillus, and the virus of syphilis."

To those who are interested in this subject we would refer them to the investigations of Professor Vicentini, translated and published in the *International Journal of Microscopy*, April, 1894, and running through several numbers; he gives plates showing 54 different species of bacteria he found in the human mouth; an article by Dr. Arthur D. Hugenschmidt,⁴ entitled "Experimental Study of the Different Modes of Protection of the Oral Cavity against Pathogenic Bacteria"; a paper by Dr. G. V. I. Brown,⁵ entitled, "Disinfection of the Mouth a Potent Factor in the Treatment of La Grippe"; and a very exhaustive article by Dr. J. Leon Williams, entitled, "A Contribution to the Bacteriology of the Human Mouth."⁶

But it is needless further to multiply quotations from authors on this subject. In recapitulation, I only wish to say that I share in the opinion expressed by others: that if we preserve and maintain by good hygiene the health of our children, and keep their mouths and nasal cavities healthy and aseptic, the lives of many thousand now sacrificed through bad hygiene, would be saved to bless and adorn our homes.

College of Physicians and Surgeons, Baltimore.—Dr. William Royal Stekes, city bacteriologist, has been elected a member of the faculty and has been given the chair of pathology.

Practised Without License.—John A. Taff and Chalmers Prentice, of Washington, were arrested recently for practising medicine without a license. Prentice claims to be a specialist in nervous diseases and has been in the city 3 months. Taff claims to be a specialist in women's diseases.

PRACTICAL THERAPEUTICS

Under the charge of

A. A. STEVENS,

Assisted by

L. F. APPELMAN.

Treatment of Acute Rheumatism by Aspiration.—Zagato (*Gazz. degli Osped.*, February 10, 1901), reports the case of a young man suffering from acute rheumatism of the right knee and foot in which the usual treatment failed to relieve the intense pain. On the tenth day, the knee being extremely swollen, instead of giving an hypodermic injection of morphin as was his first intention, the author introduced the needle several times into the joint, withdrew in all about 60 cc. of clear, olive-colored fluid. A 2% solution of carbolic acid was then injected. Pain ceased at once, and in 3 or 4 days the patient could move the knee freely, and without pain. A few days later the left knee became affected, and the same treatment was repeated with similar good results. No bad results followed the aspiration.

Treatment of Paralysis Agitans by Systematic Exercise.—J. M. Taylor (*Journal of Nervous and Mental Diseases*, March, 1901), suggests a plan of treatment intended to counteract the rigidity and impairment of movement. His treatment consisted in regulated exercises for the muscles, beginning with massage and passive movements. The muscles least used (those of the neck, hips and back) showed in one patient, an artist of sedentary life, a tendency to contracture, and felt dense and hard, while the overlying skin was dense and dry. Treatment consisted at first of passive movements and massage of the skin with oil inunction; passive movements of the limbs, back, neck, and jaws were practised to overcome the tendency to contracture; a special and graduated system of voluntary extensor movements followed, namely, extending spine after stooping, stretching out of the arms and legs to the greatest extent, and deep breathing to overcome the rigidity of the chest; suspension, as in tabes, was a valuable adjuvant to these exercises; the tissues became more elastic, "tinglings and burnings" were felt in these parts as though they "went to sleep," and it was necessary to practise deep massage to overcome the agony thus caused. This was absent when contracture was slight or absent. A severe frontal headache was usually present during and for a time after the exercise; this, some weeks after, gave place to a pleasurable sensation, and later, the patient experienced a "glow of satisfaction during and after the movements." It is important to continue the exercises daily after improvement is established, the most important movements to overcome the tremor being slow, full, forcible expansions and the attainment of normal attitudes. Full thoracic capacity should be developed by deep breathing exercises. Several cases are reported in which marked improvement followed this system of treatment.

Safe Administration of Anesthetics.—Luke (*Scottish Medical and Surgical Journal*, May, 1901) writes as follows: There is as yet no perfect anesthetic. There is no absolutely safe anesthetic. Deaths from anesthetics are most frequent in operations for trivial cases, when the administrator is liable to be off his guard, and the friends are certainly least prepared. So-called deaths from anesthetics really fall into certain groups: (a) Deaths due to the anesthetic which has been carefully administered. (b) Deaths due to the anesthetic which has been carelessly, often hurriedly administered. (c) Deaths due not so much to the anesthetic as to some disease present in the patient, or, more rarely, to his mental condition. Two golden rules should be remembered: (1) While enough of the anesthetic should be given to insure complete insensibility before the surgeon commences, and while he is operating; (2) care should be taken that the patient has no more of the anesthetic than is absolutely needed. While neglect of the first rule causes great inconvenience and waste of time, neglect of the second is sometimes responsible for loss of life, and more often for prolonged vomiting and malaise, which often interferes with the after-treatment.

Eucain in Spinal Analgesia.—Jedlicka (*Die Therapie der Gegenwart*, April, 1901) states that he had tried cocainization of the spinal cord in 7 cases, and has had unpleasant experience with the drug. He therefore replaced it with eucain (alpha eucain hydrochlorate). This he employed in 93 cases of laparotomies of various kinds, operations on the lower extremities, perineum and scrotum, and in various gynecologic operations with excellent results. He believes that this method of inducing analgesia is of inestimable value in patients suffering from heart and lung disease to whom ordinary narcosis would be extremely dangerous.

The Treatment of Pneumonia.—J. K. Crook (*Boston Medical and Surgical Journal*, February 14, 1901) states that not a single dose of medicine should be given simply because pneumonia is present; the indications should be watched for sweat. The old-time poultice is being relegated to a well-deserved oblivion, and the use of icebags and sponge-baths is happily becoming almost universal. The author favors the use of opiates, not as a routine measure, but discriminately, to meet such indications as obstinate insomnia, intense nervous excitement or delirium. The same is true of alcohol. While it is usually indicated in chronic alcoholics and in old people, it is rarely required in others if the pulse-rate keeps below 110. Digitalis is losing favor and caffeine is becoming more popular, while strychnin is generally admitted to be the most useful heart tonic in this disease. The serum treatment, the author believes, has not made much progress, the chief difficulty being the inability to prepare an antitoxin of uniform and staple quality.

Neuralgia.—S. Solis Cohen (*Merck's Archives*, May, 1901) states that the following formula is very useful in intercostal neuralgia and neuralgic headache:

℞
 Oil of gaultheria } of each 15 minims
 Guaiacol }
 Menthol } 10 grains
 Wool-fat }
 Cerate } of each 2 drams.

Sig.—Dispense in a tin tube. A small quantity (about the size of a pea) to be well rubbed in over seat of pain, night and morning.

Tetranitrol.—Huchard (*Bull. de l'Acad. de Med.*, No. lxxv, 1901) has used tetranitrol as a vasodilator in 120 patients, and has found it free from the unpleasant effects of nitroglycerin—headache, throbbing of temporals, etc. He also holds that it does not affect the hemoglobin like other nitrates. It has the great advantage of mild prolonged action. Its action is manifest in from 15 minutes to ¼ of an hour, and if continued in from 1 to 2 grain doses, 4 or 5 times a day, it keeps the vessels in a state of reduced tension. It is indicated when there is increased arterial tension, as in arteriosclerosis, in coronary angina, in dilation of the heart from peripheral vascular constriction, in uricacid dyscrasia, in tabetic crises, and in interstitial nephritis.

