UNITED STATES DEPARTMENT OF AGRICULTURE PUBLICATIONS
ABSTRACTED

Bulletin 1405, Grazing Periods and Forage Production on the National Forests, A. W. Sampson and H. E. Malmsten-----	227
Bulletin 1411, Expense Factors in City Distribution of Perishables, C. E. Artman-----	387
Bulletin 1417, Ozonium Root Rot, G. L. Peltier, C. J. King, and R. W. Samson-----	145
Bulletin 1419, Factors and Problems in the Selection of Peat Lands for Different Uses, A. P. Dachnowski-----	212
Bulletin 1421, An Economic Study of Irrigated Farming in Twin Falls County, Idaho, B. Hunter and S. B. Nuckols-----	285
Bulletin 1422, The Hevea Rubber Tree in the Amazon Valley, C. D. La Rue-----	539
Bulletin 1423, Progress of Reindeer Grazing Investigations in Alaska, L. J. Palmer-----	264
Bulletin 1426, The Clover Root Borer, L. P. Rockwood-----	158
Bulletin 1427, Dry-Land Gardening at the Northern Great Plains Field Station, Mandan, N. Dak., T. K. Killand-----	41
Bulletin 1428, The Cadelle, E. A. Back and R. T. Cotton-----	259
Bulletin 1429, The Parasites of <i>Popillia japonica</i> in Japan and Chosen (Korea) and Their Introduction into the United States, C. P. Clausen, J. L. King, and C. Teranishi-----	860
Bulletin 1430, Financial Limitation in the Employment of Forest Cover in Protecting Reservoirs, W. W. Ashe-----	76
Bulletin 1431, Effect of Winter Rations on Gains of Calves Marketed as 3-Year-Old Steers, E. W. Sheets and R. H. Tuckwiller-----	163
Bulletin 1432, The Ownership of Tenant Farms in the United States, H. A. Turner-----	83

	Page
Bulletin 1433, The Ownership of Tenant Farms in the North Central States, H. A. Turner-----	83
Bulletin 1434, Cranberry Disease Investigations on the Pacific Coast, H. F. Bain-----	453
Bulletin 1435, Economic Aspects of Citrus-Fruit Growing in Polk County, Fla., C. R. Swinson and W. C. Funk-----	583
Bulletin 1436, Utilization of Dogwood and Persimmon, J. B. Cuno-----	46
Bulletin 1437, Red Alder of the Pacific Northwest: Its Utilization, with Notes on Growth and Management, H. M. Johnson, E. J. Hanzlik, and W. H. Gibbons-----	46
Bulletin 1438, Weather Damage to Cotton, R. L. Nixon-----	36
Bulletin 1439, Fish Oil, an Efficient Adhesive in Arsenate-of-Lead Sprays, C. E. Hood-----	658
Bulletin 1440, Factors Affecting the Price of Hogs, G. C. Haas and M. Ezekiel-----	184
Bulletin 1441, Methods and Practices of Retailing Meat, W. C. Davis----	288
Bulletin 1442, Margins, Expenses, and Profits in Retailing Meat, K. B. Gardner-----	288
Bulletin 1443, Consumer Habits and Preferences in the Purchase and Consumption of Meat, K. B. Gardner and L. A. Adams-----	388
Bulletin 1444, Cotton Prices and Markets, A. B. Cox-----	586
Bulletin 1445, Services in Cotton Marketing, A. B. Cox-----	484
Bulletin 1446, Cost of Producing Winter Wheat and Incomes from Wheat Farming in Sherman County, Oreg., R. S. Washburn and H. D. Scudder--	784
Bulletin 1447, Cost of Using Horses, Tractors, and Combines on Wheat Farms in Sherman County, Oreg., R. S. Washburn and H. D. Scudder--	785
Bulletin 1448, Picking Maturity of Apples in Relation to Storage, J. R. Magness, H. C. Diehl, and M. H. Haller-----	345
Bulletin 1449, Tumors of Domestic Animals, R. J. Formad-----	278
Bulletin 1451, Methods of Eradicating the Common Barberry (<i>Berberis vulgaris</i> L.), N. F. Thompson and W. W. Robbins-----	448
Bulletin 1452, Properties of the Colloidal Soil Material, M. S. Anderson and S. Mattson-----	208
Bulletin 1453, The Cheese Skipper as a Pest in Cured Meats, P. Simmons--	859
Bulletin 1454, Factors in the Cost of Producing Beef in the Flint Hills Section of Kansas, R. H. Wilcox, W. E. Grimes, M. Evans, and H. J. Henney-----	288
Bulletin 1455, Incomes from Farming and Cost of Apple Production in the Shenandoah Valley, Frederick County, Va., C. R. Swinson-----	785
Bulletin 1456, Drainage by Means of Pumping from Wells in Salt River Valley, Arizona, J. C. Marr-----	679
Bulletin 1458, The Trend toward a More Effective Use of the Land as Shown by the Yield per Acre of Certain Crops, B. O. Weitz-----	685
Bulletin 1459, The Regal Lily, D. Griffiths-----	743
Bulletin 1460, Testing Wheat for Protein with a Recommended Method for Making the Test, D. A. Coleman, H. C. Fellows, and H. B. Dixon--	614
Bulletin 1461, Control of Cucumber Mosaic by Eradication of Wild Host Plants, S. P. Doolittle and M. N. Walker-----	449
Bulletin 1462, American Bulbs under Glass, D. Griffiths-----	743

Daily River Stages, volume 23, 1925-----	177

The first part of the book is devoted to a general introduction to the subject of the history of the United States. It covers the period from the discovery of the continent to the present time. The author discusses the various theories of the origin of the name "America" and the early explorations of the continent. He also touches upon the early settlements and the growth of the colonies.

The second part of the book is a detailed account of the American Revolution. It begins with the causes of the Revolution, such as the Stamp Act and the Intolerable Acts. It then describes the military campaigns, the Battle of Bunker's Hill, and the Declaration of Independence. The author also discusses the political and social changes that took place during this period, including the formation of the Constitution and the Bill of Rights.

The third part of the book is a history of the United States from the end of the Revolution to the present. It covers the period of the early republic, the War of 1812, and the expansion of the United States. It also discusses the Civil War, Reconstruction, and the Gilded Age. The author concludes with a discussion of the United States in the twentieth century, including the Progressive Era, World War I, and the New Deal.

CONTENTS OF VOL. 56, NO. 1

	Page
Editorial notes:	
Agricultural research at the 1926 convention of the Association of Land-Grant Colleges and Universities.....	1
Recent work in agricultural science.....	9
Notes.....	96

SUBJECT LIST OF ABSTRACTS

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Chemistry of the proteins and its economic applications, Lloyd.....	9
Some nitrogenous constituents of the cauliflower bud, I, McKee and Smith.....	9
Simpler nitrogenous constituents of yeast, I, Vickery.....	9
The chemical composition of rice oil, Jamieson.....	10
The hemicelluloses.—Part IV, The hemicelluloses of beech wood, O'Dwyer.....	10
A comparison of various methods of obtaining ash-free pectin, Emmett.....	10
Antirickettic substances.—IV, Cholesterol, Bills and McDonald.....	10
Colour reactions attributed to vitamin A, Carr and Price.....	10
The concentration of vitamin B, III, Levene and Van der Hoeven.....	11
The extraction of the vitamin B from wheat germ, McCollum and Kruse.....	11
The pigeon and the rat as test subjects for vitamin B, Laird.....	12
Action of reducing agents on the antiscorbutic factor, Daubney and Zilva.....	12
Rapid preparation of monomolybdophosphotungstic acid, Bezssonoff.....	12
A vacuum extractor for biochemical use, Guerrant.....	12
Hydrogen ion concentration, I, Michaelis, trans. by Perlzweig.....	13

	Page
Apparatus for the direct determination of carbon dioxide, Underwood	13
Estimation of tyrosine, tryptophane, and cystine in proteins, II, Looney	13
Comparison of the methods of ashing plant tissues and products, Rogers	13
Report of committee on methods of analysis for American Association of Cereal Chemists, Coleman et al	13
Oxygen-acetate method of ash determination in flour, Brendel	14
Estimation of glucose in the presence of phosphate buffers, Visscher	14
The quantitative estimation of calcium, magnesium, phosphate, and carbonate in bone, Kramer and Howland	14
Colorimetric estimation of cholesterol and lecithin in blood, DeToni	14
The metabolism of sulfur, X, Lewis and Wilson	14
A respiration apparatus for small animals, Foster and Sundstroem	14

METEOROLOGY

Solar activity and long-period weather changes, Clayton	15
Solar radiation and weather forecasting, Marvin and Kimball	15
Rain making and other weather vagaries, Humphreys	15
Influence of temperature and precipitation on vegetation, Grosse	15
Weather influence on production in regions of scanty rainfall, Mattice	15
A further study of effective rainfall, Voorhees	15
Spring and autumn night frosts, Szulc	15
Monthly Weather Review, [July-August, 1926]	16
Observations at the Massachusetts Station, Ostrander and Parkin	16
Climate of British Columbia, Denison	16
The weather of Scotland in 1925, Watt	16
Phenological observations in Italy, 1922-1925, Minio	16
Meteorological observations in the Doorns, 1925, Harler	16

SOILS—FERTILIZERS

Transactions of the Second Commission of the International Society of Soil Science, Von 'Sigmund et al	17
A suggestion concerning soil classification, Beaumont and Sessions	17
Soil survey of Iowa.—Reports 42, 43, Stevenson, Brown, et al	17
Soil survey of Rockwall County, Texas, Geib	18
Soil colloids, Sokolovskii (Sokolowsky)	18
Plasticity of soils, Antonova	19
Moisture of the podsol in freezing and thawing, Chirikov and Mal'ugin	19
Soil moisture experiments at Swift Current, Sask., Barnes	20
Report on central Nebraska irrigation project, Burr and Russel	20
The determination of available phosphoric acid of calcareous soils, Das	20
Origin of alkali soils, Vilenskii (Wilensky)	20
Influence of microorganisms on the absorption from soil, Stoklasa	20
Ammonification in red prairie soils, Murphy	21
Sunlight and chemical nitrification, Zholtinskii (Zolcinski)	21
Effect on nodulation of supplementing the legume bacteria, Wilson	21
The decomposition of toxins by soil organisms, Gardner	21
Effect of mineral fertilizers on soil reaction, Andrianov (Andrianow)	22
[Cottonseed meal as a fertilizer]	22
Investigations on fish meals, I, II, Davies	22
Comparative value of sulphate of ammonia and nitrate of soda, White	23
Potash: Significance of foreign control, Hoar and Concannon	23
Can the lime-requirements of the soil be determined from the reaction of soil suspensions containing potassium chloride? Trénel	23
Lime for West Virginia farms, Dodd	23
Gypsum in 1924, Cottrell	23

AGRICULTURAL BOTANY

Observations on nonsymbiotic germination of orchid seeds, Knudson	24
The symbiotic germination of orchid seeds, Knudson	24
Divergence of catalase and respiration in germination, Rhine	24
Effect of size of seed on plant production, Rotunno	24
Protein synthesis by plants.—I, Nitrate reduction, Eckerson	25
Quantitative relations of carbohydrates to nitrogen, Reid	25

Irradiated orange juice as an antirachitic agent, Maslow et al.....	91

	Page
Effect of ultraviolet irradiation on health of infants, Barenberg et al.---	91
Experimental rickets.—The effect of cereals, Mellanby-----	92
Test of indolinones for prevention and cure of polyneuritis, Gortner et al.	92
Discussion on food deficiency conditions and preventable illness-----	92
The composition of peanut meal and its use as a diabetic food, Neale---	92
Use of standard diet formulas in juvenile diabetes mellitus, Boyd-----	92
Diabetic diets for children, Boyd and Nelson-----	93

TEXTILES AND CLOTHING

Textiles: Handbook for student and consumer, Woolman and McGowan_	93
Textile oils applicable in the dyeing and finishing of cotton, Burnham--	93
Mildew in cotton goods, [I]-III-----	93
The behaviour of flax yarns under repeated impacts, New and Gregson--	94
The gel structure of the wool fibre, Speakman-----	94
The extension of wool fibres under constant stress, Speakman-----	94
Merino wool classing, Rose-----	94
Notes on the determination of the dry weight of wool, Barker and Hedges_	95
Tar on wool, King and Smith-----	95
Colour problems in woollen and worsted industries, Barker and Hirst--	95
Effect of dry cleaning on silks, Goldman et al-----	95
Fifty-fourth annual report of the Silk Association of America-----	95

LIST OF EXPERIMENT STATION AND DEPARTMENT PUBLICATIONS ABSTRACTED

<i>Stations in the United States</i>	Page	<i>Stations in the United States—Con.</i>	Page
Alabama Station:		West Virginia Station:	
Bul. 225-----	21	Bul. 204-----	38
Arkansas Station:		Bul. 206-----	81
Bul. 213-----	51	Bul. 215-----	23
California Station:		<i>U. S. Department of Agriculture</i>	
Hilgardia, vol. 2, No. 3, Sept., 1926-----	52	Bul. 1427, Dry-Land Gardening at the Northern Great Plains Field Station, Mandan, N. Dak., T. K. Killand-----	41
Colorado Station:		Bul. 1430, Financial Limitation in the Employment of Forest Cover in Protecting Reser- voirs, W. W. Ashe-----	76
Bul. 311-----	49	Bul. 1432, The Ownership of Tenant Farms in the United States, H. A. Turner-----	83
Bul. 313-----	40	Bul. 1433, The Ownership of Tenant Farms in the North Central States, H. A. Turner-----	83
Hawaiian Sugar Planters' Sta- tion:		Bul. 1436, Utilization of Dog- wood and Persimmon, J. B. Cuno-----	46
Circ. 46-----	38	Bul. 1437, Red Alder of the Pa- cific Northwest: Its Utiliza- tion, with Notes on Growth and Management, H. M. Johnson, E. J. Hanzlik, and W. H. Gibbons-----	46
Idaho Station:		Bul. 1438, Weather Damage to Cotton, R. L. Nixon-----	36
Bul. 144-----	84	Farmers' Bul. 1488, Diseases of Raspberries and Blackberries, B. O. Dodge and R. B. Wil- cox-----	54
Research Bul. 6-----	63	Farmers' Bul. 1515, Fur Laws for the Season 1926-27, F. G. Ashbrook and F. L. Earnshaw-----	56
Iowa Station:		Circ. 398, Directory of Officials and Organizations Concerned with the Protection of Birds and Game, 1926, compiled by T. Denmead and F. L. Earn- shaw-----	56
Bul. 237, pts. [1] and 2-----	82, 83	Misc. Circ. 72, A Decade of Negro Extension Work, 1914- 1924, O. B. Martin-----	85
Soil Survey Rpt. 42-----	17	Misc. Circ. 76, Copper Carbon- ate Prevents Stinking Smut--	48

EXPERIMENT STATION RECORD

VOL. 56

JANUARY, 1927

No. 1

The view expressed in these columns last month that research was less a dominating feature of the 1926 convention of the Association of Land-Grant Colleges and Universities than had been the case in the preceding year should not be so construed as to imply that it was either neglected or congealed by an unsympathetic environment. Somewhat of the unusual stimulation and enthusiasm aroused by the passage of the Purnell Act in 1925 had, to be sure, abated as the months had gone by and the new opportunities had become accepted facts. Particularly did this seem to have been true in the field of home economics, where the three-day section program gave little indication that the interests of research were still matters of major concern, although the explanation was suggested that this otherwise surprising condition was merely a temporary reaction from a supposed overemphasis in recent conventions. As regards agricultural research, however, a full and varied program was presented, occupying two sessions of the section program and with considerable of interest and applicability at other sessions.

The research program naturally centered around the experiment station division, which dealt with a number of matters of great importance. It was opened very appropriately with a discussion by Dr. E. W. Allen of the Office of Experiment Stations entitled *Some Features of the First Year under the Purnell Act*. This period was characterized as the most conspicuous one in the expansion and development of the stations since the national system was started, and the success attending it as "one for sincere congratulation and encouragement." Under the new act the research programs of the stations have been greatly enlarged, strengthened, and enriched. Up to November 1, 1926, 690 new projects had been adopted, of which fully half were in agricultural economics, rural sociology, and home economics.

The effects of so large a program have already been far-reaching. "Usually," as Dr. Allen stated, "it has meant an enlargement of the research field, the selection of new personnel, the setting up of projects of greater definiteness, and the fitting of the new enterprises into the general plan for the stations' activity. . . . A fine disposition

has been manifest to use the new fund in the spirit of the act and of the understanding originally entered into; namely, to conserve it for a substantial type of new investigation, represented by definite projects to which allotments and expenditures are restricted, and incidentally to increase the amount and the range of cooperation in research."

The largest number of Purnell projects is in agricultural economics. All of the States but one have undertaken investigations in this field, and fourteen have set up projects in rural sociology. Of the 224 projects in economics, 107, or about half, relate to marketing, 35 to farm management, and 45 to the economics and costs of production.

The rapid progress in developing the economic field has given ample ground for optimism, but the view was expressed that it also has revealed certain weaknesses from the viewpoint of research policy. The need for thoroughgoing studies, concentrating on specific problems with definite objectives and employing greater detail and precision in methods of procedure was pointed out, as well as the importance of a coordination or association of economic research with that along production lines.

The situation as regards home economics investigations was discussed in some detail. Under the stimulus of the new act, the number of stations carrying on work in this field has been enlarged from 4 to 36, now contributing a total of about 100 projects. "Although work has not been inaugurated at all the stations, no lack of interest or support of this work has been observed. The difficulty has been rather one of finding persons suitably equipped for investigation with the sudden expansion in this field."

Considerable variation in the attitude toward research of the heads of home economics departments in the colleges has been noted. Some, it is reported, "have grasped the idea that successful research requires persons who have had special training for it, and that these are quite as likely to be found in the basic science departments as in those of home economics. Others, however, have evidenced less conception of research and less active interest in developing it, with results that are apparent."

The year was deemed one of profit for many of the home economics workers, the experience of actual investigation proving quite educational. "It has given them a clearer conception of the essential qualities of research and of what this implies on the part of the investigator. The subject of nutrition is better organized than that of home management, for it has been subjected to more research, going back many years, and more persons are available who have had graduate work of a severe type, including advanced research in chemistry and the biologic sciences. In some other branches there

has been considerable evidence of lack of preparation, with consequent difficulty in selecting and organizing suitable projects and carrying them through. The recent development has stimulated institutions to offer graduate courses in these branches, which will doubtless correct the situation in time."

A considerable share of Dr. Allen's paper dealt with observations on the year's developments as to general methods of inquiry, types of experimentation, motives in research, "ready-made" projects, the obligations of the States under the Purnell Act, and the demands of administration. Attention was drawn to the large use being made of the survey method, embracing fully a third of the initial Purnell appropriations, and indicating how largely reliance is being placed upon this method of exploration and investigation. "How adequate it is will be discovered later when more experience has been had and the results come to be published. With some the survey has been conceived to be a quick means of cutting across the tedious path of experiment and investigation. Doubtless it will settle into its real place, but it is important at this stage to consider its limitations, to form a clear conception of what it may be adequate to accomplish, and the manner in which it may need to be supplemented. Evidently many questions that lie out in the field will need field study quite as much as a survey, for often the results of the survey will be tentative, suggestive rather than final, needing to be treated as the beginning or a feature of an investigation and not as the end of it."

The broad question of types of investigation was discussed from the standpoint of the new opportunities for work of a constructive far-reaching character. There are still, it is stated, "many experiments of the purely comparative type which have only a very short-range objective; they have in mind a purely local or temporary situation, a practical question viewed from that standpoint. Such experiments, while attempting to get the practical answer, do not use the opportunity to enlarge the view from the scientific or theoretical standpoint, or go into the matter of causes and relationships. They are supposed to be purely practical, but frequently they are unpractical because they are so limited in their viewpoint and contribute so little real information."

As to motive, Dr. Allen pointed out that the question of making investigation sound and thorough is not one of practical versus fundamental aims, but applies rather to a type of work designed to give results that can be applied intelligently and relied upon in practice. Greater progress in this direction than in any previous year is noted, but among the difficulties still encountered he enumerated a frequent failure in outlining new work to take account of what is already known and the tendency to set up large and comprehensive projects

with little differentiation of the complex problems involved. Complexity, it is pointed out, "ought not to be mistaken for profundity, for in the end it may be found to mean dissipation in the pursuit of many things rather than concentration on something in particular. It may be desirable to have a far-reaching aim, but this is not opposed to taking one step at a time."

In conclusion attention was drawn to the responsibilities of the States in relation to the Purnell legislation. Numerous expressions of opinion by various committees of the association and ratified by the executive body were cited, under which the moral obligation of the States to continue without diminution their support of the stations was set forth in convincing fashion.

The program was continued with a discussion of the social aspects of agriculture in relation to research by Dr. Dwight Sanderson. He conceived the object of what he termed social research to be the discovery of principles of social organization as a means to the readjustment to the changes in conditions whereby a steady drift from farm to town is under way. Rural sociological research he regarded as still in a nascent and unorganized state, with a need for extended structural investigations and with psychological studies of collective behavior a prerequisite. Such matters as the securing of better leaders, types of cooperative effort, the efficacy of "drives," and the adjustment of group conflicts he believed susceptible to inquiry by scientific methods, although he conceded that such results as have been brought out have not always been heeded. This he argued indicated a need for sociological education.

The application of engineering principles to agriculture, particularly as a means of increasing the efficiency of farm production, was a matter touched upon by several speakers during the convention, among them Secretary Jardine, who spoke of it as a "field for significant future development," adding that "modern agriculture can not neglect engineering any more than it can neglect economics." The principal contributions to the discussion of the subject, however, were made by Prof. J. B. Davidson and Mr. H. R. Tolley, both of whom argued for increased efficiency as well as increased production. Professor Davidson's paper took up *The Relation of Agricultural Engineering Development to Economic Adjustments in Agriculture*, seeing in an increase in efficiency a potential decrease in the proportion of the population engaged in agriculture to as little as 15 per cent. He maintained that despite many contributions along engineering lines the stations had not been large factors in handling the outstanding problems, and he urged a more active participation and leadership. The discovery of additional means of utilizing farm products and by-products was among the specific opportunities which he suggested.

In a paper entitled Organization and Development of the Federal Forest Experiment Stations, Mr. E. N. Munns of the Forest Service outlined the history of this relatively new system of stations and discussed their opportunities and outlook. Numerous analogies between the situation in forestry and that earlier encountered in agricultural research were pointed out, and the belief was expressed that when fully established with adequate staffs of men familiar with forestry principles and practices but trained along broad scientific lines and imbued with the research spirit these stations would be able to perform for forestry a function as vital and far-reaching as the mission of the agricultural experiment stations.

The reports of the three standing committees customarily presented to the experiment station division were this year of unusual importance. That on the publication of research showed a material gain in the promptness of issue of material in the *Journal of Agricultural Research* which was heartily commended. During the year 72 articles appeared in this journal from this Department, 42 from the stations, and 13 on a cooperative basis. A policy of restricting the columns of the journal to the Department and the stations and an increased scrutiny of articles by the committee was announced.

Three timely topics were considered in the report of the committee on experiment station organization and policy, the relation of the nine months' period of employment in the average college year to the twelve months' period in the stations, the necessity of maintaining high standards of research, and the extent to which the Purnell funds should be used for salaries. Of these the matter of time adjustments in college and station work was shown to be somewhat complicated, and the committee recommended a thorough study by the proper administrative authorities. Since it appeared, however, that in more than half of the colleges the salary schedules for nine months' instruction equaled those for the full year of station work, the situation was revealed as one of some seriousness if the station ranks are to be adequately manned and their positions made permanently attractive.

As regards standards of research the committee advocated a more critical habit of thinking, the knowing of more things definitely, and the working toward specific ends and aims. Little excuse was seen for the more superficial types of work or the encroaching on the field of demonstration. The survey method was described as a valuable tool if well handled, but as one with limitations which should be recognized and shortcomings which should be supplemented wherever possible. The responsibility for the maintenance of standards was placed quite definitely with the station director, with the suggestion that staff committees had frequently been found helpful and might

often be made a part of the administrative machinery to good advantage.

The policy of expending the Purnell funds for salaries and relying upon State funds and other sources for supplementary costs was shown to be open to the objections of a lack of definite assurance of means for carrying the projects to completion and the difficulty of segregating clear-cut accomplishments under the act in justification of its passage. Admitting that special circumstances were to be considered in some cases, the committee believed that as a policy the wiser course is to decide upon projects which can be brought to completion with the Purnell funds available and to concentrate upon these, thereby "doing a few things well."

The report of the committee on projects and correlation discussed quite optimistically the progress which had been achieved by the several committees in charge of the so-called "national projects," now numbering 195 as compared with 109 a year ago. A reorganization of the personnel of these committees was suggested and approved, and the new membership was announced last month. The chief gain of the year, however, was declared by the committee to be in the "imponderables," a noteworthy improvement in the attitude of individuals and institutions toward cooperation, a greatly enhanced enthusiasm, and a distinct trend and disposition toward working together, which was deemed extremely encouraging.

The joint session of the three agricultural divisions for the consideration of matters pertaining to research was devoted to a varied program. Dr. A. F. Woods, recently appointed director of scientific work of the U. S. Department of Agriculture, discussed the type of research needed at the present time for the advancement of agriculture. He emphasized the desirability of a frequent re-crystallization of our knowledge in the light of new facts and the need of a certain amount of constructive speculation for which men broadly trained are required. The advantages of carefully considered cooperation in research, both among individuals and institutions, and the possible development of centers of major research activity in special fields were also set forth. These views are, of course, in close agreement with those often expressed by the association in recent years and indicated an attitude of sympathetic understanding conducive to closer relations.

Under the title of Keeping Contacts with Farmers as an Asset to Organizing Research Work for Agricultural Experiment Stations, Director H. W. Mumford showed how the development of the extension work had operated as a wedge between the stations and the farmers and resulted in a loss of contacts which had many

disadvantages. More intimate relations between the extension specialists and the stations were advocated, and Director Mumford explained in some detail the plan followed in Illinois of conferences of farm advisors and station workers, the farmers' field days at the thirty-three experimental soil fields, and the identification through farmers' advisory committees of the organized agriculture of the State with the station work. The maintenance of such contacts he believed to be productive of increased zeal and enthusiasm, as well as tending toward a surer selection of the really important subjects for research.

An illustrated address by Dr. W. H. Larrimer of the Bureau of Entomology on the European corn borer and the research attack concluded the session. Dr. Larrimer showed the serious nature of the ravages of this pest over a steadily increasing area and the need of holding it in check as effectively as possible pending the discovery of more adequate measures for its control.

Provision was also made in the session of the section assigned to extension interests for a discussion by representatives of research and extension of the "twilight zone" between these agencies. Speaking for research, Dr. Allen pointed out as the fundamental distinction that the field of research is the unknown and of extension the known; one is a process of learning, the other a type of teaching. "In a word, the man of research adds his scientific contributions and makes his science practical; the extension worker puts these things to work and thereby makes practice more scientific. If these principles are observed by each, the boundaries of No Man's Land will shrink and there will be less likelihood of overlapping."

Regarding the realm of demonstrations or field trials, which to many has seemed a debatable land, Dr. Allen had this to say: "The utilitarian aim of agricultural research implies the obligation to carry such work to a point where, in its essentials, it is workable and demonstrable. It will not do to discover the bald fact under laboratory or purely experimental conditions and leave it there, as is often done in pure science; it must be harmonized with practical conditions, and the result placed before the public as promptly as possible. So far as field work employs farming people to test out the results of experiments in order to verify them and make them practical, it is in the field of applied research; but when it is designed to assist farmers in demonstrating things to themselves it is in the realm of extension. On the other hand, the extension worker is not warranted in setting up a series of experiments because he needs information or because he encounters difficulties with the results supplied him which indicate they are not practical. If such difficulties and doubts arise, the natural course leads back to the investigator for further test and adaptation."

Assistant Extension Director W. B. Mercier of Louisiana presented the matter from the extension viewpoint, but with surprisingly close agreement with Dr. Allen's conclusions. Little trouble would arise, in his opinion, if the stations could supply reliable information on all the problems with which the extension workers are confronted, but until this can be done they will naturally endeavor to secure information from all available sources. None the less, the belief was expressed that the extension man should stick to his own field, and that the hybrid research-extension worker is not likely to be very successful in either direction. The formal experiment, he conceded, should be left to research, and the tendency sometimes encountered to start experimental plats in demonstrations may be expected to yield results which are seldom very reliable and often quite misleading. The better and surer way to real progress is through close relations and contacts between extension and research, particularly as regards the selection of experimental projects and the prompt utilization of well-proved findings.

The attendance at the various sessions devoted to research was excellent, and the almost complete absence of discussion from the floor was doubtless due less to a lack of interest than to the congested program. It would seem that somewhat more time could have been utilized profitably at various points. Many of the papers dealt with matters of special timeliness, and their presentation served to visualize their importance and encourage their further consideration. Such consideration is particularly well warranted by a number of the administrative questions which were raised, and it is to be hoped that a definite association policy may ultimately be forthcoming concerning them.

RECENT WORK IN AGRICULTURAL SCIENCE

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Chemistry of the proteins and its economic applications, D. J. LLOYD (*London: J. & A. Churchill, 1926, pp. XII+279, figs. 50*).—This monograph, which has an introduction by F. G. Hopkins, presents in a concise manner the theories of protein chemistry and their practical applications to biology and industry. Part 1, which considers the constitutional chemistry of the proteins, contains chapters on the nature and constitution of the proteins, the methods of protein analysis, the different classes of proteins, the identification of proteins and the structure of the protein molecule, the proteolytic enzymes and the linkages in the protein molecule, the chemistry of protein foods, and the problems of food preservation. Part 2 deals more particularly with the physical chemistry of the proteins leading up to the industrial uses of the proteins in textile and leather manufacture, as adhesives, and as emulsifying agents. A comprehensive bibliography is given at the end of each chapter.

Some nitrogenous constituents of the cauliflower bud.—I, Protein fractions, M. C. MCKEE and A. H. SMITH (*Jour. Biol. Chem., 70 (1926), No. 1, pp. 273-284*).—A study of the nitrogen distribution in the edible portion of the cauliflower is reported, with the following results:

Of the total nitrogen, approximately 68 per cent belongs to constituents soluble in water and dilute salt solution, 12 per cent to compounds insoluble in water but soluble in dilute alkali, and 16 per cent to compounds insoluble in both water and dilute alkali. Fractionation of the combined expressed juice and aqueous extract yielded 8 per cent of the total nitrogen as ammonia nitrogen, 19 per cent as free amino nitrogen, and 11 per cent as nitrogen in actually isolated protein preparations. The purest proteins obtained contained 14.1 and 13.6 per cent of nitrogen in the coagulum and precipitate, respectively. The distribution of nitrogen as obtained by the Van Slyke method was similar to that of the alfalfa protein as reported by Chibnall and Nolan (*E. S. R., 52, p. 802*) and spinacin from spinach by Chibnall (*E. S. R., 52, p. 708*).

Simpler nitrogenous constituents of yeast.—I, Choline and nicotinic acid, H. B. VICKERY (*Jour. Biol. Chem., 68 (1926), No. 3, pp. 585-592*).—The methods previously employed in the study of the nitrogenous substances in alfalfa juice (*E. S. R., 54, p. 408*) have been applied to a similar study of the cell constituents of brewers' yeast. The present paper includes a brief description of the methods employed for the fractionation of the yeast extract and the results of the examination of the basic substances not precipitated by Neuberg's reagent. "These contained nitrogen equivalent to 3.35 per cent of the nitrogen of the yeast extract. When fractionated with mercuric chloride in acid solution, 2.41 per cent of the nitrogen of the yeast extract was found in the precipitate. Of this nitrogen about 86 per cent belongs to choline and 6 per cent to nicotinic acid. Further quantities of nicotinic acid were found in the filtrate from the mercuric chloride precipitate. Choline was found to account for 2.07 per cent of the nitrogen of the yeast extract and 0.29 per

cent of the nitrogen of the dry yeast. Nicotinic acid accounts for 0.28 per cent of the nitrogen of the extract and 0.039 per cent of that of the dry yeast."

The chemical composition of rice oil, G. S. JAMIESON (*Jour. Oil and Fat Indus.*, 3 (1926), No. 8, pp. 256-261).—The chemical and physical characteristics of a sample of rice oil extracted from rice bran by ethyl ether are reported as follows: Refractive index 25° C. 1.4690, acid value 73.67, iodine number (Hanus) 99.9, saponification value 185.3, saponification value corrected for unsaponifiable 194.2, unsaponifiable matter 4.64 per cent, saturated acids (corrected) 14.70 per cent, unsaturated acids (corrected) 74.30 per cent, Reichert-Meissl value 0.3, and Polenske value 0.3. The distribution of the glycerides of fatty acids is given as oleic 41 per cent, linoleic 36.7, myristic 0.3, palmitic 12.3, stearic 1.8, arachidic 0.5, lignoceric 0.4, and unsaponifiable matter 4.6 per cent. Sterols were isolated to the extent of 25 per cent of the unsaponifiable matter and ranged in melting points from 137 to 143°.

The hemicelluloses.—Part IV, The hemicelluloses of beech wood, M. H. O'DWYER (*Biochem. Jour.*, 20 (1926), No. 4, pp. 656-664).—In this report to the Forest Products Research Board, Department of Scientific and Industrial Research, Great Britain, in continuation of studies previously noted (*E. S. R.*, 50, p. 310), the author reports the isolation from beech wood of two hemicelluloses, one, hemicellulose A directly precipitable by acid and, the other, hemicellulose B obtained on precipitation from the acid filtrate by the alcohol. The former on hydrolysis yielded xylose and carbon dioxide equivalent to 11 per cent of glycuronic acid, and the latter arabinose and carbon dioxide corresponding to 63 per cent of galacturonic acid, together with small amounts of galactose.

A comparison of various methods of obtaining ash-free pectin, A. M. EMMETT (*Biochem. Jour.*, 20 (1926), No. 3, pp. 564-568, fig. 1).—A comparison is reported of the efficiency of three methods of removing mineral impurities from pectin—dialysis against distilled water, dialysis against N/50 HCl, and electro dialysis. Electro dialysis, the apparatus for which is described and illustrated, was found to be the most rapid and effective method of the three. It was found necessary to use the platinum electrode as the anode. With certain necessary precautions, such as reducing the heating effect as much as possible and changing the water in the dialyzer daily, it was found possible to reduce the ash of a sample of commercial pectin from 3.1 to 0.5 per cent in three days.

Antiricketic substances.—IV, The polymerization of cholesterol, C. E. BILLS and F. G. McDONALD (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 821-831, pls. 3, figs. 2).—Continuing the investigation previously noted (*E. S. R.*, 55, p. 711), the authors report that by slowing up the catalytic action of activated floridin on cholesterol it is possible to obtain a polymer, tentatively named tricholesterol. This has no antirachitic properties, but on further catalytic action forms a resinous mass having antirachitic properties though apparently not identical with irradiated cholesterol. The physical and chemical properties of tricholesterol are summarized.

Colour reactions attributed to vitamin A, F. H. CARR and E. A. PRICE (*Biochem. Jour.*, 20 (1926), No. 3, pp. 497-501).—In experiments undertaken with a view to improving the technique for the Rosenheim-Drummond color test for vitamin A (*E. S. R.*, 55, p. 307), it was found that the color reaction with trichloroacetic acid is apparently due to impurities in the acid and is not given by specially purified samples. Arsenic trichloride was found to be fairly satisfactory except for a marked loss of sensitiveness on dilution with chloroform or other solvents. Among other reagents tested, color reactions consisting in the main of blue, with varying proportions of red, were given by antimony

trichloride in chloroform, stannic chloride in chloroform, anhydrous ferric chloride added to a solution of the oil in chloroform, anhydrous aluminum chloride, silicon tetrachloride, and phosphorus oxychloride. Of these reagents, antimony trichloride proved to be the most satisfactory.

The technique for its use is as follows: Antimony trichloride is washed with a little B. P. chloroform, dried, weighed, and dissolved in chloroform to make a 30 per cent solution, which, after standing, is decanted and used in a burette. Two cc. of the solution is added to 0.2 cc. of a 20 per cent solution of the oil in chloroform, and the color intensity of the liquid is at once measured against standard glasses in a Lovibond tintometer. The results obtained on four oils are given, together with a report by S. W. F. Underhill of biological tests conducted with two of the oils. These corresponded closely to the ratios of blue of the two oils as determined in the colorimeter.

The concentration of vitamin B, III, P. A. LEVENE and B. J. C. VAN DER HOEVEN (*Jour. Pharmacol. and Expt. Ther.*, 29 (1926), No. 1, pp. 227-231).—Further improvement in the authors' method of concentrating vitamin B from the Osborne-Wakeman yeast fraction is reported which is said to increase the yield from previous values of 3 to 5 per cent to 35 to 50 per cent of the starting material, as well as to furnish some clue as to the chemical properties of this vitamin. The successive steps in the improved method are briefly as follows:

The Osborne-Wakeman fraction is extracted repeatedly with absolute alcohol until a dry nonhygroscopic powder is obtained. This is dissolved in water and adjusted to pH 4, at which reaction some inactive material precipitates out on standing. The active material is deaminized with barium nitrite and sulfuric acid, involving a loss in material not exceeding 10 per cent, and is then adsorbed on silica gel and extracted from it as described in the previous paper.

"The final product obtained is still a complex mixture, containing complex carbohydrates and nitrogenous substances and esters of phosphoric acid. It contains no amino nitrogen, but does contain sulfur, which is given off on treatment with alkali in the form of hydrogen sulfide. The sulfur content increases with purification, but it is premature to pass an opinion as to whether the sulfur is a part of the active substance."

Some observations on the extraction of the vitamin B from wheat germ, E. V. McCOLLUM and H. D. KRUSE (*Amer. Jour. Hyg.*, 6 (1926), No. 2, pp. 197-200).—In an attempt to find solvents for vitamin B by the use of which selective extraction of the vitamin from natural foods might be effected with minimum contamination of other substances, extracts were prepared from wheat germ with 95 per cent alcohol containing 1 per cent of various organic and inorganic acids. The solubility of vitamin B in these extracting agents was tested by using the extract as the sole source of vitamin B in feeding experiments on young rats, using the technique previously described (E. S. R., 38, p. 612).

Of the various extracts tested, those prepared from alcohol containing 1 per cent of phosphoric, hydrochloric, nitric, benzoic, or lactic acid gave results indicating the presence of vitamin B. The best results were obtained with solutions of tannic and gallic acids in the alcohol. Citric acid gave negative and acetic acid irregular results. Further tests with the alcohol-gallic acid solvent indicated that the greater part of the vitamin B which can be extracted by this agent is removed within a relatively short time.

Similar tests, using as the solvent 95 per cent alcohol containing 1 per cent of cupric, mercuric, calcium, strontium, zinc, or cadmium chloride or silver nitrate, gave negative results with all except the zinc and cadmium salts, which yielded extracts more active than those obtained with the alcohol alone.

A comparison of the pigeon and the rat as test subjects for vitamin B, C. N. LAIRD (*Amer. Jour. Hyg.*, 6 (1926), No. 2, pp. 201-210).—Continuing along the lines of the foregoing study, wheat germ was extracted with a 0.5 per cent solution of various organic acids in acetone, benzene, chloroform, and ether and the extracts tested for vitamin B by the usual feeding experiments on rats. In an effort to determine whether rats and pigeons are comparable subjects for vitamin B tests, the curative power of these extracts for pigeons in acute polyneuritis was also tested.

The tabulated results show a decided variation in the effect of the different extracts on the two species of animals. Citric acid in acetone gave negative results in the rat tests, but was effective, although somewhat slow in action, in the pigeon tests. Salicylic acid in acetone, on the other hand, gave excellent rat tests and negative pigeon tests. Some gave fair results and others negative with both species. Combinations of two preparations each of which alone gave negative results with rats were also tested on both rats and pigeons. Although some of these combinations gave positive results with rats, the results, together with those obtained with the single preparations, are thought to be too inconclusive to furnish definite proof as to whether what is known as vitamin B is a single substance or of multiple nature, or as to whether the B requirements of the pigeon are simpler than those of the rat.

The action of reducing agents on the antiscorbutic factor inactivated by aeration, C. G. DAUBNEY and S. S. ZILVA (*Biochem. Jour.*, 20 (1926), No. 3, pp. 519-523).—On the assumption that the inactivation of vitamin C by oxidizing agents is direct oxidation and that the activity may conceivably be regenerated by reduction, attempts were made to reduce decitrated lemon juice inactivated by aeration by hydrogen in the presence of platinum black as a catalyst, by electrolysis, and by nascent hydrogen obtained by the action of citric acid on magnesium. Duplicate feeding tests were run with nonaerated juice which had received the same hydrogenation treatment.

No protection against scurvy was secured with the aerated but protection with the nonaerated juice after the hydrogenation treatment by the first two methods. Reduction by magnesium and citric acid gave inconclusive results as the preparation in itself had a disturbing effect on the animals. It is concluded that inactivated vitamin C can not be regenerated by simple reduction.

Rapid preparation of monomolybdophosphotungstic acid, reagent of polyphenols and vitamins [trans. title], N. BEZSSONOFF (*Compt. Rend. Acad. Sci. [Paris]*, 182 (1926), No. 20, pp. 1223, 1224).—A more rapid method for the preparation of the reagent proposed for the estimation of vitamin C. (E. S. R., 49, p. 805) is described as follows: In 250 cc. of water distilled over permanganate are dissolved 74 gm. of sodium tungstate, 8 gm. of phosphomolybdic acid, and 10 cc. of concentrated orthophosphoric acid (specific gravity 1.75). To this solution, kept at 45° C., is added drop by drop 85 cc. of 1:1 solution of concentrated sulfuric acid in redistilled water. On cooling crystallization is complete in three hours. The crystals are further purified by washing with 50 cc. of 15 per cent sulfuric acid by volume, dissolving them in 100 cc. of redistilled water at 45°, reprecipitating with 35 cc. of 50 per cent sulfuric acid, and washing the crystals with 15 per cent sulfuric acid.

A vacuum extractor for biochemical use, N. B. GUERRANT (*Indus. and Engin. Chem.*, 18 (1926), No. 10, p. 1090, fig. 1).—A vacuum extractor said to be particularly useful when the effect of heat and oxidation must be maintained at a minimum, as in the preparation of materials for nutritional studies, is described and illustrated.

"The flask is of the thick-walled Pyrex balloon type, having 10 per cent greater capacity than the extraction chamber. The extraction chamber consists of a side-necked bell jar containing a perforated desiccator plate and covered with a well-fitting desiccator top. The two ground surfaces are sealed with a mixture of equal parts of vaseline and paraffin previously melted and well mixed. The condenser should be short, thick-walled, and have a maximum cooling surface. The Davies condenser serves the purpose very satisfactorily. The exhaust tube should be as far as possible from the path of the condensed vapor."

Hydrogen ion concentration: Its significance in the biological sciences and methods for its determination.—I, Principles of the theory, L. MICHAELIS, trans. by W. A. PERLZWEIG (Baltimore: Williams & Wilkins Co., 1926, 2. ed., rev. and enl., vol. 1, pp. XIV+299, figs. 32).—This is the authorized translation of the second German edition (E. S. R., 48, p. 412).

Apparatus for the direct determination of carbon dioxide, J. E. UNDERWOOD (Indus. and Engin. Chem., 18 (1926), No. 10, pp. 1069, 1070, fig. 1).—A simple form of apparatus for the determination of small amounts of carbon dioxide by absorption is described and illustrated.