Clinical Observations on Protargol. Reichmann (*Medicine*, May, 1901) gives a review of the literature upon the use of protargol in gonorrhoea, and cites 16 cases in private practice which demonstrate the value of the drug. Treatment in each case was begun with a ½% watery solution, which was injected 4 times daily for 3 days. The fluid was retained in the urethra for 5 minutes at the morning, noon and afternoon injections, while in the evenings 2 successive injections were to be taken, and each retained 10 minutes. At the end of 3 days a 1% solution was ordered, to be used once a day, provided the microscope revealed no gonococci. In 15 cases the gonococci disappeared entirely in from 3 to 9 days; nevertheless, 1 daily injection of a 1% solution was continued for 2 weeks. In 1 case the author was compelled to stop the treatment on account of the occurrence of complications; but even in this case protargol finally gave satisfactory results, though the treatment had to be continued for a longer time.

The Physiologic Relation of Scopolia Carniolica to Atropa Belladonna.—H. C. Wood, Jr. (*Therapeutic Gazette*, April 15, 1901), after a comparative study of these drugs, concludes that scopolia carniolica in its physiologic action so closely resembles atropa belladonna as to be practically indistinguishable. Like belladonna, scopolia raises the blood-pressure, paralyzes the pneumogastric nerve, is primarily a stimulant of the respiratory center and in fatal dose kills by asphyxia. In the frog it is a paralyzant to the spinal cord and to Setchenow's center, and when brought in direct contact with a motor nerve, lessens its function. The dominant alkaloids of the 2 plants, however, are probably not identical, since we find the scopolia apparently a little more depressant to the spinal cord, and distinctly more toxic.

The Blood-pressure-raising Principle of the Suprarenal Glands.—Takamine (*Therapeutic Gazette*, April 15, 1901) gives a preliminary report of an active principle which he has isolated from the suprarenal glands, termed "adrenalin." This is a light, white, microcrystalline substance showing a slightly alkaline reaction on moistened litmus paper. It is with difficulty soluble in cold water, and more readily in hot water. From the hot, saturated aqueous solution the crystals separate after cooling. The colorless aqueous solution of adrenalin is easily oxydized by contact with the air, its color changing from pink to red, and eventually to brown. Adrenalin is very soluble in acids, and forms salts which are crystallizable with difficulty. The author has made 3 kinds of salts—hydrochlorates, sulfates and benzoates. The physiologic activity of adrenalin is exceedingly powerful. A fraction of 1 drop of a 1 to 10,000 aqueous solution of adrenalin or its salt blanches the normal conjunctiva within 30 to 60 seconds. When given intravenously the drug exerts a powerful influence upon the general muscular system, but especially upon the muscular walls of the heart and bloodvessels, resulting in an enormous rise of blood-pressure. A comparative test of strength of the adrenalin with that of the fresh extract of suprarenal gland shows that adrenalin is 625 times stronger than suprarenal extract. The sample of adrenalin used for this experiment contained some mineral impurities, so that pure adrenalin would be over 1,000 times stronger than an extract of the fresh gland. When locally applied, adrenalin is the most powerful astringent and hemostatic known. It is nonirritating, nonpoisonous, noncumulative and has no injurious properties. It may be used in all forms of inflammations, in nasal hemorrhage, hay fever, asthma, diseases of the heart, diseases of the nose and throat and many other conditions with excellent results.

Gastric Ulcer.—Sir Lauder Brunton (*The Medical Press*, May 1, 1901) states that in a large number of cases of gastric ulcer the pain can be stopped almost to a certainty by the administration of sodium bicarbonate, provided the drug be given in sufficient dose. The author's plan is to dissolve a teaspoonful of soda, the patient to sip the solution teaspoonful by teaspoonful until the pain is gone. The best way to dissolve the soda is not to add it to water, but to lime water, flavoring with a little spirit of mint. The reason assigned for using lime water is that the bicarbonate of sodium in plain water might possibly soften the tissues to too great a degree, and thus predispose to hemorrhage. A case is reported in which this apparently occurred. To lessen the constipation caused by the lime, fluid magnesia may be given along with the bicarbonate of sodium. An alternative formula to the above is:

℞
 Spirit of peppermint 1½ drams.
 Prepared chalk ½ dram.
 Light magnesia carbonate 1 dram.
 Sodium bicarbonate 1 dram.

A teaspoonful of this preparation should be stirred up in half a tumbler of water or more and slowly sipped, a teaspoonful at a time until the pain is relieved.

Intraarachidian Injection of Cocain.—At a recent meeting of the Academy of Medicine (Paris) Tuffier (*Medical Press*, May 1, 1901) said that, having up to the present time operated

on 400 patients after practising the cocain injections, he considered it necessary to say a word on his *modus operandi*. As to the instrument, a needle should be used and not a trocar; the extremity should be but slightly beveled so that none of the liquid should escape outside the medulla. The solution he employed was 1 in 50. The consequences of that method of producing anesthesia were never in his hands such as to discourage the operator. He had never had an accident during the operation, and of the 5 deaths, postoperandum, reported, none of them could be directly traceable to the cocain.

Treatment of Pulmonary Tuberculosis in Children by Muscle-Serum.—Josias and Roux (*Bulletin General de Therapeutique*, February 23, 1901), report that the administration of raw meat juice in the treatment of tuberculosis in children is attended with good results, even in the most advanced cases, although the best results are obtained when the malady is still in its early stage. Administered in one case of intestinal tuberculosis, with severe diarrhoea, the improvement was very great; the diarrhoea ceased, the weight increased and the tubercular process in the lung became quiescent. The juice should be freshly prepared, and in summer it should be placed on ice when not wanted for immediate use. The authors administer on an average 1 pint a day.

The Aperient Action of Persulphate and of Metaranadate of Soda.—Robin (*Bulletin General de Therapeutique*, February 8, 1901), finds that the persulphate of soda is an excellent aperient, it having given good results in half the cases in which it was employed. The author uses it in a solution of 30 grains of persulphate in 10 ounces of water, of which a tablespoonful is given twice a day before the chief meals. Good results have been obtained in cancer of the stomach, in hyperacidity of the stomach and in simple or tuberculous dyspepsia. The metaranadate of soda is used in the same conditions in the dose of $\frac{1}{16}$ of a grain taken one-half hour before the 2 chief meals. The administration is not continued for more than 4 days consecutively.

The Prevention of Nausea and Vomiting during Anesthesia.—Hirschman (*New York Medical Journal*, December 15, 1900) recommends that chlorotone be given to patients $\frac{1}{2}$ hour before anesthetization, in doses of 10 grains to women and boys under 16 years, and of 15 grains to men. The patient has little or no excitement during the induction of anesthesia and needs $\frac{1}{2}$ to $\frac{1}{4}$ less of the anesthetic. A betterment of 70% in vomiting is noted, as compared with patients to whom chlorotone has not been administered.

Pyramidon and its Salts.—Bertherand (*Bulletin de Therapeutique*, February 23, 1901), mentions a case in which the nitrogenous coefficient of excretion was increased 10% after the administration of pyramidon in 5-grain doses for 8 days. Used in a case of diabetes in the same dose the sugar excreted was raised from 30 or 45 grains a day to between 225 and 300 grains. As an antipyretic the drug tends to induce profuse sweating, especially in tuberculous patients. In order to avoid this the author uses the bicamphorate of pyramidon, which acts as an antipyretic without causing sweating. In sciatica good results were obtained by the hypodermic injection of a solution containing $1\frac{1}{2}$ grains of pyramidon. In the pain of rheumatism the results obtained were less conclusive although the author considers pyramidon equal to other drugs in combating this symptom, and it may be given in smaller doses than are necessary with other drugs with equally beneficial results.

Formaldehyd.—Young (*Treatment*, April, 1901) finds that 1 to 100,000 solutions of formaldehyd will destroy the less resistant germs quite readily, while the more resistant ones are destroyed by a solution of 1 to 1,000, though this has no appreciable effect on the living human skin, even when the hands are immersed in it for a considerable time. The author has had excellent results from its use in fistulas, and in various growths and pathologic conditions of the skin, especially indolent

ulcers of the lip and face. In a severe case of bromidosis the application of a 10% solution at once stopped the sweating and so far as known there has been no return of the affection. Internally the author has used the drug in the treatment of gastric ulcer in the dose of 2 minims every 4 hours well diluted. Recovery was rapid. Similar good results followed its employment (in the dose of 1 minim mixed with egg-albumen) in dysenteric diarrhoea in a child. In scarlet fever daily sponging with a 1 to 1,000 formaldehyd solution from the appearance of the rash, shortens the stage of desquamation and renders the scales innocuous, so that the period of convalescence is hastened, and security from infection attained.

Flatulence.—(*Merek's Archives*, March, 1901).

R

Spirit of cajuput.
Aromatic spirit of ammonia.
Spirit of chloroform of each 4 drams.

Sig.—One teaspoonful in a wineglassful of water every $\frac{1}{2}$ hour or every $\frac{1}{4}$ of an hour, until relief is obtained.

Reports on Influenza (*Public Health Reports*, Nos. 6, 7, 8, 9, 10, 11, 12 and 13) show that in Cairo, Illinois, 15% of the population has had influenza during the past winter. In the majority of the cases the type of the disease has been mild; the nervous, respiratory, circulatory and digestive systems being attacked most frequently in the order named. The treatment consists in placing the patient in bed where he is kept until the fever subsides. Calomel and a saline purge is given early. Diet is restricted and consists principally of milk. Sodium benzoate, 5 grains every 3 hours. Strychnin as a respiratory stimulant when needed. Bromid acetanilid and caffen comp. are used for hemicrania. Ammonium salicylat has given satisfaction in a few cases. The effect of quinin is not constant, being of marked benefit in some cases and inert in others. Cold sponging is practised when the temperature passes 103° F. In Unity, Illinois, 150 mild cases of influenza are recorded, with a mortality of 3%. The use of quinin and whiskey is emphasized in the treatment of the disease. Considerable stress is laid upon general sanitary precautions in those cases of influenza treated at St. Mary's Hospital, Hoboken, New Jersey, and in St. Francis' Hospital, Jersey City, New Jersey. Patients are isolated in large, well ventilated rooms. Excretions are received in disinfecting fluids. All cloths are sterilized which have been in contact with the patient. After the patient has recovered the room and its contents are thoroughly fumigated with formaldehyde gas. Internal medication consists in the administration of quinin and salol, combined with coal-tar products. The bowels and kidneys are regulated by the use of proper remedies. The diet includes milk, eggs, meat juices and broths.

Treatment of Hyperacidity of the Stomach.—Hewes (*Boston Medical and Surgical Journal*, November 29, 1900) aims to reduce the acidity of the stomach by the administration of proteid food substances which combine with large quantities of acid, and by alkalies which neutralize the acid present. The patient is given a diet containing as high a proportion of proteid foods as comfortable for the individual. Six meals a day should be ordered, the constituents of each being prescribed. Starches should be limited and carbohydrate foods, sugars or predigested starches, dextrinized flours, used as much as possible since starch digestion in the stomach is impeded in these cases. For the distress or eructations, some proteid, as a raw egg, is to be taken. Sodium bicarbonat in half teaspoonful doses or 15 grains of magnesia hydrate, may be taken in addition to food or in place of it, for the relief of symptoms. Careful attention should be given to baths, exercise, the bowels and the general manner of living. Nux vomica should be given if debility exists. Anemia is to be overcome by the administration of iron. Marked improvement occurs from this treatment in the majority of cases; less than 10% of the author's cases being unrelieved. In these obstinate cases lavage proved a useful adjunct to treatment. Silver nitrate was also used in some of these cases with success.

THE WORLD'S LATEST LITERATURE

5. Effect of the Röntgen Rays in a Case of Chronic Carcinoma of the Breast. ANDREW CLARK.
6. Pathology of Toxic Amblyopias. J. HERBERT PARSONS.
7. Paralysis of the Cervical Sympathetic. PURVIS STEWART.

1.—See abstract of *Lancet*, June 8.

2.—Goldingbird on the employment of the x-rays in the case of fractures, takes up especially their use in criticism of the results obtained by the surgeon. He believes that skiagraphy should only be employed as a subsidiary agent to diagnosis and then its evidence in cases of doubt should be received with caution, and only after due interpretation by someone whose experience warrants his speaking with authority. Its use in the judgment of results is a limited one for it has been proven that a skiagram may show a fracture where none exists; that it is possible to miss seeing a fracture; that it is possible to show a fracture as still existing though long united, and that distortion may be produced in several ways. In contemporary literature, especially American, are to be found many cases where patients have or might have made use of skiagraphs in order to prove malpractice against the surgeon. The question as to how the profession is to protect itself is discussed.

4.—Gordon reports a case of cervical rib. The patient was a laborer, aged 32. The first symptom was an attack of pallor and numbness in the fingers of his right hand in the mornings. Gangrene supervened. Examination had shown the presence of a cervical rib, which was removed. This rib was in some way the cause of the arterial obliteration. The subclavian was not obstructed. If the rib acted directly on the artery it must have done so in some way upon which present pathology throws no light. It may have acted indirectly on the artery through the nerves, which lesion is capable of causing gangrene or structural changes in the bloodvessels. The absence of clear signs of a peripheral neuritis is a striking argument against the theory of nerve origin. The case resembles the local phenomena of Raynaud's disease. [C.A.O.]

5.—Clark reports a case of carcinoma of the breast, with axillary glandular involvement, occurring in a woman, aged 60 years, who also suffered with glycosuria—she having already lost 2 toes with diabetic gangrene—and who presented 2 ulcers of the leg that were ascribed to syphilis. The carcinoma of the breast was extensively ulcerated and firmly adherent to the subjacent muscles and bony structures. Under the application of the x-rays for 15 minutes, for 5 days of each week, continued for a little over 2 months, marked improvement occurred. The area of ulceration decreased, the glandular enlargement lessened, pain diminished and the general condition of the patient became improved. [A.O.J.K.]