The gas is set free by hydrochloric acid and passed through successive absorption tubes containing water, mossy zinc (to absorb any hydrochloric acid passing over), concentrated sulfuric acid, and phosphorus pentoxide, and is finally absorbed by Ascarite in an ordinary Midvale bulb. The advantages claimed for the apparatus are the rapid removal of contaminating gases, the use of liquids in the various units which have to be replaced, and rapidity of determination owing to the small volume of the apparatus.

The colorimetric estimation of tyrosine, tryptophane, and cystine in proteins, II, J. M. LOONEY (Jour. Biol. Chem., 69 (1926), No. 2, pp. 519-538).—This paper consists of a critical discussion of various methods of determining tyrosine and tryptophane and the report of a repetition of the analyses of various proteins by the colorimetric method of Folin and Looney described in the previous paper of the series (E. S. R., 47, p. 504).

The earlier results were confirmed with the exception of the tyrosine content of gliadin and edestin and the cystine content of zein. The new figures for these are more consistent than the earlier figures with the values reported by Folin and Denis and by Jones, Gersdorff, and Moeller (E. S. R., 52, p. 802).

Comparison of the Official method of ashing plant tissues and products with the Hertwig and Bailey method, C. F. ROGERS (Cereal Chem., 3 (1926), No. 4, pp. 226-232).—A comparison of the Official and the Hertwig-Bailey (E. S. R., 53, p. 314) methods for determining ash is reported for sweet corn dried in the milk stage, apple wood, pea seeds, corn smut spores, and Graham flour, these materials being taken as representative of tissues high in sugars, cellulose, protein, fat, and starch, respectively. Although the difference in accuracy between the two methods was not great, it is considered that "the saving of time alone made possible by the Hertwig and Bailey method, without any serious consequences in regard to accuracy and with the higher apparent ash content when constant weight is reached, makes this modification of the standard method worthy of careful consideration."

Report of committee on methods of analysis for American Association of Cereal Chemists, D. A. COLEMAN ET AL. (Cereal Chem., 3 (1926), No. 4, pp. 254-282, fig. 1).—Collaborative data on the technique of making protein determinations, with emphasis on the standardization of acid and alkalies employed, and recommended methods for making protein, ash, and moisture tests on wheat flour and mill feeds constitute the main part of this annual report (E. S. R., 54, p. 613).

Oxygen-acetate method of ash determination in flour, G. L. BRENDÉL (*Cereal Chem.*, 3 (1926), No. 4, pp. 222-226).—In this modification of the calcium acetate method of ash determination the flour in a porcelain or platinum crucible is first charred to a cinder in the muffle, the calcium acetate solution is added and allowed to evaporate by placing the crucible on the open muffle door, and the ashing is then carried on at about 1,500° F., with the introduction into the muffle of oxygen from an oxygen acetylene torch for 10 or 15 minutes. It is stated that the analysis can be completed within 45 minutes.

On the estimation of glucose in the presence of phosphate buffers, M. B. VISSCHER (*Jour. Biol. Chem.*, 69 (1926), No. 1, pp. 1, 2).—Attention is called to the fact that the presence of potassium acid phosphate in glucose solutions lowers the reducing power of the glucose for copper, and that this must be taken into account whenever the sugar content of buffer solutions is to be measured.

The quantitative estimation of calcium, magnesium, phosphate, and carbonate in bone, B. KRAMER and J. HOWLAND (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 711-719).—Methods are described for the quantitative determination of calcium, magnesium, inorganic phosphorus, and carbonate in from 0.5 to 1 gm. of bone.

The method for calcium and magnesium is a modification of the authors' method for calcium determination in blood serum (E. S. R., 44, p. 114) and that for phosphorus a modification of the method of Fiske for the determination of phosphates in urine (E. S. R., 45, p. 508). A modification of the Briggs method for phosphorus (E. S. R., 48, p. 111) is also recommended. The method for carbonate consists essentially in its determination as carbon dioxide gas in an enlarged form of the apparatus described originally by Van Slyke for the determination of bicarbonate in small amounts of serum.

The technique of each of these methods is described in detail, with data indicating that the accuracy of the calcium method is ± 1 per cent, phosphorus ± 2 , carbonate ± 1 , and magnesium ± 5 per cent.

The colorimetric estimation of cholesterol and lecithin in blood in connection with Folin and Wu's system of blood analysis, D. M. DETONI (*Jour. Biol. Chem.*, 70 (1926), No. 1, pp. 207-210).—In the method described the protein precipitate obtained by the method of Folin and Wu (E. S. R., 41, p. 13) is washed, dried, and extracted with hot chloroform as in the method of Myers and Wardell for total blood (E. S. R., 40, p. 15). The cholesterol is determined in the extract by the Liebermann reaction and the lecithin as lipid phosphorus by the Whitehorn method (E. S. R., 53, p. 12).

The metabolism of sulfur.—X, **The determination of cystine in the urine**, H. B. LEWIS and R. H. WILSON (*Jour. Biol. Chem.*, 69 (1926), No. 1, pp. 125-131).—In this continuation of the series of studies previously noted (E. S. R., 54, p. 292), a comparison has been made of the Looney colorimetric (E. S. R., 48, p. 505), the Gaskell gravimetric, and the Magnus-Levy polarimetric methods for the estimation of cystine in urine, with the conclusion that the direct colorimetric procedure is more accurate than methods involving precipitation, particularly where small amounts of cystine are concerned.

A respiration apparatus for small animals, G. L. FOSTER and E. S. SUNDRSTROEM (*Jour. Biol. Chem.*, 69 (1926), No. 2, pp. 565-568, fig. 1).—A respiration apparatus of the closed circuit type, which is said to have given satisfactory service in determinations of the metabolism of rats under various conditions, is described and illustrated.

The carbon dioxide absorbers, consisting of two pairs of Kjeldahl flasks joined at the bottom, are arranged on a motor-driven rocking apparatus which causes the absorbing solution of barium hydroxide to flow back and forth

from one flask to the other, thereby drawing the air out of the animal chamber. This consists of an ordinary desiccator, the animal resting on a wire gauze over sulfuric acid. The oxygen reservoir is a 1½ liter bottle fitted with a manometer tube and connected by a two-way stopcock with the animal chamber or the atmosphere. The pressure is kept constant by admitting water into the reservoir drop by drop from a burette through the manometer tube.

METEOROLOGY

Solar activity and long-period weather changes, H. H. CLAYTON (*Smithsn. Misc. Collect.*, 78 (1926), No. 4, pp. 62, figs. 13).—This paper is a continuation of one previously noted (E. S. R., 53, p. 812). It is stated that "the results of these studies indicate that there is a real relation between weather conditions and the monthly means of solar radiation and monthly sun-spot numbers, but in the average the amounts of the changes in pressure, temperature, and precipitation are not large." Twenty correlation coefficients and other evidential results favorable to solar variation and its influence on weather are presented.

Solar radiation and weather forecasting, C. F. MARVIN and H. H. KIMBALL (*Jour. Franklin Inst.*, 202 (1926), No. 3, pp. 273-306, figs. 23).—This is a very complete review, with a bibliography of the more important investigations on this subject. The general conclusion reached is that "the basis for our belief that the weight assignable to solar variability as a factor in the making of the weather is almost vanishingly small," but that this does not mean that "meteorologists in general and weather forecasters in particular are not to benefit from more accurate determinations of the value of the solar constant."

Rain making and other weather vagaries, W. J. HUMPHREYS (*Baltimore: Williams & Wilkins Co.*, 1926, pp. X+157).—This book summarizes both ancient and modern notions about the control of rain, or what Dr. David Starr Jordan has termed "pluviculture," as well as other weather vagaries, which the author terms "meteorological mumpsimus, or stupid weather errors stubbornly held to, despite all rational explanations."

Influence of temperature and precipitation on vegetation [trans. title], W. GROSSE (*Met. Ztschr. [Brunswick]*, 43 (1926), No. 9, pp. 352-355).—A number of correlations which are thought to be significant are indicated.

The weather influence on crop production in regions of scanty rainfall, W. A. MATTICE (*U. S. Mo. Weather Rev.*, 54 (1926), No. 8, pp. 336-341, figs. 3).—A study of the relation of precipitation and temperature to yields of winter and spring wheat, oats, barley, and corn in a region of scanty rainfall (Akron, Colo.), as compared with regions of generally adequate summer precipitation, indicated that "growing dry-land crops under conditions such as exist at Akron is decidedly precarious." Of the five crops referred to, winter wheat alone showed an even chance of giving an average yield.

A further study of effective rainfall, J. F. VOORHEES (*U. S. Mo. Weather Rev.*, 54 (1926), No. 8, pp. 332-336, figs. 9).—Supplementing a paper previously noted (E. S. R., 53, p. 210), the author reports a study of the relation of rainfall to yield of corn on differently cultivated and treated soils, from which he concludes that "effective rainfall is not a function of total rainfall (except when the latter is the limiting factor), but depends entirely upon the condition of the soil and the capacity of the crop for utilizing water."

Spring and autumn night frosts as a problem of agricultural meteorology [trans. title], K. SZULC ([Poland] *Min. Roln. i Dóbr Państw., Prace Met. i Hydrog. (Études Mét. et Hydrog.)*, Ser. F, No. 1 (1924), pp. 3-6; *Fr. abs.*, pp. 5, 6).—This is a brief preliminary note discussing the use of Pearson curves as a means of predicting the dates of occurrence of frosts.

Monthly Weather Review, [July–August, 1926] (*U. S. Mo. Weather Rev.*, 54 (1926), Nos. 7, pp. 281–320, pls. 10, figs. 16; 8, pp. 321–365, pls. 10, figs. 20).—In addition to detailed summaries of meteorological and climatological data and weather conditions for July and August, 1926, and bibliographical information, notes, abstracts, and reviews, these numbers contain the following contributions:

No. 7.—Lightning and Forest Fires in the Northern Rocky Mountain Region (illus.), by H. T. Gisborne; The January Storms over the North Atlantic and the Strophs of the Greenland Anticyclone (illus.), by W. H. Hobbs; On the Investigation of Cycles and the Relation of the Brückner and Solar Cycle (illus.), by A. Streiff; and The Nassau Hurricane, July 25–26, 1926 (excerpts).

No. 8.—The Vertical Distribution of Atmospheric Eddy Energy (illus.), by C. G. Rossby; A Further Study of Effective Rainfall (illus.), by J. F. Voorhees (see p. 15); The Weather Influence on Crop Production in Regions of Scanty Rainfall (illus.), by W. A. Mattice (see p. 15); A Note on Mr Mitchell's Paper on West Indian Hurricanes, by S. Hanzlik, with discussion by C. L. Mitchell; and Compensation of Altimeters and Altigraphs for Air Temperature, by W. G. Brombacher (abs.).

Meteorological observations at the Massachusetts Agricultural Experiment Station, J. E. OSTRANDER and W. H. PARKIN (*Massachusetts Sta. Met. Buls.* 453–454 (1926), pp. 4 each).—The usual summaries are given of observations at Amherst, Mass., during September and October, 1926.

Climate of British Columbia, F. N. DENISON (*Brit. Columbia Dept. Agr. Bul.* 27, 11. ed. (1926), pp. 24).—Data from nearly 200 stations distributed throughout British Columbia, with reference to monthly and annual temperature, precipitation, sunshine, and relative humidity, are tabulated.

“During the year 1925 the temperature was abnormally high, both in British Columbia and the Yukon; severe floods occurred at Dawson and in the Lower Fraser Valley in May, and owing to the summer being unusually hot and dry, forest fires were both numerous and very destructive throughout this Province. The precipitation for the entire year was considerably below the average.”

The weather of Scotland in 1925, A. WATT (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 38 (1926), pp. 275–283).—A general description is given of the weather of each month, with a table showing rainfall in different counties. The most notable feature of the year was a rainfall deficiency in June and November.

Phenological observations in Italy, 1922–1925 [trans, title], M. MINIO (*Nuovo Gior. Bot. Ital.*, n. ser., 33 (1926), No. 3, pp. 627–631+[48]).—Dates of blooming of a large number of trees, shrubs, and other plants are recorded for various places in Italy. The plan and program of the cooperative observations on this subject are briefly described.

Meteorological observations in the Dooars, 1925, C. R. HARLER (*Indian Tea Assoc., Sci. Dept. Quart. Jour.*, 1926, No. 2, pp. 61–72, pls. 2).—The relation of weather conditions in this region of Assam to the growth and quality of tea is discussed, attention being called especially to humidity as the controlling factor in the growth of the indigenous tea bush. The Assam tea plant “is constructed to live in a hot, humid climate and its leaves are designed so that they are able to transpire freely. The leaves of China bushes are slightly differently made from those of Assam and Burma bushes, and the China jat is able to withstand the drought and cold better than the other varieties.”

SOILS—FERTILIZERS

Transactions of the Second Commission of the International Society of Soil Science, A. A. J. VON 'SIGMOND, N. M. COMBER, H. R. CHRISTENSEN, and D. J. HISSINK (*Groningen: Internatl. Soc. Soil Sci., 1926, vol. A, pp. [6]+248, pls. 3, figs. 28*).—The transactions of the meeting of this commission, held at Groningen in April, 1926, contain special articles on The Determination and the Value of Soil Acidity, by O. Lemmermann; Soil Acidity, by S. D. Conner; Use of the Quinhydrone Electrode for Determining the pH of Soil, by C. Brioux and J. Pien; Value of Iron in Zeolitic Silicates to Soil Reaction, by L. Smolik; The pH Determination of Soils According to the Bilmann Chinhydrone Method, by D. J. Hissink and J. van der Spek; Soil Acidity, by O. Arrhenius; The Action of Nondiffusible Ions in Soil Phenomena, by N. M. Comber; Soil Acidity and Plant Reaction, by E. A. Mitscherlich; Soil Reaction in Finland, by W. Brenner; Some Comparative Investigations on the Determination of Exchangeable Cations, Saturation Condition, and Acidity Conditions in Soil, by A. A. J. von 'Sigmond; Titration Curves of Humus Soils, by D. J. Hissink and J. van der Spek; The Quantitative Determination of the Lime Requirement of Soil, by H. R. Christensen and S. T. Jensen; The Quantitative Determination of the Lime Requirement of Humus Sand Soils, by J. Hudig; The Effect of Regulated Treatment with Hydrochloric Acid upon the Lime Requirement of a Mineral Subsoil, by G. Milne; The Reaction between Soils and Hydroxide Solutions, by S. J. Saint; Observations on the Relation of Soil Reaction and Plant Yield, by L. von Kreybig; Determination of the Lime Requirement of Braunschweig Soils, by A. Gehring, A. Peggau, and O. Wehrmann; The Characterization of the Soil on the Basis of its Absorbing Complex, by G. W. Robinson; What Happens to the Lime when Soil is Limed? by D. J. Hissink; The Relation between the Values pH, V, and S (Humus) of Some Humus Soils, S (Humus) and V of These Soils with pH = 7, the Equivalent Weight of the Humus Substance, by D. J. Hissink; and The Relation between Soil Acidity and the Physiologically Acid Reaction of Fertilizers, by H. Kappen.

A suggestion concerning soil classification, A. B. BEAUMONT and A. C. SESSIONS (*Jour. Amer. Soc. Agron., 18 (1926), No. 3, pp. 238-247, figs. 3*).—In a contribution from the Massachusetts Experiment Station a statistical study of mechanical analyses is presented which indicates that agricultural soils are composed of mixtures of soil separates rather than any one group of particles known as a separate, and that agricultural soils containing more than 75 per cent of clay, more than 85 per cent of silt, or more than 95 per cent of sand are negligible in number. Evidence is given of variability in soils and of the failure of plants to respond to slight textural differences. A revision of the textural classification of soils is suggested which would eliminate ambiguity and tend to check the multiplication of class names.

Soil survey of Iowa.—Reports 42, 43, W. H. STEVENSON, P. E. BROWN, ET AL. (*Iowa Sta. Soil Survey Rpts. 42 (1926), pp. 79, pls. 2, figs. 14; 43, pp. 70, pl. 1, figs. 12*).—Two county soil surveys are presented, which include analyses and greenhouse and field experiments to determine the composition, fertilizer requirements, and crop adaptations of the prevailing soil types, and information on methods of conducting soil surveys in Iowa.

No. 42, Jasper County soils.—This county lies mainly in the Mississippi loess soil area in central Iowa and has an area of 467,200 acres. The topography is mainly rolling to strongly rolling. Drainage conditions as a whole are said to be quite satisfactory except in the northwestern corner where the Wisconsin drift soils occur.

The soils are grouped as drift, loess, terrace, and swamp and bottomland soils, the loess soils covering 62.5 per cent of the area. Including peat and muck, 33 soil types of 18 series are mapped, of which the Tama and Clinton silt loam loess soils and the Carrington loam drift soil cover 42.3, 12.8 and 10.1 per cent of the area, respectively. Practically all of the soils are said to be acid in reaction, and in many cases the nitrogen content is not entirely adequate. The phosphorus content is also said to be low.

No. 43, O'Brien County soils.—This county lies partly in the Wisconsin drift soil area and partly in the Missouri loess area in northwestern Iowa, and has a total area of 364,160 acres. The prevailing topography is level to undulating. It is considered apparent that while the drainage is quite adequate in parts of the county, considerable areas need artificial drainage.

The soils of the county are grouped as drift, loess, terrace, and swamp and bottomland soils, the loess soils covering 72.8 per cent of the area. Fifteen soil types of 12 series are mapped, of which the Marshall silt loam loess soil covers 72.8 per cent of the area. It is stated that many of the individual soil types of the county are acid, and that the soils are generally rather low in phosphorus.

Soil survey of Rockwall County, Texas, H. V. GEIB (U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1923, pp. III+123-152, pls. 4, fig. 1, map 1).—This survey, made in cooperation with the Texas Experiment Station, deals with the soils of an area of 95,360 acres in northeast Texas. It lies in the black waxy belt of the Black Prairie region. The topography ranges from gently undulating to strongly rolling and hilly, the greater part being rolling. It is stated that numerous streams and their branches ramify to all parts of the uplands, affording excellent outlets for the surface waters. In many places the run-off is rapid and damaging erosion is taking place.

The soils of the county are derived principally from the underlying highly calcareous beds of unconsolidated or only very weakly consolidated clays. Eight soil types of 5 series are mapped, of which the Houston clay and black clay and the Trinity clay cover 38.1, 28.1, and 18 per cent of the area, respectively.

Soil colloids [trans. title], A. N. SOKOLOVSKIĪ (SOKOLOWSKY) (Pochvovedenie (Pédologie), n. ser., 19 (1924), No. 1-2, pp. 59-79; Ger. abs., pp. 77-79).—Studies are reported which showed that the content of absorbed calcium in soils has an approximate relation to certain soil properties. Separation of the absorbed calcium from black soil and subsequent washing with distilled water resulted in the removal of a part of the soil colloid, and caused the rapid disappearance of the filtering property of the soil. It became very slimy when wet and very hard when dry, and no trace of crumb structure remained.

Soluble organic and mineral matter was also removed by this procedure, leaving considerable quantities of insoluble humus and slime which produced the compact structure on drying.

The silt content could be removed only by breaking down the connection between the humus and the slime either by oxidation of the humus or by boiling. Crumb structure was found to be governed by the presence of organic and mineral or so-called active silt and by the degree of absorption of calcium. These factors were at the optimum in black soils and were in minimum in forest, alkali, and desert soils.

The mineral and organic materials forming the active silt were for the most part not combined. The more disperse organic matter consisted of a mixture of particles of variable dispersion. It was possible to dissolve out the more disperse organic material from active silt. Only an insignificant part of the

colloidal complex of gravelly loam was removed in this matter as compared with that removed from black soil.

Active silt showed ordinary colloidal properties under the influence of heating from 40 to 60° C. (104 to 140° F.), and of storage in the laboratory in air-dry condition. The latter treatment resulted in a decrease in the active silt and an increase in the so-called passive silt, which is apparently of little or no significance. However, the active silt of black soil underwent practically no decomposition during two years of such storage.

New methods of chemical and mechanical analyses of soils are outlined which are based on these properties of the colloidal portions. In this connection different soils and the various strata thereof were found to have different coefficients of saturation for calcium, which are considered to indicate the varying conditions governing their origin. The loess soils of southern Russia, for instance, were found to have a low coefficient.

Saturation as a criterion for equilibrium between soil colloids and the most important form of absorbed calcium was found to yield a method for determining the lime requirement of soils, which is based on absorptive power and is determined by means of the absorption of ammonia and the degree of saturation with calcium.

Plasticity of soils [trans. title], M. A. ANTONOVA (*Pochvovedenie (Pédologie)*, n. ser., 19 (1924), No. 1-2, pp. 7-35, figs. 2; Ger. abs., pp. 24-35).—Studies conducted at the Institute of Experimental Agriculture of Leningrad on the plasticity of certain soils are reported.

Meadow soils containing salts showed the highest plasticities, followed in order by the humus chernozem soils, medium humus, and loamy chernozem soils, and sandy loam and podsol soils. The greatest plasticity values were given by the humus strata containing salt accumulations and the smallest in the podsol strata of soils.

Humus up to a certain limiting content was found to be a binding agent and to increase the plasticity of soils. Beyond this limit it had an opposite effect. Fine grained soils containing a large percentage of silt gave high plasticity values, while coarse grained soils gave low plasticity values. The plasticity of clay soils was reduced by admixtures of sand or calcium carbonate. The addition of talc increased the water holding power of soils and decreased their cohesive power.

It is concluded that in general the plasticity limits of soils can serve as good indications of those properties which influence their tillage.

The moisture of the podsol in freezing and thawing in the year 1923-24 [trans. title], F. V. CHIRIKOV and A. MALIÛGIN (*Nauch. Agron. Zhur. (Jour. Landw. Wiss.)*, 3 (1926), No. 1, pp. 40-51, figs. 3; Eng. abs., p. 50).—Studies conducted at the Agricultural Institute at Kazan are reported, the purpose of which was to explain the process of the movement of water in soil in the fall and in the spring. The observations of soil moisture in the field in the fall were made on plowed and unplowed soils. A movement of water from lower strata to higher strata was observed during the freezing of the soil. This was distinctly evident both on plowed and unplowed soils in the fall. A dry stratum occurred under the moist surface strata. The movement of water from one stratum to another during freezing of soil was found to proceed in the form of a vapor. Moisture movement took place more energetically in plowed than in unplowed soil. A stubble soil held snow better than a soil plowed in the fall. There was a relatively greater drying of the surface soil of a plowed field during freezing. During thawing condensed and snow water accumulated in the surface soils was pressed out, so that fall plowing was without result in moisture accumulation.

Soil moisture experiments at the Dominion Experimental Station, Swift Current, Sask., S. BARNES (*West. Canad. Soc. Agron. Proc.*, 5 (1924), pp. 14-19, figs. 2).—Controlled experiments on soil moisture in two sets of tanks, the soil in one set being fallowed and that in the other cropped to wheat, indicated that wheat on the stubble tanks reached the limit of available moisture by July 4, while that on summer fallow was able to hold out two weeks longer before reaching the same point. There was a loss by evaporation of 58.7 per cent of the moisture from the fallow tanks, and an estimated loss of about 30 per cent on cropped tanks.

Report of certain investigations on the central Nebraska supplemental irrigation project, W. W. BURR and J. C. RUSSEL (*Nebr. Dept. Pub. Works Bien. Rpt.*, 15 (1923-24), pp. 198-240, figs. 11).—A survey conducted by the University of Nebraska on the soils of the central Nebraska supplemental irrigation project and on the feasibility of irrigation in this area is presented.

The determination of available phosphoric acid of calcareous soils, S. DAS (*India Dept. Agr. Mem., Chem. Ser.*, 8 (1926), No. 6, pp. 69-104, figs. 6).—This study is in three parts. Part 1 demonstrates the inapplicability of Dyer's method for determining the available phosphoric acid of calcareous soils. Part 2 deals with the extraction of phosphoric acid of calcareous soils with salt solutions. Part 3 reports experiments which indicate that a 1 per cent solution of potassium carbonate is capable of differentiating between fertilized and unfertilized soils of known cropping and manurial history, and thus gives an indication of the probable fertility of calcareous soils with reference to available phosphoric acid.

Origin of alkali soils [trans. title], D. G. VILENSKIÏ (D. C. WILENSKY) (*Pochvovedenie (Pédologie)*, n. ser., 19 (1924), No. 1-2, pp. 36-58; *Ger. abs.*, pp. 56-58).—Studies are reported in which the extensive saline soils of Eurasia are grouped as (1) salt soils which contain large amounts of easily soluble salts and (2) alkali soils which contain practically no soluble salts in their upper strata but show very poor physical properties, as indicated by the occurrence of almost impervious layers at shallow depths.

The structure of these impervious layers of soil may be prismatic or in the shape of narrow or broad columns. The prismatic structure occurs in the desert steppes, the narrow column structure in the dry steppes, and the broad column structure in the black soil steppes.

The prismatic and narrow column structures contain significant amounts of sodium chloride and sodium sulfate, and the broad column structure contains sodium carbonate.

The conclusion is drawn that alkali soils originate from salt soils.

Influence of microorganisms on the absorption of nutritive elements from soil [trans. title], J. STOKLASA (*Bul. Assoc. Chim. Sucr. et Distill.*, 42 (1925), No. 9, pp. 350-357; *abs. in Jour. Soc. Chem. Indus.*, 44 (1925), No. 26, p. B465).—In a contribution from the Experimental Station of the Republic of Czechoslovakia, a comparison of the soils of plats on which various crops were grown continuously is reported which showed, after four years, great differences in the numbers of bacteria present and in the amount of carbon dioxide respired per unit weight of soil. An alfalfa plat yielded the highest figures, followed in order by sugar beet and wheat plats. All cultivated soils gave much higher figures than uncultivated soils.

The differences in bacterial activity were reflected in the corresponding amounts of phosphoric acid and potassium taken up by the different crops from soil. Selective absorption of anions and cations by plants and the nutritional significance of the varying numbers of bacteria around the roots of different species are also discussed.

Ammonification in red prairie soils, H. F. MURPHY (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 3, pp. 177-183).—Studies conducted at the Oklahoma Experiment Station are reported which showed that the general tendency was toward an increase in ammonification from the use of either calcium oxide or calcium carbonate on very fine sandy loam and loam soils.

Manure as a rule did not increase ammonification to any extent beyond that produced by lime. In some cases manure seemed to have a depressing effect on ammonification. A heavy application of lime caused greater ammonia production than a light application. Calcium oxide was as a rule slightly more favorable toward ammonification than calcium carbonate.

Sunlight and chemical nitrification [trans. title], I. P. ZHOLTSINSKIĪ (J. ZOLCINSKI) (*Pochvovedenie (Pédologie)*, n. ser., 19 (1924), No. 1-2, pp. 80-97; *Ger. abs.*, pp. 95-97).—Studies are reported which showed that nitrification took place in an aqueous ammonia solution of humus material under the influence of sunlight. No nitrification occurred when the sunlight was excluded, and the nitrates which were formed under the influence of sunlight disappeared with its exclusion. These reactions occurred during a relatively short period of time.

The humus solutions were found to bleach out gradually during this process, especially those artificially prepared. Nitrification proceeded more rapidly and was completed sooner in a quartz glass beaker than in a crock. This is attributed to greater action of the ultra-violet rays in the former.

Nitrification proceeded more slowly in natural humus solutions than in artificial solutions. The presence of aluminum hydrate in the solution accelerated the process. Attempts to produce chemical nitrification in solutions of other organic colloids, such as starch and gum Arabic, by means of sunlight were unsuccessful. The importance of studies to differentiate between the chemical and biological factors in soil nitrification is emphasized.

Effect on nodulation of supplementing the legume bacteria of the soil with artificial cultures, J. K. WILSON (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 3, pp. 280-294).—Studies conducted at the New York Cornell Experiment Station are reported in which soil samples from plats whose crop and fertilizer treatment for 15 years were known were used as a medium in which nodule production could be determined. Host plants of four groups of legume bacteria were grown and the nodules counted.

It was found that soils may be or may become an unfavorable habitat for the various groups of legume bacteria, that the bacteria may largely or entirely disappear from soil, that this disappearance accompanies increasing acidity of the soil, that the bacteria do not seem to be greatly influenced by the frequency of the host plant in the rotation, and that in acid soils the addition of more bacteria has resulted in the formation of a larger number of nodules per plant.

The decomposition of toxins by soil organisms, W. A. GARDNER (*Alabama Sta. Bul.* 225 (1926), pp. 38).—Studies are reported which showed that the addition of calcium sulfate improves Robbins' solution for the growth of soil organisms. Solutions but slightly acid to phenolphthalein yielded the most abundant growth of a majority of soil organisms.

Seven toxins were added to the list of those decomposed by soil organisms, namely, resorcinol, cinnamic acid, quinone, hydroquinone, caffeine, piperidine, and benzidine. Organisms decomposing vanillin, cumarin, and resorcinol were found to be very common and widely distributed. Cinnamic acid, caffeine, and quinone were decomposed by the organisms of about two-thirds of the widely distributed soils tested, while hydroquinone was decomposed by only one-third of them.

About three-fourths of the soils from several States contained organisms able to decompose pyridine and piperidine. A few soils contained organisms decomposing benzidine. In their order organisms decomposing quinone, hydroquinone, caffeine, pyridine, piperidine, and benzidine were found to occur in a decreasing number of States.

Effect of the application of mineral fertilizers upon soil reaction [trans. title], P. I. ANDRIANOV (P. J. ANDRIANOW) (*Nauch. Agron. Zhur. (Jour. Landw. Wiss.)*, 3 (1926), No. 1, pp. 30-39; *Eng. abs.*, p. 39).—Studies conducted at the Moscow Agricultural Academy to determine the effect of ammonium sulfate, calcium carbonate, sodium nitrate, phosphate rock, Stassfurt potash salt, and acid phosphate upon the reaction of uncropped soils are reported.

Calcium carbonate increased pH values and ammonium sulfate decreased them, sodium nitrate produced a slight increase and acid phosphate a slight decrease, and phosphate rock and Stassfurt potash salt had no influence. Drying of soil during 24 hours at a temperature of from 80 to 100° C. (176 to 212° F.) decreased the pH values in all cases, and especially when fertilized with ammonium sulfate. There was a marked increase in pH values as a result of leaching.

[**Cottonseed meal as a fertilizer**] (*Texas Sta. Bul.* 341 (1926), pp. 24-27).—Practical information on the relation of cottonseed meal to diversified farming and its use as a fertilizer is briefly presented.

Investigations on fish meals, I, II, W. L. DAVIES (*Jour. Soc. Chem. Indus.*, 44 (1925), No. 42, pp. 487T-491T; 45 (1926), No. 5, pp. 25T-29T).—Two contributions from the University College, Reading, on fish meals are presented.

I. *The nature of the water-soluble nitrogen compounds*.—Studies are reported of five different kinds of fish meals, indicating that fish meals of present-day commerce are greatly changed, both in the nature and the amount of their soluble nitrogenous compounds, owing to the various treatments which they have undergone. Creatine, xanthine, and related compounds have been either leached out or completely decomposed. Other nitrogen compounds have been leached out to different degrees, and some protein has been broken down to different stages of degradation. Gelatin-producing compounds have been hydrolyzed to different degrees.

The water-soluble nitrogen fractions of yellow and white fish meals were found to differ appreciably. The amount of the simpler degradation products of proteins is larger in the former, whereas the latter contain more of the higher protein fission products. This is attributed to prolonged drastic treatments such as steaming, drying, and grinding. It was found that from one-fifth to two-fifths of the nitrogen in the meals can be extracted by water.

A determination of the diamino acid content of two of the extracts showed that on the average the compositions of the extracts compare favorably with the composition of some protein hydrolysates. Various alcoholic extracts from two typical classes of meals were found to differ especially in the percentage of nitrogen extractable by hot alcohol and in their composition. A great variation was found in the amount of volatile bases in the extracts, but the ammonia content was fairly constant. A determination of the volatile fatty acids in the extracts showed that more decomposition of both fat and amino acids has occurred in the yellow meals. The amount of nonvolatile acids is fairly constant throughout.

II. *Changes occurring in the water-soluble nitrogen and in the amount of water-soluble phosphorus with different methods of treatment and storage*.—Samples of the five types of meal were stored in bags, in open vessels, and in a dry warm state for seven months. They were also stored in a cold and in a warm wet state for three weeks.

The short wet treatments increased the acidity as did also the mold growth in the long period storages. The short wet treatments generally were accompanied by increases in the water-soluble nitrogen. With long period storages the tendency was for the amount of water-soluble nitrogen to decrease. The short wet treatments caused the most breaking down. Warm dry treatment caused little change in the amount of water-soluble nitrogen. There was some decarboxylation of the soluble carbon compounds with cold wet storage, and during prolonged warm dry storage deamination of the water-soluble compounds of all meals occurred.

Wet treatment increased the amount of volatile base in the water-soluble fraction. A decrease in the amount of volatile base was observed with other treatments. No rule was found to govern the increase in the amount of soluble phosphorus with each treatment, and this amount bore no relation to the initial acidity. Warm dry treatment had the greatest effect, while other treatments caused only small changes. Mold growth caused a decrease in soluble phosphate, an increase in initial acidity, but no effect on the volatile base content of the aqueous extracts.

Wet treatments caused all the meals to become unwholesome. Dry treatment caused no fetid odor to be given off in spite of mold growth in some cases. Bag storage caused oily meals to become rancid in odor and some white meals to become unwholesome and fetid.

Comparative value of sulphate of ammonia and nitrate of soda, J. W. WHITE (*Barrett Co. [New York] Agr. Dept. [Pub.] 23, [n. ser.], 1925, pp. 12, figs. 5*).—The results of forty years' field tests at the Pennsylvania Experiment Station are briefly summarized, from which the conclusion is drawn that the relative value of ammonium sulfate and sodium nitrate as fertilizers is not indicated. However, they are thought to develop clearly the improper use of ammonium sulfate.

Potash: Significance of foreign control and economic need of domestic development, H. M. HOAR and C. C. CONCANNON (*U. S. Dept. Com., Bur. Foreign and Dom. Com., Trade Prom. Ser. 33 (1926), pp. IV+92, figs. 10*).—A general survey of the potash situation is presented for the purpose of directing the attention of the American potash consumers to the domestic and foreign status of this industry. Foreign sources of potash, their political and commercial control, with monopolistic and price raising tendencies, production, consumption, and trade are outlined for the better visualization of United States requirements for this product.

Can the lime-requirements of the soil be determined from the reaction of soil suspensions containing potassium chloride? M. TRÉNEL (*Internatl. Rev. Sci. and Pract. Agr. [Rome], n. ser., 3 (1925), No. 4, pp. 1011-1017, fig. 1*).—In a contribution from the Geological Institute, Berlin, an attempt is made to determine the lime requirement of soil from the pH value of the soil suspension in M/10 potassium chloride solution. The dependence of the lime requirement on the pH is graphically represented. The curve of the humus soils is clearly distinguishable from that of the pure mineral soils, and indicates a lower lime requirement.

Lime for West Virginia farms, D. R. DODD (*West Virginia Sta. Bul. 215 (1926), pp. 24, figs. 16*).—Practical information on the use of lime on West Virginia farms is presented, including a description of a homemade lime spreader, lime pulverization, and lime burning. Working drawings for a lime kiln are included.

Gypsum in 1924, K. W. COTTRELL (*U. S. Dept. Com., Bur. Mines, Min. Resources U. S., 1924, pt. 2, pp. II+231-240*).—Data on the production and use of gypsum during 1924 are presented. The total quantity of gypsum mined

in the United States in 1924 was 5,042,629 short tons, or an increase of 6 per cent over 1923.

AGRICULTURAL BOTANY

Further observations on nonsymbiotic germination of orchid seeds, L. KNUDSON (*Bot. Gaz.*, 77 (1924), No. 2, pp. 212-219, figs. 3).—These experiments, so far as completed, lend further support (E. S. R., 48, p. 223) to the view that germination in orchid seeds requires an outside source of organic matter. Sugar in germination acts as a food; but after the leaf has appeared growth may continue without available organic matter in the medium. Though the embryos possess chlorophyll, photosynthesis is absent, presumably owing to the lack of some internal factor. These experiments, though they do not disprove the indispensability of the fungus to germination under certain conditions, emphasize the nutritional aspects of the problem.

Physiological study of the symbiotic germination of orchid seeds, L. KNUDSON (*Bot. Gaz.*, 79 (1925), No. 4, pp. 345-379).—Previous papers (see above) have shown the necessity to germination of available organic matter, emphasizing the nutritional aspects of the problem and presenting also views regarding the possible function of the fungus in certain pure culture experimentation to which reference is made. The experimentation here detailed deals with the relation of the endophytic fungi to germination.

A fungus resembling morphologically that described as *Rhizoctonia repens* was isolated from *Cattleya*, *Cypripedium*, and *Epipactis*. This fungus was capable of inducing seeds of *Cattleya* to germinate on a medium containing starch, also of accelerating growth of orchid seeds in a solution containing sucrose. It may permit complete germination or may cause complete failure to germinate, one of the factors controlling the degree of infection being the concentration of starch (ultimately, of sugar) used. During the change, digestion of starch and production of sugar, the H-ion concentration is changed from a value unfavorable to one favorable to growth, these external changes being sufficient to bring about germination, which may be effected by the fungus even when no seeds are infected. *Phytophthora* sp. is about as favorable to germination as the orchid fungus, the chemical changes being nearly the same as those produced by the orchid fungus. Other fungi were found effective in this regard.

In determining the effect of the fungi isolated from *Cattleya*, *Epipactis*, and *Cypripedium* on seeds of *Odontoglossum* it was found that these fungi are extremely pathogenic, practically every seed being killed. Without the fungus the seeds turned green and were still living six months later. When sugar was supplied the seeds germinated.

Divergence of catalase and respiration in germination, L. E. RHINE (*Bot. Gaz.*, 78 (1924), No. 1, pp. 46-67, figs. 4).—In six kinds of seed tested, catalase showed a decrease in early germination stages, followed by an increase. Catalase decreased slowly almost to exhaustion in prolonged soaking of seeds in oxygen-free water. A simple respirometer is described as usable with large quantities of material. Catalase in ripening seeds decreased per unit both of wet and of dry weight. It increased per ovule as the seed grew, but after the ripening process began it decreased rapidly with decrease of water content. The production of catalase is indirectly connected with oxidation. Catalase could be used as an indicator of metabolism only in cases where there was no rapid change in respiration.

Effect of size of seed on plant production with special reference to radish, N. A. ROTUNNO (*Bot. Gaz.*, 78 (1924), No. 4, pp. 397-413, figs. 4).—No

definite statement is made as to which radish seed size produces the largest root. From the data herein recorded it appears that the results obtained with one variety are not necessarily comparable with the results from another variety.

Protein synthesis by plants.—I, Nitrate reduction, S. H. ECKERSON (*Bot. Gaz.*, 77 (1924), No. 4, pp. 377-390).—The phases considered in this study of protein synthesis are reduction of nitrates, synthesis of amino acids, and linkage of amino acids. This paper deals with the first of these phases.

Reduction of nitrates to nitrites and ammonia, as obtained by tomato plant extract in slightly alkaline solution in the presence of fructose or glucose and some free oxygen in darkness as well as in light, was found to be most active in solutions having a pH value of approximately 7.6. Expressed juice of nitrogen-high tomato plants containing also abundant sugar, after adding $N/10$ NaOH to produce a pH value of 7.6, gave very rapid reduction of nitrates to nitrites at 50° C. (122° F.) Tomato plant juice boiled and brought to pH 7.6 reduced nitrates as rapidly as did the unheated juice. The rate and amount of reduction of nitrates to nitrites by tomato plant extract were found to be the same in darkness as in light.

"Amino acids (newly synthesized) appeared at the nodes and in petioles and blades of young leaves and just behind the stem tips of carbohydrate-high tomato plants three or four days after nitrate had been supplied to the soil. The amino acids were aspartic acid, asparagine, alanine, leucine, cystine, and histidine."

Quantitative relations of carbohydrates to nitrogen in determining growth responses in tomato cuttings, M. E. RED (*Bot. Gaz.*, 77 (1924), No. 4, pp. 404-418, figs. 8).—The investigations here noted are the outcome of studies stimulated by the observations of Kraus and Kraybill (*E. S. R.*, 40, p. 40).

It appears that growth responses as expressed in root and shoot production may be determined at least in part by the nature of the available food materials. A high nitrogen supply plus a readily available (even if limited) carbohydrate supply appears to furnish favorable conditions for shoot growth. A somewhat limited nitrogen supply plus a readily available supply of carbohydrates appears to furnish favorable conditions for root growth. Apparently there is a greater utilization of the carbohydrate reserves in carbohydrate-high cuttings grown in light than in those grown in darkness, and the utilization is greater in the cuttings grown in the solution plus nitrates than in those grown in a solution minus nitrates. A synthesis of nitrogenous materials usable in growth probably occurs in cuttings grown either in light or in darkness, but such synthesis appears to be greater in amount in light than in darkness. Light appears particularly favorable to the growth of shoots.

"The cuttings have a tendency to do what the plant has been doing. If the plant was producing shoots abundantly and roots to a relatively small extent, the basal cutting from such a plant tends to produce a few roots and some shoots, and the top cutting chiefly shoots, the combined effect being a greater total tendency toward shoot production. If the plant was producing roots abundantly and shoots to a small extent, the basal cutting tends to produce only roots, the top cutting to produce roots and some shoots, the combined effect being a greater total tendency toward root production."

Factors governing seasonal changes in transpiration of *Encelia farinosa*, E. B. SHREVE (*Bot. Gaz.*, 77 (1924), No. 4, pp. 432-439).—This investigation was undertaken to discover, if possible, the mechanism of reduction in relative transpiration found in the previous study (*E. S. R.*, 51, p. 822) to occur in *E. farinosa* under conditions of increasing acidity.

The difference in the anatomical structure of the mesophytic and xerophytic leaves does not account for the greater resistance to water loss in the arid season.

When disks of equal areas are cut from the two types of leaves immediately before sunrise and placed under identical external conditions, the water loss from them is found to vary inversely with the total imbibitional capacity and directly with the original water content. The total imbibitional capacity of both types of leaves varies with the original water content and the dry weight. The lower the original water content, the greater the amount of soluble material diffusing into the water which surrounds imbibing disks. The dry weights after imbibition have one constant value for mesophytic and another for xerophytic leaves. The ratio of evaporation to soil moisture affects the water content of leaf tissue, which in its turn affects the imbibitional capacity and resistance to water loss of leaf tissue. The changes in imbibitional capacity are accompanied by changes in the amount of soluble material in the tissue. These changes in diffusible material are supposed to be the resultants of reversible chemical changes which take up or give up water according to the amount available.

The range of toleration of hydrogen-ion concentration exhibited by *Fusarium tracheiphilum* in culture, A. J. MIX and D. L. VAUGHN (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 63).—Cultures of a strain of *F. tracheiphilum* from cowpea grew on agar at all concentrations tried between pH 2.6 and pH 11.8 and on potato dextrose broth between pH 2.96 and pH 11.42. These wide ranges are considered interesting when the specialized nature of the parasite is considered.

Cytological and physiological changes in *Vicia faba* irradiated with Röntgen rays, H. KOMURO (*Bot. Gaz.*, 77 (1924), No. 4, pp. 446-452, fig. 1).—Continuing earlier work (*E. S. R.*, 54, p. 626), this contribution follows up the preliminary note on the cytological experiments of 1922, and gives results of observations on physiological aspects of experiments of 1923. Methods are to be detailed later.

Both cytological and physiological observations are briefly indicated. The degenerative cytological change previously noted as quickly following exposure to Röntgen rays was found to begin as early as 1.5 hours after irradiation, and within 9 hours after exposure various stages of degeneration were observable. These resembled the conditions previously described, closely approximating those noted by the author, as well as by others, in tumor cells. Intermittent use of X-rays may be summed up to harmful doses by repeated exposure. The inferred bearing of these experiments on the therapeutic employment of X-rays is briefly discussed.