6.—Parsons, in a note on the pathology of toxic amblyopias, refers to the prevalent views on the subject, details some histologic investigations of his own, and concludes that the action of nicotin may reasonably be supposed to be twofold: (1) Vascular, causing vasoconstriction of the arterioles, which would explain the selection of the sparsely supplied macular region; (2) paralytic, upon the synaptase either of the cone fibers, or of the inner granules, or of both. [A.O.J.K.]

7.—Stewart reports a case of paralysis of the cervical sympathetic, that of a soldier, aged 30 years, who was shot, the bullet entering the left side of his neck $1\frac{1}{2}$ inch below the mastoid process, and coming out through the seventh right interspace in the posterior axillary line. Originally the entire brachial plexus of the right side was involved, there developing immediately total paralysis of the limb. The practically complete recovery of power, however (save in the opponens pollicis), together with absence of muscular atrophy, shows

that the damage to the greater part of the plexus did not amount to more than a contusion. A few fibers appear to have been permanently interrupted, since there remained slight analgesia of the areas to which the posterior roots of the eighth cervical and the first and second thoracic nerves are distributed, together with slight weakness of the small muscles of the thumb, which are innervated by the first anterior nerve root. In addition to these, there occurred a total paralysis of the cervical sympathetic, narrowing of the pupil of the right side, together with absence of dilation when shaded, or when the skin of the side of the neck is pinched; narrowing of the palpebral fissure, a form of pseudoptosis due to paralysis of the non-striated muscle of the eyelid (the upper eyelid can be elevated to the full extent voluntarily by the striped portion of the levator palpebrae muscle); and enophthalmos, ascribed to paralysis of the orbital muscle of Müller. There was also anidrosis of the right side of the face, scalp, neck, trunk, and the whole of the right upper limb. This area was sharply limited by the median line, and it extends as low as the third rib in front and the third dorsal spine behind. [A.O.J.K.]

The Lancet.

June 1, 1901. [No. 4057.]

1. Acroparesthesia, Erythromelalgia, Sclerodactylia and Other Angioneurotic Disturbances; with an Attempted Classification of Angioneurotic Disorders of the Extremities. THOMAS D. SAVILLE.
2. Arterial Hypertonus and Arteriosclerosis; Their Relations and Significance. WILLIAM RUSSELL.
3. The Bacteriology of Sporadic Cerebrospinal Meningitis. WILLIAM HUNTER.
4. On the Operative Treatment of Corneal Astigmatism. A. BREUER.
5. A Further Note on the Technic of the Quantitative Estimation of the Bactericidal Power of the Blood, and (Incidentally) on the Possible Application of Such Estimations to the Standardization of Bacterial Vaccines. A. E. WRIGHT.

1.—Saville states that acroparesthesia, erythromelalgia, and sclerodactylia are terms applied to symptoms which belong to the same category as Raynaud's disease. About 90% of cases occur in female patients. Vasomotor conditions are due to some inherent and often inherited tendency. Many of them, particularly of the vasodilator kind, are amenable to treatment by bromids. A clinical classification is given which shows that these varieties correspond to the different varieties and phases of Raynaud's disease. [A.G.E.]

2.—Russell studied the arteries in 16 cases which he had observed during life, and gives his conclusions. Atheroma and arteriosclerosis are stated to be entirely different. Much confusion has arisen among writers by failing to recognize the difference in the changes occurring in the arteries inside and outside the kidney. In the former the changes are most marked in the intima; in the latter, in the media. Hypertonus, or a diminution in the lumen of the vessel, occurs in normal and sclerosed arteries. Cases are cited. This condition may occur without an increase of blood-pressure. Treatment to relieve the spasm is effective. Recurring or continued hypertonus leads to hypertrophy of the media. [A.G.E.]

3.—Details of the studies of 10 cases of meningitis are given. Fluid obtained by lumbar puncture was examined with the following results: In all cases a diplococcus was found; this diplococcus had the same biologic and morphologic characteristics as Weichselbaum's *Diplococcus intracellularis meningitidis*; in some cases, other organisms, as *Bacillus of influenza* and *Bacillus tuberculosis*, were present. [A.G.E.]

5.—Wright presents his third communication. New instruments are described, and the technic elaborated. A future paper will deal with the application of the method to the standardization of bacterial vaccines. [A.G.E.]

1.—Owens discusses the **nerve and vascular associations of the kidney** and associations with the colon, calling attention to the frequency of unusual pain symptoms not especially referred to the kidney in connection with renal diseases. [M.B.T.]

2.—Heath discusses the various causes of **retention of urine** at considerable length and quite satisfactorily without adding anything especially new to the subject. [M.B.T.]

3.—Gairdner writes a brief note on an **early experience concerning the therapeutic virtues of iodid of potassium in asthmatic affections.** The experience was an interesting one that occurred at about the middle of the past century and was doubtless the beginning of the therapeutic use of the iodids. [A.O.J.K.]

4.—Edington, in a preliminary communication on an **outbreak of plague in rats at Cape Town,** details the results of his personal investigations and concludes that there occurs in rats a disease that is communicable to guineapigs but not to rabbits, and to which rabbits are also refractory even after it has passed through the guineapig; moreover, since inoculation of the rabbit with this rat bacterium in its virulent form gives no protection against a subsequent inoculation with bubonic plague, it seems clearly proved that this rat plague cannot be bubonic plague. The peculiar susceptibility of pigeons to the rat disease also indicates the difference between that malady and bubonic plague. It is stated that in future steps will have to be taken in case of rats being affected with a disease simulating plague to inoculate other animals than guineapigs. The experiments undertaken show that the rabbit is probably the best animal to use in conjunction with guineapigs. [A.O.J.K.]

5.—Buzzard, in a study of **alcohol and arsenic in the etiology of alcoholic neuritis,** calls attention to the different opinions that recently have been advanced in regard to the relationship of alcoholism to neuritis: (1) That ethyl alcohol per se cannot produce neuritis; (2) that "alcoholic neuritis" occurs in beer drinkers only, and not in pure spirits drinkers, and (3) that alcoholic neuritis is really a misnomer and that the causal factor in those cases to which we have been accustomed to apply the name may be arsenic. Buzzard investigated the case. Histories of 120 cases of alcoholic neuritis, with special reference to the age and sex of the patients, their habits with regard to alcohol, the changes of a nutritional, vasomotor or pigmentary nature in the skin, hairs or nails, and the results of treatment with arsenic. He concludes that alcoholic neuritis is more often found in the sequel of spirit-drinking than in other forms of alcoholism, and that clinical evidence is antagonistic to the idea that arsenic is the cause of alcoholic neuritis. Of 24 cases treated with arsenic, 3 were cured; 12 were greatly improved, and 9 were improved. No case was unfavorably influenced, as one might expect were arsenic the cause of the affection. [A.O.J.K.]

6.—See editorial.

7.—Keetley reports 4 cases of **gastric ulcer.** In the first case a woman of 20 had suffered from 3 attacks of severe hematemesis in one of which she vomited a pint and a half of blood. Upon opening the abdomen a gastric ulcer was found which was adherent posteriorly to the diaphragm and the pancreas. These adhesions were separated, the ulcer was scraped and sutured and a good recovery followed. The patient remained well for some months when she was again troubled with pain and tenderness in the epigastric region. A second celiotomy was performed and anterior gastroenterostomy was done with a Murphy's button with an apparently perfect result, the patient feeling well and attending to her usual duties. In a second case a woman of 32 had been suffering from severe gastric hemorrhage. Her condition was so bad that she fainted 5 times in 24 hours. The patient was treated by rectal feeding and rest, operation not being undertaken. Death resulted on the twelfth day and it is thought that even in such a desperate case the patient's life might possibly have been saved by operation. In a third case a woman of 39 had a long history of chronic gastric disturbances with severe hemorrhages. Celiotomy was performed and Loreta's procedure of stretching the

pylorus was carried out. The patient recovered from the operation and remains well a year later. In a fourth case, a military officer of 40 had suffered from severe hematemeses. Death resulted before operation could be performed and at the necropsy a duodenal ulcer was found which had perforated the pancreato-duodenal artery. Keetley mentions as a difficulty in **operations for chronic gastric ulcers** that the ulcers are situated on the posterior wall in a region where they are not readily accessible. Such ulcers have been frequently treated by ligature en masse or by cauterization with disastrous results. In spite of the difficulties of the operation he prefers to separate the adhesions, scrape the ulcers thoroughly and close it by suture. [M.B.T.]

8.—A man of 49 years was admitted to the hospital with a history of having fallen from a ladder, **impaling himself on a railing.** His pulse was imperceptible, the heart could be faintly heard, and his clothing was soaked in blood. A large gaping wound was found in the left hypochondriac region. An exploratory operation was undertaken, but the injury was found so extensive as to render intervention useless. At the necropsy it was found that there was perforation of the stomach, diaphragm, pericardium, and heart, with fracture of 5 ribs and other severe injuries. The interesting feature of the case was the **remarkable vitality** shown by the patient, who, after this severe injury, lived 9 hours. [M.B.T.]

9.—See editorial.

Medical Record.

June 22, 1901. [Vol. 59, No. 25.]

1. *Hernia of the Urinary Bladder.* W. S. CHEESMAN.
2. *The "Nauheim Treatment."* H. NEWTON HEINEMAN.
3. *On Nephrorrhaphy with Flap Fixation.* ARNOLD STURMDORF.

1.—Cheesman, in reviewing the literature of **hernia of the urinary bladder,** finds records of 180 cases. He classifies them as follows: (1) Cases discovered at autopsy; (2) cases in which the bladder was found in a hernia, but was recognized and not wounded; (3) cases in which there were symptoms of vesical hernia; (4) and cases in which the bladder was wounded, intentionally or unintentionally, during operations for hernia. Of the latter some 93 cases are reported, including 1 by the writer. He says the principal cause of bladder hernia is direct traction exercised through the peritoneal coat by the weight of the hernial mass, or by pulling on the sac during ligation in operation for radical cure. In 16% of the cases symptoms occur sufficient to arouse suspicion, sometimes amounting to certainty, of the existence of the abnormality. In about 25% of the cases it may be possible during operation to recognize the bladder and avoid injuring it; and after 1 hernial sac has been found, any structure resembling a second should be regarded as bladder, till proved otherwise. When the bladder is wounded, the best procedure is immediate suture by 2 layers of catgut, and closure of the hernial wound by Bassini's method; a small drain only being left leading to the bladder suture line. The bladder wall, when thinned, may be freely resected preparatory to closure. The catheter *a demeure* is not essential to primary union of wounds thus closed. Urinary fistula nearly always closes spontaneously, and injuries of the bladder have been directly responsible for death in only 10% of the hernia cases in which they have occurred. [C.A.O.]

2.—For **successful treatment in cardiac cases at Nauheim,** as elsewhere, there must be complete freedom from mental annoyances. It has been shown by various writers that excitement produces cardiac dilation. The hospital patient must know that his family is being cared for; the private patient must be relieved of business worries and often separated from his family. The different grades of baths are described, their stimulating qualities being due to their natural warmth, their alkaline and metallic salts, the large quantity of carbonic acid, and a certain quantity of electromagnetism. The indications for the temperature, length and frequency of the baths are given. The effect in decreasing the pulse-rate and contracting the heart, in increasing the hemoglobin and red cells, and the systolic electric discharge, and the effect on metabolism, are considered at length. The technic and physiology of graded exercises, including massage, deep respiration, resistance

movements and hill and stair climbing, are next described. Dietary rules are given in detail. In 25% of the cases immediate improvement follows; in 50% only the physician's examination can determine that improvement has occurred, as the patient may feel temporarily less strong. Over 90% find some improvement, decided in most cases, in the winter succeeding their treatment. The indications and contraindications for this treatment are named, and it is emphasized that it is only by the utmost painstaking and by many different avenues that the Nauheim treatment produces its effect. Several cases are reported. [H.M.]

3.—Sturmdorf describes a method of **anchoring the kidney by the formation of flaps** which is similar to that described by Dr. Robert T. Morris, who makes use of a single flap of fibrous capsule in addition to the adventitious tissue produced to secure permanent fixation and omits the usual transparenchymatous sutures. Sturmdorf forms 2 flaps by slitting the capsule laterally at each end of a longitudinal incision and passes 2 silk-worm retention sutures through skin, superficial fat, the tendons of the abdominal muscles, the cut and trimmed edges of the perirenal fatty capsule, the fibrous capsular flaps, and the parenchyma of the kidney at a depth of $\frac{1}{2}$ of an inch from the surface and leaves them untied for the time being. Slits are then made through the adjacent muscular tissue, the flaps drawn through and secured by a catgut suture. Interrupted sutures of chromicized gut are then passed so as to embrace muscle and kidney substance at a level with and equidistant from the silk-worm sutures and tied. The final suture includes skin, superficial fat and fascia. The silk-worm sutures are then drawn taut. [C.A.O.]

New York Medical Journal.

June 15, 1901. [Vol. LXXIII, No. 24.]

1. An X-Ray Study of the Causes of Disability Following Fractures Involving the Elbow Joint. SAMUEL LLOYD.
2. A Modified Urethral Dilatorhandle. FERD. C. VALENTINE.
3. Hyperacidity (Superaecidity, Hyperchlorhydria, Superaeciditas Chlorhydrica); A Clinical Study. H. ILLWAY.
4. Penetrating Wounds of the Abdomen. RUSSELL S. FOWLER.
5. Paramyoclonus Multiplex. L. J. MORTON, Brooklyn.
6. A Case of Cerebellar Apoplexy, with Autopsy. LEONARD WEBER.

1.—Lloyd discusses the subject of **fractures involving the elbow joint** and presents a series of pictures of cases coming under his observation because of limitation of motion. Of these cases 3 had been supracondyloid fractures of the humerus, 1 shows the good results that may be obtained in a similar case by a careful reposition of the fragments, and others represent separation of the lower epiphysis of the humerus with dislocation of the radius and ulna; in others the olecranon is also involved. The pictures here shown illustrate forcibly the fact that the bony lesions, displacements and callus cause most of the disability. Lloyd has operated on 21 cases and in each motion has been gained. The essential point in the whole operation is the removal of all bone or callus that in any way interferes with the proper motion of the joint. [C.A.O.]