Preliminary study of rôle of salts in pollen tube growth, R. A. BRINK (*Bot. Gaz.*, 78 (1924), No. 4, pp. 361-377).—"The most striking feature of these results is the extreme sensitiveness shown by pollen tubes to salts."

The phenomena of antagonism between salts in relation to bacteria [trans. title], E. MISHUSTIN (MISCHUSTIN) (*Nauch. Agron. Zhur. (Jour. Landw. Wiss.)*, 1 (1924), No. 4, pp. 274-284; *Ger. abs.*, p. 284).—A study of the behavior of univalent and bivalent salts in connection with the development of bacterial cells has shown that the concentration of a salt, requisite to cause an inhibitory action on the development of an organism, depends wholly upon the properties of the components, as cation or anion in case of each salt. Osmotic pressure is not significant in this connection, the specific toxicity of the salt being the determining factor. The phenomena of antagonism of salts as between univalent and polyvalent metals vary with different bacteria analogously with the corresponding phenomena among more highly organized plants.

The measure of nontoxic antagonistic action of salts depends upon the concentration of the toxic salts. The phenomena of antagonism appear to be conditioned by the influence of the undissociated molecule. The greatest protection is afforded by such systems as those in which the anion of the antagonistic salts agrees with the anion of the poisonous salt, where dissociation of the antagonists is minimized.

Clogging of stomata of conifers in relation to smoke injury and distribution, J. B. RHINE (*Bot. Gaz.*, 78 (1924), No. 2, pp. 226-232).—The black deposit in the stomatal pits of certain conifers, thought to be soot, was found to be a natural product of the leaf. The substance in the stomata of fir, juniper, and Austrian pine proved to be a wax, finely granular. Though permeable to gases, it is thought to retard gas exchange, metabolism, and water loss. A remarkable parallel is evident between presence of this wax and xerophytism in the conifers, and between absence of this wax and mesophytism, as well as hygrophytism. No relation was found between wax in the stomata and the high sensitiveness of certain conifers to smoke, except that as a factor inducing xerophytism the wax may lower the resistance of the tree.

Crop injury resulting from magnesium oxide dust, F. J. SIEVERS (*Phytopathology*, 14 (1924), No. 2, pp. 103-113, fig. 1).—The injury to crops from a deposit of magnesium oxide from a magnesite plant in eastern Washington is described. It is shown that magnesium, when present in soils beyond certain amounts, produced injurious effects on oats, but that the normal soil in the valley in localities where it is outside the zone of influence from the calcining plant did not carry enough magnesium or alkali salts to cause injury to crops.

Wound healing of mesophytic leaves, R. B. WYLIE (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 53, 54).—A brief description is given of the method by which leaves repair damage done to them. The author believes that the temporary and permanent cicatrices formed protect leaves from the entrance of fungi.

GENETICS

Recent results relating to chromosomes and genetics, T. H. MORGAN (*Quart. Rev. Biol.*, 1 (1926), No. 2, pp. 186-211, figs. 16).—This paper presents an analysis of the more recent experiments bearing on polyploidy, sex chromosomes in dioecious plants, and the genetic factors carried in the Y chromosome.

Chromosome morphology in *Fritillaria*, *Alstroemeria*, *Silphium*, and other genera, W. R. TAYLOR (*Amer. Jour. Bot.*, 13 (1926), No. 3, pp. 179-193, figs. 60).—Following a general review of the phenomena of satellites and of chromosome constrictions, the author reports upon cytological studies of root tip cells in several species, *Fritillaria imperialis*, *Alstroemeria braziliensis*, *Silphium perfoliatum*, *Allium cepa*, *Bryophyllum calycinum*, *Freesia refracta*, and *Ricinus communis*.

Cytological studies in the Cucurbitaceae.—I, Microsporogenesis in *Cucurbita maxima*, E. F. CASTETTER (*Amer. Jour. Bot.*, 13 (1926), No. 1, pp. 1-10, pls. 2).—Using as a source of material young blossoms of a pure line of Hubbard squash developed by the Vermont Experiment Station (E. S. R., 46, p. 138), the author found that quadripartition of the pollen mother cell is effected by partition walls which originate on the inner surface of the special wall which is formed just inside the original mother cell wall. Definite but transitory cell plates were observed on the heterotypic and homoecotypic spindles, but these take no part whatever in the division of the pollen mother cell. The haploid number of chromosomes is 20.

Genetical and cytological studies of the origin of false wild oats, C. L. HUSKINS (*Sci. Agr.*, 6 (1926), No. 9, pp. 303-313, figs. 40).—Continued investi-

gations at the University of Alberta on the origin of false wild oats (*Avena sativa* mut. *fatuoida*) (E. S. R., 54, p. 442) are reported on, and the general trend of the work is pointed out, reference also being made to recent work of others.

Significant cytological irregularities were found in the reduction divisions of the pollen mother cells of fatuoid oats. In the three strains of homozygous fatuoids so far investigated the normal number (42) of univalent chromosomes appears to be present in all cells at diakinesis, but instead of these forming 21 pairs as in the normal *A. sativa*, abnormal groups of three or four united chromosomes are often seen in a high proportion of cells in the heterotypic division. Faintly staining masses, apparently chromosomes undergoing decomposition, are occasionally observed in the cytoplasm during the homotypic division. Much of the pollen is abortive. Similar but more frequent irregularities were observed in one strain of heterozygous fatuoids and its segregates. The following chromosome numbers have been found in *Avena*: *A. sativa*, *A. fatua*, *A. nuda*, *A. sterilis*, and *A. ludoviciana* 21 (42); *A. barbata* 14 (28); and *A. brevis*, *A. strigosa*, and *A. wiestii* 7 (14).

All homozygous fatuoids and normal segregates from heterozygous fatuoids have been found to breed true. Homozygous fatuoids, heterozygous fatuoids, and normal segregates in the ratio of 64:153:76 were obtained from a heterozygous fatuoid of Banner oats. The F_1 of reciprocal crosses between normal Banner and homozygous fatuoid Banner were indistinguishable from ordinary heterozygous Banner fatuoids, and gave similar progenies and ratios in F_2 . Statistical studies on the number of culms and height of the three classes of segregates from the heterozygous Banner fatuoid and from homozygous fatuoid \times Banner showed no significant differences in the means of the three forms. However, there seems to be a greater degree of variability among the homozygous fatuoid segregates. The author considers that the evidence is overwhelmingly against the theory that fatuoids arise by natural crossing. "They differ from normal oats by either a single factor or a group of factors very closely linked, probably the latter, and are considered to be true mutations. The cytological observations indicate that some chromosomal aberration rather than a change in a single gene is instrumental in causing their appearance. The genetic facts could also best be explained on the basis of a regional change or whole chromosome difference."

Cytological studies in *Trifolium* [trans. title], G. D. KARPECHENKO (KARPETSCHENKO) (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 14 (1924-25), No. 1, pp. 271-279, figs. 29; *Ger. abs.*, p. 279).—The diploid chromosome numbers in 24 species of *Trifolium* are listed.

Genetic-physiological analysis of heterostyly [trans. title], G. VON UBISCH (In *Bibliographia Genetica. The Hague: Martinus Nijhoff, 1925, vol. 2, pp. 287-340, figs. 21*).—An extensive review of studies on the genetics of heterostyly in *Primula*, *Fagopyrum*, *Forsythia*, *Linum*, *Lythrum*, *Oxalis*, etc., is presented, with discussion of physiological and environmental factors involved. The bibliography includes 81 titles.

A preliminary note on reversed badger-face pattern in sheep, J. A. F. ROBERTS and T. J. JENKIN (*Welsh Jour. Agr.*, 2 (1926), pp. 70-73, pl. 1).—In a previous report (E. S. R., 53, p. 228) the badger-face pattern in sheep was found to be inherited as a simple recessive factor, although considerable variation was also apparent. In the present paper, three ewes are described which possessed the reversed badger-face pattern. The limited data available indicate that this characteristic is inherited as a simple recessive to white, and that it is independent of the badger-face pattern and of black color.

Intelligence as a Mendelian character, H. R. HUNT (*Jour. Heredity*, 17 (1926), No. 2, pp. 53-58).—The author discusses the inheritance of intelligence from data from various sources, from which it is assumed that the multiple factor hypothesis offers the best explanation of the mode of inheritance. The theoretical offspring expected from matings of different genotypes on the assumption that five pairs of factors are responsible are tabulated. It is concluded that this theoretical explanation fits the available data quite accurately.

The evolution of the horse: A record and its interpretation, W. D. MATTHEW (*Quart. Rev. Biol.*, 1 (1926), No. 2, pp. 139-185, pl. 1, figs. 27).—An account is given of the evolution of the horse, based largely on a study of the series of fossils in the American Museum of Natural History. The steps in the evolution of the teeth and feet are particularly complete, and an effort is made to interpret the meaning of the changes in these parts.

The relation of inheritance studies to corn improvement, A. M. BRUNSON (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 4, pp. 308-314, fig. 1).—The findings to date in genetic research with corn are evaluated from a practical viewpoint.

Inheritance of carbohydrates and fat in corn, E. W. LINDSTROM and F. GERHARDT (*Abs. in Iowa Acad. Sci. Proc.*, 31 (1924), p. 133).—Chemical analyses of hybrid ears involving Iodent (yellow dent) and Evergreen (white sweet corn) varieties have shown that high sugar and dextrin (also low starch) are distinctly recessive in inheritance, although there is a small cumulative effect of the genetic factors represented in the endosperm development with its 3x condition. No such cumulative effect is present with respect to fat, the hybrids (reciprocal) being identical in value and intermediate in percentage but with a slight tendency toward a dominance of low fat. Carbohydrate and fat values are interrelated genetically, but this probably indicates a morphological relation within the kernel.

Genetic relation of endosperm and chlorophyll characters in maize, W. A. CARVER (*Iowa Acad. Sci. Proc.*, 31 (1924), p. 129).—In a study of the interrelation of sugary endosperm, virescent, and brindled (a chlorophyll defect in corn), brindled was found to be a simple Mendelian recessive to normal green and independent of virescent in inheritance. The double recessive condition of the factors for virescent and brindled produces an albino plant. The brindled character and sugary endosperm showed a linkage (in the repulsion phase) with 26.3 per cent of crossing over.

Notes on grasses [corn], P. WEATHERWAX (*Ind. Acad. Sci. Proc.*, 40 (1924), pp. 227, 228).—Preliminary reports are made on two investigations with corn at Indiana University.

Carpellody in maize.—A type of imperfect grain resembling defective kernels inherited as recessive seed characters is inherited as a recessive plant character, may occur in few or many of the spikelets of the ear, and is indicated as a case of carpellody. One, two, or all three of the rudimentary stamens in the functional pistillate flower are metamorphosed into the semblance of pistils. The style and stigma of these resemble those of the normal pistil, but the ovarian portion has neither true ovarian cavity nor ovule.

Many-flowered spikelets in maize.—A supposedly hereditary variation was found in which some spikelets of the corn tassel have assumed the indeterminate form, the lower flower being more advanced in development and the number of flowers increased to three or more. This is accompanied by a change in sex, the pistils instead of the stamens being functional.

Fasciated kernels, reversed kernels, and related abnormalities in maize, T. A. KIESSELBACH (*Amer. Jour. Bot.*, 13 (1926), No. 1, pp. 35-39, pls. 2).—A systematic search at the Nebraska Experiment Station disclosed that fasciated

or fused kernels occur rather frequently, being found in the 38 varieties, inbred pure lines, and crosses listed. In an average run of corn about 1 kernel in 200,000 was fasciated, but in some varieties this abnormality was 20 times as frequent. Fused kernels, misplaced germs, and reversed kernels all occur most often near the tips of the ears. The degree of fusion in fasciated kernels varies greatly.

False polyembryony in maize, T. A. KIESSELBACH (*Amer. Jour. Bot.*, 13 (1926), No. 1, pp. 33, 34, pl. 1).—Several cases of false polyembryony found during germination tests at the Nebraska Experiment Station are described and illustrated.

Some differences in the functioning of selfed lines of corn under varying nutritional conditions, G. N. HOFFER (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 4, pp. 322-334, figs. 7).—Experiments in progress at the Indiana Experiment Station in cooperation with the U. S. Department of Agriculture showed that the absorption abilities of selfed lines of corn and of crosses between them vary widely with respect to certain of the essential mineral nutrients and to the iron and aluminum salts in the soil solution. The quantities of certain ash constituents absorbed by the hybrids were intermediate between the amounts absorbed by the parent selfed lines, while the hybrids absorbed less iron and aluminum than either of the parent lines. Less iron and aluminum were absorbed by the hybrid in loam than in clay, the differences being inversely related to the increased growth. The absorption tendencies of the plants which resulted in the vigorous hybrid absorbing less of the two elements than either of the less vigorously growing parents seemed to be associated with heterosis. The heritable tendencies of certain selfed lines to have leaves develop "dying-between-the-veins" were apparently associated with a relatively higher percentage content of iron and aluminum in the dry matter of such leaves than in the normal leaves of each generation.

The comparative water economy of selfed lines of corn and their hybrids, T. A. KIESSELBACH (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 4, pp. 335-344, figs. 3).—Transpiration studies were conducted at the Nebraska Experiment Station, supplementary to field experiments, to indicate the relation of heterozygosity to the water economy of corn and to suggest the variability expected in this regard between different selfed lines and hybrids.

A definite relation apparently exists between heterozygosity and the water requirement of corn. Selfed lines reduced in size and productivity by inbreeding have higher water requirement ratios than either F_1 hybrids between them or than the original variety from which they were developed. F_2 hybrids also reduced in productivity have somewhat higher average water requirement ratios than the F_1 hybrids from which they are produced, although the effect is not so marked as with long-continued selfed lines. Considering water requirement ratios, no advantage accrues from having more than two selfed lines recombined into an F_1 hybrid. Double crosses and single crosses were about equally efficient in the use of water. The high efficiency of an F_1 hybrid involving eight selfed lines suggested that efficient synthetic varieties may also be produced. Different F_1 hybrids vary widely as to productivity, water requirement ratios, and total water transpired per plant.

Genetic linkage between chlorophyll and carotinoid pigments in maize, E. W. LINDSTROM (*Abs. in Iowa Acad. Sci. Proc.*, 31 (1924), p. 132).—Genetic analysis of the inheritance of the pigments chlorophyll and carotin (and xanthophyll) in corn indicated that these pigment groups are controlled by different genetic factors. Most of the genes for chlorophyll development seem to be inherited independently of the yellow-producing gene, *l*. However, a

case of linkage involving this yellow factor and one of the three complementary genes responsible for chlorophyll development in the seedling stage of corn has been found. These two linked genes, *w₂* and *l*, apparently belong with the *R-L-G* linkage group since they show typical linked inheritance with about 21 per cent of crossing over.

Cytological investigation of rye-wheat hybrids [trans. title], V. R. ZALENSKIĪ (ZALENSKY) and A. V. DOROSHENKO (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant Breeding)*, 14 (1924-25), No. 1, pp. 185-210, figs. 25; *Eng. abs.*, pp. 209, 210).—Cytological studies on rye × wheat hybrids from the F_1 to F_6 generations revealed that the processes in the somatic cells of the F_1 and subsequent hybrids take place normally, the difference between these and pure forms being limited to chromosome number. Anomalies characteristic of hybrids, observed in meiosis in the pollen mother cells, were most pronounced in the F_1 . Since F_1 pollen was not functional, pollination in this generation evidently took place from rye or wheat. F_2 and subsequent generations segregated into plants resembling (1) wheat, (2) rye, and (3) intermediates. The segregates resembling either parent were characterized by reestablishment of normal cytological processes and the return of normal fertility, whereas those in the intermediate group retained the anomalies in different degrees in the generations studied.

Pseudo-fertility in Nicotiana, F. F. SMITH (*Ann. Missouri Bot. Gard.*, 13 (1926), No. 2, pp. 141-172, figs. 4).—According to investigations at the Missouri Botanical Garden, in the *N. alata* × *N. forgetiana* hybrids, pseudo-fertility as defined by East and Park (*E. S. R.*, 38, p. 823) is exhibited in both self- and cross-sterile combinations and is of the same order in both cases. In *Nicotiana* pseudo-fertility was not found of the same order as true fertility, whereas it stands in direct relation to true sterility. No seasonal change in the degree of expression of pseudo-fertility was observed. Bagging the panicle increased the degree of pseudo-fertility, but since the effect was constant throughout these investigations the conclusions were not influenced. Pseudo-fertility was not seen in any of the self- and cross-sterile pollinations on plants of *N. alata*. Pollen measurements indicated that a larger percentage of abnormal pollen exists in families arising from self pollinations than in cross bred strains.

Investigation of the factorial constitution of some complex heterozygotic Oenothera, O. RENNER (*Untersuchungen Über die Faktorielle Konstitution Einiger Komplexheterozygotischer Önotheren*. Leipzig: Borntraeger Bros., 1925, pp. [2]+168, figs. 58).—The studies reported dealt with the behavior of hybrids between different forms of *Oenothera*, segregation ratios, the factors isolated and their linkage relations, lethal factors, and pollen characteristics.

Renner's studies on the genetics of Oenothera, A. H. STURTEVANT (*Quart. Rev. Biol.*, 1 (1926), No. 2, pp. 283-288).—The present review endeavors to show how the studies by O. Renner in Germany on the peculiarities of the evening primrose (*Oenothera* sp.) aid in explaining the genetic behavior of *Oenothera*.

Parthenogenesis in the grouse locust, Paratettix texanus Hancock, R. K. NABOURS and M. E. FOSTER (*Abs. in Anat. Rec.*, 31 (1925), No. 4, p. 358).—Among 2,479 matings of *P. texanus*, 15 produced 82 offspring, which were, with one exception, females, showing exclusively segregate and crossover patterns of the female parents, with no trace of the contrasting dominant color patterns of the males. Eleven offspring successfully tested were found to be homozygous for dominant maternal patterns. Further experiments with parthenogenetical offspring showed that they were those that would be expected from noncrossover and crossover gametes of the parents. Thus

segregation and crossing over appear to occur in individuals producing parthenogenically to the same extent as those producing bisexually. Reproduction seems to occur in either way, but females are much more prolific when mated than when unmated.

Piebald (Spanish) sheep and their crosses with other breeds, J. A. F. ROBERTS (*Welsh Jour. Agr.*, 2 (1926), pp. 66-69, pls. 2).—Crosses of various breeds of sheep with Piebald ewes and rams were found to give all black offspring except for a few with white spots on the top of the head and tip of the tail. When an F₁ ram resulting from the cross Piebald × Southdown was mated with Welch mountain ewes 6 white and 5 black lambs were produced, which indicated that the Piebald sheep possess a dominant factor for black. These sheep also appear to be homozygous for a recessive factor for spotting, but this has not been completely established.

Non-inheritance of the temperature effect on bar eye in *Drosophila melanogaster*, C. ZELENY (*Abs. in Anat. Rec.*, 31 (1925), No. 4, pp. 356, 357).—Since it has been demonstrated that the number of facets in bar-eyed *Drosophila* is affected by the temperature at which the larvae develop, tests were made to determine whether differences in hereditary constitution could be produced by continued subjection to different temperatures. The facet number of one group of individuals produced by inbreeding from a single pair of flies and allowed to develop at 17° C. was approximately two and one-half times that of the second group descending from the same individuals but kept at 27°. Transfers of the one line to the temperature of the other have been made in four tests, one after 64 generations, but so far no germinal changes have appeared which can be ascribed to the temperature effect.

Effects of ten generations of alcoholism upon albino rats, F. B. HANSON (*Abs. in Anat. Rec.*, 31 (1925), No. 4, p. 357).—Data are reported on control rats and rats treated with alcoholic fumes through 10 generations of brother and sister mating. All the individuals from both groups descended from a single pair of parents. In 4 of the 10 generations, the mean birth weight of the treated individuals was greater than that of the controls but not significantly greater. In the other generations the birth weight of the treated rats was lower than that of the controls, and in some cases this difference appeared to be significant. The experimental animals produced larger litters than controls in every generation except the first, and in some generations this difference was significant. The size of litter and birth weight were negatively correlated. At 20 days of age the treated animals were equal in weight to the controls, but after this age the treatment which began at that time tended to slow the growth rate. The grandchildren of the tenth treated generation showed no greater resistance to the alcoholic fumes than the corresponding control generation.

Alcohol and the sex ratio, F. HEYS (*Abs. in Anat. Rec.*, 31 (1925), No. 4, pp. 357, 358).—Data on the 10 generations of inbreeding for the 3,123 treated and control animals used in the above experiment showed that in 9 of the 10 generations there was no significant difference in sex ratio between the treated and control stocks. The combined results indicated that severe and prolonged administration of alcoholic fumes did not have a significant effect upon the sex ratio.

The physiological factors governing the proportions of the sexes in man, A. S. PARKES (*Eugenics Rev.*, 17 (1926), No. 4, pp. 275-293, fig. 1).—Data from various sources are presented which show the sex ratio of man at birth and for abortions at various ages, from which it is concluded that there is a large percentage of males at conception and that this percentage is reduced differently in different races by a differential mortality of the two sexes during gestation.

On the phenomena of sex transition in *Arisaema japonica* Bl., T. MAEKAWA (*Jour. Col. Agr., Hokkaido Imp. Univ.*, 13 (1924), No. 3, pp. 217-305, pl. 1, figs. 9).—Among the four species of *Arisaema* known to grow wild in the forests of Hokkaido, *A. japonica* has the widest distribution, and with 231 corms of this plant the author experimented from 1917 to 1922. He has been able to show that this species undergoes some conspicuous sex transformations in a very regular way. Transformation of sex does not ordinarily occur at random but in a definite manner from year to year. The process commences in its asexual state and proceeds through the male to the female state in which the plant is said to thrive for years. Sometimes the order in which sex transformation takes place is reversed, although this retro-transition of sex is limited to certain conditions, tending to revert to a normal course on reversal or removal of the disturbing conditions.

This plant, or its parts, may present aspects characterizing it as male, female, or asexual. The sexual expressions of this plant are not fixed characters. A relation of corm weight to sex reversion is noted. Sex in corms was successfully controlled by cutting away certain portions. The author believes that sex in this plant is determined by the quantity of the formative assimilation products; that is, by the assimilation products in the fresh form before they are stored in the reserve organ. The corm weight can, it is claimed, be regarded as an index of the sex of the corm. The formation process of the apical buds proceeds regardless of the presence or absence of the assimilation organs.

The process of the transition and retro-transition of sex may be predictable from the quantity of the assimilation products present when the formation of the new apical bud for the next year is taking place. For the female expression the greatest quantity of the formative assimilation products is required; for the male expression a medium quantity of these products is needed. In the asexual state, the sexual expression is not attained, presumably on account of the insufficient supply of the formative assimilation products.

The bibliography includes 55 titles, covering the period 1892-1924.

FIELD CROPS

Studies on the origin of cultivated plants, N. I. VAVILOV (*Tsentry Proiskhozhdeniia Kul'turnykh Rastenii*. Leningrad: Inst. Bot. Appl. et Amélior. Plantes, 1926, pp. 248, pls. 8, figs. 4; *Eng. trans.*, pp. 139-248).—Extensive accounts are presented in both Russian and English of the investigations of the author on the origin of the principal crops of the Old World. Special attention is paid to wheat, barley, oats, rye, millet, flax, and hemp. The several chapters dealing with geographical centers of origin of cultivated crops touch on investigational methods, principal forms of Old World crops, the ecological principle involved, geographical regularities, and the origin of primary crops. Weeds as progenitors of cultivated plants and mountain districts as the home of agriculture are also considered.

The relation of seeding practices to crop quality, T. A. KIESSELBACH (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 661-684).—Review of experimental data obtained at the Nebraska Experiment Station and other stations indicated that, as a general principle with cereal crops, practices leading to maximum average yields are also satisfactory from the viewpoint of crop quality.

Where corn is a full-season crop, seeding early during the normal planting season insures earlier maturity, lower moisture content, better keeping qualities, and higher viability if exposed to low freezing temperatures. Seeding all

small grains relatively early commonly leads to higher test weight and low percentage of hull in hulled crops. Although delayed seeding of wheat tends to increase its percentage of protein, a quality sought by the milling trade, its attainment by this means is at too much sacrifice of yield to be justifiable. Under climatic conditions represented by the State of Washington, where wheat may become infected through soil-borne smut spores, minimum smut infection may be attained by extremely early or late seeding, at the expense, however, of yield. A medium early date results in reasonably low percentage of smut and maximum yield of grain.

So far as concerns quality of grain, cereals may be planted at a rate conducive to highest acre yield. With forage crops, where fineness of stem adds to palatability and reduction in waste when fed, it is desirable to seed thicker than necessary to get the maximum yield. Ordinarily the yield will not be reduced thereby, and the forage will be finer and more leafy. For silage purposes, corn may be spaced somewhat closer than for grain to get maximum tonnage of feed. Unduly heavy seeding, however, results in no gain in yield and produces silage relatively low in proportion of grain. Concerning the manner of planting, practices designed to give maximum yield are satisfactory from the quality standpoint and are most effective in farm practice.

The formalin and copper carbonate treatments of smut-infected seed wheat seem to be efficient means in most of the country for increasing the yield, test weight, and freedom from smut. Treatment with copper carbonate containing about 20 per cent metallic copper is especially recommended.

Controlling quality of crops, H. L. WALSTER (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 618-622).—From the viewpoint of the usual methods of grading which emphasizes test weight, wheat in the rotation of potatoes, wheat, barley, and red clover at the North Dakota Experiment Station was lower in quality in three out of four years than wheat in the rotation of oats, wheat, red clover, flax, proso, and mangels (or sugar beets). However, the flour from wheat after potatoes was uniformly of high protein content, and in two of four years produced significantly larger loaves of bread.

Variation in the chemical composition of the seeds of oleiferous plants in dependence on geographical factors [trans. title], N. N. IVANOV (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 3, pp. 3-88, figs. 2; *Eng. abs.*, pp. 60-88).—Analyses of seed of flax, hemp, poppy, mustard, castor bean, colza, sunflower, sesame, safflower, and *Camelina glabrata*, grown under widely different environmental conditions in the Union of Socialist Soviet Republics, revealed a tendency for these crops to retain the constancy of their chemical composition. Regardless of the extreme climatic conditions, flax, for instance, produced seeds with almost the same oil and protein contents at all points; only the iodine values of the oil varied. The fact that certain flax varieties had high oil contents at all stations was apparently due to their larger size of seed. The fluctuations in protein content were also slight in comparison with that observed in wheat in the same localities.

Electroculture investigations (*Jour. Min. Agr. [Gt. Brit.]*, 33 (1926), No. 2, pp. 102-104).—Further pot experiments (E. S. R., 54, p. 434) at Rothamsted showed the consistent effect of electrification in increasing the grain yield of barley even in the absence of increased vegetative growth. Only small differences were observed between electrified and control plats with barley at Rothamsted and oats at Lincluden near Dumfries. A careful physiological study indicated that electrification of the plant led to fewer sterile flowers, less shriveled grains, and increased weight of grain. That in general a better result is had by electrification for a period less than the whole growing season

was again confirmed by the pot cultures of 1925. Low voltages continuously applied (1,000 volts and less) produced results as good as or better than high voltages (10,000 to 20,000).

Longevity of the legume nodule organism, T. E. RICHMOND (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 5, pp. 414-416).—Observations at the University of Illinois showed that legume nodule organisms can survive for many years in an acid soil in situ but are quickly killed by air drying the soil. The nodule organisms of the soy bean and cowpea were killed by a 3-year storage of a soil with a 6,000-lb. lime requirement, whereas only the soy bean organism was killed by similar storage of a soil with a 3,000- to 4,000-lb. lime requirement and both organisms survived 3 years' storage in soils needing 1 ton or less of lime. Seeds inoculated by the muddy water method retained viable organisms for only a very few days where an acid soil was used, but for almost a year with a neutral soil.

[Field crops experiments in British Guiana, 1922, 1923, 1924, and 1925], J. B. HARRISON and W. FRANCIS (*Brit. Guiana Dept. Sci. and Agr. Rpt.* 1922, pp. 4-10; 1923, pp. 4-10; 1924, pp. 4-10; 1925, pp. 4-10).—Experiments with sugar cane and rice are reported on as heretofore (E. S. R., 50, p. 134). Of the total cultivated area of the colony in 1925, 41.2 per cent was devoted to sugar cane and 21 per cent to rice. Leading among the sugar cane varieties in the 1926 crop were D. 625, D. 145, and D. 118, constituting 72.5, 5.2, and 3.5 per cent, respectively, of the total area in sugar cane.

[Agronomic experiments in Morocco, 1922-23 and 1923-24], E. MÈGE (*[Morocco] Dir. Gén. Agr., Com. et Colon., Expt. Agr. Rap. Ann.*, 1922-23, pp. 128, figs. 7; 1923-24, pp. 158, figs. 4).—Experiments at Casablanca, Fez, Marrakesh, and Meknes reported in these pages included varietal and cultural tests with wheat, barley, oats, rye, potatoes, and sugar beets; irrigation tests with wheat, alfalfa, cotton, tobacco, and potatoes; fertilizer trials with sugar beets, tobacco, and potatoes; and comparisons of miscellaneous legumes and grasses.

Angleton grass, V. E. HAFNER (*Texas Sta. Bul.* 342 (1926), pp. 3-11, figs. 2).—The characteristics and habits of Angleton grass (*Andropogon annulatus*) are described, with notes on methods of handling and the results of tests with the grass in different Texas localities. This grass, introduced from India, is considered valuable for pasture and hay and well adapted to the humid part of the Gulf Coastal Plains of Texas and to parts of the State having 30 in. or more of rainfall. It has succeeded on soils ranging from sandy loam to heavy clay. The grass is readily propagated from rooted runners and rooted plants and also from seed, although seed tested at the Angleton Substation have not germinated well. While Angleton grass has a deep fibrous root system and easily competes with other vegetation, it lacks root stocks and is readily eradicated.

Broomcorn, G. R. QUESENBERRY and R. R. WILL (*N. Mex. Agr. Col. Ext. Circ.* 91 (1926), pp. 26, figs. 18).—Production practices considered suitable for broomcorn raising in New Mexico are outlined, with instructions on harvesting and preparation for the market.

Seed corn curing and storing, D. F. RAINEY and F. E. FOGLE (*Michigan Sta. Circ.* 96 (1926), pp. 3-15, figs. 12).—Practical information is presented on the care and preservation of seed corn, equipment for drying and preparing seed is described, and plans, elevations, and illustrations show the essentials of several types of storage houses.

The effect of spacing on the yield of cotton, E. B. REYNOLDS (*Texas Sta. Bul.* 340 (1926), pp. 3-77, figs. 15).—Extensive spacing experiments with cotton

conducted at the station and substations since 1914 are reported on, and the results of spacing investigations without the State are summarized. The references include 123 citations.

The highest yields in general resulted from the close and medium spacing, 6 to 21 in., in the different parts of the State, except in eastern Texas, where comparatively wide spacing, 27 to 36 in., excelled. Twelve in. was found the optimum spacing at Angleton, Lubbock, and Spur, 9 to 12 in. at the station, 21 in. at Beeville and Temple, 27 in. at Nacogdoches, and 30 in. at Troup and Chillicothe. The cotton plant appears to be able to adjust itself to produce satisfactory yields within a comparatively wide range of spacing. Thinning cotton at the usual time generally produced larger yields than late or deferred thinning.

Cotton spacing, W. B. ROGERS (*Clemson Agr. Col. S. C., Ext. Circ. 78 (1926)*, pp. [4], fig. 1).—Spacings for cotton recommended as a result of experiments by the South Carolina Experiment Station (E. S. R., 54, p. 636) are for the Piedmont section 1 to 2 plants per hill spaced 8 to 12 in. apart in rows 3 to 3.5 ft. wide and for the Coastal Plain section 1 to 2 plants per hill spaced 8 to 12 in. apart in 4-ft. rows. The width of the row should be varied with the fertility of the soil. These spacings did not seem to affect the normal functions of the plant or the quality of the final product.

The effect of the sharâqi period upon the yield of cotton in Egypt, E. MCKENZIE-TAYLOR (*Egypt Min. Agr., Tech. and Sci. Serv. Bul. 57 (1926)*, pp. [1]+22).—Cotton yields were considerably larger on land subjected to a long summer fallow than after a short summer fallow. The decline in the yield seems directly attributable to the almost complete elimination of summer fallow due largely to the early seeding of corn. The author suggests postponing corn planting until August 10 and using the available water on rice in the northern areas.

Weather damage to cotton, R. L. NIXON (*U. S. Dept. Agr. Bul. 1438 (1926)*, pp. 15, figs. 4).—Bales of cotton were fully protected in the warehouse while others were variously exposed to the weather (E. S. R., 49, p. 33) in tests at 5 representative points in the Cotton Belt.

Unprotected bales placed with their flat surfaces next the ground without turning averaged a loss of 54.7 per cent of their original gross weight, bales on poles and protected by canvas lost 2 per cent, and bales placed on poles and turned once a week, or at least after each rain, lost an average of 3.9 per cent. All of the tests showed a direct relationship between the amount of moisture absorbed and the resulting damage. Since the fungi responsible for discoloration and decay of the fibers thrive best under temperate conditions, the cotton damaged much faster during spring and summer months.

Baled cotton should evidently be placed in a properly constructed warehouse under responsible management as soon after ginning as possible. If warehousing is impracticable, the bales should be stored in a dry place out of the weather or, as a last resort, they should be edged up on poles and turned at least weekly.

Report on the cotton-growing industry of Nigeria, 1926, C. N. FRENCH (*London: Empire Cotton Growing Corp., 1926, pp. 48, pl. 1*).—The status of the industry is described from the results of surveys early in 1926.

The production of cotton, G. H. COLLINGS (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, pp. XI+256, figs. 92*).—This volume relates the history and the climatic and soil requirements of cotton; discusses the morphology, classification, physiology, and chemistry of the plant; describes varieties and their classification; outlines cultural and fertilizer practices and breeding

methods; indicates important diseases and insects and their control; and traces the course of the fiber from the field to the market. Space is also accorded to by-products, feeding value of the plant and products, and the growing of American-Egyptian cotton.

Elephant grass, a new and useful fodder crop in western India, H. H. MANN (*Bombay Dept. Agr. Bul.* 127 (1926), pp. [1]+7).—Experiments at different centers in western India indicate that elephant grass should be tried as a perennial, heavy-yielding grass using a limited amount of water.

Critical notes on the Nicotiana in Argentina [trans. title], A. R. MILLÁN (*Rev. Facult. Agron. y Vet. Buenos Aires*, 5 (1926), No. 2, pp. 172-188, figs. 2).—Twenty-two wild species of Nicotiana are listed, omitting *N. tabacum*, *N. rustica*, and their cultivated varieties.

Potato storage investigations, 1924-1925 (Canton, Pa.: Marble Lab., [1926], pp. 174, pls. 16, figs. 36).—This report of the Pennsylvania Committee on Storage Investigations embraces a report of the investigational work carried on at the Marble Laboratory, Canton, Pa., 1924-1925, by L. M. Marble; a report of the condition of potatoes in experimental storage in the Marble Laboratory, by W. A. McCubbin; an account of field tests of the stored potatoes, by W. A. McCubbin and R. E. Hartman; and observations on potato storage conditions at the Coudersport, Pa., warehouse, 1924-1925, by W. A. McCubbin.

Rice in Azerbaijan and the adjoining districts of Persia [trans. title], M. BRZHEZITSKIĬ (BRJEZITZKY) and G. GUSHCHIN (GUSTCHIN) (*Trudy Prikl. Bot. i Selek. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 3, pp. 235-267; *Eng. abs.*, pp. 266, 267).—The results of a preliminary investigation of rice in Azerbaijan and Persia indicated that local rice in these countries is a mixture of varieties which in turn are mixtures of races.

Moisture in rice before and after milling, W. D. SMITH (*Rice Jour.*, 29 (1926), No. 6, p. 28).—Investigations by the Bureau of Agricultural Economics, U. S. D. A., showed that a moisture test for rough rice indicates fairly accurately within certain ranges the amount of moisture that may be expected in the rice after milling.

[Experimental work with sugar cane in Queensland, 1924 and 1925], H. T. EASTERBY (*Queensland Bur. Sugar Expt. Stas. Ann. Rpt.*, 24 (1924), pp. 1-12, 19-53, 57-59; 25 (1925), pp. 1-17, 26-79).—These reports describe the further progress (*E. S. R.*, 52, p. 735) of cultural, fertilizer, liming, green manure, and irrigation tests, trials of varieties and seedlings, and breeding work at the experiment stations in Queensland, and relate the status of the sugar industry in the State.

Sugarcane-breeding technique: Isolation of live arrows from undesired pollen through artificial rooting of canes, T. S. VENKATRAMAN and R. THOMAS (*Agr. Jour. India*, 21 (1926), No. 3, pp. 203-209, pls. 2, figs. 3).—A method by which a cane in short blade can be severed from the clump and isolated consists in inducing special rooting on the above ground portion of the stalk and removing the cane with the roots induced. Earthenware pots resembling flower pots were the only apparatus employed. The treatment had no appreciable harmful effect either on pollen formation or seed setting in the arrows.

Sulphur as a cane fertilizer, W. E. CROSS (*Facts About Sugar*, 21 (1926), No. 29, pp. 688, 689).—Application of sulfur to P. O. J. 36 and 213 sugar cane at planting at the Tucumán Experiment Station, Argentina, resulted in small but distinct increases in yields of cane and sugar during each of 3 years.

A study of cane burning before cutting, C. ALINCASTRE (*Sugar Cent. and Planters News*, 7 (1926), No. 5, pp. 272-285; also in *Facts About Sugar*, 21 (1926), No. 25, pp. 591-594, 599).—Observations made in Occidental Negros, P. I., during the 1924-25 season on the sugar losses due to delay in milling burnt sugar cane and comparisons of the rendements from burnt and unburnt cane indicated that when the points are not needed burning sugar cane before cutting would prove of much value if proper care were taken. By burning the cost of harvesting may be reduced from 1.50 to 1.20 pesos (75 to 60 cts.) per ton of sugar cane. Deterioration of the juice is quite rapid after 2 days of burning, and if the cane is not milled within this period the saving in labor may not compensate for the sugar loss. Burning should be done late at night or very early in the morning to avoid excessive "sweating out" of the juice and possible caramelization of sugar. The practice may be limited also by the number of cars to be loaded daily. Previous work along this line is reviewed.

An acreage census of cane varieties for the crops of 1925, 1926, 1927, J. A. VERRET (*Hawaii, Sugar Planters' Sta. Circ.* 46 (1926), pp. 40).—Tabulations show the different varieties of sugar cane and the areas devoted to each for the crops indicated on the islands of Hawaii, Kauai, Maui, and Oahu. Leading in the combined areas of 1926 and 1927 are H. 109 with 93,934 acres, Yellow Caledonia 71,299, D. 1135 33,077, Yellow Tip 14,626, Striped Tip 7,523, and Lahaina 3,583 acres.

Cultural experiments with sunflowers and their relative value as a silage crop, T. E. ODLAND and H. O. HENDERSON (*West Virginia Sta. Bul.* 204 (1926), pp. 16, fig. 1).—In comparisons on the station dairy farm, silage corn (Cocke Prolific) and sunflowers averaged about the same tonnage of green material per acre for two normal seasons, both outyielding the grain type of corn (Leaming) on this basis. The silage and grain corn in order outyielded sunflowers considerably on the air-dry basis. In the short growing season of 1924 sunflowers outyielded the two corns on both green and air-dry bases. On a somewhat poorer soil at the agronomy farm sunflowers averaged a little heavier in green tonnage per acre, but were far outyielded by both corn varieties on an air-dry basis.

Spacing the sunflowers 10 in. apart in the rows gave the best results, considering both yield and ease of handling. Leaming corn and sunflowers was not a satisfactory mixture, chiefly because of differences in maturity. Sunflowers planted at later dates did not give as uniformly good yields as when sown at the same time as corn. Sunflowers contained considerably more moisture than corn, whereas corn had a much higher carbohydrate content. Differences between the two crops in protein, ash, fat, and fiber contents were relatively small.

Botanical and agronomic investigations of annual vetches [trans. title], A. Ū. ТУРИКОВА (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 1, pp. 151-246, pls. 7, figs. 6; *Eng. abs.*, pp. 244-246).—Annual vetches are classified into a forage group, a grain-forage group, and a third group, chiefly weeds, on the basis of extensive studies with material grown in the vicinity of Moscow. The morphological characters of the vetches studied are grouped according to their systematic value in Russian-English tables.

The determination of the most important forage vetches [trans. title], V. S. МURATOVA (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 1, pp. 99-149, pl. 1; *Eng. abs.*, p. 105).—A dichotomous key has been devised for the determination of important agricultural species of *Vicia*. The areas of geographical distribution of 12 species are indicated on an outline map.

Liguleless durum wheats of the island of Cyprus [trans. title], K. FLÄKSBERGER (C. FLAKSBERGER) (*Trudy Prikl. Bot. i Selek. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 3, pp. 123-150, figs. 6; *Eng. abs.*, pp. 146-150).—Liguleless durum wheats from the island of Cyprus are described, and the phylogenetic and biological significance of the ligules in Gramineae is discussed. The author concludes that liguleless durum wheats (*Triticum durum eligulatum*), as well as soft liguleless wheats (*T. vulgare eligulatum*) and inflated forms (*T. vulgare inflatum*), are ancient forms preserved in the centers of origin.

Controlling the quality of wheat through rotation and proper crop sequence, R. I. THROCKMORTON (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 623-629, figs. 4).—The effect of cropping systems on the quality of wheat was studied at the Kansas Experiment Station. The systems included (I) a 16-year rotation comprising 4 years of alfalfa and 1 year of corn and 2 years of wheat alternating for 12 years; (II) the same as (I), but 5 tons of manure per acre applied every third year; (III) the same as (II), except that brome grass replaces alfalfa; (IV) a 3-year rotation of corn, cowpeas and hay, and wheat; (V) 2 years of corn and 1 of wheat; and (VI) continuous wheat.

During the 7 years, 1916 and 1919-1924, inclusive, wheat in cropping system I averaged 19.3 bu. per acre, II 21.4, III 25.1, IV 19.2, V 14.4, and VI 15.8 bu.; contained average protein contents on 12.5 per cent moisture basis, I 15.3 per cent, II 15.1, III 12.1, IV 12.8, V 12.7, and VI 14.2 per cent; produced averages of I 169 lbs., II 185.3, III 180.1, IV 144.2, V 106.6, and VI 130.1 lbs. protein per acre of wheat; and averaged I 54 lbs., II 55.2, III 58.4, IV 56.8, V 56.8, and VI 55.5 lbs. in test weight.

Wheat grades and wheat quality, C. E. MANGELS (*Natl. Miller*, 31 (1926), No. 8, pp. 25-27, 71, 72, figs. 3).—According to this contribution from the North Dakota Experiment Station the present specifications for numerical grades indicate the flour-producing capacity of wheat. The current grading system, however, does not reflect to any extent the capacity of wheat to produce flour of high baking strength. The protein content of the wheat at present is considered the best index of flour strength, and the subclass divisions of hard red spring wheat grades do not seem to be an accurate index of protein content.

Milling and baking tests with foreign and domestic wheats [trans. title], W. LAESSER (*Ann. Agr. Suisse*, 26 (1925), No. 5, pp. 683-704, figs. 21).—The results of comparative tests at Bern are tabulated and discussed for varieties of wheat, spelt, and rye.

Germination of old seeds of red and sweet clover and alfalfa, G. H. DUNGAN (*Seed World*, 19 (1926), No. 13, p. 26).—An experiment in the agronomy department, University of Illinois, demonstrated that seed of red clover, sweet clover, and alfalfa with initial high viability is not entirely unfit for seed purposes after 3 years. The percentage germination is reduced, and more seed should be sown to compensate therefor. Germinable seeds of red clover are injured more by age than sweet clover seed, which in turn are injured slightly more than alfalfa seed. Hard seeds of alfalfa are softened more readily by age than those of red clover, while hard seeds of sweet clover are the least affected.

Hard seed question at present, D. SCHMIDT (*Seed World*, 20 (1926), No. 1, p. 28, fig. 1).—Progress is reported on a project noted previously (*E. S. R.*, 54, p. 834).

Report of analyses of samples of seed collected in New York State, 1925 (*N. Y. State Dept. Farms and Markets, Agr. Bul. 182* (1925), pp. 69).—

Tabulations show the purity, weed seed content, and germination for 569 samples of agricultural seed, 12 samples of timothy-alsike mixtures, and 52 samples of special seed mixtures collected during 1925 and analyzed at the New York State Experiment Station.

The official seed-testing station, N. R. Foy (*New Zeal. Jour. Agr.*, 32 (1926), No. 5, pp. 340-347).—Records of the average germination and purity and incidence of the principal weed seeds are tabulated and discussed for 8,146 samples of agricultural seed tested at the New Zealand Seed-Testing Station at Wellington during 1925.

Spraying and dusting experiments with weeds in 1924 and 1925 [trans. title], P. BOLIN (*Meddel. Centralanst. Försöksv. Jordbruksområdet [Sweden]*, No. 303 (1926), pp. 117, fig. 1; *Eng. abs.*, pp. 106-110).—Continued investigations in Sweden (*E. S. R.*, 54, p. 239) showed sulfuric acid solutions (3 to 4 per cent) to average more effective in controlling weeds in cereals than solutions of iron sulfate, sodium nitrate, or brine, or dusting with Hoefer's weed powder or calcium cyanamide. The greater average yields made by the crops sprayed with sodium nitrate solution seem largely due to its fertilizing effect. Calcium cyanamide similarly surpassed Hoefer's weed powder. Dusting was not as effective as spraying in weed control. Best results with powdered chemicals seemed to be had by dusting the crop when wet with dew, i. e., early in the morning, especially when the dewy morning is followed by a hot, sunny day.

Destruction of the khaki weed, C. T. WHITE (*Queensland Agr. Jour.*, 25 (1926), No. 6, p. 512).—The khaki weed (*Alternanthera achyrantha*), native of South America and said to be spreading in parts of Queensland, is reported to be easily destroyed by common salt at the rate of 1 to 2 tons per acre. A solution containing 0.2 per cent of arsenic is also indicated as effective. Hand grubbing is best in small areas.

Some crops subduing weeds [trans. title], V. P. STRUVE (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 3, pp. 171-179; *Eng. abs.*, p. 179).—Potatoes, summer fallow, flax, *Brassica rapa*, and a mixture of vetch and oats showed ability to suppress weeds in the order given during three years at the Marussino (Tambov) Experiment Station. The seeding rate and the individual development of the crop seemed of essential importance. Too thick seedings showed as many impurities as thin ones. Only normal seedings could smother weeds. With normal seedings the weeds are subdued most effectively by crops whose growth curve parallels that of the weeds.

Three important perennial weeds of Colorado, C. F. ROGERS, L. W. DUBRELL, and L. B. DANIELS (*Colorado Sta. Bul.* 313 (1926), pp. 3-15, figs. 7).—Control methods are outlined for perennial weeds, with descriptions and specific information for the elimination of wild morning glory or bindweed (*Convolvulus arvensis*) and the two poverty weeds, woolly Franseria (*F. tomentosa*) and lesser marsh elder (*Iva axillaris*).

Idaho weeds: How to know and control them, J. C. AYRES, H. W. HULBERT, and C. B. AHLSON (*Idaho Agr. Col. Ext. Bul.* 65 (1926), pp. 73, figs. 32).—A general discussion of weeds and their control, with specific information on weeds important in Idaho.

Weeds of cultivated crops in the district of Pergamino, Buenos Aires [trans. title], L. R. PARODI (*Rev. Facult. Agron. y Vet. Buenos Aires*, 5 (1926), No. 2, pp. 75-171, pls. 7, figs. 19).—The characteristics and habitats are indicated for the commonest weeds in cultivated crops in the district of Pergamino, northwest of Buenos Aires. The weed flora in the flax and wheat seed are described, with a determinative key to the weed seeds, based on structure.

Weeds: Their identification and control, M. P. TULLIS (*Saskatchewan Dept. Agr. Bul. 57, 5. ed., rev. and enl. (1926), pp. 88, figs. 119*).—Practical information is given regarding weed habits and on the control and eradication of annual, biannual, and perennial weeds. The characteristics and illustrations of the plants and seeds of weeds important in Saskatchewan are presented to aid in identification.

HORTICULTURE

[**Horticultural investigations at Cheshunt, England**] (*Expt. and Research Sta., Cheshunt, Herts, Ann. Rpt., 11 (1925), pp. 8-67*).—Computed acre yields for tomatoes receiving top, base, and combined top and base dressings of manure were 40.6, 39.2, and 42.8 tons, respectively, a reversal of the previous season's results (E. S. R., 53, p. 639), when the base treated plants were slightly in the lead. Applications of graduated amounts of phosphorus, nitrogen, and potassium to tomatoes showed no benefit from the phosphates, regardless of the amount. Applications of sulfate of ammonia not only increased yields but reduced the percentage of blotchy fruits. Sulfate of potash was also effective in decreasing blotchy fruits and in stimulating yields. Indication that the maximum effective application of fertilizers had been reached in the tests was shown in reduced yields on plants receiving double the usual application of artificial fertilizers. In tomato variety tests Radio and Ailsa Craig gave the highest yields, 43.9 and 43.6 tons per acre, respectively.

In studies concerning the reduction in yield of the tomato crop resulting from the continuous use of the same soil, the maximum yield, 70.1 tons per acre, was obtained on manured plats allowed to lie idle in 1923 and 1924, leading to the suggestion that better results might be obtained with compost heaps to which the necessary fertilizers are added long in advance, rather than by applying raw materials directly to the plants. The application of grass cuttings restored the yields to practically the first year's standard, suggesting the value of green manures in soil renovation.

Work with cucumbers continued to show the value of steam sterilization. However, the character of the weather following planting determined the benefits of steaming. The application of animal manures following steaming gave poor results, a net loss of 23 per cent below the controls. The admixture of ashes in the soil was beneficial. A layer of gravel beneath the cucumber beds gave excellent results, as did the turning under of a mustard cover crop.

Steam sterilization increased the yields of plats from 28 tons in 1924 to 51 tons in 1925. The combination of steaming with cresylic acid treatment gave excellent results, suggesting the desirability of combining chemical and heat sterilization.

Carbon dioxide investigations, O. OWEN and T. SMALL (*Expt. and Research Sta., Cheshunt, Herts, Ann. Rpt., 11 (1925), pp. 119-122*).—As in the preceding year (E. S. R., 53, p. 640), an increase in the amount of carbon dioxide in the atmosphere of greenhouses increased the yield of tomatoes, in this instance over 20 per cent above the controls. Cucumber yields were also markedly benefited. Treated plants of both species were more vigorous at the end of the growing season than control plants. A commercial apparatus for liberating carbon dioxide failed to give sufficiently high concentrations of gas, but the decomposition of sodium bicarbonate in large earthenware vessels was successful.

Dry-land gardening at the Northern Great Plains Field Station, Mandan, N. Dak., T. K. KILLAND (*U. S. Dept. Agr. Bul. 1427 (1926), pp. 16, figs. 6*).—Information is offered upon climatic relations, rotations, varieties, time of

planting, time of maturity, yields, and the general performance of various species, with suggestions upon vegetable growing in the northern Great Plains area.

Sweet-corn breeding experiments, K. SAX (*Maine Sta. Bul. 332 (1926), pp. 113-144, figs. 11*).—Following a brief discussion upon sweet-corn improvement, the author suggests that the decrease in vigor generally accompanying self-pollination is more likely due to the recombination of hereditary factors in a more or less pure homozygous condition than to any injurious effect of the process itself. This was shown in the fact that no significant differences were found in the height of plant or the weight of ear of F_1 plants, whether inbred or crossed among themselves. The second generation of crosses between Golden Bantam and Black Mexican yielded black, yellow, and white kernels in the proportion of 12:3:1. The white segregates bred true, were of high quality, and proved valuable for crossing with other varieties. The progeny of crosses between inbred strains, especially those from different sources, were usually about twice as productive as the inbred parents and were frequently much more productive than the original parents.

Crosby corn reached canning maturity about 35 days after the first silk appeared and remained in good canning condition for approximately 5 days. The comparatively long period of retaining quality is considered one of the principal reasons for the superiority of Maine sweet corn over that grown in sections where higher temperatures prevailing at time of maturity tend to hasten changes in composition.

A preliminary report on the blooming and fruiting period of the tomato plant, W. CORBETT (*Expt. and Research Sta., Cheshunt, Herts, Ann. Rpt., 11 (1925), pp. 132-135, fig. 1*).—Daily records taken on the development of tomato plants showed periodic changes in the length of time elapsing between the opening of the blossoms and the ripening of the fruit. This period lengthened through the third truss but decreased in the fourth and fifth, and had a tendency to again lengthen thereafter.

The fruiting habit of the tomato, W. KRASSOWSKA (*Kwitnienie i Owocowanie Pomidorów Przy Różnych Formach Prowadzenia Roślin. Krakow: Nakładem Towarzystwa Ogrodniczego, 1926, pp. 20, figs. 4; Eng. abs., pp. 19, 20*).—Studies at the College of Agriculture, Warsaw, Poland, indicated that in pruning the tomato the natural bearing habit of the variety must be considered. Varieties tending to produce large clusters on the lower part of the stem may be pruned lower than those tending to bear their best fruits higher up the stem. Pruning gave an increased yield of early ripe fruit.

The manuring of tomatoes, B. THOMAS (*Jour. Min. Agr. [Gt. Brit.], 33 (1926), No. 4, pp. 342-346*).—In a greenhouse test at the Kirton Agricultural Institute, England, tomato plants fertilized with organic manures yielded more and better grade fruit than plants treated with inorganic materials. Of three substances, dried blood, guano, and fish meal, blood was most effective. Steamed bone meal proved a better source of phosphoric acid than did superphosphate.

Some factors influencing the period of blossoming of apples and plums, R. G. HATTON and N. H. GRUBB (*East Malling [Kent] Research Sta. Ann. Rpt. 1924, pp. 81-86, pls. 3*).—Data recorded on the blossoming of apple trees budded on ordinary mixed commercial fruit stocks showed a natural grouping of varieties into early, midseason, and late season, indicating that the effect of the rootstock was not dominant over that of the inherent varietal characters. Although the blooming periods of the earliest and the latest varieties generally overlapped, in some cases this overlapping was not enough

to insure satisfactory pollination. Seasonal conditions had a marked effect upon the length of the blooming periods. Observations on unpruned and pruned trees of a single variety showed that pruning delays blossoming. In one case the unpruned trees bloomed 15 days earlier than the pruned. A well-defined effect of rootstocks on blooming period was noted in plantings of a single variety budded on a number of different stocks.

Physiology, R. C. KNIGHT (*East Malling [Kent] Research Sta. Ann. Rpt. 1924, pp. 103, 104*).—Investigations conducted by the East Malling Research Station in collaboration with the plant physiology department of the Imperial College of Science and Technology indicated that the transpiration rates of leaves of different apple stocks were differently influenced by the same factors, while a single variety worked on the various stocks failed to show any such differences. Hence the author concludes that the effect of stock on scion can not be attributed to transpiration differences.

Studies in hardwood cutting propagation indicated that callus formation is favored by high soil moisture content, while soil aeration favors root formation. Attempts to influence rooting by the introduction of various substances into the cuttings failed to yield satisfactory results. Notable variation was recorded in the rooting ability of plum seedling stocks. Myrobolan B generally rooted 70 per cent while Myrobolan A, C, and D gave less than 10 per cent.

Observations upon softwood cuttings showed that varieties differed markedly in the optimum time for taking, in the best rooting media, etc. The Mahaleb and some of the Austra cherries, which root with difficulty by stool and layer and not at all from hardwood cuttings, may be readily rooted with softwood.

The insertion of two or three buds upon a certain stock resulted in less new stem and more blossom buds per branch, indicating that quantitative factors, apart from the normal influence of the rootstock, may affect the growth of the tree.

On "burr-knots" of fruit trees, R. G. HATTON, H. WORMALD, and A. W. WITT (*Jour. Pomol. and Hort. Sci., 5 (1926), No. 3, pp. 195-204, pls. 2*).—Based on propagation tests and microscopic examinations at the East Malling Research Station, the authors conclude that burrknots are a normal characteristic of certain apple trees, thus corroborating the conclusions reached in the United States by Swingle (*E. S. R., 53, p. 843*). A review of early English horticultural literature and observations among practical growers showed that knot-bearing limbs have long been considered as favored propagating material because of the easy rooting tendencies.

Two years work with commercial fertilizers, C. C. VINCENT (*Idaho State Hort. Assoc. Proc., 24 (1924), pp. 39-43*).—Two years' records of yields obtained by the Idaho Experiment Station following the application of various fertilizer materials in apple orchards at Dalton Gardens and Lewiston, and in apple, pear, and prune orchards in the vicinity of Moscow, failed to show any profitable results from fertilizer treatments.

Adsorption as a means of determining relative hardness in the apple, S. DUNN and A. L. BAKKE (*Plant Physiol., 1 (1926), No. 2, pp. 165-178*).—Determinations made at the Iowa State College with the aid of a colorimeter of the amounts of various dyes adsorbed from solution by the ground tissue of apple twigs of 22 varieties collected in November, 1924, at Shenandoah, Iowa, showed in the case of methylene blue and malachite green a definite alignment in accord with established hardness. The results of the studies are believed to indicate rather conclusively that the hydrophilic colloids are able, by virtue of their relatively enormous adsorptive surfaces, to hold water within the cell and prevent death from the dehydrating force of freezing, and that the prop-

erty may be measured quantitatively by adsorption of aniline dyes from solution.

Some results of apple pruning in New Jersey, A. F. MASON (*Penn. State Hort. Assoc. Proc.*, 66 (1925), pp. 9-12).—The severe pruning in 1923 of overgrown, bushy Rome Beauty apple trees resulted in decreased yields the season following the pruning. However, in 1924 the pruned trees outyielded the controls, and in both years the pruned trees produced a much higher percentage of high-grade fruit.

Progress report on apple root stock investigations, G. T. SPINKS (*Jour. Bath and West and South. Counties Soc.*, 5. ser., 20 (1925-26), pp. 183-187).—By the process of layering, selected apple stocks, described in an earlier report (E. S. R., 39, p. 645), were sufficiently increased to furnish material for budding to standard varieties. An examination of the root systems of clonal stocks worked with the Lane Prince Albert variety showed considerable differences in type from those of the parent rootstock. Realizing that stock propagation by seed is a more rapid and economical method of propagation, the author has budded seedlings of known parentage to the Stirling Castle variety. To test the effect of quantitative factors a lot of seedlings of unknown parentage were worked with the Bramley Seedling, following careful grading according to the size and character of the root systems. Seedlings of fruits which breed fairly true are being studied as regards their stock value.

Cherry stocks: Their behaviour in the nursery, N. H. GRUBB and A. W. WITT (*East Malling [Kent] Research Sta. Ann. Rpt. 1924*, pp. 87-92, pl. 1).—A comparison of selected clonal varieties of cherry stocks with ordinary mixed commercial seedlings showed the superiority of the clonal varieties. In 14 asexually propagated stocks, 94 per cent of the trees were ready for budding at 3 years of age. At the same time seedlings at 4 years contained less than 34 per cent of comparable plants. Analyzed statistically, asexual stocks were found to be very much more uniform.

The peach orchard from cleared land to bearing trees, W. S. ANDERSON (*Mississippi Sta. Circ. 66* (1926), pp. 4).—Brief directions are given for the selection of varieties, planting, cultivating, fertilizing, pruning, and the control of pests.

Studies in the root and shoot growth of the strawberry in season 1924-25, E. BALL and C. E. T. MANN (*Jour. Bath and West and South. Counties Soc.*, 5. ser., 20 (1925-26), pp. 190-199, pls. 3).—Observations upon Royal Sovereign strawberry plants deflorated in the spring following their setting in the field showed them to be much more vigorous in the weeks following the natural fruiting season than comparable untreated plants. In respect to season of planting, Sir Joseph Paxton plants set in early September made much more satisfactory growth than those set in late October of the same year. Deep planting was much less harmful than shallow planting. The trimming of the roots of young strawberry plants had no effect upon the ultimate condition of the plants, although it resulted in the development of more new roots.

Banana investigations, J. S. DASH (*Trop. Agr. [Trinidad]*, 3 (1926), No. 8, pp. 167-169).—Time of planting studies at the Imperial College of Tropical Agriculture, Trinidad, with suckers of the Gros Michel variety indicated the inadvisability of planting during the dry season. Furthermore the plants which survived were less productive than those set out in favorable seasons. Observations on several introduced lots of the Gros Michel banana failed to reveal any individuals resistant to Panama disease. Sugar cane served as an effective windbreak for bananas.

Grenada Giant Fig bananas placed in cold storage at temperatures averaging 48° F. failed to ripen satisfactorily, all the fruits turning black within three

weeks. However, when the bananas were subjected to a moderate cooling, about 60° for three days and then lowering to about 48°, the fruits kept in good condition and ripened satisfactorily at between 60 and 70°. A third test in which Gros Michel and Canary bananas were included gave favorable results, indicating that all three varieties are suitable for transportation to distant markets.

Regarding the curing of cacao, F. L. STEVENS (*Trinidad and Tobago Dept. Agr. Bul.*, 21 (1925), No. 1, pp. 27-35; also in *Trop. Agr.* [Ceylon], 66 (1926), No. 6, pp. 328-333).—Experiments conducted at the University of Illinois with cacao pods supplied by the United Fruit Company indicated that a much higher grade product may be obtained by careful curing. Temperatures ranging from 40 to 60° C. (104 to 140° F.) maintained for several days killed the embryo of the seeds without destroying the enzymes, which are believed by the author to be essential in oxidizing the embryo to the desired light tan color. Beans cured by the experimental methods were much freer from objectionable acidity than ordinary commercial stock, leading the author to suspect that acidity is probably due to yeasts and bacteria which can not occur at the temperatures utilized in the studies. Oxidation proceeded equally well, whether beans were submerged in water or were dry.

Citrus-culture: Variety and root-stock experiments at Tauranga, J. H. DAVIDSON (*New Zeal. Jour. Agr.*, 32 (1926), No. 4, pp. 219-232, figs. 17).—Brief observations are presented upon the behavior of orange and lemon varieties upon various stocks, including lime and *Citrus trifoliata*.

Improvement of trees by bud selection, E. S. WEST (*Agr. Gaz. N. S. Wales*, 37 (1926), No. 6, pp. 469-473, fig. 1).—Observations at the Commonwealth Citrus Research Station at Griffith, N. S. Wales, revealed instances of bud mutation in oranges.

Manurial experiments with citrus trees, W. LE G. BRERETON and W. B. STOKES (*Agr. Gaz. N. S. Wales*, 37 (1926), No. 6, pp. 463-468).—Records taken at Narara, N. S. Wales, upon three plats of Valencia orange trees, all receiving 3 lbs. of bone dust and 3 lbs. of superphosphate per tree but differing in potash treatments, showed that potash favorably influences yield and the size of the fruit, but has little effect on skin texture.

Experiments on the germination of African oil palm seeds, E. A. CURTLER (*Malayan Agr. Jour.*, 14 (1926), No. 4, pp. 84-87).—Observations upon the effect of soaking in warm water and of immersion in 1 per cent hydrochloric acid upon the rapidity and amount of germination of African oil palm seeds showed both treatments to be slightly beneficial. However, in the case of 5 per cent hydrochloric acid germination was reduced.

Growth and correlation in the oil-palm (*Elaeis guineensis*), T. G. MASON and C. J. LEWIN (*Ann. Appl. Biol.*, 12 (1925), No. 4, pp. 410-421, figs. 3).—Observations upon 77 oil palms growing near Ibadan, Nigeria, showed that young trees have two flowering cycles, one in the autumn and one in the spring, closely corresponding to the periods of equal day and night. As the trees grow older the spring flowering cycles tend to disappear, due, in the authors' opinion, to the exhaustion of food reserves caused by the increased size of the bunches. The sex ratios of individual trees varied from season to season, the excess of male inflorescences becoming particularly noticeable in the December flowering period.

The effect on tea crop of a leguminous crop while growing, H. R. COOPER (*Indian Tea Assoc., Sci. Dept. Quart. Jour.*, 1925, No. 4, pp. 127-137).—Heavy cover crops of *Cajanus indicus*, induced by large applications of lime, had a deleterious effect on tea yields, reaching a maximum of 37 per cent decrease in

one instance. The author recommends that cover crops of the nature of *C. indicus* be planted very early and cut down frequently to prevent competition with the tea.

Practical soil sterilization by heat for glasshouse crops, W. F. BEWLEY (*Jour. Min. Agr. [Gt. Brit.]*, 33 (1926), No. 4, pp. 297-311, pl. 1, figs. 2).—A comprehensive discussion of the principles and practices of soil sterilization based on investigations at the Experimental and Research Station, Cheshunt. Of three methods, namely, steaming, baking, and chemical treatment, steaming is deemed by far the most efficient.

School and home gardens, C. L. QUEAR (*Lincoln, Nebr.: University Pub. Co.*, 1926, pp. VIII+248, figs. 123).—A small handbook of practical information.

Ancestral lines of the cactus, A. BERGER (*Die Entwicklungslinien der Kakteen. Jena: Gustav Fischer, 1926, pp. IV+105, figs. 87*).—The botanical relationships and probable origin of various forms of cactuses are discussed. It is considered likely that South America was the original home of the cactus family.

FORESTRY

Red alder of the Pacific Northwest: Its utilization, with notes on growth and mangament, H. M. JOHNSON, E. J. HANZLIK, and W. H. GIBBONS (*U. S. Dept. Agr. Bul. 1437* (1926), pp. 46, figs. 11).—Red alder, described as the leading hardwood of the Pacific Northwest, is, because of its color, medium weight, and ease of working, extensively used in the manufacture of furniture, cabinets, etc. This paper discusses the distribution; supply; annual consumption; properties of the wood; seasoning practices; utilization by industries; methods of lumbering; transportation; stumpage, log, and lumber values; characteristics, growth, and yield; and perpetuation of the supply. Volume tables are presented, with notes on the uses of the wood, and a directory of producers and consumers.

Utilization of dogwood and persimmon, J. B. CUNO (*U. S. Dept. Agr. Bul. 1436* (1926), pp. 43, figs. 24).—Dogwood and persimmon woods, because of their hardness, toughness, fineness of texture, and smooth wearing qualities, are highly prized in the manufacture of shuttles, bobbins, mallet heads, pulleys, golf-club heads, and many other articles. This paper discusses the present distribution and the extent of the supplies of the two woods, the annual cut, methods of cutting and handling, structure and physical and mechanical properties of the wood, the manufacture of shuttle blocks and other products, and substitute species with notes on their possible value.

The mahogany tree [trans. title], A. C. NOLTÉE ET AL. (*Dept. Landb., Nijv. en Handel Nederland Indië., Meded. Proefsta. Boschw.*, No. 15 (1926), pp. II+125, pls. 30; *Eng. abs.*, pp. 95-101).—Information of a general nature is given concerning species furnishing commercial mahogany, the distribution of the trees throughout the world, and the silvicultural requirements.

An elementary manual on Indian wood technology, H. P. BROWN (*Calcutta: Govt.*, 1925, pp. XIII+121, pls. 47, figs. 2).—Original information is presented upon the gross and anatomical structure of important Indian woods.

DISEASES OF PLANTS

[**Plant diseases and plant protection**], SCHANDER (*Landw. Jahrb.*, 60 (1924), No. 2, pp. 162-191).—Results obtained from a considerable number of tests of protectives against common diseases affecting important plants are presented, with a report and discussion of meteorological conditions in the Provinces Grenzmark and Brandenburg east of the Oder.

Spray injury, H. C. YOUNG and R. C. WALTON (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 61).—A study of spray injury to apple, pear, and peach showed that injury following sulfur sprays could be classed as edge burn, leaf scald, and gooseneck with lime sulfur, and injury following scab, and yellow leaf with most types of sulfur sprays. Copper spray injury was as serious on leaves as the sulfur sprays and caused russetting on the fruit of Greening apples. Weather conditions are believed to influence the amount of injury.

Colloidal sulphur as a spray material, H. C. YOUNG (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 61, 62).—A preliminary report is given of tests of the fungicidal value of colloidal and precipitated sulfur in New York, Pennsylvania, Virginia, Illinois, and Michigan. In all States both mixtures controlled scab, and there was no injury to foliage except with one application of colloidal sulfur in New York. When applied to peaches, grapes, cherries, and pears colloidal sulfur slightly injured the foliage in some instances, but the precipitated sulfur caused no damage.

Colloidal sulphur as a spray material, H. C. YOUNG (*Ann. Missouri Bot. Gard.* 12 (1925), No. 2, pp. 133-143).—Recent studies (E. S. R., 50, p. 345) not in accordance with conditions in most of the sulfur sprays in general use, led to experimentation testing the comparative values of representative sprays in a commercial way. Although the seasonal conditions made it difficult to draw definite conclusions, the results show that the precipitated sulfur was not quite so effective as lime sulfur, although it was more effective than dusts, dry mix, or wettable sulfur. Its value exceeded that of lime sulfur on account of comparative freedom from foliage injury and high percentage of clean fruit.

Precipitated sulfur showed no spray injury to apple foliage or young peach leaves. Colloidal sulfur caused some burning, but this was not economically important.

On sweet and sour cherries, grapes, and plums, colloidal sulfur caused injury in the form of burning on grapes, while precipitated sulfur caused none in any case. Both showed inferiority in cases cited as regards adherence.

Commercial products listed are expected to prove fungicidal, provided their reaction point is around pH 4.2-5.

Experiments with inoculated sulphur for scab control, J. G. LEACH and R. C. ROSE (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 57).—Experiments with inoculated sulfur are said to have yielded variable results, and the type of soil on which the sulfur is applied is believed to influence the effectiveness of the treatment.

Fusarium culmorum in Oregon, its varieties and strains that cause disease of cereals and grasses, J. P. ROSE (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 49).—The author claims that in addition to *F. culmorum* there are in Oregon at least three varieties and one strain, all of which cause disease in Triticum, but in different degrees. *F. culmorum* and closely allied forms attack wheat and oats, and *F. culmorum leteius* attacks wheat, oats, corn, rye, barley, and various grasses.

Fusarium culmorum var. leteius, a cause of disease in cereals and grasses, J. P. ROSE (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 50).—As a result of laboratory, greenhouse, and field experiments it was found that this fungus caused a seedling blight of spring and winter wheats, as well as diseased conditions of mature plants of barley, oats, rye, and several grasses. In controlled inoculation experiments the fungus was found to cause a severe scabbing of wheat.

A bacterial disease of broomcorn and sorghum, C. ELLIOTT and E. F. SMITH (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 48).—Broomcorn, sorgo,

grain, and grass sorghums are said to be attacked by *Bacterium andropogoni*, sorgos being most susceptible, grass sorghums most resistant, and the grain sorghums intermediate. Attempts to infect maize and millets were unsuccessful.

Mosaic cross-inoculation studies, O. H. ELMER (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 55).—The transmission of mosaic is reported from 14 other genera of plants to tobacco; from 8 genera to tomato; from *Curcubita moschata* to cowpea and soy bean; from tomato to *C. moschata*; from eggplant to cowpea; and from tobacco to *Martynia louisiana*.

Wheat resistant to mildew, Erysiphe graminis, E. B. MAINS (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 48).—Tests were made of 650 strains of wheat grown under greenhouse conditions to determine their susceptibility in the seedling stage to mildew. Several varieties of bread wheats were practically immune, while among the other wheats Khapli, Vernal emmer, and einkorn were outstanding in resistance.

Copper carbonate prevents stinking smut (*U. S. Dept. Agr., Misc. Circ. 76* (1926), pp. 4, figs. 2).—Directions are given for the use of copper carbonate for the control of bunt or stinking smut of wheat.

Relative susceptibility of red clover to anthracnose and mildew, J. MONTEITH, JR. (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 62, 63).—Italian clovers which are susceptible to anthracnose are most resistant to mildew, while some American strains which are resistant to anthracnose are very susceptible to mildew.

An investigation of clover root rot, W. J. YOUNG (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 63).—The author claims that some species of *Fusarium* associated with clover root rot are weak parasites which infect clover but require the cooperation of other deleterious agencies to cause serious damage.

Experiments to show the effects of certain seed treatments on corn, C. S. REDDY and J. R. HOLBERT (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 44, 45).—Tests are reported of the effect of treating corn with a number of seed disinfectants used in various ways.

Formaldehyde, calcium hypochlorite, corrosive sublimate, and copper sulfate treatments decreased stands and yields. No detrimental effects, and frequently increased stands, followed the use of Chlorophol on nearly disease-free seed, or in composite samples of corn infected with *Fusarium*, *Cephalosporium*, *Diplodia*, and scutellum rot. There was an increase in stands and yields from *Diplodia*-infected seed treated with Chlorophol, and a decrease from composite seed samples infected with *Cephalosporium*, *Fusarium*, and scutellum rot.

Second progress report on studies of corn seed germination and the prevalence of *Fusarium moniliforme* and *Diplodia zeae*, L. E. MELCHERS and C. O. JOHNSTON (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 45).—In continuation of previous observations (*E. S. R.*, 53, p. 850) the authors report that practically every ear of commercial white and Pride of Saline corn examined was infected with either or both *F. moniliforme* and *D. zeae*. *D. zeae* varied in its occurrence from year to year, but *F. moniliforme* was always abundant. Freedom from *F. moniliforme* is not considered as important as seedling vigor in securing a stand and yield of corn.

Common molds of corn seed in relation to yield, C. D. SHERBAKOFF (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 46).—Field experiments are said to indicate that corn seed freed from *Fusarium moniliforme* did not give any better yield than untreated seed of the same corn. The author concludes that under the conditions of his experiments contamination of corn seed with the mold had no effect on the yield.

Relation of internal cob-discoloration to yield in corn, R. A. JEHL, F. W. OLDENBURG, and C. E. TEMPLE (*Abs. in Phytopathology, 14 (1924), No. 1, p. 46*).—Plats of corn were grown from seed taken from ears, the cobs of which were discolored, and from ears that showed no discoloration. A correlation was shown between internal cob discoloration and yield of corn which was pronounced on light sandy and poor clay soils.

Corn resistant to rust, *Puccinia sorghi*, E. B. MAINS, F. J. TROST, and G. M. SMITH (*Abs. in Phytopathology, 14 (1924), No. 1, pp. 47, 48*).—A report is given of tests of about 2,800 plants of 15 selfed varieties of sweet and 5 selfed varieties of dent corn to determine their susceptibility to corn rust. Varying resistances were noted. Ten varieties of sweet and all dent varieties produced some resistant individuals.

Studies of anthracnose infection in cotton seed, C. A. LUDWIG (*Abs. in Phytopathology, 14 (1924), No. 1, p. 52*).—A summary is given of investigations on the control of cotton anthracnose. Seed stored for three years under laboratory conditions was found safe for planting. Heating and drying the seed did not control the disease, and delinting seed with sulfuric acid, followed by sterilizing with corrosive sublimate, reduced but did not eliminate it.

***Physalis* and cucurbit mosaic intertransmissible,** M. N. WALKER (*Abs. in Phytopathology, 14 (1924), No. 1, p. 56*).—Inoculation experiments have shown that mosaic of *Physalis* sp. and cucurbits is interchangeable.

Experiments on the control of cucurbit mosaic, S. P. DOOLITTLE and M. N. WALKER (*Abs. in Phytopathology, 14 (1924), No. 1, p. 56*).—The elimination of pokeweed, milkweed, *Physalis* spp., and wild cucumber practically controlled mosaic disease of cucumbers.

Further investigations on the pasmo disease of flax, W. E. BRENTZEL (*Abs. in Phytopathology, 14 (1924), No. 1, pp. 48, 49*).—Additional information is presented regarding the disease of flax caused by *Phlyctacna linicola* (E. S. R., 53, p. 851).

Tipburn of lettuce, R. C. THOMPSON (*Colorado Sta. Bul. 311 (1926), pp. 3-31, figs. 6*).—The results are given of three years' field and greenhouse studies of some of the factors involved in tipburn injury, and the data presented are said to give a new aspect to the physiology of lettuce tipburn. The author claims that the generally accepted supposition that the disease results from excessive loss of water from the leaf has not been substantiated by his experiments. The failure met with in every attempt to produce tipburn by subjecting plants to conditions favorable for rapid transpiration, in contrast with the ease with which the disease can be produced under other conditions, indicates that the injury does not result from desiccation of the tissue. Furthermore, high humidity was found to be favorable for the development of the disease. The development of tipburn in an environment of very reduced light intensity, at a temperature near 70° F., and under conditions of high humidity, is believed to eliminate the possibility of its resulting from direct physical injury by heat, light, or dry atmosphere.

Summarizing other conclusions, it appears that lettuce plants high in sugar content are more resistant to tipburn than those low in total sugars. Diseased plants are usually more succulent than healthy ones, and excessive irrigation favors the development of tipburn. Light was found to have little influence as a causal agent, practically all the burning occurring in darkness. The disease is said to develop under conditions favorable for active respiration, and the indications are that it is a respiration phenomenon due to excessive accumulation of respiratory products.

It was found that the conditions which limited the rate of growth reduced the extent of tipburn. Limited water supply, low temperature, concentrated

soil solution, and root binding when grown in pots, all resulted in checked growth and less tipburn.

Formaldehyde and other disinfectants in the control of lettuce diseases, W. S. BEACH (*Pennsylvania Sta. Bul. 202 (1926)*, pp. 3-28, figs. 7).—The growing of lettuce in the open field, coldframe, or seed bed is said to be seriously affected by attacks of *Sclerotinia sclerotiorum*, *Botrytis* sp., *S. minor*, and *Rhizoctonia solani*.

The author conducted a series of experiments at the station field laboratory at Bustleton, near Philadelphia, for the control of these diseases, especially lettuce drop caused by *S. sclerotiorum*.

As the result of tests of various treatments extending from 1919 to 1926, lettuce seed beds treated with formaldehyde showed a reduction in the prevalence of *S. sclerotiorum*, and seedlings transplanted to the field showed an increase in the percentage of stand with seed-bed treatment. In the transplanted crop the control was mainly that of *Botrytis* sp. and *R. solani*. Treatments with formaldehyde gave a largely increased return only when the soil was used primarily for the growth of lettuce seedlings.

An investigation of the killing effect of formaldehyde upon the sclerotia of *S. sclerotiorum* in garden soil at the laboratory showed that efficient destruction of the sclerotia occurred when near the surface of the soil. The treatments were less effective than those reported by Krout (*E. S. R.*, 49, p. 246), due, it is believed, to the heavier nature of the soil, preventing the thorough distribution of the fungicide. Factors of importance to be considered as favoring the efficiency of formaldehyde control of lettuce drop are a damp condition of the sclerotia prior to treatment, a loose or friable condition suitable to the soil, and the working of the soil in the course of treatment to aid the even distribution of the disinfectant.

In the author's experiments formaldehyde was spread upon the soil in very concentrated strength followed by the application of water. This did not show any difference in efficiency as compared with applications of a 1:100 strength of formaldehyde, but there was an important saving in the labor of application.

The test of a considerable number of fungicides and chemicals besides formaldehyde for the control of drop showed that none were efficient in reducing the disease that were not injurious to the crop or too expensive for use.

Pocket atlas of potato diseases.—II, Plant excepting tubers, O. APPEL (*Taschenatlas der Kartoffelkrankheiten. II. Teil. Staudenkrankheiten. Berlin: Paul Parey, 1926*, pp. [25], pls. 20).—This little book, uniform in plan and treatment with the first volume, previously noted (*E. S. R.*, 55, p. 47) and treating of tuber diseases, deals with diseases of the rest of the plant, considered separately.

Potato seed treatment tests in Manitoba, G. R. BISBY (*Abs. in Phytopathology, 14 (1924)*, No. 1, p. 58).—Neither corrosive sublimate, copper sulfate, copper carbonate, nor Semesan exerted any effect in preventing the development of black scurf in the soil. Semesan increased the yield somewhat. Both inoculated and noninoculated sulfur reduced scab but did not lessen the amount of black scurf. All treatments gave better results in controlling scab than black scurf.

Loss of strength of mercuric chloride solutions used for treating potatoes, R. P. WHITE (*Abs. in Phytopathology, 14 (1924)*, No. 1, p. 58).—Experiments are said to show that the strength of a 1 to 1,000 corrosive sublimate solution, used to disinfect potato tubers, was reduced to 57.4 per cent of the original when 4 lots of whole tubers were treated, and to 12.5 per cent when cut tubers were so treated. The weakening of the strength of the solution is

said to be proportional to the surfaces exposed that may act as absorbers of the mercury ions.

Spraying vs. dusting for potatoes, J. G. LEACH (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 57, 58).—Experiments conducted in 1922 and 1923, in which Bordeaux mixture, copper calcium arsenate, and nicotine dusts were compared, show increased yields of 34 per cent for the liquid and 12 per cent for the dust applications in 1922, and 9 and 3 per cent, respectively, in 1923.

Some factors influencing the development of potato scab, G. B. SANFORD (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 58, 59).—Experiments under controlled conditions of moisture and temperature showed that a maximum of scab occurred in dry soils at from 14 to 22° C. (57.2 to 71.6° F.) and soil moisture appeared to exert a greater effect on the development of scab than temperature. Scab developed in the drier soils, while moist soils tended to inhibit growth. Dry soils were more acid than the same soils moistened. Tubers were most susceptible to scab before they reached 0.5 in. in diameter. With the Cobbler variety the maximum infection occurred between 40 and 50 days after planting.

Further results in the inheritance of immunity to potato wart, F. WEISS and C. R. ORTON (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 59).—Tests of first generation hybrid potatoes and a few F₂ plants showed in their reaction to wart disease that immunity was dominant and that reciprocal crosses between immune and susceptible parents reacted similarly. Indications were obtained of there being two factors producing immunity which act simultaneously.

Infection-court in radish black-root, J. B. KENDRICK (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 66).—The natural wound at the point where the secondary root emerges from the cortex of the primary root is said to be the avenue of infection for the black root fungus (*Rheosporangium aphanidermatus*).

The relation of *Chenopodium murale* to curly-top of the sugar beet, E. CARSENER and C. F. STAHL (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 57).—Attention is called to the fact that leafhoppers which winter on *C. murale* do not transmit curly top to sugar beets or produce it in a very mild form. This is believed due probably to an attenuation of the virus when passed through a resistant plant.

Sugar beet seed disinfection with formaldehyde vapor and steam, C. RUMBOLD (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 66).—Exposing sugar beet seed balls for 20 minutes to a mixture of formaldehyde vapor and steam, with a temperature of 140° F., was found to kill fungus spores and bacteria associated with the seed balls. Field tests have shown no decrease in germination, and an increase in production from treated seed is reported.

Root diseases of sugar cane in Porto Rico, M. T. COOK (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 59).—The author reports the presence of *Colletotrichum falcatum* on roots of weak and dead canes.

Minnesota sunflower diseases in 1923, A. W. HENRY and H. C. GILBERT (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 64).—Sunflowers are said to have been defoliated in different sections of Minnesota by *Septoria helianthi* and *Puccinia helianthi-mollis*.

The mosaic disease of sweet potatoes, with special reference to its transmissibility, H. R. ROSEN (*Arkansas Sta. Bul.* 213 (1926), pp. 16, pl. 1, figs. 3).—In 1920 the author described a mosaic disease of sweet potatoes occurring in Arkansas (E. S. R., 44, p. 345), and since that time it has been reported to occur in Florida, Mississippi, Texas, and Kansas. Only one variety, Nancy Hall, has thus far been found susceptible to the disease.

In the previous account the author reported his inability to transmit the disease through artificial infections, but subsequent experiments have proved

its infectious nature. It was found necessary to keep the plants in a growing condition for 12 or 13 months by inoculating them in the field, growing slips from them in the greenhouse over winter, and transplanting into the field. When this procedure is followed, it is found that the disease develops gradually, becoming more severe as time advances, until a certain maximum is reached. Frequently only a small proportion of the runners show the disease on any one plant. There was also noted a recedence of the disease on some plants which had at one time been severely infected.

The results of this investigation are said to suggest that the disease is not capable of being transmitted to healthy plants under natural conditions in the northern sweet potato sections, while in the southernmost regions, as around the Gulf of Mexico, there is ample opportunity for transmission.

Observations on malformed tassels of teosinte plants infected with downy mildew, J. H. CRAIGIE and W. H. WESTON, JR. (*Abs. in Phytopathology, 14 (1924), No. 1, p. 49*).—A description is given of abnormal growths of teosinte infected with *Sclerospora philippinensis*.

Angular leaf-spot and wildfire infection of tobacco plant beds by spitting, W. D. VALLEAU and C. HUBBARD (*Abs. in Phytopathology, 14 (1924), No. 1, p. 51*).—The authors claim that the habit of laborers of chewing natural leaf tobacco of the previous crop and spitting in seed beds is responsible for the occurrence and spread of diseases.

Disinfection of tobacco seed against wildfire, J. JOHNSON and H. F. MURWIN (*Abs. in Phytopathology, 14 (1924), No. 1, pp. 50, 51*).—Formaldehyde and corrosive sublimate treatments have been found not suited for disinfecting tobacco seed against *Bacterium tabacum*. Experiments of the authors with other methods showed that treatment of seed for 15 minutes in a 1 to 1,000 solution of silver nitrate gave good disinfection without injury to the seed.

Experiments with dusting and spraying for the control of tobacco wildfire in seed-beds, J. JOHNSON (*Abs. in Phytopathology, 14 (1924), No. 1, p. 50*).—The application of copper-lime dusts and Bordeaux mixture sprays to control seed bed infection was insufficient in most cases to overcome possible damage resulting from transplanting slightly diseased plants in the field. Dusts and sprays are believed to be partially beneficial through the mechanical barrier they offer to infection.

Progress report on Phytophthora-resistant tobacco, W. B. TISDALE (*Abs. in Phytopathology, 14 (1924), No. 1, pp. 51, 52*).—When tested on infested soil, plants grown from seed of healthy Big Cuban tobacco in badly diseased fields showed a high degree of resistance to black shank caused by *P. nicotianae*.

Progress report upon the resistance of commercial strains of tobacco to root-rot, C. R. ORTON and O. OLSON (*Abs. in Phytopathology, 14 (1924), No. 1, p. 51*).—Three commercial strains and two others of less importance of Pennsylvania Broadleaf and Havana types of tobacco have been found highly resistant to *Thielavia basicola*.

Cytological studies on tobacco mosaic, T. E. RAWLINS and J. JOHNSON (*Abs. in Phytopathology, 14 (1924), No. 1, pp. 55, 56*).—Cytological studies on tobacco mosaic are said to have shown at least three distinct abnormal cell inclusions in chlorotic tissue, but no conclusion is reached as to their causal connection with the disease.