2.—Valentine has modified the handle of the Oberlander and Kollmann dilator. The improvement consists essentially in having the dial at the top of the instrument and 2 heavy metal projections for the easy grasp of the operator's left thumb and index finger. [C.A.O.]

3.—In the third installment of his paper on **hyperacidity**, Illway refers to the following factors as the most important in causing the condition: (a) constipation; (b) alcoholic liquors; (c) smoking; (d) food of a very heavy or rich character, and (e) disturbances of the nervous system (hysteria, neurasthenia, etc.). The diagnosis is based on the high total acidity, the large percentage of free HCl with gastralgic paroxysms, burning sensation, etc. The most frequent complications are atony and gastropnoia. He divides the treatment into either (a) removal of the cause or causes and (b) the cure of the ailment itself. With regard to the former he formulates the following set of rules: (1) All alcoholic liquors of whatsoever nature are prohibited; (2) all smoking of tobacco in whatsoever form (pipe, cigar or cigaret) is strictly prohibited; (3) all acid or acidulated drinks are forbidden; (4) all foods or condiments prepared with vinegar or lemon juice are forbidden; (5) all

sharp condiments (pepper, black or red, ginger, the various sauces) are strictly prohibited. Under the second group he considers diet as the principal form of treatment, confining the entire cuisine to the nitrogenous foods (eggs, milk, meat, etc.). As medicinal remedies he recommends vichy water—half a glass between 10 and 11 a. m., 4 and 5 p. m., and just before retiring—and Fowler's solution 3 times a day. [H.H.C.]

4.—Fowler, in discussing **penetrating wounds of the abdomen**, says there is one rule in the treatment of abdominal injuries in civil life which should be a law—explore. Everything should be ready to proceed with a laparotomy before the wound is explored in any manner. Identify each layer and examine thoroughly. If there is the slightest evidence that the peritoneal cavity has been invaded, make an exploratory laparotomy. The technic of preparing the patient and of operation are given. [C.A.O.]

5.—Morton reports a case of **paramyoclonus multiplex** occurring in a young woman, 26 years of age. The condition was brought on by muscular overexertion and mental worry, and first manifested itself by clonic spasms of the muscles of the right arm and leg, which then passed over to the left side and finally to the neck and lower face. Morton outlines his treatment of the case as follows: "Tonics, rest and fresh air are necessary, but in this individual case the prescribing of remedies has not been an easy task. She cannot tolerate cod-liver oil in any form, iron produces headache, strychnin causes intense irritability, and sodium bromid cannot be taken for any length of time, owing to its depressing effect on the heart. To overcome obstinate constipation, she takes a pill composed of aloin, compound extract of colocynth and belladonna. I urge her to try to be cheerful and hopeful, and avoid as much as possible all depressing influences. Galvanism and my favorite remedy for all ills, *i. e.*, living out of doors in the sunshine and drinking large quantities of good spring water, have proved very efficient in her case, and her appetite has improved." [H.H.C.]

Medical News.

June 22, 1901. [Vol. LXXVIII, No. 25.]

1. Psychic Epilepsy, with the Report of a Case. J. W. COURTNEY, M.D.
2. The Medical Expert Evidence in the Case of the Davis Bellevue Hospital Homicide. R. L. PRITCHARD.
3. Obstipation. STERLING B. TAYLOR.
4. A Study of Some Complications and Sequels of Typhoid Fever. H. A. HARE and H. R. M. LANDIS.

1.—**Psychic epileptic attacks** are the result of inhibitory or irritative explosions on the cortical territory presiding over psychic processes. The 2 types are the intellectual petit mal and grand mal. In the first the obtundation of intelligence greatly varies in degree. Sometimes the patient sees vaguely the persons about him, but does not hear what is said; at other times he has no sense of what has happened, and in the more prolonged and severe attacks occur those cases of ambulatory automatism lasting for weeks and months. The intellectual grand mal can never be regarded as a first symptom of **epilepsy**. It manifests itself in impulsive and ferocious acts against the sufferer himself or others. After the most brutal act the patient may sink into profound slumber and awake with complete amnesia for the attack. An incoherence or dissociation of ideas is the most essential feature of the picture. If there is marked inhibition of thought, incoherence is substituted by stupor. When incoherence alone is at play, there is marked motor excitation. As a rule, the severe type follows frequently repeated convulsions. When the transitory psychosis follows a single or abortive convulsion, it is probably the result of a postponement by treatment of an attack which would otherwise tend to recur frequently. Complete amnesia usually follows closely insane outbursts; sometimes it is not so deep; or there may be retroactive amnesia which goes back farther than the attack. The relation of alcohol to attacks and the differentiation of raptus melancholicus, transitory mania, and somnambulism and the forensic bearings of the disease are considered. A case of petit mal is reported. [H.M.]

2.—Was the **expert medical evidence** in this case brought out on a full statement of facts? As the medical issues were framed by the District Attorney, did he make clear all the evi-

dence so that reasonable men could read in them only strangulation? The people's witnesses testified that death was due to strangulation, not by relying on postmortem appearances, but by taking into consideration extraneous facts. The defendant's experts excluded from their consideration the same extraneous facts. Even the defendant's experts would have admitted the possibility of the hyoid bone breaking from irregular muscular action, though it was fairly open to doubt whether the injury could follow direct pressure from the sheet. Medical expert testimony is defective, as this case demonstrates, from the mode of its presentation oftener than from an assumed yielding of the expert witness to whatever opinion is desired of him. [I.I.M.]

3.—Obstipation is dependent on mechanical interference in rectum or sigmoid flexure. The form considered is that due to hypertrophy of the normal rectal valves with interruption of the lumen and distortion of the gut above, begetting an atonic state. The valves are described together with conditions that may cause pathologic changes, and also the mechanism of obstruction. The symptoms are chronic irregularity, frequent, partially successful attempts, flattened stools, inordinate desire for defecation, distension of colon with pain over colosigmoidal angulation preceding evacuation, pain in genitocrural nerve from gaseous distension, mucous discharge, evidence of auto-intoxication, fitful appetite and coated tongue. Exploration with Martin's proctoscope is described. Radical treatment consists in division of the free border of the valve down almost to the gut wall. Sutures should be placed in the angle of the wound and I on either side to avoid hemorrhage. A tampon dusted with Monsell's powder may also be introduced. Daily lavage and food that does not produce gas or a solid stool, are the after treatment. The operation is one of the most delicate in surgery. [I.I.M.]