The mosaic disease of *Nicotiana glutinosum* not distinct from tobacco mosaic, M. N. WALKER (*Abs. in Phytopathology, 14 (1924), No. 1, p. 57*).—The identity of the mosaic of *N. glutinosum* with that of tobacco is affirmed.

A study of resistance to western yellow blight of tomato varieties, J. W. LESLEY (*Hilgardia [California Sta.], 2 (1926), No. 3, pp. 47-66, fig. 1*).—The

results are given of comparative tests of the resistance of varieties, selections, and hybrid tomatoes to the western yellow blight. The experiments were carried on in two localities for three seasons.

The disease is said to have varied widely, according to the season and place of trial. Against an attack of moderate severity in which about half the plants of the check varieties Stone and Santa Clara Canner blighted in the whole season, Dwarf Champion, Red Pear, and Dwarf Aristocrat showed a fair degree of resistance. They also showed resistance to a more severe attack if the first part of the blight period only was taken into account. The Globe variety is reported somewhat resistant, while Norton was found about as susceptible as Stone. The currant tomato appeared somewhat more susceptible to blight than Santa Clara Canner. None of the varieties had sufficient resistance to survive an attack of extreme severity in the early part of the season. Three years' selection for blight resistance in the commercial variety Santa Clara Canner resulted in strains with resistance about equal to that of the dwarfs and Red Pear.

The author claims that the resistant character of the dwarfs behaves as a recessive and appears to depend on the gene for dwarf or possibly on a gene or genes more or less closely linked with it. The reaction of the variety Red Pear and the standard selection showed that resistance might be obtained without the gene for dwarf. It is believed that if resistance is genetically of more than one kind, it might be possible by crossing to breed a variety with increased resistance to blight.

Studies on apple blotch in Ohio, W. G. STOVER and C. MAY (*Abs. in Phytopathology, 14 (1924), No. 1, p. 60*).—An examination of Smith Cider apple twigs showed viable spores in blotch cankers from the middle of April until the middle of August. The first infections were found from June 4 to 8, inclusive, or 16 days after the fall of the petals, and they continued until after July 27. The disease was first observed on fruits on June 29. It is believed that many, if not all, twig cankers originate from petiole infections.

Bordeaux mixture in five applications gave an average of 90 per cent of the fruit blotch free. No one application was more important than any of the others.

First progress report on the study of apple scab under Ohio conditions, W. G. STOVER and H. W. JOHNSON (*Abs. in Phytopathology, 14 (1924), No. 1, p. 60*).—Several phases of the apple scab problem were studied on Rome Beauty trees in a season favorable for scab development, 86 per cent of the fruit being scabbed on unsprayed trees. The discharge of ascospores of *Venturia inaequalis* began on April 4 and continued until June 8. The disease was noticed first on the leaves on May 22 and on the fruit on June 4.

Liquid lime sulfur and Bordeaux mixture gave good control, but neither sulfur dust nor copper arsenic dust was commercially satisfactory. Fair control was secured on trees sprayed with lime sulfur before bloom and dusted with sulfur afterwards. Some foliage injury followed the application of Bordeaux mixture after blooming. The pink spray was the most important single application, the prepink spray having been of practically no value.

Functional diseases of apples in cold storage, F. KIDD and C. WEST (*Gt. Brit. Dept. Sci. and Indus. Research, Food Invest. Bd. Spec. Rpt. 23 (1925), pp. VI+15, pls. 13, fig. 1*).—The several sections of this report (which is said in a prefatory note to bring to date a previous paper bearing the same title) deal with apple scald, internal breakdown, brown heart, and frost injury. Literature cited includes 33 titles.

Functional diseases of apples in cold storage (*Jour. Dept. Agr. Victoria*, 24 (1926), No. 3, pp. 152-154).—An abridgement by J. E. Harrison has been prepared of the report presented by Kidd and West as above noted.

Seed transmission of root-knot nematode resistance in the peach, J. A. McCLINTOCK (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 62).—Second generation seedling peach trees grown in nematode-infested soils are said to indicate that nematode resistance is transmitted to a high degree through at least two generations.

Diseases of raspberries and blackberries, B. O. DODGE and R. B. WILCOX (*U. S. Dept. Agr., Farmers' Bul.* 1488 (1926), pp. II+33, figs. 20).—Popular descriptions are given of mosaic and related diseases of raspberries and various fungus diseases of raspberries, blackberries, and dewberries, together with suggestions for their control.

Powdery mildew of raspberries, J. G. LEACH and J. L. SEAL (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 61).—Attention is called to a mildew affecting red and black raspberries in Minnesota, the affected plants showing considerable resemblance to mosaic or leaf curl.

Transfer of mosaic disease from red to black raspberries, R. B. WILCOX and F. F. SMITH (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 55).—Field and greenhouse experiments have shown that the aphid (*Amphorophora rubi*) is capable of transmitting mosaic from red to black raspberries.

Three little known diseases of strawberries, C. D. SHERBAKOFF (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 60, 61).—The author reports the occurrence in Tennessee of a lilac soft rot of strawberries associated with a species of *Pythium*; a hard rot, from which a *Rhizoctonia* was isolated; and a black rot, from which a sterile fungus was cultured.

Fungous diseases of the China aster, W. O. GLOYER (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 64).—The leaf spots caused by *Ascochyta asteris*, *Botrytis cinerea*, *Coleosporium solidaginis*, and *Septoria callistephi* were controlled with Bordeaux mixture. *Ascochyta*, *Botrytis*, *Fusarium* sp., and *Septoria* are seed borne, and seed treatment with corrosive sublimate is said to be more practicable than spraying. *Botrytis*, *Fusarium*, *Rhizoctonia solani*, and *Septoria* may cause damping-off and rot. Asters are said to be subject to other diseases during the seedling and seed producing stages, but *Fusarium* and *Septoria* may attack them at any period in their growth.

Septoria and damping-off were controlled by applying corrosive sublimate (1 to 2,000) about the seedlings.

Insect transmission of aster yellows, L. O. KUNKEL (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 54).—Experiments are cited which indicate that aster yellows is transmitted by the leafhopper, *Cicadula sex-notata*. This insect is believed to be responsible for most if not all of the spread of the disease about New York City.

Two bacterial diseases of gladiolus, L. McCULLOCH (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 63, 64).—A leaf blight of gladiolus caused by *Bacterium gummysudans* and a rot of the basal portions of the leaves due to *B. marginatum* are briefly characterized. *B. marginatum* also causes a characteristic disease of the corms (*E. S. R.*, 52, p. 654).

A flagellate infection of milkweeds in Maryland, F. O. HOLMES (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 54).—The presence of *Herpetomonas elmasiani* in all parts of *Asclepias syriaca*, except the seeds and roots, is reported.

Present status of stem and bulb nematode in America, G. H. GODFREY (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 62).—Attention is called to the increasing importance of *Tylenchus dipsaci*, which is becoming widespread in

this country. The possibility of strains of the nematode and the adaptation of new hosts to it are pointed out.

Chestnut blight in Europe (*Endothia parasitica*), H. METCALF (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 52).—The occurrence of chestnut blight is reported at Bruges, Belgium, and the dead fungus has been found on a chestnut staging pole in London. It is thought that the fungus may have been carried to Europe on chestnut poles or timber during the war.

Control methods against chestnut black canker [trans. title], J. DUFRENOY (*Off. Agr. Régional Massif Cent., Clermont-Ferrand, Bul. 5* (1925), pp. 27, pl. 1, figs. 11).—Recognizing, as most probably the primary agent in European chestnut black canker, *Blepharospora cambivora*, previously described and more recently reported upon by Petri (E. S. R., 54, p. 255), the author gives a somewhat circumstantial discussion of this disease, control measures tested or proposed, and attempts at reconstitution of growths destroyed by chestnut black canker.

Observations on the Douglas fir canker (*Phomopsis pseudotsugae*) in Great Britain, H. METCALF (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 52).—Douglas fir canker is reported in England and Scotland, where the Douglas fir has been extensively planted, but not as yet in America or Continental Europe.

Wind dissemination of aeciospores of *Cronartium ribicola*, L. H. PENNINGTON (*Abs. in Phytopathology*, 14 (1924), No. 1, pp. 52, 53).—The extensive distribution of the white pine blister rust in the Pacific Northwest is attributed to the dissemination of wind-borne aeciospores of the fungus.

Survey of blister rust infection on pines at Kittery Point, Me., and the effect of *Ribes* eradication in controlling the disease, G. B. POSEY and E. R. FORD (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 53).—Complete eradication of *Ribes* in 1917 is said to have prevented further infection of pines and permitted natural restocking of the area.

Controlling white pine blister rust in the Northeastern States, E. C. FILLER (*Abs. in Phytopathology*, 14 (1924), No. 1, p. 53).—Since the inauguration in 1917 of the campaign for the eradication of *Ribes* as a control measure against the spread of white pine blister rust, more than 2,500,000 acres have been practically cleared, and the cost has been reduced from 72 cts. per acre in 1918 to 20 cts. in 1923. Further commercial damage to white pines is believed to have been prevented in the areas treated through the eradication of *Ribes*.

ECONOMIC ZOOLOGY—ENTOMOLOGY

Voles of the genus *Phenacomys*, A. B. HOWELL (*U. S. Dept. Agr., Bur. Biol. Survey, North Amer. Fauna No. 48* (1926), pp. IV+66, pls. 7, figs. 11).—The first part of this work (pp. 1-37) consists of a revision of the genus *Phenacomys*, in which 10 forms are recognized. The second part (pp. 39-60) deals with the life history of the red tree mouse (*Phenacomys longicaudus* True), including an introduction, description of the nests, young, food, habits, behavior, and enemies. A bibliography of four pages is appended.

The normal food of *P. longicaudus* apparently consists solely of the fleshy part of the needles and the bark from the tenderest growth of the twigs of fir trees, and in captivity it will accept no items other than coniferous even though reduced to dire straits of hunger. Experiments with various fare, including cereals, fruits, vegetables, grasses, and twigs of deciduous trees and of redwood, failed to show that any of these was sampled or even noticed. The mouse's manner of obtaining food is to cut from the tree tender, terminal twigs 3 to 8 in. long. Some of these are inadvertently dropped to the ground,

many are probably eaten upon the spot, and some are carried to the nest, if near by, for more leisurely consumption.

A short season and its effect upon the preparation for reproduction by the Columbian ground squirrel, W. T. SHAW (*Ecology*, 7 (1926), No. 2, pp. 136-139, pl. 1).—This is a further contribution on the biology of the Columbian ground squirrel from the Washington Experiment Station (E. S. R., 55, p. 757).

The susceptibility of the coyote (*Canis lestes*) to tularaemia, R. R. PARKER (*Pub. Health Rpts.* [U. S.], 41 (1926), No. 28, pp. 1407-1410).—The author found that three young coyotes, 4 to 6 months of age, became infected with acute tularaemia by feeding them the tissues of Belgian rabbits and guinea pigs just dead of typical infections. Death occurred in 13, 22, and 53 days after the first feed of infectious material. It is pointed out that the susceptibility of coyotes and the evident possibility of fatal infection suggest that tularaemia may be a factor, at least, in the diminution of the abundance of coyotes which is so frequently noted following the decimation of rabbit populations in the same localities.

Fur laws for the season 1926-27, F. G. ASHBROOK and F. L. EARNSHAW (*U. S. Dept. Agr., Farmers' Bul. 1515* (1926), pp. II+28).—This is the twelfth annual summary of the fur laws (E. S. R., 54, p. 52).

Directory of officials and organizations concerned with the protection of birds and game, 1926, compiled by T. DENMEAD and F. L. EARNSHAW (*U. S. Dept. Agr., Dept. Circ. 398* (1926), pp. 12).—This is the usual annual directory (E. S. R., 54, p. 256).

The evolution of ornithology, M. BOUBIER (*L'Évolution de l'Ornithologie. Paris: Libr. Félix Alcan, 1925, pp. II+308*).—A discussion of the advancement made in the field of ornithology.

Aviculture (*London: Avicultural Society, 1925, vol. 1, pp. [7]+326+16, pls. 27*).—A treatise consisting of contributions from nine authors on the management of foreign and British birds in captivity.

New records of nematodes of birds, E. B. CRAM (*Jour. Parasitol.*, 12 (1926), No. 3, pp. 180, 181).—The author records the collection of *Dispharynx spiralis* from the turkey (*Meleagris gallopavo*), at Churchton, Md., and the collection by A. A. Allen, of Cornell University, of *Echinuria uncinata* from the black duck (*Anas rubripes*), *Contracaecum micropapillatum* from the goldeneye (*Glaucionetta clangula*), and *Contracaecum* sp. from the ruffed grouse (*Bonasa umbellus*). It is said to be apparent from the examination of specimens from New England, New York, and Michigan that *B. umbellus* commonly harbors *Ascaridia lineata*, the species that is common in chickens in the United States.

A key to the snakes of the United States, Canada, and Lower California, F. N. BLANCHARD (*Mich. Acad. Sci., Arts, and Letters, Papers, 4* (1925), pt. 2, pp. XIII+65, figs. 78).—An illustrated key for the separation of 191 species and subspecies of snakes, with data on the geographic distribution of each.

The bull snake as a natural enemy of injurious rodents, F. L. HISAW and H. K. GLOYD (*Jour. Mammal.*, 7 (1926), No. 3, pp. 200-205, figs. 3).—This contribution from the Kansas Experiment Station discusses methods by which the bull snake *Pityophis sayi* (Schl.) captures its prey, the relation of ecdysis to feeding habits, and the potentiality of the snake as a destroyer of rodent pests. It is shown to be an important enemy of pocket gophers, the burrows of which are entered by the snake.

The relation of animal pest control to conservation, J. J. DAVIS (*Ind. Acad. Sci. Proc.*, 40 (1924), pp. 375-382, figs. 8).—This account is based upon the replies received to a questionnaire sent to the county agricultural agents of Indiana.

Fighting pests with airplanes, A. W. MORRILL (*Calif. Cult.*, 67 (1926), No. 3, pp. 53, 71, fig. 1).—In reviewing control work through use of the airplane, the author records the application of dust to tomatoes and peas on the west coast of Mexico and to melons in the Imperial Valley in California during the season of 1925–26. It was thoroughly demonstrated on the west coast of Mexico that large areas of vegetable crops can be economically treated with insecticides and fungicides under conditions making the successful operation of ground machinery impossible. It was found that from 8 to 10 ft. was the best height for the plane to travel above the tops of the tomato vines, and that calcium arsenate could be effectively distributed for a distance of about 150 ft., or 75 ft. on each side of the plane.

The ecology of parasites, A. S. PEARSE (*Ecology*, 7 (1926), No. 2, pp. 113–119, fig. 1).—A brief discussion presented as the presidential address before the Ecological Society of America, at Kansas City, in December, 1925.

Entomology: Programme of research with brief progress reports (*East Malling [Kent] Research Sta. Ann. Rpt. 1924*, pp. 139–166, pls. 2).—Papers here presented include the following: The Study of Resistance of Various Apple Stocks to Attacks of Certain Insect Pests (pp. 139–142), Preliminary Field Trials of Tar Distillate Washes (pp. 143, 144), and The Control of the Apple Blossom Weevil, *Anthonomus pomorum* L., Curt. (pp. 145–157), previously noted from another source (*E. S. R.*, 53, p. 558), all by a A. M. Masee; The Control of Big Bud Mite in the Field, by R. G. Hatton, J. Amos, and H. M. Tydeman (pp. 158–164); and Specimens and Pests Received during the Year, by A. M. Masee (pp. 165, 166).

Report of the chief entomologist for the year 1925, R. W. JACK (*South Rhoësia Dept. Agr. Rpt. Sec. 1925*, pp. 19–23).—The work of the year is considered under the headings of pests of citrus fruits, cotton pests, medical and veterinary entomology, mosquitoes, bloodsucking midges, etc.

Two important enemies of bluegrass pastures, H. GARMAN (*Kentucky Sta. Bul. 265* (1926), pp. 31–47, figs. 4).—The first part of this bulletin (pp. 31–44) deals with the blue-grass plant bug, officially known as the meadow plant bug. It was first observed in blue-grass Kentucky in 1908, and gradually increased in numbers until in 1924 the pest drew the attention of seed handlers and stockmen. It became evident that year that it is capable of ruining the seed crop. A study of its life history shows that it does much damage when the seeds are immature. It does no harm after the crop is stripped, remaining in the egg stage in the old grass stems during the summer and the following winter. It hatches in greatest numbers among blue grass that has not been closely grazed by stock, along fences both inside and outside of pastures and by roadsides where stock is not permitted to roam. In Kentucky the author found it to place its eggs only in blue-grass stems, but observations made in Maine indicate that it also utilizes the stems of timothy and other grasses. It is believed that getting rid of old growths of stems by any practical means will reduce the injury, and close grazing at all times in infested pastures is the most practical means for accomplishing this end.

The second part (pp. 44–47) deals briefly with the spring grain aphid or green bug (*Toxoptera graminum*), which was found in April, 1925, to be present in large numbers in and about blue grass and associated with the meadow plant bug. By May they had completely disappeared from the pastures, not merely by migrating to other host plants, but many having been killed by a parasitic fungus (*Empusa* sp.), lady beetles (*Hippodamia parenthesis*), and syrphus fly larvae.

Notes on the insect pests of red clover in mid and west Wales, J. R. W. JENKINS (*Welsh Jour. Agr.*, 2 (1926), pp. 221–228, pl. 1).—The author gives a

list of the more important and commonly occurring insect pests of red clover in mid and west Wales, together with a brief account of the damage caused by each pest. Investigations conducted showed that insect attack on red clover in the seedling stage results in a lowering of the plants' vitality and consequent reduction in the first year's yield.

Insect pests of cotton in New South Wales, W. R. GURNEY (*Agr. Gaz. N. S. Wales*, 34 (1923), No. 12, pp. 887-893, figs. 7; 35 (1924), Nos. 1, pp. 49-55, figs. 7; 2, pp. 137, 138, figs. 3; 6, pp. 422-428, figs. 4).—This is a summary of information on the insects attacking cotton, together with control measures.

Notes on insects feeding on hops in 1925, F. V. THEOBALD (*Entomologist*, 59 (1926), No. 756, pp. 129, 130).—Notes are presented on the occurrence of *Macrosiphum gei* Koch, the hop aphid, *Myzus chelidonii* (Kalt.), *Typhlocyba lethierryi* Edw., *Euacanthus interruptus* L., *Calocoris fulvomaculatus*, *Vanessa io*, and several tortricids, particularly *Cacoecia rosana* and *C. podana*, etc.

Biological notes on important Opuntia insects of the United States, J. C. HAMLIN (*Pan-Pacific Ent.*, 2 (1926), No. 3, pp. 97-105).—This paper supplements an earlier account by the author (*E. S. R.*, 54, p. 755). A report is given of studies of *Mimorista flavidissimalis* Grt., a species attacking the new growth; the cottony cochineal insects *Dactylopius tomentosus* Lmrk. and *D. confusus* Ckll.; *Asphondylia opuntiae* Felt, a species inhibiting the development of seeds; and of *Moneilema crassa* Le C., an *Opuntia* longicorn.

Diocalandra taitensis (Guerin) and other coconut pests of Fanning and Washington Islands, W. B. HERMS (*Philippine Jour. Sci.*, 30 (1926), No. 2, pp. 243-274, pls. 8, figs. 3).—The author reports that the pests of the coco palm on Fanning and Washington Islands include rats (*Epimys alexandrinus*), which gnaw young nuts and the bases of spikelets; robber crabs (*Birgus latro*), almost extinct on Fanning; fern scale, well parasitized by *Aspidiotiphagus citrinus*; mealybugs (*Pseudococcus pandani*), not abundant; caterpillars, belonging to two species not identified, particularly damaging to very young trees; *Xyleborus confusus*, a shot-hole borer, in old fallen nuts in particular; and the lesser coconut borer (*Diocalandra taitensis*), the most important of all.

"The larva of *D. taitensis* bores into the healthy plant tissue, attacking fronds, trunks, spikes, spikelets, and young nuts. Trees from about three years of age to very old ones are attacked by the beetles, the greatest amount of damage being done to trees which have recently come into bearing, and here the damage consists primarily in the loss of nuts through bored spikes and spikelets. A combined *Diocalandra* and caterpillar attack will cause young trees to become badly twisted and stunted, and death may ensue."

Since the usual methods of insect control can not be applied economically, it is recommended that frequent inspections be made and badly infested young trees be cut down and burned, as well as badly infested fronds, and that a determined effort be made to locate a parasite that will prey effectively on *D. taitensis*, preferably on the egg or the adult.

The engineer and the prevention of malaria, H. HOME (*London: Chapman & Hall*, 1926, pp. X+176, pls. 14, figs. 30).—A practical discussion of this subject, including a final chapter on biological means of attack (pp. 123-132) and appendixes dealing with Mosquito Netting, by W. P. MacArthur (pp. 133-151); Applied Entomology (pp. 152-158) and House Flies (pp. 159-162), both by P. A. Buxton; and Water (pp. 163-172).

Clinical observations on endemic typhus (Brill's disease) in southern United States, K. F. MAXCY (*Pub. Health Rpts. [U. S.]*, 41 (1926), No. 25, pp. 1213-1220, pl. 1).—The author points out that the epidemiology of the disease observed in the southern United States presents certain differences from that

of Old World typhus which suggest that the mode of transmission may not be the same, and that there may be some mode other than direct transmission from man to man by means of the bite of a louse. This conclusion follows a clinical description of endemic typhus based upon 114 cases observed in the southern United States.

The spotted locust, *Aularches miliaris* L., J. C. HUTSON (*Ceylon Dept. Agr. Yearbook, 1926, pp. 36-44, pl. 1*).—An account of the life history, habits, and means of control of this grasshopper, which has been known in Ceylon for a long time as a pest of miscellaneous crops.

The actual status of organization for combating the migratory locust in various countries, compiled by G. TRINCHIERI ET AL. (*Etat Actuel de l'Organisation de la Lutte Contre les Sauterelles dans Divers Pays. Rome: Inst. Internatl. Agr., Bur. Renseig. Agr., 1926, pp. 131*).—A review of the control work in various countries, which supplements the report of the proceedings of the international conference held at Rome in 1920 (E. S. R., 46, p. 853).

A revision of the American lice of the genus *Pediculus*, together with a consideration of the significance of their geographical and host distribution, H. E. EWING (*U. S. Natl. Mus. Proc., 68 (1926), Art. 19, pp. 30, pls. 3, figs. 8*).—The author recognizes two distinct groups of *Pediculus* as occurring in America. One is confined to monkeys, to which he recognizes four species as belonging, two of which are described as new. The other is confined to man, to which he recognizes five varieties as belonging, one of which is described as new.

The cicadas or harvest flies of New Jersey, W. T. DAVIS (*N. J. Dept. Agr. Circ. 97 (1926), pp. 27, figs. 15*).—The author presents a table for the separation of the genera and species of New Jersey cicadas, followed by brief accounts of the 11 forms occurring in the State.

Revision of the American leaf hoppers of the jassid genus *Typhlocyba*, W. L. McATEE (*U. S. Natl. Mus. Proc., 68 (1926), Art. 18, pp. 47, pls. 6*).—The author recognizes 59 forms belonging to the genus *Typhlocyba*, of which 38 are described as new.

Studies on leafhopper injury to apple leaves, A. A. GRANOVSKY (*Phytopathology, 16 (1926), No. 6, pp. 413-422, pl. 1*).—This is a report of studies made at the Wisconsin Experiment Station of the cause of a peculiar yellowing of the marginal areas of apple leaves, commonly occurring during the past three years in many orchards at Sturgeon Bay and other points of the peninsular region of the State.

Feeding experiments indicate that the potato leafhopper, *Empoasca fabae* (Har.), is not only able to produce the symptoms of the disease, but prolonged confinement of the insects on apple leaves intensifies the symptoms. The symptoms are distinct from the ordinary feeding injury caused by leafhoppers, which is characterized by the downward curling of the lower surface of the leaves, always rolled in, without the marginal discoloration along the lateral veins. The apple hopperburn, on the other hand, is characterized by a marginal yellow discoloration of the leaves which moves progressively downward along the lateral veinlets and midrib. It is invariably more rapid in its development on the proximal side of the lateral veins than on the distal reference to the petiole of the leaf. In cases of severe injury, the apical margins of the leaves turn brown and often curl upward.

These symptoms, observed on apple leaves, strongly resemble the hopperburn of potato, suggesting the existence of some toxic or specific infective principle within the insect. This specific infective principle moves downward in vascular bundles, discoloring the veins, but is localized in the leaves sub-

jected to leafhopper feeding. The symptoms can be produced artificially by needle inoculations with inoculum prepared from macerated adults and advanced nymphal stages of the insect. Crushing the nymphs and adults on apple leaves resulted in a smaller percentage of infection. The sap of affected leaves gives only a very small number of infections, probably due to the crudeness of inoculation technique and to dilution of the infective principle in the sap of the plant. The definite association of certain species of leafhoppers with the symptoms, the progressive downward movement of symptoms in the vascular system, and the artificial production of symptoms with inocula prepared from the insects and affected leaves indicate that the insect in question is a carrier of some specific infective principle, possibly a virus, in nature. The leafhoppers may be looked upon as a major factor in dissemination and transmission of important virus diseases of plants.

Cotton flea in the South, C. A. WHITTLE (*Manfrs. Rec.*, 90 (1926), No. 3, pp. 74, 75).—The cotton flea is said to have appeared in 1926 in damaging numbers over a wider territory than ever before known. This was due, it is thought, to climatic conditions that favored a large survival over the winter, and to the presence of early host plants in great profusion, such as evening primrose, croton, and horsemint, on which plants the insects feed and breed in late winter and early spring. It is pointed out that, when some of these early host plants matured and died down, their flea population migrated to the cotton plants and there resumed feeding and breeding.

Notes on the English and American races of the greenhouse white-fly (*Trialeurodes vaporariorum*), F. SCHRADER (*Ann. Appl. Biol.*, 13 (1926), No. 2, pp. 189-196, figs. 5).—The author's studies indicate that the American race of greenhouse whitefly is spreading rapidly to all places where it was formerly unknown, which seems to show that it reproduces at a greater rate or is more resistant to detrimental environmental factors than the English race.

Another year's experience with citrus aphid: New ways to combat this damaging pest, J. R. WATSON (*Fla. Grower*, 34 (1926), No. 1, p. 7).—In this contribution from the Florida Experiment Station, the author reports that the damage caused by the citrus aphid during 1926 has been less than 10 per cent of that of the preceding year. He points out that the vast majority of aphids that go through the winter do so as adults on citrus, and that spirea and other host plants are of minor importance. The author has never found an egg nor an egg-laying aphid on citrus, the latter being of a bright yellow color, very different from the stem mothers which bring forth their young alive. Methods of control, dusting under tents, and natural enemies are considered.

The control of aphides infesting bulbs in store, R. STENTON (*Jour. Min. Agr. [Gt. Brit.]*, 32 (1926), No. 11, pp. 1037-1041).—This account relates to the control of *Anuraphis tulipae* B. de F. in the storage warehouse, the life history of which is still somewhat obscure.

The primary food plant of the melon aphid, E. M. PATCH (*Science*, 62 (1925), No. 1614, p. 510).—The author records finding that the primary food plant of *Aphis gossypii* is *Sedum telephium*, from which it migrates to its various summer food plants. See also a previous note (*E. S. R.*, 55, p. 153).

Recent insecticide experiments in Illinois with lubricating oil emulsions, S. C. CHANDLER, W. P. FLINT, and L. L. HUBER (*Ill. Nat. Hist. Survey Bul.*, 16 (1926), Art. 2, pp. 101-126, figs. 2).—The authors report upon the results of four years' experiments on the control of the San Jose scale at various points in southern Illinois. The superiority of oil sprays over lime sulfur was demonstrated, 11 per cent of the scale remaining alive after being hit with lime sulfur as compared with less than 2 per cent with most of the oil sprays. Boiled

emulsion was as effective as the various miscible oils used, and cold-mixed oil emulsions were about equally as effective but somewhat more unstable. The boiled soap emulsions are considered the most reliable type of homemade emulsions.

Vegetable oil soap was as effective as fish oil soap in making the boiled emulsions. Emulsions made from oils with viscosities below 80 have not shown uniformly good kill of scale. There were apparently no differences in effectiveness on San Jose scale in emulsions made from oils of 90 to 220 viscosity. Tests with boiled potash fish oil soap emulsions in summer showed very little injury to apple foliage, but considerable injury to peach and a few other plants under some conditions. Due to the difficulty in reaching the scale when the trees are in foliage, summer sprays are not recommended except in case of very severe scale infestation. Where oil emulsions were properly mixed and applied, no injury to trees has resulted.

Non-inflammable fumigant for use against wax moth (*Galleria mellonella* L.), R. HUTSON (*Amer. Bee Jour.*, 66 (1926), No. 6, pp. 273, 274).—In this contribution from the New Jersey Experiment Stations, the author calls attention to the fact that ethyl acetate with carbon tetrachloride, in the proportion of 30 lbs. or more to 1,000 cu. ft., will kill larvae and pupae of the wax moth if exposed for 48 hours at temperatures of from 60 to 85° F.

The small tussock moth (*Notolophus posticus* Wlk.), a pest on dadap (*Erythrina lithosperma* Bl.), E. DE ALWIS (*Ceylon Dept. Agr. Yearbook*, 1926, pp. 19-21, pl. 1).—A general account of this species, the life history of which has not hitherto been worked out in detail under Ceylon conditions. A tachinid fly, *Tricholyga sorbillans* W., is an important parasite of the pest.

A three-year study of the codling moth with particular reference to "side worm" injury, A. I. BOURNE (*Mass. Fruit Growers' Assoc. Rpt.*, 32 (1926), pp. 181-190).—The data here presented have been noted from another source (*E. S. R.*, 55, p. 256).

Oil spray for codling moth tested, A. F. DEVER (*Better Fruit*, 20 (1926), No. 12, p. 7).—The author reports on tests made of oil in an old Spitzenberg orchard, with and without spreader and in strengths varying from 0.5 to 1 per cent, to 1.5 per cent. The results indicate that 1.5 per cent oil spray is effective as an ovicide and an insecticide at any stage from fresh eggs to hatched larvae. It is pointed out that the degree of control attained is based not so much on whether the application is 1 or 1.5 per cent in the tank, but upon the amount of solution that is applied to the fruit.

How to fight the European corn borer this fall, D. J. CAFFREY and L. H. WORTHLEY (*U. S. Dept. Agr., Misc. Circ. 84* (1926), pp. 4, fig. 1).—A practical account.

Some factors responsible for the decrease of the European corn borer in New England during 1923 and 1924, G. W. BARBER (*Ecology*, 7 (1926), No. 2, pp. 143-162, figs. 2).—In this continuation of the author's investigations of the European corn borer for the U. S. D. A. Bureau of Entomology (*E. S. R.*, 53, pp. 256, 653, 757; 54, p. 157; 55, p. 762), it is pointed out that the decrease in its abundance in New England in 1923 and 1924 was probably caused by an association of factors, some of major importance and others contributory but increased in value through the effect of the major limiting factors.

Natural causes of decrease included heavy winds and rains, destroying some of the moths as well as preventing others from laying the normal number of eggs; low night temperatures, decreasing the number of eggs deposited, an important factor in 1923; drought, preventing some eggs from hatching; heavy rains, destroying larvae before they had bored in; certain individuals having only a single generation; the abundance of larvae that failed to attain full

growth before hibernation; winter mortality; birds feeding on moths, taking larvae from burrows in the growing plant, and feeding on overwintering larvae; mice feeding on overwintering larvae; predacious insects feeding on larvae, adults, and eggs; parasites destroying eggs, larvae, and pupae; and disease of larvae.

Of artificial control measures, burning the crop refuse containing larvae is considered to be the most effective, and to be rendered more so by plowing in the stubble to a depth of 6 in. or more. Feeding the infested cornstalks to cattle also destroys the larvae and fully utilizes the crop. Trap crops planted early, and also late planting of the main crop, decreases the extent of the infestation. The natural succession of vegetation sometimes greatly reduces the number of corn borers through weeds that are unavailable for food taking the place of suitable food species. Constant shifting in importance of the limiting factors, and new alignments, seem to cause the seasonal variation in population of the European corn borer.

The Hessian fly in Oregon, L. P. ROCKWOOD (*Oregon Sta. Circ.* 77 (1926), pp. 7, figs. 4).—A practical account of this pest and means for its control in Oregon.

Substantial accomplishments in New Jersey mosquito control, T. J. HEADLEE (*New Jersey Stat. Bul.* 437 (1926), pp. 8).—A study was made of the tax valuations from 1900 to 1925 in 16 areas along the Atlantic Ocean and Delaware Bay coast to determine the effect of the antimosquito work done since 1915 upon property values. Yearly increases in tax valuations from 1916 to 1925 in 8 areas in which mosquitoes have been greatly reduced or practically eradicated were 1.7 times those from 1900 to 1915 as compared with 1.5 times for 1 area where mosquitoes have always been scarce, and 0.95 times for 7 areas in which mosquitoes have been and are still troublesome in varying degrees.

Destroying engorged Anopheles as a malaria control measure, J. A. LE PRINCE (*Pub. Health Rpts.* [U. S.], 41 (1926), No. 25, pp. 1220-1226).—Data are presented to show that the destruction of engorged Anopheles is an important means of combating malaria.

Relationship of plankton to anopheline larvae, L. T. COGGESHALL (*Amer. Jour. Hyg.*, 6 (1926), No. 4, pp. 556-569).—The author reports upon dissections of larvae made to determine whether the anopheline species exhibit preference for certain types of food. From the information gained it is evident that the three species examined, namely, *Anopheles quadrimaculatus* Say, *A. crucians* Say, and *A. punctipennis* Wied., show no discrimination in their selection of food.

Observations on the emergence of Anopheles mosquitoes, G. H. BRADLEY (*Amer. Jour. Trop. Med.*, 6 (1926), No. 4, pp. 283-297, figs. 3).—This contribution from the U. S. D. A. Bureau of Entomology records the emergence of 585 adults from 904.9 sq. yds. of water surface in selected anopheline breeding areas.

The further development of Onchocerca volvulus Leuckart in Simulium damnosum Theob., D. B. BLACKLOCK (*Ann. Trop. Med. and Parasitol.*, 20 (1926), No. 2, pp. 203-218, pl. 1, fig. 1).—Experiments conducted, in continuation of those previously reported (*E. S. R.*, 54, p. 773), showed that larvae of *O. volvulus* taken up from the skin by *S. damnosum* in biting undergo progressive development in the fly and finally reach the proboscis, the time taken to complete the development depending largely upon temperature. The shortest period which elapsed after feeding before the proboscis became infected was seven days. The mature larvae were found in the labium of the fly and

escaped through the membranous portion of it. It is concluded that, in so far as experiments with wild flies can be accepted as evidence in the absence of actual transmission to man or animal, *S. damnosum* is a vector of *O. volvulus*.

Leatherjackets and their control, H. W. THOMPSON (*Welsh Jour. Agr.*, 2 (1926) pp. 228-233).—The author finds that naphthalene has some value as a deterrent against leatherjacket attack; that kainite has no insecticidal value and apparently no value as a deterrent against the pests; that sodium fluoride as a bait poison is not satisfactory, at least at the strength tested; and that Paris green is a satisfactory poison, and if carefully used should prove of considerable value as a control for leatherjackets.

Further experiments in the control of certain maggots attacking the roots of vegetables, K. M. SMITH (*Ann. Appl. Biol.*, 12 (1925), No. 1, pp. 77-92).—Experiments here reported, conducted in continuation of those previously noted (*E. S. R.*, 48, pp. 157, 459), deal with the onion maggot, carrot rust fly, and cabbage maggot, maggot and the turnip gall weevil (*Ceuthorrhynchus pleurostigma* Marsh). Control experiments with the first two have been carried on since 1920, a list of all the chemicals used being given.

As a result of the 1924 experiments, nicotine sulfate dust in a 5 per cent mixture with precipitated chalk and chlorocresylic acid in a 1 per cent mixture with precipitated chalk are recommended for use against the onion maggot. After three seasons' trials, creosote is not considered an efficient remedy for this pest.

For the carrot rust fly nicotine sulfate dust in a 5 per cent mixture and creosote in a 1 per cent mixture, both in chalk, gave promising results in the 1924 trials.

Of chemicals used in field trials against the cabbage maggot, the most successful were (1) chlorocresylic acid, (2) green tar oil, and (3) creosote. Anthracene oil and nicotine sulfate also gave fair results. The results of a number of pot experiments designed to test the efficacy of corrosive sublimate as a control for the cabbage maggot do not appear to justify the use of this substance, but further trial is necessary.

In order to ascertain the effect of galls of the turnip gall weevil upon the health of the cabbage plant, 400 cabbages, 200 galled by the larvae and 200 healthy, were grown under test conditions. The results of this experiment indicate that the galls are attractive to slugs. The critical time in the life of a galled cabbage is the seedling stage, but given good cultural conditions at the time of setting out, the cabbage will flourish normally.

Studies of *Oscinella frit* L.: A preliminary investigation of the extent of the recovery power of oats when subject to injury, N. CUNLIFFE (*Ann. Appl. Biol.*, 12 (1925), No. 2, pp. 276-286).—This is a report of investigations made during the summer of 1924 of the extent of the recovery power of oats after injury such as is inflicted by the larvae of *O. frit*.

Plague fleas, with special reference to the Milroy Lectures, 1924, L. F. HIRST (*Jour. Hyg. [London]*, 24 (1925), No. 1, pp. 1-16).—This paper discusses the flea species factor, comparative experiments on the transmission of plague by rat fleas, factors governing distribution of rat fleas, *Xenopsylla cheopis* and imported plague, and distribution of *X. cheopis* and *X. astia* in relation to plague in Colombo.

False wireworms injurious to dry-farmed wheat and a method of combating them, C. WAKELAND (*Idaho Sta. Research Bul.* 6 (1926), pp. 3-52, figs. 24).—This is an account especially of the life history, habits, and means of control of *Eleodes hispilabris* Say, the most important of 11 species and 15 varieties known to occur in Idaho. Its injury to dry-farmed wheat is caused by the destruction of the germ in planted kernels, the devouring of the sprout, or

the gnawing of the stem below the surface of the ground. The adults hibernate in protected places during the winter and emerge early in the spring, soon dispersing over cultivated fields. Eggs are deposited in late May and June in dry soil close to where it joins the moist subsoil. The average incubation period of eggs was found to be 14.91 days, the average larval period (11 instars) 369.19 days, the average pupal period 33.59 days, and the average complete life cycle 721.69 days.

Numerous laboratory and field tests showed arsenical poisons when combined with bran and moisture to be effective in killing *Eleodes* beetles. It was found that carefully and uniformly conducted poisoning for two consecutive seasons over an extensive area results in nearly complete destruction. Natural enemies are said to be of little importance, and cultural practices to be of little direct benefit as means of control.

A bibliography of 68 titles is given.

The tobacco flea-beetle, H. H. JEWETT (*Kentucky Sta. Bul.* 266 (1926), pp. 51-69, figs. 7).—This is an account of studies of *Epitrix parvula*, including its life history and means of control. The author finds the incubation of the egg to last from 5 to 13 days, the larval stage from 13 to 29 days, and the pupal stage from 3 to 9 days—from 23 to 45 days being required for the completion of the life cycle. It was found that three broods may appear during the season. The beetle hibernates in the adult stage under loose litter or other materials near the plant beds or tobacco fields. A list of 33 references to the literature is included.

Notes on the life history and habits of the curry-leaf beetle, *Silana farinosa* Boh., F. D. PERIES, JR. (*Ceylon Dept. Agr. Yearbook*, 1926, pp. 51-54, pl. 1).—The chrysomelid beetle here reported upon is said to damage the foliage of the curry-leaf tree (*Murraya koenigii* Spreng) in Peradeniya.

On the early stages of some weevils (Curculionidae), A. W. R. ROBERTS (*Ann. Appl. Biol.*, 13 (1926), No. 2, pp. 197-218, figs. 24).—The species dealt with are *Phyllobius urticae* Deg., *P. pyri* L., and *Polydrusus cervinus* L.

Report of the Maryland State Beekeepers' Association (*Md. Agr. Soc., Farm Bur. Fed., Rpt.*, 10 (1925), pp. 332-367).—This is a report of the proceedings of the seventeenth annual meeting of the association, held at Baltimore, in January, 1926. Among the papers presented are the following: The Life-Sustaining Value, for Honeybee Larvae, of Various Carbohydrates and Honeys, by L. M. Bertholf (pp. 334-339); Keeping Bees in Outyards, by R. A. Nusbbaum (pp. 340-345); *Braula coeca*, by W. J. Nolan (pp. 346-352); Producing Comb Honey That Can Be Graded, by E. L. Sechrist (pp. 353-361); and Fall Management, by J. E. Eckert (pp. 361-367).

In experimental work conducted by Bertholf at the Bee Culture Laboratory of the U. S. D. A. Bureau of Entomology, a comparative study was made of the value of various honeys as food for bees, including basswood, white clover, tulip tree, alfalfa, buckwheat, mountain laurel, sage, wild buckwheat, aster, goldenrod, and locust. A series was run in which lots were fed on all these honeys, on 75 per cent cane sugar, and on water. The various honeys were chosen with a view to securing the widest possible variation in source, color, dextrin content, dextrose-levulose ratio, tannin content, etc. For comparing with the various single carbohydrates used in this investigation, the lengths of life on all the honeys were averaged together and divided by the length of life of the water check to obtain the life-sustaining quotient. When the quotients obtained for each carbohydrate and for the honeys were all compared it was found that sucrose gave the highest quotient (7.4), and that next in order came levulose (4.7), maltose (4.3), melizitose (4.3), dextrose (3.9),

honey (3.6), trehalose (3.0), dextrin (2.9), galactose (0.9), lactose (1.7), glycogen (1.0), and starch (0.9).

The life history of the saskatoon sawfly (*Hoplocampa halcyon* Norton), R. D. BIRD (*Sci. Agr.*, 6 (1926), No. 10, pp. 353-357, figs. 3).—This is a report of life history studies of a sawfly which attacks the fruit of the saskatoon (*Amelanchier spicata*), which is probably used on the Canadian Prairies as a preserve more than any other native fruit with the exception of the raspberry. Technical descriptions of its life stages are included.

Miscellaneous new chalcid-flies of the hymenopterous family Encyrtidae, P. H. TIMBERLAKE (*U. S. Natl. Mus. Proc.*, 69 (1926), Art. 3, pp. 34, pls. 2, fig. 1).—The author erects seven genera and describes nine species as new to science.

Biological investigations on the Hymenoptera of Chile: Mellifera [trans. title], F. CLAUDE-JOSEPH (*Ann. Sci. Nat., Zool.*, 10. ser., 9 (1926), No. 3-4, pp. 113-240, figs. 78).—A report of studies of the bees of Chile.

The fern mite (*Tarsonemus tepidariorum* Warburton), W. P. L. CAMERON (*Ann. Appl. Biol.*, 12 (1925), No. 1, pp. 93-112, pls. 3, figs. 5).—It is shown that the fern mite is of distinct economic importance, its attack being on the younger parts only of the fern (*Asplenium bulbiferum* and its varieties), causing the fronds to become distorted and the plant to be so dwarfed that it is unsalable.

"The disease spreads rapidly in a greenhouse due to the rapid multiplication of the mite and the very short life cycle of 17 days, on the average. All stages of the pest may be found during the summer, and the winter is passed mainly as an adult female, although a few eggs may also be found at that time. The mites spread from one nursery to another by the introduction of infested plants; from one plant to another by crawling from leaf to leaf where these touch, and probably by walking along the surface of the moist earth, and by the planting of young 'pips' taken from infested plants. The disease is difficult to control. Preventive measures offer more chance of success than do remedial. The young pips should be planted clean, and then kept free from the pest by means of deterrent sprays. The pips are treated with some insecticide before planting."

Tick destruction in Jamaica, H. H. COUSINS (*West Indian Agr. Conf., Kingston, Proc.*, 9 (1924), pp. 153-161, pl. 1).—A discussion of the work under way.

A filter-passing virus obtained from *Dermacentor andersoni*, H. NOGUCHI (*Jour. Expt. Med.*, 44 (1926), No. 1, pp. 1-10, figs. 4).—The author reports having isolated an invisible, filter-passing virus, pathogenic for the guinea pig and capable of cultivation on special media for at least seven generations. One of two rhesus monkeys inoculated became infected, and in one rabbit the result was negative. The virus was transmitted from infected guinea pigs to ticks, and in one instance by tick feeding from an infected tick to a guinea pig.

ANIMAL PRODUCTION

Diet in relation to reproduction and rearing of young.—I, II (*Amer. Jour. Physiol.*, 76 (1926), No. 2, pp. 325-338, 339-348).—In the first paper, entitled Observations on the Existence of Vitamin E, V. E. Nelson, R. L. Jones, V. G. Heller, T. B. Parks, and E. I. Fulmer have presented the results of 8 different experiments in which the rate of reproduction and growth of rats on synthetic diets has been determined. The synthetic rations included casein, minerals, butterfat, yeast, and dextrin, and some contained lard. The amounts of certain ingredients were varied in the different experiments.

The results show that rats on rations containing 5 per cent of Fleischmann's yeast as the only source of vitamin B were carried through the sixth generation, but that the postnatal mortality was heavy. When lard was added in amounts varying from 7 to 25 per cent, and casein in amounts from 18 to 40 per cent, reproduction was much below normal. Animals were carried through the third generation on diets containing from 15 to 30 per cent of casein and 5 per cent of Fleischmann's yeast, although the mortality was also very high. Similar results were obtained with 5, 8, and 12 per cent of Harris' yeast and 18 per cent of casein. Undried yeast and larger amounts of butterfat were supplied in an effort to lower the mortality of the young without success. It was, however, noted that reproduction occurred in high butterfat diets but was prevented when equal amounts of lard were included in the ration. The results of 2 experiments showed that xerophthalmia developed on rations containing 5 per cent of butterfat and a high lard content, but this condition disappeared when the lard was replaced by dextrin. The authors believe that the lard causes the destruction of the fat-soluble vitamin.

It is concluded that "the failure of these diets for reproduction and rearing of young is not due to a deficiency of fat-soluble vitamins, but may be due to an insufficiency of vitamin B and an inadequate quantitative relation between the known constituents of the diet."

In the second paper the results of experiments with rats which were conducted to determine the vitamin B content of white and yellow corn, wheat, barley, and rye, and the efficiency of these sources of vitamin B for growth, reproduction, and rearing of young are reported by A. E. Guest, V. E. Nelson, T. B. Parks, and E. I. Fulmer. The rations consisted of 18 per cent of casein, 3.7 per cent of minerals, 5 per cent of butterfat, 10 to 60 per cent of the seeds, and the balance of dextrin. The rats weighed from 50 to 60 gm. at the beginning of the experiment. Growth records were obtained through the second generation except on the barley ration. The results are tabulated showing the numbers of young produced and reared on each ration and the relative growth curves.

More litters were produced when the seeds formed the only source of vitamin B than in the above experiment when yeast was used. The mortality of the young and the number of females dying during pregnancy and parturition were, however, very high on many of the diets.

In discussing the results it is pointed out that the high mortality is not due to a deficiency of fat-soluble vitamins. It is also noted that young were produced when the rations contained insufficient vitamin B for normal growth. It is concluded therefore that the requirement of vitamin B for reproduction is less than that for growth, but approximately 50 per cent more vitamin B is required for normal reproduction than for normal growth. The inability to rear young is associated with the lack of milk secretion, for which the vitamin B requirement appears to be very high.

Fertility of the white rat on purified rations, A. L. DANIELS and M. K. HURTON (*Soc. Expt. Biol. and Med. Proc.*, 23 (1925), No. 3, pp. 225-227).—In studies at the University of Iowa of the factors which limit normal reproduction on purified rations, it was found that supplementing a milk diet with the ash of soy beans, lettuce, and yeast in amounts equal to that in quantity of the nonincinerated substances which overcame sterility on milk diets resulted in the birth of normal young. On the other hand, animals failed to reproduce when the purified diets were supplemented with the different sources of ash, but when the purified rations were supplemented with various substances containing vitamin E normal reproduction occurred. It is therefore concluded

that milk is lacking in minerals rather than in vitamins for reproduction, while the purified ration was deficient in this vitamin. Since much better growth was obtained in these experiments when yeast was used as the source of vitamin B in a purified ration than when an alcoholic extract of wheat embryo was used, it is assumed that yeast contains the essential inorganic substances.

Studies on the physiology of reproduction in birds.—XXI, **Blood calcium changes in the reproductive cycle**, O. RIDDLE and W. H. REINHART (*Amer. Jour. Physiol.*, 76 (1926), No. 3, pp. 660-676, figs. 4).—In studies at the Carnegie Station for Experimental Evolution, determinations have been made of the calcium content of the blood of 191 healthy adult male and female ring doves and common pigeons and of 47 ring doves, common pigeons, and generic hybrids from 3 to 6 months of age. The two species were very similar in the calcium content of the blood, and the results were, therefore, combined and grouped according to sex and 13 stages of the females' reproductive cycle.

The blood of the males was practically constant at all stages, containing approximately 9 mg. of calcium per 100 cc. The calcium in the blood of the females varied with relation to the time of ovulation. In the nonovulation stages the amount of calcium in the blood was very similar to that of the males, but it began to increase during the period 73 to 108 hours before ovulation and reached a maximum during the 44-hour period of ovulation of more than double the amount present in the resting stage of the reproductive cycle. It dropped rapidly to normal within the next 108 hours. No difference in the calcium in the blood of the two sexes was observed in the immature birds, but there appeared to be a distinct increase during both the spring and summer months as compared with winter. The seasons of high blood calcium correspond to the season of small size of thyroids and large size of testicles and ovaries. The occurrence of certain irregularities in the amount of blood calcium of individuals is noted.

The increases in the blood calcium associated with ovulation are discussed in relation to the reproductive cycle of mammals and the influence of the parathyroid glands, from which it appears that the latter play an important part in reproduction, especially in relation to the experimental modification of sex.

The effect of gonadectomy on the weight of the kidney, thymus, and spleen of mice, K. MASUI and Y. TAMURA (*Brit. Jour. Expt. Biol.*, 3 (1926), No. 3, pp. 207-223, figs. 8).—The body weights and lengths and the weights of the kidneys, thymus, and spleen of normal and castrated mice were obtained for a study of the effects of sex and gonadectomy on these characters at the University of Tokyo. In the investigation litters were divided into two groups, one group of which was gonadectomized at 20 days of age. There were between 100 and 200 individuals in each group, and all were killed when 90 days of age. The data are summarized in the following table:

Effect of sex and gonadectomy on the size of the body and the organs of mice

Sex	Body weight	Body length	Kidney weight	Thymus weight	Spleen weight
	<i>Grams</i>	<i>Centimeters</i>	<i>Grams</i>	<i>Grams</i>	<i>Grams</i>
Males.....	22.70±0.09	6.085±0.007	0.418±0.003	0.021±0.0004	0.081±0.002
Females.....	21.11±.19	6.156±.018	.289±.002	.038±.0007	.134±.006
Castrated males.....	22.99±.13	6.198±.006	.274±.002	.052±.0007	.125±.003
Castrated females.....	22.66±.24	6.134±.017	.266±.002	.051±.0005	.129±.005

The results showed that there were distinct sexual differences in the weights of the body, kidney, thymus, and spleen, and a slight difference in body length.

The removal of the male gonads caused the weight of the kidney, thymus, and spleen to approach that of the female type, while there was little or no effect from gonadectomy on the weight of these organs in the female. The body weight of the male showed no change after castration, while that of the female increased quite rapidly after spaying.

On the migration of ova from one uterine horn to the other in the albino rat; and some evidence indicating a new ovarian hormone, F. B. HANSON and C. BOONE (*Amer. Nat.*, 60 (1926), No. 668, pp. 257-265).—In one experiment 20 female rats were semispayed, part on one side and part on the other, to study the migration of ova from one horn of the uterus to the other. The females were bred after recovery and killed prior to parturition. No embryos were found implanted on the uterine horn of the side from which the ovary was removed, indicating that crossing over does not occur in the albino rat. The average size of the litters produced was 5.70 ± 0.24 , which was quite comparable to the size of litters of the control stock. The one ovary had thus produced as large litters as two.

In further studying the factors responsible for the production by semispayed rats of as large litters as normals, a portion of one oviduct of 14 females was excised and the ends were tied. A total of 45 litters were produced by these females, of which the average size was 3.80 ± 0.156 . The difference between the litter size of semispayed individuals and those having a portion of one oviduct excised was 1.90 ± 0.29 . In explaining the differences it is suggested that there is a reciprocal hormone relationship between the two ovaries, each tending to suppress the other, but that when one ovary is removed the other hypertrophies and produces larger numbers of ova.

The coat of the mouse (*Mus musculus*), F. W. DRY (*Jour. Genetics*, 16 (1926), No. 3, pp. 287-340, pls. 4, figs. 103).—This paper presents the results of microscopic studies of the types and development of hair found in the mouse. The specimens studied were mainly taken from the mid-dorsal line, but hair from other portions of the skin was also examined for comparison. It was found that the hairs were grown in distinct generations on the main areas, but that there was considerable variation in the succession of hairs in isolated follicles.

The nutritive value of various layers of the wheat and corn kernel, A. KLEIN, B. HARROW, L. PINE, and C. FUNK (*Amer. Jour. Physiol.*, 76 (1926), No. 2, pp. 237-246, fig. 1).—Data are presented dealing with the nutritive value of the proteins in corn meal, corn feed meal, wheat bran, standard wheat middlings, red dog flour, and the first clear, second clear, and patent flours, as determined by chemical fractionation of the proteins and by feeding experiments with rats.

The results show that much difference exists in the nutritive properties of the different layers, but those parts containing the bulk of the vitamins also have proteins of high biological value. The milling fraction, red dog flour, gives the best combinations of the highest biological value, together with the highest general dietetic value. The corn feed meal was superior to corn meal. The possibility of certain vitamins increasing the biological value of the proteins is suggested.

Cottonseed products as feed, fertilizer, and human food (*Texas Sta. Bul.* 341 (1926), pp. 5-28).—This bulletin discusses briefly the properties and composition of cottonseed meal and hulls, together with directions for feeding these products to the various classes of animals and suggested rations for each, and information as to cottonseed meal as a fertilizer, noted on page 22 and as to cottonseed flour as a human food.

Feeding experiments with pineapple bran at the University of Hawaii (*Hawaii Univ. Quart. Bul.*, 4 (1926), No. 4, pp. 27-32).—A ration of one-third each of barley, wheat bran, and pineapple bran was fed to 3 grade Percheron horses for 18 months with excellent results.

When 2 purebred Berkshire and 2 crossbred (Tamworth × Berkshire) pigs were given free access to a mixture of pineapple bran, wheat middlings, coconut meal, and tankage (5:3:1:1), together with 0.5 lb. of green alfalfa daily during the 12 weeks following weaning, the purebred Berkshires made an average daily gain of 0.96 lb. and the crossbreds 1.13 lbs. An average of 3.43 lbs. of grain was required per pound of gain.

Two lots of 4 crossbred (Tamworth × Berkshire) pigs each were also fed during an 84-day period on rations containing 50 and 60 per cent pineapple bran. The other feeds included wheat middlings, coconut oil cake meal, tankage, salt, and raw rock phosphate. During the test period an average daily gain of 1.08 lbs. was made on the 50 per cent pineapple bran mixture and 0.72 on the 60 per cent pineapple bran mixture. The two lots required 4.59 and 4.96 lbs. of grain, respectively, to produce 1 lb. of gain. The results indicate that the 50 per cent pineapple bran mixture is superior to the mixture containing the larger amount of this feed.

Straw hydrolyzation with special regard to the significance and profit from the process, as well as analytical-chemical and microchemical investigations [trans. title], J. SCHEELE (*Landw. Jahrb. Bayern*, 16 (1926), No. 1-3, pp. 93-109, figs. 2).—This deals with the hydrolyzation of straw, reviewing the historical development of the methods of treatment and describing the chemical, microscopical, and anatomical make-up of straw, the different methods of hydrolyzation, and their effect on the resulting product.

Commercial feeding stuffs, 1925-1926, J. M. BARTLET (*Maine Sta. Off. Insp. 120* (1926), pp. 33-52).—This gives the guaranties and analyses of the samples of feeding stuffs officially inspected during the year ended June 30, 1926 (E. S. R., 54, p. 758).

Analyses of mixed feeds on sale in North Carolina, 1924, J. O. HALVERSON and L. M. NIXON (*N. C. Dept. Agr. Bul.*, 1925, Sept., pp. 51, fig. 1).—This reports the guaranties and analyses of feeding stuffs officially inspected in North Carolina during the year 1924, and includes miscellaneous information related to feeding.

Inspection of feeds, J. B. SMITH and L. J. HARDIN (*Rhode Island Sta. Ann. Feed Insp. Circ.*, 1926, pp. 8).—The guaranties and analyses for protein and fat are presented for the feeds officially analyzed during the season of 1925-26, with suggestions for calculating the relative value of the feeds (E. S. R., 53, p. 465).

Feeding stuffs, F. T. SHUTT (*Canada Expt. Farms, Div. Chem. Rpt. 1925*, pp. 25-34).—This reports chemical analyses of samples of various feeding stuffs which have been studied by the division of chemistry.

The feeding of domestic animals, N. HANSSON, trans. by F. VON MEISSNER (*Fütterung der Haustiere. Dresden: Theodor Steinkopff, 1926*, pp. XII+230, figs. 7).—The book is divided into three parts, dealing with the principles of animal nutrition and giving descriptions of various individual feeds and the nutrient requirements of the various classes of farm animals.

Proceedings of the twenty-eighth [and twenty-ninth annual conventions] of the American National Live Stock Association (*Amer. Natl. Live-stock Assoc. Proc.*, 28 (1925), pp. 132, pls. 8, figs. 4; 29 (1926), pp. 150, pls. 7).—These are the usual reports of the meetings of this association (E. S. R., 53,

p. 167), held at Albuquerque, N. Mex., in January, 1925, and at Phoenix, Ariz., in January, 1926.

Proceedings of the twenty-first annual convention of the Corn Belt Meat Producers' Association and of the fifth annual convention of Iowa Co-operative Livestock Shippers (*Corn Belt Meat Prod. Assoc. [etc.] Proc.*, 21 (1924), pp. 70).—This consists mainly of papers of popular interest as in previous reports (E. S. R., 52, p. 168).

Horse and cattle production in the Dutch East Indies [trans. title], J. MERKENS (*Dept. Landb., Nijv. en Handel [Dutch East Indies], Veeartsenijk. Meded.*, No. 51 (1926), pp. VIII+252, pls. 44).—Descriptions are given of the many different breeds and types of horses and cattle in the Dutch East Indies, including accounts of the measures taken for the improvement of horses and cattle through breeding.

A quarterly bulletin on the condition of range, water, and cattle throughout New Mexico (*N. Mex. Cattle and Horse Growers' Assoc. Quart. Bul.* 13 (1926), pp. [32], fig. 1).—This publication deals in general with range legislation and statistics of cattle production, but includes other information of popular interest to New Mexico livestock producers.

Shipping cattle to Britain (*Canada Dept. Agr. Bul.* 62, n. ser. (1926), pp. 51).—This gives complete accounts of six experimental shipments of beef cattle to Great Britain, the last of which was made in April, 1925. The results of the individual experimental shipments have been briefly noted from the reports of the experimental farms (E. S. R., 55, p. 358).

The general results have indicated that the shipping of chilled beef to Great Britain is unprofitable, but that the popularity of Canadian store cattle is increasing in the British market and the enterprise is profitable provided suitable grades of animals are shipped at the proper time and under the proper conditions. The British prefer the younger steers of good quality, 1,100 to 1,200 lbs. being the most desirable weight. Older cattle must be better finished than younger cattle, since the former are ordinarily slaughtered immediately. Any of the three major beef breeds, Aberdeen Angus, Hereford, or Shorthorn, purebreds or grades, are acceptable, but the Herefords should be shipped in time for finishing on grass.

The importance of uniformity in the shipments is emphasized. It is suggested that individuals may ship either through exporters or cooperatively. The facilities available at the three major markets, Glasgow, Liverpool, and Manchester, are briefly summarized.

Results of experiments in breeding for fleece improvement, [D. A. SPENCER] (*Natl. Wool Grower*, 16 (1926), No. 4, pp. 25-28, figs. 8).—The relation of various factors to the scoured fleece weights of individual ewes has been studied from the records of 1,496 Rambouillet fleeces sheared during the years 1921, 1923, and 1924, at the Sheep Experiment Station, Dubois, Idaho. The fleece weights were found to increase with the age of the ewes from yearlings to 3-year-olds and then in general to decrease as age advanced.

The length of staple was one of the most important factors as related to heavy fleece weight, although density was also of considerable importance. There was, however, a slight negligible relation between length of staple and density. Fineness of fleece and large amounts of dirt were related to smaller weights of scoured fleece. Studies of the effect of percentage of grease gave somewhat variable results, but indicated that fleece should not be overloaded with grease for the maximum scoured weights.

Studies of the average percentages of clean wool, grease, and dirt in various parts of 50 of the fleeces showed that the necks yielded the highest percentage

of clean wool and the lowest percentage of dirt, while the reverse was the case with the bellies. Both the necks and bellies contained 13 per cent of grease, and the sides, backs, and rumps 15 per cent each. Grease appears to be the most constant of the three factors in different parts of the fleece.

Are twin lambs desirable? W. E. JOSEPH (*Natl. Wool Grower*, 16 (1926), No. 4, pp. 19-21, figs. 4).—From records of approximately 300 fine-wool ewes, 2, 3, and 4 years of age, bred and raised on the range at the Montana Experiment Station, the desirability of single and twin lambs has been compared in the lambing seasons of 1923, 1924, and 1925. The results showed that during 1923 the 13 pairs of twin lambs born in May averaged 95.8 lbs. in weight in October as compared with 60.4 lbs. for the single lambs of other ewes. Similar or somewhat more favorable results were shown for the twins born in 1924 and 1925. The averages for the twin pairs in the two years were 119.5 and 112.8 lbs. of lamb per ewe as compared with 72.8 and 71.5 lbs. of lamb per ewe for those producing singles in the respective years.

The ewes which raised twins did not show any reduction in their ability to raise lambs in the succeeding year.

The average weights of lambs born as twins but raised as singles were compared with the average weights of singles, and it was found that the handicap of being born as one of twins only amounted to 2 or 3 lbs.

The British Goat Society's year book for 1926, compiled by T. W. PALMER (*London: Brit. Goat Soc.*, 1926, pp. 163, pls. 34).—This is the sixth yearbook of the British Goat Society, containing numerous articles of popular interest similar to those of a previous number (*E. S. R.*, 54, p. 466).

The fattening of pigs (*North. Ireland Min. Agr. Leaflet 35* (1926), pp. 10).—This deals with the principles of feeding and fattening pigs, including several rationings suggested for different ages.

Brood sow and litter, L. A. WEAVER (*Missouri Agr. Col. Ext. Circ. 172* (1926), pp. 11, figs. 4).—This circular gives brief popular directions for the care, management, and feeding of the brood sow and her litter.

Studies on the sex-ratio and related phenomena.—VIII, **The seasonal sex-ratio in the pig**, A. S. PARKES (*Ztschr. Induktive Abstam. u. Vererbungslehre*, 40 (1926), No. 3, pp. 121-138, fig. 1).—In continuing this series (*E. S. R.*, 55, p. 635) it was found that the numbers of individuals, litters, and sex ratios given for the pigs recorded in the National Duroc-Jersey Record, vol. 67, as born during the four quarters of the year, i. e., September, October, and November; December, January, and February; March, April, and May; and June, July, and August were respectively 19, 10.3, 56, and 14.7. The average litter size and the sex ratios were relatively constant, the extremes for the average size of litter in the different quarters being 8.04 and 8.31, and for the sex ratios 46.1 and 44.4 per cent.

Other data on seasonal variations in the sex ratios of man and animals are discussed, from which it is concluded that seasonal variations are apparent under the more primitive conditions of breeding.

Sugar beet tops as a substitute for oats in the feeding of heavy draft horses [trans. title], E. BAETSCH (*Landw. Jahrb.*, 63 (1926), No. 2, pp. 157-206, pl. 1).—The results of an experiment are reported in which one horse of each of three teams received during the period October 1 to November 17 a daily ration per 600 kg. of live weight of 5 kg. of rye straw, 5 kg. of meadow hay, and 7.5 kg. of oats, as compared with 5 kg. of rye straw, 7 kg. of alfalfa hay, 3.5 kg. of oats, and 25 kg. of sugar-beet tops without leaves for the other horse of each team. The amount of work done and the weights of the horses taken at different intervals were used for determining the value of the sugar beets as a partial substitute for oats.

During the experiment the horses receiving oats lost a total of 5 kg., while their team mates receiving beets made a total gain of 23 kg. The experiment showed that the beet tops were very palatable, and proved to be a satisfactory feed for work horses when fed in amounts up to 25 kg. daily.

The mineral metabolism in horses fed exclusively on bran, O. BANG (*K. Vet. og Landbohøjskole [Denmark], Aarsskr. 1925, pp. 383-404*).—Data are presented showing the intake and outgo of various minerals by a 12-year-old gelding receiving daily rations of 7 kg. of wheat bran alone and with 200 gm. of calcium carbonate, or of 7 kg. of rye bran and 44.3 gm. of sodium chloride. The horse was placed in a sling for the collection of feces and urine, following a preliminary feeding period on the same ration. The data dealing with the metabolism of the more important base- and acid-forming minerals are summarized in the following tables:

Average daily mineral metabolism of acid-forming minerals

Ration	P ₂ O ₅		SO ₃		Cl	
	Intake	Outgo	Intake	Outgo	Intake	Outgo
	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>
Wheat bran.....	180.6	176.1	26.7	23.8	6.0	3.7
Wheat bran plus CaCO ₃	180.6	173.3	26.5	26.1	5.7	1.8
Rye bran plus NaCl.....	163.0	168.7	25.2	32.2	31.2	29.2

Average daily mineral metabolism of base-forming minerals

Ration	CaO		Mgo		K ₂ O		Na ₂ O	
	Intake	Outgo	Intake	Outgo	Intake	Outgo	Intake	Outgo
	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>	<i>Gram</i>
Wheat bran.....	14.9	32.5	46.0	41.3	91.0	90.8	4.9	5.0
Wheat bran plus CaCO ₃	122.7	104.8	47.6	43.2	91.0	85.3	4.9	7.4
Rye bran plus NaCl.....	12.6	23.8	45.5	41.7	100.9	97.1	28.6	26.7

The results are discussed from the standpoint of acid and base equilibrium of the intake and outgo of minerals. In the first experiment the analyses showed that the feeding of a substance like wheat bran, containing a considerable excess of phosphoric acid and a deficiency of bases, resulted in a considerable loss of calcium. When the calcium carbonate was added to the bran ration much less phosphoric acid was excreted in the urine, and 3.5 times as much calcium oxide was found in the feces as during the preceding experiment when the ration consisted of bran only. The horse did not lose as much base equivalent during the rye bran experiment as during the wheat bran feeding, due to the lower phosphoric acid content and the smaller base deficiency of the former. In the rye bran experiment the horse appeared to show a small loss of phosphoric acid.

Textbook of horse breeding, G. SCHWARZNECKER, rev. by G. FRÖLICH (*Lehrbuch der Pferdezucht. Berlin: Paul Parey, 1926, 6. ed., rev., pp. VIII+682, pls. 41, figs. 140*).—This book gives accounts of the different breeds of horses and the principles of feeding, breeding, and stabling horses, and includes a chapter on conformation.

Poultry feeding experiments, J. E. THOMAS (*Jour. Dept. Agr. Victoria, 24 (1926), No. 4, pp. 193-205*).—The results of feeding experiments with poultry

conducted at the State Research Farm at Werrabee from 1921 to 1925 are summarized (E. S. R., 53, p. 374).

The raising and fattening of turkeys (*North. Ireland Min. Agr. Leaflet 37* (1926), pp. 6).—The principles of turkey raising are described, and measures for the control of the most important diseases are recommended.

DAIRY FARMING—DAIRYING

The effect of ultra-violet light on the calcium and phosphorus metabolism of the lactating animal, J. MCA. HENDERSON and H. E. MAGEE (*Biochem. Jour.*, 20 (1926), No. 2, pp. 363-373, fig. 1).—This paper gives a more detailed account of the results of experiments previously noted (E. S. R., 54, p. 274), including the results of a fourth experiment in which the calcium and phosphorus balances were determined in one animal during 58 days, starting one month after parturition. The animal was irradiated for 16 days, during which the calcium excretion in the feces averaged 7.85 gm. per day, as compared with 8.00 gm. in the preceding 16-day period and 8.85 gm. in the following period. The daily amounts of phosphorus in the feces during the respective periods averaged 4.20, 3.90, and 4.97 gm. There was an increased urinary excretion of calcium during the period of irradiation. The conclusions are in general agreement with those given in the earlier paper.

The mineral metabolism of dairy cows as affected by distilled water and previous feeding, C. F. MONROE and A. E. PERKINS (*Jour. Dairy Sci.*, 8 (1925), No. 4, pp. 293-311).—Essentially noted (E. S. R., 55, p. 169).

Effect of bone meal on growth of dairy heifers, W. D. SALMON and W. H. EATON (*Jour. Dairy Sci.*, 8 (1925), No. 4, pp. 312-317, figs. 2).—Two lots of four heifers each were selected for a study of the effect of feeding 2 oz. of steamed bone meal daily to the heifers of one lot at the Alabama Experiment Station. The remainder of the ration consisted of corn and oats and Johnson grass and timothy hay, with Bermuda, carpet grass, and dallis grass pasture during the grazing season. Weights and measurements taken at 28-day intervals from December 10, 1922, to April 26, 1924, showed only slight differences in the two groups, though both the ration and pasture were very low in calcium.

Handbook of modern milk utilization, C. KNOCH (*Handbuch der Neuzeitlichen Milchverwertung. Berlin: Paul Parey, 1926, pp. XII+564, pl. 1, figs. 153*).—The various processes in the handling of milk and the manufacture of dairy products are described in the different portions of the book, including special reference to various kinds of dairy equipment and the bacteria associated with the manufacture of the different products. The properties of milk, butter, cheese, condensed and dried milk, and dairy by-products are discussed.

On the physiology of lactic acid bacteria [trans. title], A. VOËTKEVICH (WOJTKIEWICZ) (*Vest. Bakt. Agron. Sta. (Ber. Bact. Agron. Sta. Moskau)*, No. 24 (1926), pp. 113-128; *Ger. abs.*, p. 128).—This deals with the effect of various factors on the activity of lactic acid bacteria and the variations in types found in Swiss cheese.

Coli types and ropy milk, W. SADLER and J. D. MIDDLEMASS (*Sci. Agr.*, 6 (1926), No. 9, pp. 297-302).—Organisms causing ropy milk were isolated from milk produced on a certain farm. Samples of milk aseptically drawn into sterile test tubes, of milk taken at different stages in the usual process of straining, cooling, bottling, etc., and of the feed, bedding, and water were tested for the presence of rope-producing organisms.

The milk coming directly from the udder did not contain these organisms when aseptic precautions were observed, but such organisms were recovered from bottled milk, bedding, washings from a presumably clean pail, and from

milk at various stages after entering the milk pail. Eighteen typical strains were selected for a more detailed study of the characteristics of the organisms. The number of strains was later reduced to six. In general these types were short rods arranged singly or in clumps, were Gram-negative, and without capsules or motility. They produced an abundant growth on whey agar and in gelatin stab cultures, and produced ropiness in 7 to 17 hours at 21° C. in litmus milk, but no clotting occurred in several days.

Dextrose, lactose, galactose, saccharose, maltose, mannite, salicin, and glycerol were fermented with the formation of gas. Indol was not produced, but nitrates were reduced. All strains were killed by heating to 63° for 10 minutes.

A study of the cultural characteristics showed that all strains were closely allied to *Escherichia neapolitana* according to Bergey's classification, though slight differences were observed.

The original infection from the litter or manure probably infected the utensils, which continued the infection when improperly sterilized.

Carbonation of butter, M. J. PRUCHA, J. M. BRANNON, and H. A. RUEHE (*Jour. Dairy Sci.*, 8 (1925), No. 4, pp. 318-329).—In continuing the studies of the carbonation of dairy products at the Illinois Experiment Station (E. S. R., 47, p. 180), the effects of treating sweet cream with carbon dioxide, churning milk in a carbon dioxide atmosphere, and storing butter in a carbon dioxide atmosphere were determined, especially as related to the flavor and keeping qualities of the cream and butter and its influence on the development of germ life.

In the treatment of the sweet cream, gas was bubbled through different samples for 3 minutes on successive days, and the cream was kept at 40 and 70° F. The results showed that the first carbonation usually caused a slight reduction in the number of bacteria and retarded the development of acidity. It did not prevent bacterial growth, which later occurred at practically the same rate as in uncarbonated cream, though the types of bacteria were somewhat different. At room temperature both carbonated and uncarbonated cream kept about the same length of time, but at 40° F. the treated cream was sweet for 2 or 3 days longer.

In both laboratory and creamery tests churning in an atmosphere of carbon dioxide did not have any pronounced effects on the quality of the butter. A sour taste was evident in carbonated butter immediately after churning, which disappeared in storage. The treatment did not appear to affect the development of bacteria, molds, or yeasts.

Storing butter in a carbon dioxide atmosphere tended to suppress bacterial activity, especially at the lower temperatures, and such butter was always free from molds. The types of off-flavors developed after long storage were different from those found in uncarbonated butter.

The care of the churn and the quality and storing properties of the butter produced [trans. title], E. HAGLUND, C. BARTHEL, and E. WALLER (*Meddel. Centralanst. Försöksv. Jordbruksområdet [Sweden]*, No. 297 (1926), pp. 23; *Eng. abs.*, pp. 22, 23).—In these investigations the authors have shown that an improperly sterilized oak churn may contaminate the butter made in it with yeast and molds. Various methods of treating the churn were compared, the most satisfactory of which appeared to be the use of steam for boiling the water in the churn. When the churn was allowed to stand for 3 to 5 days without use, it was again strongly infected. Butter made in a sterilized churn had a slightly better score after 10 to 20 days' storage than butter made in an infected churn.

Extra sterilization of the churns in 14 different dairies did not definitely improve the quality or keeping properties of the butter, indicating that satisfactory sterilization was employed.

A study of the organisms causing thickening of sweetened condensed milk, P. A. DOWNS (*Jour. Dairy Sci.*, 8 (1925), No. 4, pp. 344-369).—In a study of the organisms causing thickening of condensed milk various types of bacteria from different sources were tested for their ability to thicken condensed milk. One thickened sample of commercial milk was found to contain almost a pure culture of a coccus.

Samples of fresh condensed milk were diluted in various ways and inoculated with creamery waste. The samples showed thickening and the presence of large numbers of cocci. A high acidity and a fruity odor were developed. Organisms producing thickening were later isolated from condensed milk, powdered milk, and from the air. A total of 1,054 cultures were studied, of which 318 caused thickening. The results indicated that the original source of the thickening organisms was the air, and that the milk probably became contaminated after manufacture.

The morphology and cultural characteristics of 32 of the cultures were studied to see if they were all of the same type. This study showed that these organisms were probably all variations of one type, resembling *Staphylococcus pyogenes albus* as closely as any. One of the strains was identical with this organism in cultural characteristics except that the latter would not thicken milk. Another strain did not reduce nitrates to nitrites and failed to ferment lactose. From the biochemical reactions of the thickening bacteria it was concluded that the thickening was caused by the production by the organism of a rennin-like enzyme.

Condensed milk and milk powder, O. F. HUNZIKER (*La Grange, Ill.: Author, 1926, 4. ed., rewritten and enl., pp. [16]+619, figs. 153*).—This is a revised edition of the book previously noted (*E. S. R.*, 44, p. 373), which has been much enlarged to include the newer developments in equipment and processes resulting from dairy research, and deals especially with the physical, chemical, and bacteriological phenomena that influence the quality of condensed and powdered milk.

AGRICULTURAL ENGINEERING

Soil erosion from early plowed wheat land, F. L. DULEY (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 11, pp. 731-734).—Studies conducted at the Missouri Experiment Station are reported which showed that under the conditions existing at the station the increased loss of soil by erosion due to early plowing for wheat may be considerable, and during this period has been slightly more than that during the rest of the year. On the whole, however, erosion from wheat land is not extremely serious, being only about half as much as from corn land. Where wheat follows another crop like corn or soy beans, and is itself followed by clover, the erosion is very greatly reduced. It is considered likely that on rolling lands in regions of rather high August and September rainfall it will be found more advisable to adjust the rotation so that the land will be covered with a crop practically all the time, rather than to emphasize the advantages of early plowing.

Soil erosion experiments on the experiment station, Peradeniya, T. H. HOLLAND (*Ceylon Dept. Agr. Yearbook, 1926, pp. 5, 6, pls. 2*).—Data from experiments on the measurement of erosion in tea soils are presented. The data were obtained from isolated plats washing into tanks. The amounts of erosion from

the different plats varied, the variations being caused largely by the uneven number of fully grown tea bushes.

Ridge cultivation in lower Gujarat, B. M. DESAI and K. B. NAIK (*Bombay Dept. Agr. Bul. 123 (1925), pp. 30, pls. 8*).—A new method of cultivation is described, and the results of experiments in its application to the black soil tracts in lower Gujarat are presented. In this method crops are grown on ridges and not on the flat. With judicious cultivation between the ridges the yield of cotton can be raised either in wet, dry, or normal years by an average of from 23 to 25 per cent, and that of sorghum by an average of over 23 per cent of grain and from 5 to 10 per cent of fodder.

The experiments showed that ridge cultivation affords good surface drainage, and prevents the land from becoming partially water-logged in the upper 8 or 10 in. during the period of heavy rain. The amount of weeding in ridged plats was found to be considerably less than on the flat. The experiments were made on fairly clean fields, however. The root developments of both cotton and sorghum were deeper on the ridged plats. The ridge system of cultivation was found to permit late intertillage. In the early stages of growth the crop on ridges remained green while that on the flat became yellow during heavy rain. It was possible to work the soil on the ridges after heavy rains much earlier than on the flat.

Flow of water in 54-in. concrete conduit, Denver, Colo., F. C. SCOBEEY (*Engin. News-Rec., 96 (1926), No. 17, pp. 678-680, figs. 3*).—Tests conducted by the U. S. D. A. Bureau of Public Roads of a 54-in. reinforced concrete conduit are reported which showed the capacity greater by 15 per cent than that accepted for the best conduits a few years ago. The results are taken to indicate that the Scobey formula, $V=C_s H^{0.5} d^{0.625}$, with a coefficient C_s of 0.37, as recommended for the best of concrete pipe, is very conservative. In this formula V is the velocity in feet per second, H is loss of head in feet per 1,000 ft. of pipe, and d is internal diameter in inches.

Public ground-water supplies in Illinois, G. C. HABERMAYER (*Ill. State Water Survey Bul. 21 (1925), pp. 710, pl. 1, figs. 10*).—This bulletin presents information relating to the quantity and quality of ground water available throughout the State of Illinois.

Financial limitation in the employment of forest cover in protecting reservoirs, W. W. ASHE (*U. S. Dept. Agr. Bul. 1430 (1926), pp. 35, pls. 18, figs. 4*).—In this bulletin those regions in which the influence of forests in protecting reservoirs used for power purposes is most important are pointed out, and the value of forest cover and the financial limitations in its employment to prolong the utility of a reservoir are discussed.

The principles and practice of surveying.—II, Higher surveying, C. B. BREED and G. L. HOSMER (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, vol. 2, 3. ed., pp. XVIII+489, figs. 184*).—This is the third edition of this handbook, which deals with higher surveying and is chiefly devoted to a consideration of the various methods of conducting topographic and hydrographic surveys. The subject matter is divided into the control of the survey, filling in topographic details, hydrographic surveying and stream gauging, and constructing and finishing maps.

Highway curves and earthwork, T. F. HICKERSON (*New York and London: McGraw-Hill Book Co., 1926, pp. XIV+382, figs. 50*).—This handbook presents briefly the problems of highway location, laying emphasis on the subject of curves and earthwork, including the banking and widening of pavements. The economic and aesthetic advantages of easement spirals are explained, and a variety of original tables is presented to facilitate the layout of these curves.

A theoretical treatment of curves illustrated with numerous examples is also given.

High-alumina hydraulic cements, P. H. BATES (*Indus. and Engin. Chem.*, 18 (1926), No. 6, pp. 554-559, figs. 5).—In a contribution from the U. S. Bureau of Standards the composition and properties of high alumina cement, especially as compared with Portland cement, are described, and its commercial uses are pointed out. This cement has a high strength and resistance to sulfate-bearing water, and attains the same strength in 24 hours that ordinary cements acquire in 28 days.

Strengthening and indurating concrete with sulphur, W. H. KOBBE (*Engin. News-Rec.*, 96 (1926), No. 23, pp. 940-942, figs. 2).—The results of tests extending over a number of years are briefly summarized which indicate that concrete may be impregnated with sulfur with an increase in strength and decrease in absorption. Commercial flour of sulfur, or sulfur in any other form, when added to the mix has little or no effect on the strength even though this contained sulfur is subsequently melted. In carrying out the sulfur treatment the precast concrete products, preferably well cured, are immersed in a bath of molten sulfur until the requisite degree of absorption has resulted. The treatment is applicable to all types of concrete and cement mortars, including high alumina cement, and with any aggregate chemically inert toward sulfur.

Tests show how calcium chloride affects concrete, A. S. LEVENS (*Engin. News-Rec.*, 97 (1926), No. 6, pp. 214, 215, figs. 4).—Studies conducted at the University of Minnesota to determine the effect of calcium chloride when used as an integral part of the mix upon the tensile and compressive strengths and the shrinkage effects of concrete are reported.

In the tension tests the strongest concrete was that which contained 2 per cent of calcium chloride and was cured one day in the moist chamber and then dried. Percentages of calcium chloride over 2 tended to weaken the concrete. During the earlier periods of set the increase in strength of the concrete containing 2 per cent of calcium chloride was 40 per cent greater than that of plain concrete. After 21 days concrete containing from 2 to 3 per cent of calcium chloride was stronger than concrete containing no calcium chloride, but the difference in strength was not very great.

In the compression tests an enormous increase in strength was noted during a very short period, amounting to 106 per cent over that of plain concrete. The strongest cylinders were those containing 2 per cent of calcium chloride and cured in air for the entire period.

In the shrinkage tests the use of calcium chloride increased the shrinkage and hastened the setting time, this continuing throughout the entire test period.

Compressive and transverse strength of hollow-tile walls, A. H. STANG, D. E. PARSONS, and H. D. FOSTER (*U. S. Dept. Com., Bur. Standards Technol. Paper 311* (1926), pp. 317-353, figs. 19).—Strength tests of 70 hollow-tile walls constructed with ordinary workmanship under average indoor conditions are reported. The walls were all 6 ft. long, 9 ft. high, and were either 8 or 12 in. thick. Fourteen different lots of tile and 4 different mortars were used in their construction. Twenty-seven of the walls were subjected to a transverse test before being tested in compression under central loading. Fifty-three of the walls were tested in compression under central loading and 17 under eccentric loading.

The mortar and workmanship seemed to be the most important factors affecting the strength of the end construction walls. Those with cement lime mortar were about 5.1 times as strong as those with lime mortar. The

mortar had relatively less effect upon the strength of the side construction walls. Those with cement lime mortar had 2.4 times the strength of those with lime mortar. There seemed to be no constant ratio between the strength of the walls and the strength of the tiles, but in general, using the same mortar, this ratio decreased with an increase in tile strength. With the eccentrically loaded walls, the maximum loads supported were about 60 per cent of the loads for similar walls centrally loaded.

The transverse strength of the walls was largely affected by differences in mortar and in the position of the tiles. In general the stronger mortars gave higher transverse strengths, and the walls having the tiles laid on the side were stronger under side load than with the tiles on end.

Roof coverings: Their manufacture and application, E. G. BLAKE (*New York: D. Van Nostrand Co., 1925, pp. XI+264, figs. [143]*).—This book describes the origin, nature, and methods of preparing the various materials and substances that are employed for covering the roofs of all classes of buildings. It contains chapters on the character and properties of a roof covering, thatch, organic roof coverings, metallic coverings, mineral coverings, manufactured mineral coverings, asbestos cement, bituminous felts, asphalt, glass, and cement concrete.

Heat transfer and evaporation, W. L. BADGER (*New York: Chem. Catalog Co., 1926, pp. 306, figs. 113*).—This book is intended for research workers in heat transfer and evaporation as well as for engineers designing and operating evaporating systems. It contains chapters on general theory of heat transmission—conduction and radiation; heat transfer by convection—general; heat transfer between solids and gases, solids and liquids, and between solids and condensing vapors, especially steam; heating and heater design; evaporator bodies; heat transfer in evaporators; theory and calculations for multiple-effect evaporators; multiple-effect operation; evaporator auxiliaries; evaporators as applied in specific industries; and costs.

Relation between fuel deposition temperature and equilibrium boiling point, W. A. WHATMOUGH (*Indus. and Engin. Chem., 18 (1926), No. 6, pp. 609-612, figs. 3*).—Studies are reported the results of which are taken to indicate that equilibrium boiling point is a real measure of the volatility of a motor fuel under running conditions. Furthermore, the equilibrium boiling point of a motor fuel is an accurate guide to the induction pipe temperature necessary to maintain a combustible mixture in a stable condition and thereby prevent fuel deposition.

Influence of temperature, fuel, and oil on carbon deposition, S. P. MARLEY, C. J. LIVINGSTONE, and W. A. GRUSE (*Jour. Soc. Automotive Engin., 18 (1926), No. 6, pp. 607-612, figs. 6*).—Studies conducted at the Mellon Institute of Industrial Research are reported which showed that high operating temperature, the use of the more volatile fuels and a lean air-fuel mixture, and the use of lubricating oils of relatively high volatility which contain little carbon residue all tend to reduce the deposition of carbon in an internal-combustion engine.

The data indicate that the carbon values are fairly constant until the head temperature rises somewhat above 400° F., after which there is a drop in them as the heat is increased. Deposits formed at the lower temperatures are much more asphaltic, softer, and less adherent than those formed at the higher temperatures. With evaporative or steam cooling, the head temperature was as low as or lower than the lowest with water cooling, and carbon deposition was almost at the same rate as with water cooling at the same temperature.

No marked change in quantity of carbon was noted with different fuels through the series of commercial gasolines, but excessively high carbon values

were obtained with heavy cleaners' naphtha and kerosene. A benzol blend gave slightly more deposit than motor fuel, but the deposit was softer and more soot-like. Natural gas gave only 5 per cent less deposit than commercial gasoline. This is taken to indicate that in a 12:1 mixture a good average grade of gasoline plays a very small part in the deposition of carbon.

In runs simulating ordinary cool-weather operation, with a 10:1 ratio of air and ordinary gasoline, lubricating oils distilled from Pennsylvania and Mid-Continent crudes gave considerably higher carbon deposits than oils derived from Gulf Coastal crudes.