4.—This section of the paper deals with the complications and sequels of the well developed stage of typhoid. Croupous pneumonia is frequent and is supposed to be due to the typhoid bacillus, one holding that the pneumococcus is always present. Diphtheria occasionally occurs. Bronchitis may be called a symptom. Congestion at the base of the lungs is a late manifestation due to cardiac enfeeblement. Pleurisy is no longer rare, its commonest form being fibrinous but when effusion occurs it is apt to be hemorrhagic or purulent. Persistent sub-normal temperature has been observed. Hyperpyrexia as a rule occurs in the septicemic type. Sudden rises usually indicate increased infection. Fever has lasted from 81 to 114 days. Low fever with marked infection is graver than hyperpyrexia. Petechial rashes, boils, scarlatiniform and rubeoliform rashes are described with their significance. Purpura is now not rarely reported; the prognosis is grave. Albumin with granular and hyalin casts occurs frequently. Epithelial and blood casts signify nephritis. Violent delirium may appear suddenly. Neuritis generally occurs during convalescence. Three cases of catalepsy are reported. Convulsions develop without ascertainable cause and rarely indicate hemiplegia. Twenty per cent. of cases are said to show ulceration of fauces and palate. Stomatitis, glossitis, stricture of the esophagus and vomiting are reported. Perforation causes 10% of all deaths. There is now a decided tendency toward surgical interference with favorable results. One case of intestinal hemorrhagic lesions is reported. Absence of these lesions is noted in 24 cases. Disease of the arteries is rarer than of veins. Secondary anemia is usual. Leukocytosis occurs with abscess, phlebitis, peritonitis and perforation. [I.I.M.]

Philadelphia Medical Journal.

June 22, 1901. [Vol. 7, No. 25.]

1. Further Notes of a Case of Pernicious Anemia Reported at the Meeting of the Association of American Physicians in 1900; with Remarks on the Diagnosis of the Disease. FREDERICK P. HENRY.
2. A Case of Severe Anemia with Changes in the Spinal Cord. WILLIAM E. HUOHES and WM. G. SPILLER.
3. The Teaching of Chemical Pathology. ALONZO ENGLEBERT TAYLOR.
4. Theoretical and Practical Considerations on the Treatment of Jacksonian Epilepsy by Operation; With the Report of 5 Cases. JAMES JACKSON PUTNAM.
5. What I Have Learned from 161 Operations for the Relief of Senile Hypertrophy of the Prostate Gland. ORVILLE HORWITZ.

2.—Hughes and Spiller report a case of severe anemia,

which in the postmortem showed marked changes in the spinal cord. The sclerosis was found to be most marked in the upper thoracic and cervical regions, and was greater in the left lateral column than in the right. In these parts of the cord it was diffuse, *i. e.*, not confined to any distinct system of fibers. Posteriorly the degeneration was most noticeable in the ventral portions, the anterior columns being nearer the normal than any part of the white matter of the cord. The only variation in these regions consisted of a slight proliferation of the neuroglia. The crossed pyramidal tracts had degenerated as far down as the sacral region, the left being more abnormal than the right. Below the midthoracic region the degeneration was limited to the crossed pyramidal tracts, while in the lumbar region the posterior column showed a slight degeneration. The right column in the medulla oblongata showed great change, while the left appeared to be nearly normal. Stained specimens of the cervical and lumbar regions showed a distinct abnormality of the nerve cell-bodies, together with marked pigmentation. [I.I.C.]

3.—Taylor, in his paper on the teaching of chemico pathology, gives an outline of the course as taught in the University of California. It includes: (1) The consideration of the relations of the disturbed functions to the lesions. That in many instances we are not able to define such relations is all the more reason for attempting to fix them in all cases; (2) the determination of the relations between the particular functional disturbance and the general metabolism, perhaps the most valuable aspect of the subject; (3) the training in the diagnostic procedures employed in the study of the chemism of disease, and instruction as to their real worth. [I.I.C.]

4.—Putnam, in considering the operative treatment of Jacksonian epilepsy, reports 5 cases. He believes that many kinds of operations are of value and that the beneficial action of these operations are mainly due to the induction of a temporary inhibition of the morbid action of the cortex, which permits of the establishment of a more normal tendency. He says the removal of the apparently normal cortex is rarely advisable. Clinical observation and laboratory experiment seems to indicate that even a simple exposure of the cortex may damage its nutrition enough to cause temporary paralysis of sensation and motion without inducing permanent impairment of function of serious amount. This operation can be repeated if necessary and cortical excision may be done later. He states that the cause of the persistence of the epileptic habit is not to be sought alone in anatomic peculiarities of the brain, but that it shares the vitality and independent endurance of memories in general. [C.A.O.]

5.—Horwitz concludes his article on senile hypertrophy of the prostate gland. He gives concisely the results obtained by means of various operations in 161 cases, and draws conclusions as to the indications for, and value of each of the operations employed. Of the 161 patients, 8 died; 2 deaths following bilateral castration, 2 suprapubic and 4 perineal prostatectomy. Vasectomy is stated to be of little value as a curative measure. Bilateral castration is of value in selected cases, primarily relieves congestion and secondarily causes atrophy, is of no value in fibrous prostates, and is a serious operation in old subjects with extensive disease of bladder and kidneys. Suprapubic cystotomy is indicated where retention cannot be otherwise relieved, and as a temporary palliative means where a more serious operation cannot be resorted to. The most satisfactory method of performing complete prostatectomy is that of Fuller's. The operation is the most dangerous of all that have been recommended, except ligation of the internal ilia. The suprapubic is the safest method, and the operation should be done early. The Bottini operation was performed on 33 patients with no deaths. This method is discussed at length, and the technic detailed. In suitable cases it is the safest and best method thus far advised. It is often efficacious as a palliative measure in advanced cases, and is of especial service early in the disease as a means of preventing catheter life. Pyelitis is not a contraindication, and the character of the prostatic growth has no bearing on the results of the operation. When suprapubic lithotomy is necessary, the stone should be removed and the Bottini operation deferred until a later date. [A.G.E.]