Under conditions simulating summer operation, with a mixture ratio of 12:1, the carbon deposit with Gulf Coastal oil was only half of that with Pennsylvania oil, while that from Mid-Continent oil was midway between. Carbon deposits from Gulf oils were, in general, dry, powdery, and friable, while those from Pennsylvania oils were very hard and adherent over the hotter areas and sticky and asphaltic over the cooler areas of the combustion chamber. It is considered probable that the belief that there is a connection between so-called heat-resisting properties of an oil and its desirability as a lubricant is erroneous. The results indicate that oil which will leave the least residue upon evaporation from the metal surfaces will give the least trouble from carbon deposition.

Antiknock materials, W. H. CHARCH, E. MACK, JR., and C. E. BOORD (*Abstr. in Indus. and Engin. Chem.*, 18 (1926), No. 4, pp. 334-340, figs. 7).—Studies conducted at Ohio State University on antiknock materials are reported.

Nickel as the carbonyl was found to have an antiknock coefficient of 30; bismuth in its trialkyl and triaryl derivatives possessed a coefficient of from 18.2 to 20.2; and cadmium in its alkyl compounds and titanium as the tetra-chloride were also found to function but in a less marked degree. The state of valence of the antiknock element is not essential in determining which of its compounds should function.

Experiments on suppression of detonation in an open tube led to the conclusion that an attempt to apply the results obtained with the detonation tube to a study or an explanation of the suppression of the fuel knock in a motor is unjustified.

Studies on the electrical conductivity of the cylinder gases as a function of detonation showed that gaseous ionization decreases with decreasing detonation in internal-combustion engines. This decrease is noted irrespective of whether the knock is suppressed by the addition of an anti-knock compound or by changing the composition of the fuel. This is taken to indicate that antiknock materials affect this ionization only in so far as they tend to suppress detonation.

A chemical theory of antiknock materials and their action in suppressing detonation is presented.

Audibility anti-knock tests and knock-intensity evaluation, D. ROESCH (*Jour. Soc. Automotive Engin.*, 19 (1926), No. 1, pp. 17-23, figs. 18).—In a contribution from the Armour Institute of Technology a method of studying antiknock qualities of fuels, combustion chamber shapes, and efficiency of gasoline dopes is described.

The gas engine on the farm.—II, Starting troubles and their remedy, F. L. FAIRBANKS and F. G. BEHREND (N. Y. Agr. Col. (Cornell) Ext. Bul. 133 (1926), pp. 60, figs. 43).—Practical information on troubles encountered in the starting of farm gas engines is presented, continuing the series (E. S. R., 52, p. 288).

The wind-driven electric light plant, F. C. FENTON (*Iowa Agr. Col. Off. Pub.*, 24 (1926), No. 32, pp. 6-9, figs. 3).—Data from experiments at the Iowa Experiment Station on wind-driven electric light plants are briefly presented.

It was found that in most respects the airplane propeller wheel is apparently an improvement over the old type of windmill wheel, although the output of current, judging by three months' observation, was somewhat less. The airplane wheel began to send current into the batteries at a wind velocity of about 10 miles per hour. The current increased rapidly as the wind velocity increased from 15 to 20 miles per hour. Wind velocities above 25 miles per hour brought little increase in current, because the wheel did not remain facing the wind. This is taken to indicate that the propeller may be somewhat more efficient in high winds than the old type wheel, but it is much less efficient in low winds, since it can not utilize a velocity below 10 miles per hour.

Tests of agricultural machines [trans. title], M. RINGELMANN (*Ann. Sci. Agron. Franç. et Étrang.*, 43 (1926), No. 1, pp. 35-44).—Methods of testing agricultural machines and of mechanical experimentation followed in the station for testing machines of the National Institute of Agronomy of France are briefly described.

Plows and plowing, E. A. HARDY (*Saskatchewan Univ., Col. Agr. Ext. Bul.* 32 (1926), pp. 29, figs. 30).—Practical information on walking and riding plows, moldboard and disk plows, plow adjustments and hitches, and methods of plowing is presented.

Motor plowing tests with monopolin and benzol [trans. title], F. FRITZ (*Technik Landw.*, 7 (1926), No. 7, pp. 45-47).—Plowing tests with tractors and motor plows under as nearly as possible identical conditions to compare an alcohol-benzol mixture with straight benzol for fuel are briefly reported.

In all cases more of the mixed fuel was used than of the straight benzol, but this was apparently more than compensated for by the lower cost of the mixed fuel. The estimation of fuel consumption on the basis of time was found to be erroneous, a better basis being area plowed or volume of soil turned.

The conclusion was drawn that fuels consisting of mixtures of alcohol with more volatile materials, such as benzine or benzol, may be successfully used in tractor plowing.

A study of the dynamics of the disk harrow, E. G. MCKIBBEN (*Agr. Engin.*, 7 (1926), No. 3, pp. 92-96, figs. 7).—Studies conducted at the California Experiment Station are reported which showed that by the proper arrangement of gangs it is possible to obtain a disk harrow which tills a strip of land, the center of which is offset from the center of the tractor, and which at the same time operates without side draft upon either the harrow or the tractor. Only one position behind the tractor could be found where a given disk harrow with a given arrangement, position, angle, and weighting of gangs, operating at a given speed on given soil conditions, could be operated without side draft. It was found possible to design a disk harrow in which the gang arrangement could be easily changed so that it might be operated without side draft, either directly behind the tractor or with either a large right or left hand offset.

Single grain seeding machines [trans. title], A. NACHTWEH (*Deut. Landw. Presse*, 51 (1924), Nos. 12, pp. 126, 127; 13, p. 137, figs. 5; 15, p. 160, figs. 10; 16, p. 174, figs. 10; 17, pp. 186, 187, figs. 7; 18, p. 197, figs. 2).—A review of the history of the development of single grain seeding machines is given.

Tests of fertilizer spreaders and grain binders [trans. title], MARTINY and FISCHER (*Arb. Deut. Landw. Gesell.*, No. 330 (1925), pp. 68, figs. 42).—Comparative service tests of a number of different makes of fertilizer spreaders and grain binders are reported.

The fertilizer spreader tests showed that with heavy fertilizer applications distribution was generally quite uniform, but that uniformity of distribution decreased as the size of application decreased. This was especially true with such materials as lime and kainit. Uniformity of distribution was found to depend upon the discharging apparatus and vibration of the machine, the uniformity of speed of operation, and the nature of the fertilizer.

German binders gave as good results as American machines.

Automatic feed grinding with motors, J. B. DAVIDSON (*Iowa Agr. Col. Off. Pub.*, 24 (1926), No. 32, pp. 4-6, fig. 1).—Experiments conducted at the Iowa Experiment Station indicated that a small motor can be used for feed grinding, that time control is practicable, and that quantity control is easily arranged. The small grinder was found to have as high an efficiency as larger grinders, and the use of magazine bins saved labor.

A survey of farm fires (*Harrisburg: Penn. State Police, 1925, pp. 35*).—This survey, made by the Bureau of Fire Protection of the Pennsylvania State Police in cooperation with the Pennsylvania Experiment Station, deals with the cause of farm fires in the State and gives practical information on prevention. Special attention is drawn to the danger of spontaneous combustion, and this phenomenon is discussed in some detail, with special reference to means for preventing its occurrence. A list of 32 references to literature bearing on the subject is included.

North Carolina poultry houses, A. G. OLIVER, H. H. GORDON, C. F. PARRISH, and B. F. KAUPP (*N. C. Agr. Col. Ext. Circ. 161* (1926), pp. 8, fig. 1).—Information on the construction of poultry houses adapted to North Carolina conditions is given, together with bills of material for typical houses.

Colony brooder houses, A. C. SMITH, C. E. COOKE, and H. B. WHITE (*Minn. Univ. Agr. Ext. Spec. Bul. 105* (1926), pp. 12, figs. 7).—Practical information on the planning and construction of colony brooder houses adapted to Minnesota conditions is presented, together with working drawings of typical structures.

Equipment for hogs, A. L. DURANT (*Clemson Agr. Col. S. C., Ext. Bul. 71* (1926), pp. 27, figs. 16).—Structural equipment for hog farms, including fencing, buildings, feeders, watering devices, breeding crates, etc., is described. Working drawings and bills of materials for this equipment are included.

Mechanical conservation of organic manures, E. BERENDT (*Mechanische Konservierung des Organischen Düngers. Neudamm: J. Neumann, 1925, pp. 86, pls. 3, figs. 20*).—This is a handbook of information on the construction of liquid and solid manure pits, compost pits, and sanitary cow stables.

Farm water supply and sewage disposal in West Virginia, F. D. CORNELL, JR. (*West Virginia Sta. Bul. 206* (1926), pp. 27, figs. 23).—Studies of the sanitary conditions on 287 farms in three West Virginia counties are reported. Of the farms visited, 66 could have had the convenience of running water in the house by merely piping the water direct. Cisterns seemed to be growing in popularity as a source of water supply, but not enough attention was being paid to properly filtering the cistern water used for drinking purposes.

On 124 of the farms the open back privy was in use, 90 others were built on the surface but closed at the rear, and on 21 farms there were no privies at all. No septic tank privies were found, and only 44 of the farms had pit privies.

Where bath equipment was found the effluent was either drained out on the surface of a field or into a near-by creek. No septic tanks were found, although the need for them was apparent.

A septic tank, E. R. GROSS (*N. J. Agr. Col. Ext. Bul. 52* (1926), pp. 16, figs. 13).—Practical information on the disposal of farm sewage is given, together

with working drawings and data for typical structures adapted to New Jersey conditions.

Some observations on sewage tank gases, A. M. BUSWELL and S. I. STRICKHOUSER (*Indus. and Engin. Chem.*, 18 (1926), No. 4, pp. 407-409).—The results of studies conducted by the Illinois State Water Survey Division are reported which show that gases from foaming Imhoff tanks contain more carbon dioxide, less nitrogen, and substantially the same amount of methane as gases from nonfoaming tanks. It is thought that the amount and heating values of gas available from Imhoff tanks are sufficient to warrant its collection and use for fuel purposes.

RURAL ECONOMICS AND SOCIOLOGY

Variations in costs of producing corn, wheat, and other crops in Greene County, Ohio, J. I. FALCONER and J. F. DOWLER (*Ohio Sta. Bul.* 396 (1926), pp. 233-284).—The cost of producing crops was studied on 25 farms during 1920 to 1924, the data being collected by the route method. The average area of the farms was 162 acres, of which 137 acres were in rotated crops and 10 acres in permanent pasture. An average of 51 acres was in corn, 27 in wheat, 13 in oats, 24 in rotated pasture, and 17 in hay. Tables are given showing for each farm the man, horse, and tractor labor used per acre, the expenditures for labor, manure and fertilizer, taxes, interest, seed, equipment, overhead, etc., the yields, and the total costs per acre and per bushel of growing corn up to harvest and of growing and harvesting wheat and oats. Similar tables are included for harvesting corn by different methods and for growing and harvesting hay and alfalfa and for producing pasture. The costs, including interest, were found to be 34 to 57 cts. per bushel, with an average of 46 cts., for growing corn up to harvest; 81 cts. to \$1.32, averaging 94 cts., for growing and harvesting wheat; 30 to 98 cts., averaging 50 cts., for growing and harvesting oats; \$5.88 to \$15.07 per ton, averaging \$11.46, for growing and harvesting hay; and \$1.41 to \$3.13, averaging \$2.18, per animal-unit-month for producing clover and timothy pasture.

Analaysis is made of the costs on the several farms to show the factors that increase costs, and the methods of gaining efficiency and lower costs of production. The costs per bushel of harvesting corn, allowing credit for stover, varied as follows, with labor charged at the average regular labor price: Husked from stalk 9.9 cts., cut by binder and husked from shock 13.2 cts., cut by hand and husked from shock 11.2 cts., and cut by hand and shredded 10.4 cts. With labor for cutting, shredding, and husking from shock at contract prices, the costs were from 2 to 7.2 cts. per bushel higher. The following standard labor requirements per acre for the different crops were obtained: Growing corn 7.9 man-hours, 24.9 horse-hours; husking corn from stalk 6.3 man-hours, 12.6 horse-hours; cutting corn with binder and husking from shock 16.5 man-hours, 9.4 horse-hours; growing and harvesting wheat 6.2 man-hours, 10.3 horse-hours; growing and harvesting oats when seed was drilled 6.1 man-hours, 11.2 horse-hours; growing and harvesting oats when seed was broadcasted 5.6 man-hours, 9.3 horse-hours; and growing and harvesting hay 5.1 man-hours and 7.4 horse-hours.

Cost of living on Iowa farms, [I], G. H. VON TUNGELN, J. E. THADEN, and E. L. KIRKPATRICK (*Iowa Sta. Bul.* 237 (1926), [pt. 1], pp. 56, fig. 1).—This study, which was carried on cooperatively with the Bureau of Agricultural Economics, U. S. D. A., is one of the series previously referred to (E. S. R., 50, p. 595) and covers 472 farms in 4 areas in Boone, Story, and Sac Counties, of which 212 were operated by owners, 239 by tenants, and 21 by hired men. The average size of the families was 4.7 persons for owners and hired men

and 4 persons for tenants. Tables and interpretative text are included showing for each class of operators the size of family, ages of parents and children, relation of tenants to landlords, education of operators, their wives and children, reading matter in homes, size of farms, size and value of houses, modern conveniences and labor-saving devices, and by class of operators and area studied the expenditures for the different items entering into the cost of living, the proportion of the living furnished by the farms, etc.

The average total annual family costs of living in the 4 areas were \$1,875.90 for owners, \$1,506.40 for tenants, and \$1,431.50 for hired men, of which \$1,119.20, \$861.20, and \$842.40, respectively, was expended in cash, the balance in each case being furnished by the farm. Of the average total costs for the families of the 451 owners and tenants food, clothing, rent, furnishings and equipment, operating expenses, health, advancement, personal expenses, and insurance represented 37.1, 14.6, 15.5, 2, 14.2, 5, 6.5, 1.6, and 3.5 per cent, respectively. Of the families of owners 6.6 per cent had expenditures of \$1,000 or less, and an equal number had expenditures of \$3,000 or more. The corresponding percentages for tenants were 9.2 and 1.2. Tenants averaged 12.8 years younger than owners, and their families averaged 0.8 of a person smaller.

Cost of living on Iowa farms.—II, Household expenditures, H. KYRK (*Iowa Sta. Bul. 237 (1926), pt. 2, pp. 57-79*).—Part 2 is based upon the study of the account books of 10 farm families, the average size of which was 3.5 persons. The average cash expenditures were \$927, of which the expenditures for food, clothing, furnishings and equipment, operating expenses, and health were 21.7, 19.1, 6.3, 26.5, and 4.4 per cent, respectively, as compared with \$982.50 and 13.2, 14.6, 2, 12, and 5 per cent, respectively, for the 451 families of owners and tenants included in part 1 (see above).

The ownership of tenant farms in the United States, H. A. TURNER (*U. S. Dept. Agr. Bul. 1432 (1926), pp. 48, figs. 21*).—This study is based on data of the U. S. Bureau of the Census of 1920 for 256,175 rented farms in 184 selected counties in 24 States. Tables and explanatory texts are given covering the concentration of ownership; residence, age, farming experience, and occupation of owners of rented farms; method of acquiring ownership; kinship of tenants to owners; supervision and advice given tenants by owners; and the tendency with regard to fertility on rented farms. Comparisons are made with data of the census of 1900 for all rented farms in the United States.

The landlords in 1920 owned an average of 1.65 farms and 169 acres, as compared with 1.54 farms and 147 acres in 1900. Large holdings of rented farms are few in the Northern States, but are fairly common in the Southern States. The percentage of landowners resident in the same State as the lands owned increased from 94.7 in 1900 to 94.9 in 1920, and of those resident in the same county from 78.8 to 80.4. Only 16 per cent of the acreage owned by landlords in 1920 had been inherited and only 8 per cent of the landlords had not had farm experience. In the South 54 per cent of the owners were farming themselves, 67 per cent lived on farms, and only 10 per cent reported themselves as having no occupation. In the North only 20 per cent of the owners were farming, 37 per cent lived on farms, and 35 per cent were without occupation. On an average only 12 per cent of the tenants in the southern areas were related to their landlords, while in several of the northern areas as high as 33 per cent were related by blood or marriage.

The ownership of tenant farms in the North Central States, H. A. TURNER (*U. S. Dept. Agr. Bul. 1433 (1926), pp. 40, figs. 17*).—This bulletin deals with the conditions in 85 counties in 12 of the North Central States, being a special report of part of the counties covered in the preceding bulletin.

About 4 per cent of the rented farms were owned by men owning five or more farms and about 10 per cent of the rented acreage by owners of 1,000 acres or more. Landlords owning one or two rented farms owned 88.7 per cent of the rented farms in 1920, as compared with 87.4 per cent in 1900. In 1920, 73.7 per cent of the rented farms were owned by persons living in the same county and 89.2 per cent by persons living in the same or adjoining counties. Forty per cent of the owners were found to live within 3 miles of their rented farms. The average age of landlords was nearly 60 years, over 90 per cent of them had had farm experience, and a large proportion had been tenants. Over one-third of the tenants were related to their landlords. The landlords had acquired only about one-seventh of their acreage by inheritance and 70 per cent of them had more than one child.

The taxation system of South Carolina, W. H. MILLS (*South Carolina Sta. Bul. 231 (1926), pp. 79, figs. 2*).—This investigation was conducted jointly with the tax conference called by the Governor, the object being "to study the tax system of South Carolina, its manner and method of return of property for taxation, particularly as related to agriculture; to discover inequalities as between county and county, person and person, class and class; to determine what tax revisions are necessary and where they can be made, to get the facts of the present system, and use these as a basis for legislation to effect a just and equitable tax system for the State."

The present constitutional provisions and statutes pertaining to taxation are set forth and the actual workings thereof discussed. The recommendations to the tax conference for improving the taxation system made by the committee of seventeen appointed by the chairman of the tax conference and referred to the 1926 session of the legislature are given, together with a discussion of the legislation passed. The changes still most desired are such supervision and control by the tax commission as will place all tangible property, real and personal, upon the same basis; such amendments to the constitution and the statutes as will permit the classifying of property into tangible and intangible and the assessing of the two classes at different rates; and the subdivision of these classes for State, county, and municipal taxing purposes.

Cooperative cream pools in Idaho, F. W. ATKESON and D. L. FOURT (*Idaho Sta. Bul. 144 (1926), pp. 33, figs. 6*).—From 4 pools organized in 1922 the number to May, 1926, had increased to 14, besides 2 which had developed into cooperative creameries. The 9 pools operating in 1925 paid from 2.86 to 7.34 cts. more per pound for butterfat than the cream station prices, the average being 4.7 cts. on 1,999,660 lbs. handled. The number of cream stations or buyers in the territory of 8 of the pools was reduced during the first year of operation of the pools from 29 to 11. In 3 pools organized in 1922 and 1923 the percentage of sweet cream handled increased from 58.8, 48, and 70 per cent, respectively, in 1923, to 81.8, 78, and 78 per cent in 1925. The outstanding advantages of cream pools are set out and suggestions given as to the methods of organization and operation, including legal forms.

AGRICULTURAL AND HOME ECONOMICS EDUCATION

Farm youth: A selected list of references to literature issued since January, 1920, compiled by M. T. OLCOTT and L. O. BERCAW (*U. S. Dept. Agr., Bur. Agr. Econ., Agr. Econ. Bibliog. 17 (1926), pp. [3]+40*).—A mimeographed list of the literature on rural youth in the United States, prepared for use at the Ninth National Country Life Conference, November, 1926.

Boys' and girls' 4-H club work, C B. SMITH (*U. S. Dept. Agr., Misc. Circ. 77 (1926), pp. II+16, figs. 13*).—In 1925 about 565,000 rural boys and girls out of 11,000,000 in the United States from 10 to 18 years of age were enrolled in

about 41,000 4-H clubs. This circular, prepared at the request of the committee on extension organization and policy of the Association of Land-Grant Colleges, presents a statement of the object of club work, what club work is and does, and the club problem, and outlines the national program for expanding the work.

A decade of negro extension work, 1914-1924, O. B. MARTIN (*U. S. Dept. Agr., Misc. Circ. 72 (1926), pp. II+30, figs. 12*).—A historical account of the development, activities, and results of negro extension work from 1914 to 1924.

FOODS—HUMAN NUTRITION

A study of certain factors affecting shrinkage and speed in the roasting of meat, A. F. MORGAN and P. M. NELSON (*Jour. Home Econ., 18 (1926), Nos. 7, pp. 371-378, figs. 3; 8, pp. 441-448*).—In an effort to determine means of hastening the roasting process for meats without detracting from the quality of the finished product, 2-rib standing beef roasts were roasted under varying conditions with thermometers inserted in the meat to record internal temperatures as in previous studies of Sprague and Grindley (*E. S. R., 19, p. 665*).

The effect was first studied of nickel-plated copper skewers plunged hot into the raw meat and kept there during the roasting. The roasts were removed when internal temperatures were reached of 51° C. for rare meat, 60° for medium, and 70° for well done. The time required to reach these temperatures was considerably shortened by the use of the skewers, the average decrease being 6.6 minutes per pound or about 30 per cent. The decrease in time appeared to be proportional to the amount of copper (number of skewers) introduced. The total loss of weight was less with the skewered than with the unskewered meat. When the skewers were removed as soon as the meat was taken out of the oven the usual rise in internal temperature of the roast occurred, but when left in the cooling was immediate. The skewered roasts were uniformly more juicy, tender, and appetizing in appearance than the unskewered.

A comparison of the results obtained in covered and uncovered pans was also made, with the general conclusion that with respect to speed of roasting, shrinkage, appearance, and taste there was no great difference between the two. In comparing the speed of cooking and the shrinkage of roasts in which the initial temperature of 250° was lowered after 15 minutes to 175° with that of roasts cooked throughout at the initial high temperature, it was concluded that there is relatively small advantage in decrease of shrinkage in the first method but a decided advantage in speed in the second. This was particularly true when skewers were used.

No definite relation appeared to exist between size of roast and length of time per pound required to reach a given internal temperature in the unskewered roasts. With the skewered meats there was a more definite decrease in time per pound with decreasing size. Shrinkage depended entirely upon the length of time of roasting. The speed was directly proportional to the surface area of unskewered and inversely proportional in the case of skewered roasts. The loss of weight from bones when roasted in their natural place in the cut was found to be negligible. The loss of fat was irregular, depending upon its location and concentration in the raw meat.

The problem of test bakes, with a discussion of certain of their chemical and physical aspects, F. L. DUNLAP (*Cereal Chem., 3 (1926), No. 4, pp. 201-215*).—In this discussion the author emphasizes the importance of the initial H-ion concentration of the flour as affecting the quality of the test loaf, presenting evidence from the literature and from his own experience that flours with a lowered initial pH and short fermentation periods yield better results

than fresh flour under any conditions of working and fermenting the dough. Attention is called to the fact that the personal element enters into baking tests, and that tests conducted on the same flour simultaneously by different workers may give quite different results. In the use of flours with a lowered pH, reversing the time periods of fermentation by having the shorter period first is recommended.

The problem of standardizing the experimental baking test, M. J. BLISH (*Cereal Chem.*, 3 (1926), No. 4, pp. 216-222).—Attention is called chiefly to different interpretations of the term "baking quality." In the author's opinion this term should refer to the inherent possibilities of a given flour, and "baking strength" to this quality, together with the ability more or less successfully to withstand a certain amount of variation in handling. With this distinction of terms it is thought that a standard experimental baking process should indicate strength rather than quality alone.

Woman's Institute library of cookery, I-V (*Scranton, Pa.: Woman's Inst. Dom. Arts and Sci.*, 1925, vols. 1, pp. VI+[233]+XIII, figs. 87; 2, pp. VI+[218]+XI, pl. 1, figs. 71; 3, pp. VII+[250]+XII, pl. 1, figs. 155; 4, pp. VI+[251]+X, figs. 127; 5, pp. VIII+[311]+XIV, pl. 1, figs. 93).—These five volumes comprise the instruction papers of the courses in cookery of the Woman's Institute of Domestic Arts and Sciences, Scranton, and as such include instruction covering the various phases of the subject of cookery as it is carried on in the home, together with selected recipes for the various types of foods discussed. The arrangement of subject matter is as follows: Essentials of cookery, cereals, bread, and hot breads; milk, butter, and cheese, eggs, and vegetables; soup, meat, poultry and game, and fish and shellfish; salads and sandwiches, cold and frozen desserts, cakes, cookies, and puddings, and pastries and pies; and fruit and fruit desserts, canning and drying, jelly making, preserving, and pickling, confections, beverages, and the planning of meals.

Foods and drugs, J. M. BARTLETT (*Maine Sta. Off. Insp.* 119 (1926), pp. 32).—This is the annual tabulation of the results of the examination of food and drug samples collected by the inspectors of the division of inspection of the State department of agriculture (E. S. R., 54, p. 790).

Ice cream as a cause of epidemics, F. W. FABIAN (*Amer. Jour. Pub. Health*, 16 (1926), No. 9, pp. 873-879).—A review of the literature on epidemics which have been traced to ice cream is reported, with recommendations for sanitary precautions to protect the ice cream supply. The safeguards suggested are pasteurizing the ice cream mix at 150° F. for 30 minutes, establishing a bacteriological standard of 100,000 colonies per gram, and regular sanitary inspection of ice cream plants. A list of 44 references to the literature is appended.

Can purines, creatinine, or creatine replace histidine in the diet for purposes of growth? G. J. COX and W. C. ROSE (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 769-780, figs. 4).—In this and the following paper are presented the results of growth experiments in which young rats received diets deficient in histidine but supplemented with organic compounds similar to histidine in their chemical structure, the object being to determine whether or not these compounds can replace histidine in metabolism.

In the present study adenine, guanine, creatine, and creatinine alone and in combination were substituted for histidine in an otherwise complete diet. In no case was there any growth response. "It is evident that the purines, despite the fact that they contain the imidazole grouping, are quite unable to replace histidine in nutrition. This fact would appear to indicate that the formation of purines from histidine is an irreversible reaction in the animal body."

The availability of synthetic imidazoles in supplementing diets deficient in histidine, G. J. COX and W. C. ROSE (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp.

781-799, figs. 5).—Several synthetic compounds containing the imidazole ring were substituted for histidine in a basal diet in which the nitrogen was supplied in the form of completely hydrolyzed casein from which most of the histidine had been removed by precipitation with silver sulfate and barium hydroxide. All of the compounds tested were without effect with the exception of *dl*- β -4-imidazole lactic acid, which caused an immediate resumption of growth at a rate only slightly slower than that induced by an equivalent quantity of histidine. "It is evident that under the conditions of the experiments the synthetic product in question is capable of serving in place of histidine, probably through being transformed by the cells into the amino acid. The above results constitute the first successful attempt, by means of growth experiments, to replace an indispensable amino acid of the diet by a nonamino compound."

Studies in carbohydrate metabolism.—I, The utilisation of dihydroxyacetone by the animal body and a method for its estimation, W. O. KERMACK, C. G. LAMBIE, and R. H. SLATER (*Biochem. Jour.*, 20 (1926), No. 3, pp. 486-496).—Evidence is presented that dihydroxyacetone is capable of curing insulin hypoglycemia in rabbits and mice in approximately the amounts and time required for glucose, and that it is more rapidly removed from the blood stream by the muscles than is glucose or levulose. This was also demonstrated in diabetic individuals, and is thought to indicate that dihydroxyacetone is directly utilizable by the normal animal organism without being first converted into glucose.

A method is outlined for the detection and estimation of dihydroxyacetone in small amounts of blood.

The vitamins (A, B, and C) of papaya, C. D. MILLER (*Biochem. Jour.*, 20 (1926), No. 3, pp. 515-518).—A limited amount of evidence is given that Hawaiian papaya "is only a fair source of vitamin B, a good source of vitamin A, and an excellent source of vitamin C." In the vitamin A and B studies the amounts of papaya fed daily varied from 5 to 20 gm. There was some growth even on the smallest amount in the A experiments, but satisfactory growth was not secured in the B experiments on amounts below 20 gm. The minimum dosage for protection against guinea pig scurvy was not determined, but 3 gm. appeared to give as complete protection and to cause as good gains in weight as 5 gm.

The bodily store of vitamin A as influenced by age and other conditions, H. C. SHERMAN and L. B. STORMS (*Jour. Amer. Chem. Soc.*, 47 (1925), No. 6, pp. 1653-1657, fig. 1).—"The experiments described in the present paper deal (1) with the age at which experimental animals (albino rats), under known conditions of feeding, attain their maximum store of vitamin A as indicated by the length of time they are able to survive when transferred to a diet devoid of this vitamin but adequate in all other respects, and (2) with the influence of previous feeding upon the relative store of vitamin A in the body at different ages as indicated by the period of survival when placed on vitamin A-free food."

In the first series male white rats, which had previously received a diet of $\frac{1}{3}$ whole milk powder and $\frac{2}{3}$ ground whole wheat, with salt in the proportion of 2 per cent of the weight of the wheat, were transferred to a vitamin A-free diet at different ages, and their survival periods noted. The average survival period for rats placed at 4 weeks of age on the basal diet was 63 days, at 2 months 111, at 3 months 122, at 4 months 148, at 6 months 171, and at 9 months 140 days. The age at which the survival period was the longest is that at which full adult size is reached, showing that storage of vitamin A increases with growth to maturity. In the animals in this series, three-fourths of those placed at 4 weeks upon the vitamin A-free diet developed ophthalmia before death, while among those from 2 to 9 months of age only one-fourth developed

it on the same diet. The older animals proved more susceptible than the young to lung infection. Other clinical symptoms noted in animals dying from vitamin A deficiency were pus in one or more of the glands at the base of the tongue and pus in the middle ear, both affecting about 75 per cent of the animals, and sinusitis in about 50 per cent.

Parallel with this series similar experiments were carried on with female rats on the same diet and with males and females on a diet consisting of $\frac{1}{6}$ milk powder and $\frac{5}{6}$ whole wheat and consequently furnishing less vitamin A. The survival periods were in all cases longer for the animals which had been fed the diet richer in vitamin A, and on both diets increased with the age of the animals when placed on the deficient diet. A comparison of the survival periods of males and females from the same stock on the same diet showed differences in favor of the females negligible at 4 weeks but becoming more distinct with age and development. "It is interesting that pregnancy and suckling of young have not, in the few cases yet studied, seemed to deplete the female organism of vitamin A to the extent of noticeably shortening her survival period. The possibility is therefore suggested that the development and exercise of the reproductive functions in the female may enhance the ability to conserve vitamin A or in some way to use it more economically in case of need."

A quantitative study of the storage of vitamin A, H. C. SHERMAN and M. L. CAMMACK (*Jour. Biol. Chem.*, 68 (1926), No. 1, pp. 69-74, figs. 2).—In continuation of the above-noted studies on vitamin A storage under varying conditions, a series of rats was fed from weaning on the one-third whole milk powder two-thirds ground wheat diet alone and with 1, 2, and 4 per cent of cod-liver oil for 3, 4, and 6 months after weaning, after which the vitamin A-free diet was fed until death. Grouped by the age at which the transfer to the deficient diet was made, the survival periods increased with the length of time on the original diet, and within the age groups increased, although not in the arithmetical proportion, with the richness of the original diet in vitamin A.

In the second series, the vitamin A-containing diet was given for 2 and 6 months, respectively. In addition to the groups on this diet alone, other groups were given 4 per cent of cod-liver oil for varying lengths of time, 1, 2, and 4 weeks for the first group and 1, 2, 4, 8, and 20 weeks for the second. The addition of cod-liver oil for only 1 week increased the survival period by more than 40 days. With longer periods the survival periods were lengthened, but again not in arithmetical proportion.

In a supplementary experiment, 3 rats from a single litter were given 4 per cent of cod-liver oil for 2, 4, and 7 days, respectively, after weaning, and the remaining one was placed at once on the vitamin A-free diet. The survival period was increased by 30 days or over 50 per cent by the 2 days' feeding, about 90 per cent by the 4 days', and 120 per cent by the 7 days' feeding of the cod-liver oil. In another instance 1 day's feeding of cod-liver oil ad libitum increased the average survival period of 2 rats by more than 50 per cent over that of 2 controls from the same litter, all of which had been kept on the vitamin A-free diet until growth ceased.

It is concluded that "attainment of the maximum store of vitamin A is apparently a process of gradual accumulation which is relatively rapid in its earlier stages and becomes slower as the maximum is approached. A rapid storage of the entire maximum amount is apparently not possible."

Destruction of vitamin A in milk by ultra-violet light, R. W. TITUS, J. S. HUGHES, W. R. HINSHAW, and J. B. FITCH (*Indus. and Engin. Chem.*, 18 (1926), No. 8, p. 843, fig. 1).—Two lots of day-old White Leghorn chicks, 14 in each lot, were fed identical rations of 90 per cent white corn chop and 10 per cent tankage supplemented with 5 cc. of fresh whole milk as the sole source of

vitamin A. The milk fed one lot was untreated and the other irradiated in shallow pans. All of the chicks were irradiated for 15 minutes daily.

At the end of 7 weeks all but 1 of the chicks receiving the irradiated milk had died as against only 2 of the lot receiving the nonirradiated milk. Two of the chicks which died in the first lot showed well advanced stages of ophthalmia. Other lesions noted were enlargement of the kidneys, with deposits of urates in the tubules, and similar deposits in the pericardial sac, over the pericardium, and covering the liver and intestines. The results are thought to point to a definite destruction of vitamin A through irradiation, and to indicate that while the irradiation of milk increases its nutritive value for infant feeding through increasing its content of vitamin D it at the same time decreases its value as a source of vitamin A.

The difference in chemical composition of the skeletons of young rats fed (1) on diets deprived of fat-soluble vitamins and (2) on a low phosphorus rachitic diet, compared with those of normally nourished animals of the same age, H. CHICK, V. KORENCHEVSKY, and M. H. ROSCOE (*Biochem. Jour.*, 20 (1926), No. 3, pp. 622-631).—Extensive data on the composition of the bones of rats on various diets of known composition are summarized and discussed. For purposes of comparison the animals whose skeletons were studied were classified in three groups, the first receiving a complete diet, the second a diet lacking in vitamins A and D but adequate in other respects, and the third a low-phosphorus, high-calcium, rickets-producing diet containing a moderate supply of vitamin A.

The chemical composition of the osteoporotic bones of the young rats on the diet deficient in fat-soluble vitamins alone was characterized by a proportion of fat (alcohol and ether-soluble material) in excess of the normal, a proportion of ash (A) less than normal, a normal proportion of organic material, cartilage, and connective tissue (R), and a ratio of A : R varying from 0.9 to 1.2 as compared with a normal value of about 1.5. Compared with this the bones of the animals on the low-phosphorus, rickets-producing diet were characterized by a content of ash (A) very much below normal, a water content much above normal, a slightly higher content of fat and organic material (R), and a very low value of the A : R ratio (from 0.4 to 0.8). In the bones of the rats receiving cod-liver oil in addition to the low phosphorus diet, the A : R ratio was 1.

"If chemical examination is used in the diagnosis of rickets, the best criterion of defective calcification is given by the value of the A : R ratio, or the ratio of the amount of ash to the amount of organic material contained in the fat-extracted bone."

The white potato as a source of vitamin B, F. J. LYMAN and I. BLYSTONE (*Jour. Home Econ.*, 18 (1926), No. 4, pp. 199-204, fig. 1).—On account of the fact that the data on the vitamin B content of white potatoes reported by Osborne and Mendel (*E. S. R.*, 42, p. 759) were obtained with the older technique in which care was not taken to prevent access of the rats to their excreta, the authors have determined by the newer method of caging the vitamin B content of two varieties of white potatoes, an Early Ohio variety grown in Ohio and an unknown variety grown in Michigan. The basal diet used was that of Sherman and Spohn (*E. S. R.*, 51, p. 368), modified by increasing the fat content and decreasing the starch to make a pasty mixture not easily scattered. The potatoes were boiled, peeled, riced, dried for 24 hours at a temperature not exceeding 70° C., ground through a 20-mesh screen, and incorporated in the diet in amounts of 5, 10, 20, 40, and 80 per cent, replacing equivalent amounts of starch.

Satisfactory growth was not secured on amounts up to and including 40 per cent. On 80 per cent good growth was secured. It is concluded that

"the white potato contains somewhat more vitamin B than is required for its own metabolism in the rat. If human requirements are of the same order, the white potato can not be depended on safely to make good any considerable deficiencies of vitamin B in other articles of the diet. With only 5 per cent of potato present, typical polyneuritis appears almost as soon as when vitamin B is absent from the ration."

A vitamin B deficiency manifesting itself for the first time in the second generation, I. A. MANVILLE (*Science*, 64 (1926), No. 1654, pp. 256, 257).—A preliminary report is given of evidence that on a ration furnishing insufficient vitamin B pregnant rats may show no evidence of this deficiency while the young develop symptoms of polyneuritis about two weeks after birth, although growing normally up to the onset of these symptoms. This is considered of significance as indicating that the maternal organism does not always deplete its store of the antineuritic vitamin to supply a sufficiency of it to the young, as well as furnishing further evidence that the growth-promoting vitamin B and the antineuritic vitamin are not identical. The failure to reproduce on diets deficient in vitamin B is thought to be due to this failure to transfer the necessary amount at the expense of the mother. The importance is emphasized of increasing the vitamin B (antineuritic) content of the diet during pregnancy and lactation.

The signs of health with special reference to nutrition, H. CHAPLIN (*Jour. Home Econ.*, 18 (1926), No. 9, pp. 485-492).—In this paper presented at the American Health Congress, May, 1926, the author discusses briefly the outstanding clinical signs of health in children in respect to the eyes, color, teeth, hair, skin, fat, muscles, chest, extremities, foot-arch, position of foot, and weight. Under manifestations of a well-functioning body are discussed expression, muscular coordination, breathing, appearance of the tongue, bodily repose, freedom from fatigue, and good posture, with the influence of age upon some of these signs of health.

Basal metabolism in prolonged fasting in man, N. KLEITMAN (*Amer. Jour. Physiol.*, 77 (1926), No. 1, pp. 233-244, fig. 1).—Data are reported on the basal metabolism during and after a 41-day fast undergone by the male subject in the previously reported studies of Kunde (*E. S. R.*, 51, p. 67).

During the fasting period the body weight of the subject fell from 65.5 to 48.9 kg., a decrease of 25 per cent, and the basal metabolism from 1,517 to 978 calories per 24 hours, a decrease of 36 per cent. Calculated per kilogram of body weight, the heat production fell from 24.1 to 19.5 calories, a decrease of 19 per cent. The corresponding values per square meter of body surface were 904 and 639 calories and 29 per cent, respectively. When the subject resumed eating, the basal metabolic rate began at once to rise and at the end of one month was 1,570 calories per 24 hours. Following marked variations in the composition of the diet in the postfasting period there were decided differences in the metabolic rate. A high protein-high caloric diet appeared to have the most stimulating effect upon the basal metabolism.

Maternal diet and lactation, P. M. NELSON (*Jour. Home Econ.*, 18 (1926), No. 7, pp. 383-388).—The work reported is essentially a repetition of the earlier studies of Hartwell (*E. S. R.*, 52, p. 364) in which the conclusion was drawn that a lactating rat on a high protein diet produces milk which is poisonous to the young. The results obtained in the present study point to a lack of vitamin B rather than an excess of protein as the cause of the spasms noted in the young on the diets used, a conclusion substantiated by later work of Hartwell (*E. S. R.*, 53, p. 163).

The nutritional requirements of nursing mothers (*Amer. Jour. Hyg.*, 6 (1926), No. 2, pp. 211-227, figs. 5; 228-237).—In the first of these two papers

the effect of a deficiency of the antirachitic vitamin only, in the diet of the mothers, upon the development of rickets in the young, was studied by A. H. Grant and M. Goettsch. That the diet of the mother is an important factor in increasing or decreasing the resistance of the young to the effects of a deficiency of antirachitic vitamin in the diet of the young is shown in this investigation, in which female rats were kept in darkness on diets adequate except for being low in the antirachitic vitamin. Successive litters of these rats became more and more susceptible to rickets when fed a diet lacking in antirachitic vitamin, the rapidity with which the disease developed and the severity of the lesions depending upon the degree of depletion of the mother's reserves. By increasing the content of antirachitic vitamin in the mother's diet through cod-liver oil or an abundance of milk, the resistance of the succeeding litters was again increased. On a diet rich in antirachitic vitamin, the vitamin reserves were found to be sufficient to produce four successive litters showing normal resistance to a lack of this vitamin.

The effect of lowering both the antirachitic vitamin and calcium in the diet of the mother upon the development of rickets in the young was studied by Grant. As a result of the double deficiency the resistance to rickets was almost completely broken down in the fourth litter, and the progress of the disease was much more rapid.

The anti-rachitic properties of breast milk, C. KENNEDY and L. S. PALMER (*Soc. Expt. Biol. and Med. Proc.*, 23 (1925), No. 3, pp. 230, 231).—In this preliminary note it is stated that the fat of breast milk from women on a diet furnishing an abundant supply of green vegetables, fruit, eggs, and milk and supplemented by a small daily dosage of cod-liver oil was found to be definitely antirachitic as judged by the line test on rachitic rats. In one case a composite sample of the fat of milk from three sources was fed at a level of from 15 to 20 per cent of the food intake. The second sample was fed at levels ranging from 5 to 25 per cent. At least 8 per cent was necessary to produce a distinct line test.

Irradiated orange juice: Its value as an antirachitic agent, H. L. MASLOW, D. H. SHELLING, and B. KRAMER (*Bul. Johns Hopkins Hosp.*, 39 (1926), No. 1, pp. 56-61).—Preliminary experiments are reported showing that orange juice irradiated for 3 hours under a mercury vapor quartz lamp at a distance of 18 in. acquired sufficient antirachitic properties to initiate healing in rachitic rats in 5 days and to complete the healing in 15 days. The juice used was the commercial product, Mission Orange Juice, which was diluted with 2 parts of distilled water before irradiation. Further experiments are in progress.

The effect of ultraviolet irradiation on the health of a group of infants, L. H. BARENBERG, I. FRIEDMAN, and D. GREEN (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 14, pp. 1114-1117).—To determine whether systematic irradiation with ultraviolet light is capable of preventing respiratory infections and improving the general nutritive condition of young children during the winter months, some of the children in two wards of a large child-caring institution received daily irradiations for a period of 4 months, while others in the same wards and receiving the same diets were not irradiated. All of the children received liberal amounts of cod-liver oil and orange juice daily.

The chief improvement resulting from the irradiation appeared to be in the texture of the skin and the turgor of the muscles. There was an initial increase in weight, but this did not continue during the subsequent months. There was no decrease in the number of infections, nor did the irradiation protect against or lessen the severity of whooping cough. The hemoglobin count was not increased by irradiation, but the percentage rose with the lessening of infections in the spring.

Experimental rickets.—The effect of cereals and their interaction with other factors of diet and environment in producing rickets, E. MELLANBY ([*Gt. Brit.*] *Med. Research Council Spec. Rpt. Ser. No. 93 (1925)*, pp. 66, pls. 40).—This is the complete report of the investigations which have led the author to believe that cereals, particularly oatmeal, have a definite rickets-producing effect (E. S. R., 52, p. 367) through the presence in them of an unknown substance interfering with the normal deposition of calcium in the bones.

A test of indolinones as agents for prevention and cure of polyneuritis, R. A. GORTNER, L. S. PALMER, and S. J. DAHL (*Soc. Expt. Biol. and Med. Proc.*, 23 (1925), No. 3, pp. 231-234).—On the theory that the antineuritic vitamin may owe its properties to keto-enol isomerism, as suggested by Williams (E. S. R., 46, p. 864), β -methylindolinone and β -propylindolinone were tested for antineuritic properties by the Seidell constant weight method (E. S. R., 47, p. 408) and also by the curative method on polyneuritic pigeons.