 stage, 610
 cultures, 314
 diagnosis of, in the laboratory, 490
 early diagnosis by blood-cultures, 2
 endocarditis resulting from, 105
 epidemic, 58, 224
 epididymitis and orchitis as sequels of, 413
 fever, 150, 192, 238, 427
 hemorrhagic, 47
 immunity to, 330
 in an infant, 490
 in South Africa, 428
 in the Philippines, 315
 means of infection in, 315
 modified treatment of, 481
 mortality in private practice, 58
 multiple gangrene with cholangitis, 490
 oyster as a carrier of, 108
 perforation and leukocytosis, 178
 purpura in, 108
 Remy's gelatin in diagnosis of, 315
 responsibility for, 233
 symptoms in infancy and childhood, 490
 treatment of, 125, 491
 with an intestinal perforation, early operation
 in, 39
 to prevent, 239
 urine, disinfection of, 340
 Widal test in, 314
 Typhus fever, 238, 242, 388
 Ulcer and fistula, chronic, 222
 gastric, 90, 91, 130, 224, 284, 475, 517, 605, 608
 treatment of, 539
 intractable or relapsing, 515
 of duodenum from surgical standpoint, 338
 of stomach, treatment of chronic, 335
 perforation followed by rigors, 364
 Ulcer, surgical treatment of, 515
 Ulcers, leg, 273
 Umbilical hernia, operation for radical cure, 335
 in adults, operative treatment, 413
 United States, increase of smallpox in the, 279
 leprosy in the, 577
 marine hospital service, 427
 ports, consumptive aliens barred out, 326
 Universities of Scotland, gift to, 476
 University of Paris, the, 476
 of Pennsylvania, new medical laboratories, 326
 Uranoplastic operations, 286
 Urea formation, intermittent hepatic fever on, 290
 Uremic manifestations, relation of osmotic pressure to, 479
 Ureter, stone impacted in the, 314
 Ureteral calculus, 492
 and renal calculi, diagnosis of, 434
 surgery skiagraphic diagnosis of, 530
 implantation into bowel for diversion of urine, 412
 or renal calculi, 320
 Ureterointestinal anastomosis, natural, 272
 pathology and bacteriology, 316, 414
 Ureteroureteral anastomosis, relative merits of different
 methods of, 488
 Ureters and kidneys, physiology of, 369
 Urethra and bladder, partial excision, for carcinoma, 245
 gonorrheal stricture, treatment, 368
 rupture of the, 245
 Urethral and vesical irrigation, new piston syringe, 179
 disease, fallacies in the treatment of, 531
 Urethritis, acute gonorrheal posterior, treatment of the,
 and nephritis, calculus, the indications for
 operation in, 533
 complications of, 368
 Uric acid formation in the animal body, 336
 excessive formation of, in gout, 225
 Urinary antiseptic, urotropin as a, 50
 bladder, hernia of the, 608
 removal for malignant disease, 432
 sulfates, estimation in diagnosis of pancreatic dis-
 ease, 274
 Urination, frequent, painful, gnaiccol in, 362
 Urine and stools, analyses from epileptic patients, 515
 carbohydrates of the, in diabetes insipidus, 318
 congenital incontinence of, 134
 diversion, by ureteral implantation into bowel, 412
 errors in the examination of, 180
 examination during gestation, 422
 nephritic, albumin in, 224, 317
 quantity of sugar present in, 567
 retention of, 608
 typhoid, disinfection of, 340
 Urogenital colibacillosis, 417
 Urotropin as a urinary antiseptic, 50
 the best results from, 235
 Urticaria tactitia, 223
 pleuritic, 143
 with albuminuria, 519
 Uteri, prolapsus, mechanism of, 134
 Uterine abortion, ectopic gestation diagnosed as, 314
 and mammary cancer, early diagnosis, 338
 appendages, disease relation to appendicitis, 134
 painful menstruation a factor in determining
 character of operations, 430
 cancer, methods of operating for, 418
 status of hysterectomy for, 431
 curement, 182
 displacements, intrapelvic operations for, 182
 fibroid degeneration, 199, 153
 hemorrhage, treatment of, 409
 myomas, how shall we deal with? 488
 retraction, 228
 segment, lower, 464
 Uterus bicornate, pregnancy in a, 319
 and vagina, cancer, radical operation, 527
 cancer of body of, 431
 of the, a new series of operations for, 528
 radical operation for, 527
 statistics of, and operation for, 528
 cancer, the operative treatment of, 319
 carcinoma of, 198
 early signs of carcinoma, 291
 epithelium identity, the syncytium, 586
 fibroid tumors of the, 181
 lipomyoma of, 13
 metastases from malignant diseases of tube, 587
 mobility of the, 418
 mucous membrane, effects of atokausis, 419
 muscular tumor of the, 371
 operative treatment for carcinoma, 197
 osteofibromyoma of the, 272
 paravaginal method for extirpation of the, 527
 pathologic fixation of, 138
 prolapse and proclivencia of the, 431
 pregnant, germs found in the, 587
 retrorplacements of, 47
 the, new operation for, 534
 retroversion of the, surgical treatment of, 534
 subinvolution of the, 318
 sarcoma of, 135, 365
 treatment of cancer of the, 273
 ventrosuspension of, 106
 with adhesions, treatment of displacement, 272
 Uvula, pulsation of the, in aortic insufficiency, 505
 Vacation schools, 373
 Vaccination, 13, 44, 61, 103, 150
 a little knowledge of the history of, 470
 aseptic, importance of, 94
 compulsory, 61, 240, 334, 426

- Vaccination, hitherto undescribed reaction following, 351
scar, erythema, multiforme following, 464
scar, development of a keloid on a, 315
- Vaccine, yellow fever, 425
- Vaccinia, clinical course of, 44
relationship to the inoculated form of smallpox, 410
serous, with cretinism and rickets, 364
- Vagina, primary tuberculosis of, 4
radical operation, cancer of the, 527
- Vaginal ablations, in pelvic inflammation and uterine fibroid degeneration, 153, 199,
douching in obstetrics, 363
extirpation total, a new method, 198
false membrane due to bacterium coli, 205
hemorrhages in newborn, 40
injections, use of hot-water, 179
laparotomy compared with ventral laparotomy, 197
operation in pelvic diseases in women, 79
total extirpation, new method of, 586
- Variocoele, suprapubic operation for, 434
- Variocose veins, operations for, 223
- Variola, 530
lantern slide demonstration of, 496
- Vascular diseases, relation of, to heart disease, 414
and nerve associations of the kidney, 608
- Vasectomy, 245
- Vasodilator congestions, 243
- Vasodilators, in cardiovascular disease, 249
- Vasomotor and cardiac therapy, 243
drug, value of iodine as a, 289
nerves in the brain, 327
neurosis, in varying regions same patient, 128
role of iodids, 419
- Vaughan, Victor C.: The toxin of colon bacillus, 302
- Vegetarian regime in Japan, 323
- Veins, varicose, operations for, 223
- Veld sores, 267
- Veneral disease, circumcision as a preventive of, 55
prevention of, 56, 132
the limitation of the, 500
- Venesection for gunshot wounds of chest, 268
- Venous and intraorganic injections, 492
angioma of fingers, 133
thrombosis, peripheral, in cardiac disease, 353
- Ventilation, crusade against poor, 284
- Ventral hernia, 135
laparotomy compared with vaginal, 197
- Ventrosuspension of the uterus, 106
- Veratrin in pruritus, 216
- Veratrum viride, 310
- Vermiform appendix, how to deal with, 109
- Vermont, use of narcotics in, 282
- Vertebra, cervical, fracture and dislocation of, 177
- Vesical and urethral irrigation, new syringe for, 179
calculi, 42
- Vesicles, seminal, total extirpation of the, 569
- Vesicular murmur, 366
- Vesiculitis, seminal, chronic, 565
- Vessels, the effect of external stimulation on the, 289
- Veterinary school to be closed, 103
- Vice, suppression of, in the Philippines, 477
- Victoria Cross, 150
- Virulence, morphology of bacteria, and relation to, 567
- Virus, method of preparing, 359
- Viscera abdominal, 41, 128
- Viscosity of the blood and the clinical importance of its determination, 244
- Vision, inverted, and mirror writing, 541
of the Boers, 526
- Visual and cosmetic results in squint, 498
- Vitality after severe injury, 608
acuity, economic, limitations of the, in the various trades and professions, 542
and aural qualifications of transportation employes, 542
- Vitreous humor and retina, idiopathic hemorrhage between the, 225
- Volvulus and intussusception of Meckel's diverticulum, 272
- Vomiting and nausea, the prevention of, during anesthesia, 606
recurrent, 220
- Wagoner, G. W.: Transfusion, infusion, autotransfusion, 263