In the first test β -methylindolinone was fed in amounts varying from 3 to 50 mg. every other day for periods of 6 to 18 days, with resulting loss in weight in all cases and with the development of polyneuritis in one of the pigeons receiving 10 mg. The same general results were obtained with β -propylindolinone fed to three pigeons in amounts of 15 mg. daily. Thyroxin fed in 2 mg. daily doses brought about rapid decline in weight.

The curative tests were on the whole inconclusive, although temporary relief from acute polyneuritis was obtained with β -methylindolinone after the ingestion of 100 mg. in two doses.

Discussion on food deficiency conditions in relation to preventable illness (*Brit. Med. Jour.*, No. 3421 (1926), pp. 185-194).—In this symposium, held by the section of public health of the British Medical Association at its annual meeting in July, 1926, the general subject of food deficiency diseases, particularly pathological conditions attributable to lack of vitamins, was discussed from the scientific, clinical, tropical medicine, and public health points of view by S. J. Cowell, H. M. M. Mackay, P. W. Bassett-Smith, and J. Wheatley, respectively.

The composition of peanut meal and its use as a diabetic food, M. K. M. NEALE (*Jour. Amer. Dietet. Assoc.*, 2 (1926), No. 2, pp. 73-85).—Data on the composition of choice peanut meal, including the distribution of carbohydrates, are given as follows: Moisture 6.50 per cent, ether extract 10.50, alcohol extract 16.07, carbohydrate of alcohol extract as glucose 3.49, carbohydrate hydrolyzed by enzymes as glucose (other than alcohol extract) 3.19, carbohydrate hydrolyzed by acid as glucose (other than alcohol extract) 10.96, total hydrolyzable carbohydrate 14.45, utilizable carbohydrate 6.68, nonutilizable carbohydrate 7.77, pentosans 4.99, nitrogen \times 6.25 51.56, ash 3.77, crude fiber 4.50, and undetermined by difference 8.72 per cent.

On account of the small amount of utilizable carbohydrate, as compared with 8.15 per cent for soy bean commonly used as a diabetic food and 75.01 per cent for wheat flour, a study was made of the possibility of using peanut meal in bread making as a substitute for wheat flour in proportions higher than those recommended by Johns and Finks (E. S. R., 43, p. 763). It was found possible to make a palatable bread with the substitution of peanut meal for as much as 50 per cent of the wheat flour by first toasting the meal and making it into a mush before mixing with the other constituents. This is estimated to reduce the available carbohydrate about 45 per cent (from 20 to 8.4 gm. per slice).

The use of standard diet formulas in the control of juvenile diabetes mellitus, J. D. BOYD (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 13, pp. 1020-1022, figs. 2).—The system of dietary management of juvenile diabetes described in this contribution from the department of pediatrics, State University of Iowa,

has been designed to furnish the theoretical energy requirement of an active child, with 1 gm. or more of protein for each theoretical pound of body weight and potential glucose and fatty acids in a ration of 1:1.5. In the unit diet formulas selected to fulfill these requirements, protein, carbohydrate, and fat are supplied in the ratio of 7:9:21, respectively. To determine the needs of a patient the theoretical body weight is estimated from the standing height, using the Baldwin-Wood-Woodbury height-weight tables, and the theoretical caloric requirement for the weight is estimated from charts prepared from the Holt-Fales standards (E. S. R., 45, p. 162). In the selection of foods for these formulas, special attention has been paid to the mineral salts and vitamins. A specimen diet is given to illustrate the system.

As far as can be judged by clinical evidence extending over a year, the diets appear to be physiologically adequate. "It will require longer periods of observation before final conclusions may be drawn safely as to the adequacy of this system. It has seemed satisfactory from the standpoint of the patient's progress. From an administrative point of view it has greatly lessened the labor of diet calculation, and has permitted a comparative study of a large group of children of different ages on equivalent diets."

Diabetic diets for children, J. D. BOYD and M. V. NELSON (*Jour. Amer. Dietet. Assoc.*, 2 (1926), No. 1, pp. 45-51).—This paper supplements the foregoing by additional diets calculated for use in this system of dietary management and applicable to diabetic patients throughout the period of childhood, the range in protein being from 28 to 105 gm. daily. A table expressing the quantitative relationship between height-weight calories for full activity and grams of protein for boys and girls up to 68 in. in height, and many practical suggestions for slight modifications in the diets to meet special needs are included.

TEXTILES AND CLOTHING

Textiles: A handbook for the student and the consumer, M. S. WOOLMAN and E. B. MCGOWAN (*New York: Macmillan Co., 1926, rev. ed., pp. XIV+572, pl. 1, figs. 143*).—A revision and enlargement of the book noted earlier (E. S. R., 30, p. 598).

Textile oils applicable in the dyeing and finishing of cotton, F. E. BURNHAM (*Amer. Dyestuff Rptr.*, 15 (1926), No. 18, pp. 709-712).—The nature of some of the important textile oils is described, with the purposes for which they are best adapted.

Mildew in cotton goods, [I]-III (*Brit. Cotton Indus. Research Assoc., Shirley Inst. Mem.*, 3 (1924), No. 26, pp. 295-306, pls. 4; 4 (1925), Nos. 12, pp. 129-150, pl. 1, figs. 4; 13, pp. 151-165, figs. 4).—In the first of these three articles T. B. Bright, L. E. Morris, and F. Summers indicate several fungi, with favoring factors and conditions, which tend to lessen values in raw cotton or cotton fabrics. The effects of the activity of these organisms are also indicated, with means for their control. Present knowledge of antiseptics gives less encouragement than does knowledge regarding methods of sanitation and conditions of packing and storage.

The second paper, by Morris, deals with the growth of mold fungi on sizing and finishing materials. Seven fungi, obtained from cotton goods mildewed under ordinary conditions are described as studied in connection with nutrient materials present.

In the third paper a description is given by Morris of experimentation involving the growth of eight species of mold fungi on hard (strong) and on soft (weak) wheat flours which had been steeped during different periods, all these species having been isolated from cotton goods mildewed under industrial conditions.

The results as a whole support the general view that fermentation decreases liability to mildew, but they also emphasize the influence of specific differences which are discussed in this connection. The chemistry of the products of fermentation is discussed in relation to the growth of mold fungi.

The behaviour of flax yarns under repeated impacts, G F. NEW and A. L. GREGSON (*Jour. Textile Inst.*, 17 (1926), No. 9, pp. T437-T452, figs. 7).—Consideration of the tensile stresses imposed on warp yarns by loom motions indicates that the maximum stress induced in each individual warp thread depends on its extension properties, and that besides strength and regularity high recoverable extensibility is to be sought in yarns for good weaving quality rather than a large total extension to breaking strength. The effects of repeated impacts by a falling weight on a flax yarn are discussed, and experimental apparatus for such treatment is described.

The progressive extension of a yarn receiving repeated impacts was shown to be irregular, but a smooth curve could be had from the means of observations of 20 specimens. This mean curve is of the same general form, very closely logarithmic, for all flax yarns and under all conditions examined. The mean extension is rapid with the first few impacts and gradually becomes slower but never decreases to 0. The number of unbroken specimens decreased with the number of impacts applied, rapidly at first and more slowly later, the order of superiority being green yarn sized, green yarn, boiled yarn sized, and boiled yarn. Changes in the tensile strength of a yarn due to repeated impacts were insignificant, and fractures occurring on the application of repeated impacts seemed due in part at least to the gradually lessening extensibility of the yarn. This necessitates an increasing maximum tension for the absorption of the constant energy of impact until the breaking strength is reached.

The gel structure of the wool fibre, J. B. SPEAKMAN (*Jour. Textile Inst.*, 17 (1926), No. 9, pp. T457-T471, figs. 5).—According to studies at Leeds University, the wool fiber possesses a true yield point and after extension remains permanently more extensible at low tension. "The behaviour of a wool fibre under stress is the behaviour of a single cell, which consists essentially of three phases, (1) the elastic cell wall, enclosing (2) a fibrillar structure which is not in physical equilibrium with (3) a viscous phase of gelatinous character included in its interstices." These observations seemed to necessitate fundamental changes in Shorter's¹ views on the internal mechanics of fibers.

The extension of wool fibres under constant stress, J. B. SPEAKMAN (*Jour. Textile Inst.*, 17 (1926), No. 9, pp. T472-T481, figs. 6).—Investigation confirmed views expressed above concerning the gel structure of the wool fiber. The existence of a definite yield point was demonstrated, and the occurrence of a second point of inflexion on the stress-strain diagram for wool was shown to be independent of the rate of loading. Andrade's² expression for the rate of extension of metal wires under constant stress applied equally well to wool fibers, and the data given enabled the calculation of the extension and rate of extension of English Cotswold wool at 15° C. in saturated air under any stress. The gelatinous phase in the wool fiber was shown to vary in composition from one wool to another and to change in viscosity with temperature.

Merino wool classing, P. D. ROSE (*Wool Rec. [Bradford]*, 30 (1926), Nos. 899, pp. 366-371; 900, pp. 433-438; 901, pp. 499-504).—The objects and methods

¹ An Investigation of the Nature of the Elasticity of Fibres, S. A. Shorter. *Jour. Textile Inst.*, 15 (1924), No. 4, pp. T207-T229, figs. 14.

² On the Viscous Flow in Metals and Allied Phenomena, E. N. da C. Andrade. *Roy. Soc. [London], Proc., Ser. A*, 84 (1910), No. A 567, pp. 1-2, figs. 8.

of classing wool are outlined, with the classing standards adopted in South Africa in May, 1924.

Notes on the determination of the dry weight of wool, S. G. BARKER and J. J. HEDGES (*Jour. Textile Inst.*, 17 (1926), No. 9, pp. T453-T456).—The commercial regain in moisture content of wool as determined by a conditioning house using a type of oven in which the air is preheated and forced through the wool at a temperature of 235–240° F. was about 0.5 per cent low as compared with the true regain (e. g., 15.5 instead of 16 per cent). The ordinary commercial gas and electric ovens tested gave a figure about 1 per cent low.

Tar on wool, A. T. KING and R. J. SMITH (*Wool Rec. [Bradford]*, 30 (1926), Nos. 908, pp. 973–978; 909, pp. 1041–1046, figs. 8).—In this contribution from the British Research Association for the Woollen and Worsted Industries, the sheep-marking problem is reviewed from the viewpoints of the wool grower, the maker of sheep-marking materials, and the wool manufacturer. The tests reported were made upon a number of commercial branding agents and 40 experimental fluids with regard to their injurious effects and ease of scouring out. Formulas suitable for Great Britain and for warmer climates are indicated. It is suggested that a ban on all black marking materials would effectively stamp out the use of tar.

Colour problems in the woollen and worsted industries, S. G. BARKER and H. R. HIRST (*Jour. Textile Inst.*, 17 (1926), No. 10, pp. T483–T510, pls. 4, figs. 7).—The status of color or colored pattern in textile materials is surveyed from physical, chemical, technical, and trade points of view, together with citations of the results of practical work in the laboratories of the British Research Association for the Woollen and Worsted Industries at Leeds. The main questions considered are the choice of standard illumination, the fastness and durability of a color to the influence of external conditions, and the determination of the exact shade of a color and its numerical representation.

Effect of dry cleaning on silks: A comparison of the effect of dry cleaning and some service conditions on the strength of silk, M. H. GOLDMAN, C. C. HUBBARD, and C. W. SCHOFFSTALL (*U. S. Dept. Com., Bur. Standards Technol. Paper 322* (1926), pp. 605–634, figs. 17).—A study of tin-weighted and unweighted samples of silk after various treatments and exposures to sunlight and storage at standard conditions (of 65 per cent relative humidity at 70° F.) led to the following conclusions:

No deterioration results from exposures to standard atmospheric conditions over a period of 2.5 months, even when acid or alkaline perspirations are applied. Sunlight exposure causes a marked deterioration in both unweighted (but dyed) and tin-weighted silks, the loss in strength in 100 hours' exposure amounting to about 25 per cent for unweighted and about 50 to 75 per cent for weighted silks. Acid and alkaline perspiration treatments increase the deterioration when sunlight exposures are given, so that the loss in strength in 100 hours' exposure is about 35 per cent for unweighted and about 65 to 100 per cent for weighted silk. In no case did dry-cleaning solvents cause any appreciable deterioration of the silk fabrics.

Fifty-fourth annual report of the Silk Association of America (*Silk Assoc. Amer. Ann. Rpt.*, 54 (1926), pp. 143, figs. 9).—This gives an account of the organization and its activities during 1925, and includes reports on different phases of the silk industry in addition to silk statistics.

NOTES

Florida Station.—Dr. Marion N. Walker, for two years pathologist with the Tropical Plant Research Bureau in Cuba, has been appointed assistant cotton specialist beginning December 1, 1926. He will continue certain physiological studies of cotton already under way and will also inaugurate a number of pathological studies.

Jackson B. Hester, assistant chemist at the Texas Station, has been appointed assistant chemist in connection with the studies of soil chemical problems.

Georgia College.—A special school of cooperative marketing was held January 24 to 28. The school was conducted by the college, assisted by the cooperative associations of Georgia and the Division of Cooperative Marketing of the U. S. Department of Agriculture.

Emphasis was placed on problems in business management and membership relations. The program was designed especially for directors and employees of cooperative associations, county agents, and agricultural workers, bankers, farmers, and others interested directly in the operations of cooperative marketing organizations. The list of lecturers and speakers included representatives of the college, specialists from the U. S. D. A. Bureau of Agricultural Economics, and the general managers of cooperative associations handling cotton, peaches, watermelons, apples, pecans, sirup, peanuts, and other commodities.

Kansas College and Station.—State appropriations aggregating \$1,444,500 for 1927-28 and \$1,362,500 for the succeeding year are to be requested by the board of regents, together with \$101,840 per annum for the duplication of Federal funds for extension work in agriculture and home economics and \$58,782.78 for the reimbursement of certain funds depleted in 1922. The principal items of increase are those of \$97,000 per annum for salaries, partly for additional employees and partly for promotions, \$375,000 for a new power plant, \$49,900 additional per year for maintenance, \$20,000 per year additional for improvements and repairs, \$60,000 for equipping the new library and \$24,000 for remodeling the old building, \$2,000 for the purchase of land, \$21,000 for campus roads, walks, and lights, and \$20,000 per year for laboratory equipment and improvements. The estimates for the substations include \$32,000 in 1927-28 and \$29,500 in 1928-29 for the work at Hays, \$2,500 of which is for new machinery, \$11,700 and \$11,500 for that at Garden City, \$6,000 and \$5,750 for that at Colby, and \$3,500 and \$4,000 for that at Tribune.

Missouri University.—Because of the gratifying attendance in 1926, another special four-day course for graduate veterinarians was offered from January 25 to 28. Special attention was given to sterility and other diseases in cattle, poultry diseases, tuberculosis, and abortion in cattle and hogs. Opportunity was also afforded for instruction in related lines, such as animal feeding, poultry culling, and dairying.

A portrait of the late Dr. Henry J. Waters, former dean of the College of Agriculture, was recently unveiled in the library of the College of Agriculture and presented to the college as the gift of members of the faculty and a number of the alumni.

New York State Station.—Three new varieties of apples and three of grapes, constituting an exhibit of the work of the fruit breeders at the station, were awarded the Marshal P. Wilder medal for new fruits at the last annual meeting of the American Pomological Society. The station collection included the Cortland, Orleans, and Sweet Delicious apples and the Sheridan, Urbana, and Golden Muscat grapes.

Oregon College and Station.—According to a note in *Oregon Countryman*, Donald D. Hill has been appointed instructor in farm crops and assistant agronomist.

Pennsylvania College and Station.—Dr. J. R. Haag, assistant professor of agricultural and biological chemistry, has resigned to accept an appointment in the Oregon Station.

Rhode Island College and Station.—Dr. Henry G. May, since 1920 professor of bacteriology in the college and head of the research work in animal breeding and pathology, died December 23, 1926, at the age of 40 years. Dr. May was born in Germany, graduating from the University of Rochester in 1913, and receiving the Ph. D. degree from the University of Illinois in 1917. He had also served as junior zoologist with the U. S. D. A. Bureau of Animal Industry, bacteriologist in the U. S. Army, and professor of biology in Mississippi College.

Utah College.—According to a note in *School and Society*, Miss Christine B. Clayton, assistant professor of foods and dietetics, has been appointed a fellow of the Laura Spelman Memorial Foundation and will study at the University of Minnesota and Columbia University.

Wisconsin University.—Dr. E. J. Kraus, professor of applied botany, has accepted an appointment in the University of Chicago.

Northeastern Forest Experiment Station.—Samuel T. Dana, director since the establishment of the station three years ago, has been appointed provisional dean of the new School of Forestry of the University of Michigan.

Agricultural Research in Australia and New Zealand.—An act passed by the Australian Commonwealth Legislature last June provides for a Council of Scientific and Industrial Research and a system of State committees, with three representatives appointed by the Governor General and as the representative of each of the six States the chairman of its State committee. The representative of New South Wales is J. D. Watt (agriculture) and of South Australia T. B. Robertson (physiology).

Annual estimates for the special work of the year must receive the sanction of the Commonwealth Parliament in the usual manner, and £50,000 has been requested for the current year. The sum of £250,000 has also been set aside as a trust account, the capital and interest of which are to be used for scientific and industrial investigations, and an endowment fund of £100,000 has been established to assist individuals in scientific research and train students for undertaking it. Under the latter provision an interchange of students with Great Britain is being worked out.

The field work of the council in the immediate future will include studies of cold storage problems, with special reference to beef in cooperation with the British Food Investigation Board; the utilization of forest products; diseases and pests of cattle, sheep, and horses, including blowflies and buffalo flies; and attempts to check the spread of prickly pear, which has now overrun 29,000,000 acres.

In New Zealand an advisory council of scientific and industrial research is to be formed. An agricultural college is to be built and an institute of dairying established to collaborate with it.

British Aid to Agricultural Education and Improvement in China.—A report has recently been made to Parliament by a committee appointed to

advise the Secretary of State for Foreign Affairs of Great Britain as to the best methods of applying the so-called "Boxer Indemnity" to purposes "beneficial to the mutual interests of His Majesty and the Republic of China." This report, which is based on a study of the situation in China, recommends the immediate expenditure, from the total of about £11,000,000 which is estimated to be available between 1922 and 1945, of about £350,000 per annum and the investment of the remainder to provide a permanent fund upon the cessation of the Chinese indemnity payments. Of the amount scheduled for immediate expenditure, it is recommended that 30 per cent, or approximately £100,000 per annum, be devoted to agricultural education and improvement, this including 5 per cent for famine relief and rural credit. An additional 23 per cent would be devoted to scientific research through the establishment of a national research institute, 17 per cent for medical and public health work, and 30 per cent for educational purposes. The agricultural program proposed would include the establishment of agricultural colleges, scientific research into silkworm culture, and the formation of an institute of rural economics.

American Society of Animal Production.—The annual meeting of this society was held in Chicago on November 26 and 27, 1926. The attendance was large, and the papers represented approximately 20 experiment stations, the U. S. Department of Agriculture, and commercial organizations. Special interest centered around the cooperative study of Factors Influencing the Quality and Palatability of Meat.

The program was opened with an address of President H. P. Rusk, in which the necessity of cooperation between different specialized departments was pointed out as an aid to the proper interpretation and solution of investigations having a bearing on several sciences. Several papers followed relating primarily to the protein and mineral metabolism of animals. These included the results of a study of the mineral requirements of dairy cows by J. B. Lindsey and J. G. Archibald, Calcification Studies with Menhaden Fish Meal, by L. A. Maynard and R. C. Miller, and The Value of Different Carriers of Phosphorus in Mineral Mixtures for Swine, by W. L. Robison. E. B. Forbes presented a paper on The Variability of the Computed and Directly Determined Fasting Katabolism of Cattle, while J. M. Evvard discussed The Protein Requirements of Fattening Cattle as determined from an analysis of investigations conducted at the Iowa Station. One of the outstanding contributions was that of H. H. Mitchell, T. S. Hamilton, and R. L. Zimmerman dealing with the Determination of Connective Tissue in Meats. Analyses were presented in this paper of the total nitrogen, collagen nitrogen, and elastin nitrogen found in various duplicate samples of beef, pork, and chicken. The method suggested for the determination of the connective tissue proteins included the separation of the soluble nitrogen by grinding the meat with water and filtering through a fine mesh sieve. The collagen was removed by steaming in an autoclave, and the remaining nitrogen was digested through the residue by trypsin. That portion remaining was considered as elastin.

The society was divided into three luncheon sessions dealing, respectively, with extension work, disease resistance, and feeding experiments. At the first of these the topics included Problems of Shrinks and Fills in Livestock Marketing, by E. N. Wentworth; The Livestock Man's Concern in the Corn Borer Infestation, by C. W. Gay; The Missouri Beef Herd Demonstration Work, by J. W. Burch; Recent Trends in the Export of Livestock Products, by D. M. Strail; and When Should an Owner of Livestock Be Considered a Breeder in the General Acceptance of the Term "Breeder"? by J. W. Wilson.

At another session E. Roberts gave a paper on The Inheritance of Resistance to Disease, which was essentially a progress report of the endeavor to select chicks resistant to bacillary white diarrhea at the Illinois Station. At the third session the papers included Wintering Steers with and without Corn Silage Preparatory to Finishing on Grass without Grain, by E. S. Good; Corn and Cob Meal for Fattening Baby Beef Calves, by H. W. Vaughan; A Comparison of Roughages Supplemented with Cottonseed Meal as a Concentrate, by W. L. Blizzard; and The Influence of the Addition of Oats to a White Corn Ration in Growing and Fattening Hogs, by E. A. Livesay and E. C. Stillwell. G. Haines also discussed the methods employed in the planning and conduct of feeding experiments.

At the afternoon session the accuracy to be gained in weighing cattle on three days instead of one at the beginning and end of a feeding experiment was shown by J. L. Lush and W. H. Black to be less than is ordinarily considered. An analysis by H. C. McPhee of the sex ratio and frequency of sex combinations among the individuals listed in two swine herdbooks and in experimental herds indicated that inaccuracy of a certain type was quite common in the herdbook data, making their use in genetic studies somewhat questionable. E. W. Sheets briefly discussed the cooperative project relating to the factors influencing the quality and palatability of meat from the standpoint of its influence on animal husbandry research, especially the progress which it has made and the expectation for bigger things from it. P. E. Howe presented a scale for color which has been prepared for use in this study. Other papers presented at this session included those by W. J. Loeffel dealing with the relation of light to the calcification of bone, and the rate of growth of swine, by H. J. Gramlich, in which no particular favorable effect was found to result from spaying heifer calves, by F. S. Hultz dealing with the ability of the judge to determine differences in characteristics of the fleeces of Rambouillet sheep, by G. Bohstedt in which baby calves were found to feed better as a group than when fed alone in stanchions, and by M. A. R. Kelley on the length of the stabling season.

The evening session included several papers on conditions in Denmark. E. F. Ferrin discussed particularly the type of swine and methods of swine production as practiced in Denmark, and T. U. H. Ellinger showed motion pictures of the Danish Agricultural College and three reels of films portraying different portions and conditions of Denmark as prepared by the Danish Government.

A feature of the society's banquet was the serving of rib roasts from prime and good carcasses. Each person received a portion of a similar cut from the two carcasses and was requested to grade each for tenderness, juiciness, and flavor. From a discussion of the results led by P. E. Howe there appeared to be much diversity of opinion, especially with relation to the flavor of the meat. Miss L. A. Alexander had previously described the desirable method of roasting meat and the uniform type of roasting practiced in the cooperative studies of the factors affecting the quality and palatability of meats.

The session on the following morning dealt largely with extension problems, and that afternoon committee reports and other business were taken up. E. S. Good was elected president, E. W. Sheets vice president, and J. R. Wiley secretary-treasurer of the society. P. Gerlaugh and C. W. McDonald were elected president and secretary, respectively, of the extension division.

It has been customary for a number of years for the society to honor some outstanding individual, and the meeting was concluded by a dinner in honor of Dr. J. R. Mohler, Chief of the Bureau of Animal Industry of the U. S.

Department of Agriculture. At this dinner the achievements of Dr. Mohler and the character of his service to the livestock and meat industry were set forth by A. Eichhorn, R. F. Eagle, E. W. Sheets, and Assistant Secretary of Agriculture R. W. Dunlap. Dr. Mohler responded with a paper dealing with the interrelation of disease control and animal husbandry problems. The stock-judging team from the Oklahoma college, which won the intercollegiate contest at the 1926 International Livestock Exposition, was presented, and prizes were awarded for the Saddle and Sirloin essay contest, written on the subject of the contribution of livestock to stability in farming. An innovation which is expected to be continued was a roll call of the stock-judging teams of 1907.

Fifth International Congress of Genetics.—This congress will be held in Berlin from September 11 to 18, 1927, immediately following the Zoological Congress. The six morning sessions are to be opened with an address by some authority who will present a comprehensive account of the present status and future outlook of his special phase of research. The remainder of the session will be devoted to papers of from 20 to 30 minutes each. At the conclusion of the conference, excursions to Potsdam, Halle, and some of the plant breeding centers are planned.

New Journals.—*Iowa State College Journal of Science* is being issued as a quarterly of research. The purposes in mind are set forth as follows: To furnish a medium for the prompt publication of the results of research, to give opportunity for the publication of preliminary notes, to afford space for the publication of some articles of greater length than can usually be accepted by special journals, to give a publication channel to such results of workers on the research staffs as are scarcely long enough to warrant publication as separate bulletins, and to provide for the prompt publication of certain of the doctoral dissertations. The initial number contains the following articles: Linked Inheritance in Tomatoes, by E. W. Lindstrom; Taxonomic Studies on Soil Fungi, by E. V. Abbott; The Relation Between pH and the Reaction of Aqueous Solutions at Various Temperatures, by E. I. Fulmer; Geographical Variation in the Nigricornis Group of *Oecanthus* (Orthoptera), by B. B. Fulton; Nomogram for Determination of Generation Time and Velocity Coefficients for Rates of Growth or Death, by R. E. Buchanan; and A Study of Crown Gall Caused by *Pseudomonas tumefaciens* on Rosaceous Hosts, by J. H. Muncie.

Archivio Botanico is being published as a quarterly bulletin of the Botanical Institute of the University of Modena. Special emphasis will be given to systematic, phytogeographic, and genetic phases of botany. The initial number contains an article by A. Béguinot and C. Mezzatesta entitled A Biometric Study of Variability in the Ligulate Flowers of *Bellis perennis* L. and *B. annua* in Sicily and Calabria, and another by F. Panini entitled The Chemical Constitution of the Cellular Membrane in the Myxophyceae.

Studi e Notizie is a quarterly issued by the Institute of Economics and Agricultural Statistics at Rome. The initial number contains several original articles, statistics for agricultural and forest products, and data relative to the institute and its work.

Anales de la Facultad de Ciencias is being published from time to time at Lima, Peru, by the University of San Marcos. The initial number contains a number of contributions of general scientific interest.

EXPERIMENT STATION RECORD

VOL. 56

FEBRUARY, 1927

No. 2

Efforts to facilitate the prosecution of agricultural research on a national scale and by cooperative effort continue to receive attention as never before. A revised edition of the mimeographed pamphlet outlining national problems for cooperation by the experiment stations and the United States Department of Agriculture has just been issued by the joint committee on projects and correlation of research of the Association of Land-Grant Colleges and Universities. This revision adds to the original edition data as to projects worked out in 1926 under the auspices of the committee on such questions as agricultural surpluses, a modification of the rural home management studies on food consumption and expenditures of farm families, and a new project on standards of living and expenditures of farm families. Supplementing as it does the numerous projects previously set forth by the committee on marketing, the vitamin content of food, the use of time by farm home makers, the efficiency studies of the household plant, the group of projects on rural social organizations and agencies, and the comprehensive project on the factors which influence the quality and palatability of meat, an impressive showing of opportunities is presented in a number of important directions.

Interest in the matter, however, is by no means confined to the fields of inquiry selected by the association. The problem of assisting research in still another line has been taken up by agencies concerned with agricultural engineering, and a report has recently become available in mimeographed form which deals with the status of studies of mechanical farm equipment. This report has been issued by the Department of Agriculture and embodies the findings obtained in an inquiry instituted by an advisory council of 20 members appointed in 1925 to represent the National Association of Farm Equipment Manufacturers, the American Society of Agricultural Engineers, and the Department. The work was performed under the direction of Prof. J. Brownlee Davidson while on leave of absence from the Iowa State College under an appointment in the Bureau of Public Roads.

The objective of the survey was the formulation of a national cooperative and coordinated research program in the United States between Federal, State, commercial, and private agencies. In an effort to attain this objective, the existing status of research into farm equipment as revealed in current experiment station projects was reviewed, visits were made to and conferences held with 45 State experiment stations and several commercial laboratories, and suggestions as to problems needing investigation were obtained from members of the participating organizations. The data so obtained have been summarized and discussed, and as an aid to the organization of projects there have been appended to the report an agricultural engineering classification of subject matter and examples of a number of typical research project outlines.

The summary of research now in progress was prepared by Mr. R. W. Trullinger, agricultural engineer of the Office of Experiment Stations. It reveals a total of 143 projects, of which 130 are being conducted by 27 agricultural experiment stations, 12 by 6 engineering experiment stations, and 1 by a State normal school. As would be expected, the majority of these projects are dealing directly with mechanical farm operating equipment and are carried on exclusively or cooperatively by engineering departments, although a few are entrusted to departments of agronomy, agricultural economics, and similar branches. At many stations the number of projects is comparatively small, but a total of 37 are in progress at the stations in California, Kansas, and Illinois. The classified list of these projects reveals a wide range of subjects, the largest number centering around the use of electricity on farms.

Much interest was reported in the outlining of needed experimentation. Over 800 suggestions were received by the committee, and from these a classified list of over 400 topics has been compiled. This list includes both basic problems to ascertain the scientific soundness of the various farm operations involved in production and problems of efficiency and economy in which improvements are sought in existing methods and machines. Here, too, the range of subjects is wide, and the council has not deemed it practicable to attempt to point out their relative importance or urgency.

The need of cooperation in undertaking many of these subjects is emphasized, and the relation to a national research program of the farm equipment industry is discussed at some length. It is pointed out that thus far much of the agricultural investigation which has been carried on "has not extended into those phases of experimental research where the new knowledge is applied and organized into productive systems of farming, but has been left almost entirely to the practical farmer and machine manufacturer.

During the early periods of the growth of the farm equipment industry, when agricultural research was in its infancy, the design and production of equipment was much in advance of agricultural research. However, in the last three-quarters of a century the situation has changed materially. A mass of agricultural knowledge is available waiting for utilization, and the demand for better practice is acute."

It is concluded that if full advantage is to be taken of all resources making for advancement some working plan for correlated effort is called for. "This view, it appears, is that of the American manufacturer. It is not expected that the public research agencies shall undertake to design farm machines or to indicate how they may be produced, but rather to set forth the principles of agricultural production and the essential requirements of best farm practice upon which the design and production of machines must be based. For instance, if the essentials of a good seed bed can be clearly defined, then it is the obligation of the producer of machines to provide the equipment which will enable the desired results to be attained. Or if the principles involved in the control of injurious weeds are determined and proved, the furnishing of equipment to utilize these principles is a duty of the manufacturing industry."

Because of the necessity of carefully guarding the freedom of education and research and insuring their independence of commercialism, it is concluded that an industry vitally concerned with agricultural progress has been more or less isolated from the work of public investigational agencies in this country. The present movement is described as "an earnest effort to improve the present situation and to arrange for such a working arrangement as will make for economy and efficiency of effort and insure rapid progress." However this may be, the attempt to stimulate and encourage experimentation in this field is of much significance and promise. If a program of coordinated attack upon the many important problems awaiting solution can be formulated and carried through to completion, the undertaking should be productive of much good.

For many years it has been the endeavor of the Office of Experiment Stations to obtain as complete and comprehensive information as has been available concerning the progress of agricultural education and research in foreign countries. This duty has been carried on in the belief that developments abroad are not only of general interest but often of direct value to workers in this country. It is a truism that science knows no boundaries, and it is equally clear that to the investigator acquaintance with the status of existing knowledge is of outstanding importance. For this reason news notes

of foreign institutions and their personnel are being collected wherever possible as a means of developing closer relationships, and it is hoped that sufficient data may ultimately become available to permit of a revision of the publication issued by this office in 1902 describing the organization and work of the experiment stations of the world. Additional information along these lines is greatly desired, and assistance from travelers and others having first-hand information of conditions abroad will be most welcome.

Opportunity has recently been afforded to gain an insight into the agricultural conditions prevailing in the ancient but little-known realm of Persia. Some time ago a commission of enquiry into the production of opium in Persia was constituted by the League of Nations, and while the United States was not officially connected with this undertaking the presidency of the commission was intrusted to an American citizen, Mr. Frederic A. Delano. The international significance of the subject lay in the possibilities of ultimately eradicating the traffic in opium. Of late much of this opium has been grown in Persia, and in certain portions of that country the culture of the opium poppy has become the principal agricultural enterprise.

It was early realized that if undue economic hardship was to be avoided an important factor in any prohibition of opium production would be the question of substituting other remunerative crops for the region. Information on this matter was virtually lacking, and the commission sought the services of an agricultural expert for a study of the situation. Eventually there was selected to carry on this work Mr. Jewell B. Knight, a graduate of the Massachusetts Agricultural College and widely known for his services to Indian agriculture as its first agricultural missionary and the principal for many years of the Government Agricultural College at Poona. A mimeographed report of his findings based on a survey of some months and entitled *The Existing State of Persian Agriculture; Opportunities for Improvement and Suggestions as to How They can be Effected*, has recently been issued.

The report is noteworthy not only as a contribution to existing information and as an example of a careful and conscientious survey but for the clear intent to formulate specific recommendations which would prove practicable under the economic conditions prevailing. These conditions are both numerous and complex, involving wide variations and extremes in climate, a precarious water supply, limited areas of desirable soils, inadequate transportation facilities, primitive methods of agriculture, and a distinctly unprogressive but firmly entrenched economic and social system. Under all these handicaps the development of a prosperous agriculture is an undertaking of heroic proportions.

The introduction of improved strains of farm crops and domestic animals, the provision of suitable agricultural machinery and better roads, the greater use of legumes and other promising crops, and the further extension of such phases of agriculture as sericulture, rose growing for perfumery, cruciferous and other oil crops, flax and millets, and the development of animal husbandry and dairying are suggested as remedies. Attention is also called to the need of providing a new system of land tenure and improved credit facilities.

A final chapter deals with institutions for effecting improvements in agriculture. In the words of the report, "if Persian agriculture is to be developed along modern lines and avail itself of the results of recent scientific research, an efficient agricultural department is *sine qua non*. This department's first duty is the formulating of a comprehensive plan for the development of the department and the improvement of Persian agriculture to extend over a period of years, due consideration being given to the size of the available budget and to the priority of the different undertakings. The work of the department will naturally fall under three heads: (1) Education (both of staff for its use and for villagers), (2) experimentation, (3) demonstration. A fourth branch, the establishment of seed growing farms and stock farms for raising breeding animals, may, as funds become available, be included in the work of the department. The most important condition of success in this plan will lie in the personnel of the staff in all grades."

As regards agricultural education, the immediate need is seen less for institutions to teach the theoretical side of the subject now covered by the Agricultural School of Teheran than for the training of practical workers. A system of vocational schools distinct from the general agricultural system is advocated, in charge of a director who has had both agricultural and educational training and with its most important duty "to establish and maintain a training school for assistants in the various branches of the department." Here, too, emphasis on the practical side is stressed. "Work must be actually performed, each student doing it with his own hands and not as was seen at Karedge by following a laborer and taking notes."

Before launching upon any radical agricultural change, preliminary experiments as to their adaptability to the region are deemed essential. "For this purpose numerous experimental stations or plats will be needed. These, however, need not be and should not be fixed institutions with expensive staffs and equipment, but each should be instituted to settle some definite question or questions, and as soon as the problems have been solved, the staff and budget should be allotted to other problems in other places.

"The problems should be very definitely visualized, and only such problems should be attempted as can be solved within a comparatively short time—one or two seasons—with simple apparatus

and by workers who, though well trained, are not of necessity highly educated. The more exact and comprehensive scientific investigations should be postponed until the simpler and more important questions as to the adaptation of methods and varieties to the different regions have been settled."

Despite the elementary nature of the experimental work advocated, a clear distinction is drawn between its function and that of demonstration. "The worker in the experiment branch of the department requires considerable scientific knowledge as well as a thorough practical training, and should form habits of accuracy, truthfulness, and careful observation. Experimenters are born and not made. Students in training for work in this branch who show no aptitude should be transferred to some other branch. The prospects of the efficient experimenters should be so favorable that talent of this kind would not be wasted in administrative or demonstration work.

"Once an improvement of any kind, whether it be a new method, an implement, a new crop or variety, has been tried by the experimental branch and proved beyond reasonable doubt as suitable to some tract, the real work of the department begins in securing its adoption by the farmers. Telling them about any such innovation is not effective; only actual demonstration in the place where the change is to be made will produce the desired results. Demonstration plats and itinerant demonstrators are the most efficient agents for this purpose. The demonstration plat should be even a simpler affair than the experiment station, and should be moved about as soon as the suggested improvement has been adopted by a number in the immediate vicinity. Usually one, or a very few, new things should be demonstrated at a time."

Throughout the report an effort is made to emphasize those phases of the existing situation which appear to be capable of improvement by comparatively simple and inexpensive measures. Many of the suggested changes, it is thought, could be inaugurated at once, but most "must be achieved by the slow and steady following of a well-formulated plan." Whether the opportunity will be afforded to test such a plan can not be predicted, as the functions of both the agricultural expert and the commission itself were evidently mainly advisory. In any event, however, the report is to be commended as an example of careful and comprehensive observations and their utilization as a basis for clear-cut and positive conclusions and suggestions. The survey is thus much more than a collection of data or a summary of existing knowledge. It furnishes a definite program of action which is directly applicable to the immediate end in view. As such, and without reference to the merits of its program, it is worthy of study as a contribution to the larger problem of the most suitable methods of inquiry into agricultural questions in general.

RECENT WORK IN AGRICULTURAL SCIENCE

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

The chemistry of cellulose and wood, A. W. SCHORGER (*New York and London: McGraw-Hill Book Co., 1926, pp. XIV+596, figs. 13*).—“It is the aim of this book to cover completely the scientific and empirical data available on the chemistry of wood. This has necessitated the inclusion of cotton cellulose and its modified forms. Industrial processes are treated mainly from the side of the fundamental reactions involved.” The greater part of the volume is devoted to the chemistry of lignin, hemicelluloses, and wood cellulose, and the constitution of cellulose, its colloidal properties and derivatives, pulp processes, and products of distillation. Chapters 14 and 15 on the fermentation of cellulose and wood by bacteria and filamentous fungi and on the digestion of cellulose and wood by animals are of particular interest from the standpoint of agricultural chemistry. The final chapter on analytical methods consists of a critical discussion of the methods which have proved most serviceable for determining the various constituents and groupings in wood and allied substances. Abundant references to the original literature are given as footnotes throughout the volume.

The chemistry of wood, L. F. HAWLEY and L. E. WISE (*New York: Chem. Catalog Co., 1926, pp. 334, figs. 19*).—In this monograph emphasis has been placed on the results of purely scientific investigations in wood chemistry rather than on the practical phases of chemical wood utilization. The arrangement of subject matter consists of sections on the chemical components, proximate and summative analyses, and decomposition of wood, and on wood as an industrial material. This final section deals particularly with the physical properties of wood, such as its microscopic structure, penetrability to liquids, etc., and the deterioration of wood under various conditions of use. Numerous literature references are given as footnotes.

The chemistry of the natural and synthetic resins, T. H. BARRY, A. A. DRUMMOND, and R. S. MORRELL (*London: Ernest Benn, 1926, pp. VII+196, figs. 3*).—This volume, which is one of the series of monographs on oil and color chemistry edited by R. S. Morrell, deals with the origin, methods of collection, physical and chemical properties and uses of the natural resins and with the properties and manufacture of synthetic resins and the fundamental principles of resinification.

The lime sulphur-calcium arsenate spray, W. GOODWIN and H. MARTIN (*Jour. Agr. Sci. [England], 16 (1926), No. 4, pp. 596-606*).—Using methods similar to those of a previous investigation of the possible chemical changes taking place when lead arsenate is mixed with lime sulfur (E. S. R., 54, p. 709), the authors have studied the reaction between lime sulfur, dicalcium arsenate, and commercial calcium arsenates. From the results reported the following general conclusions have been drawn:

The interaction of calcium hydroxide and dicalcium arsenate results in the formation of a continuous series of basic calcium arsenates which are hydro-

lyzed in aqueous suspension. Although this reduces the amount of arsenic in solution, the reaction is temporary, the original solubility of the dicalcium arsenate being restored by exposure to atmospheric carbon dioxide. The concentration of soluble arsenic in the dicalcium arsenate lime spray is, however, not as great as in the dicalcium arsenate spray, and there is consequently less risk of spray injury with the former.

The concentration of soluble arsenic in the dicalcium arsenate and lime spray is reduced by the admixture of lime sulfur. The precipitation of sulfur from the calcium polysulfides of the lime sulfur is not affected by the addition of dicalcium arsenate, but may be decreased by the addition of lime to an extent dependent on the rate of carbonation of the free lime on the leaf surface.

The chemistry of wheat flour, C. H. BAILEY (*New York: Chem. Catalog Co., 1925, pp. 324, pl. 1, figs. 21*).—Following a brief historical introduction, the extensive literature on the chemistry of wheat flour is reviewed in relation first, to the effect of various factors such as growth, maturity, environment, and storage on the chemical composition of the wheat kernel; second, to the changes in composition resulting from processes of manufacture or milling; and third, to the effect of variations in the composition of the flour upon its baking qualities. An extensive bibliography is appended.

The water-soluble content of calcium and phosphorus in cabbage, W. H. and C. B. PETERSON (*Jour. Agr. Research [U. S.], 33 (1926), No. 7, pp. 695-699*).—Previously reported studies on the chemical composition of cabbage (*E. S. R., 54, p. 803*) have been extended to determinations of the soluble calcium and phosphorus, the ratio of soluble to total calcium and phosphorus, and the variations of each with the type of soil and maturity of the plant. Most of the cabbage was grown in two types of soil—an upland sandy loam which had been cropped for many years and an alkaline marsh soil which had been drained and kept under cultivation for about 10 years. Samples were picked at various stages from young green to fully mature. From 50 to 60 heads were taken at each time of harvesting and the samples used for analysis taken from 100- to 125-lb. lots of the shredded material. For the soluble calcium and phosphorus the method of Totttingham, Schulz, and Lepkovsky (*E. S. R., 51, p. 309*) was used to obtain the extract.

The minimum, maximum, and average percentages of total calcium for the 12 samples of cabbage were 0.038, 0.053, and 0.046 per cent. The marsh samples contained approximately one-third more calcium than the upland samples. The soluble calcium averaged 60 per cent of the total calcium, the amount decreasing from the immature to the mature samples. Corresponding figures for total phosphorus in the same samples were 0.023, 0.036, and 0.028 per cent, respectively. The soluble phosphorus averaged 61 per cent of the total, and as in the case of calcium the amount decreased as the season advanced.

The average results for both calcium and phosphorus differed by less than 10 per cent from those reported in the previous paper for 18 samples grown in 1924.

The composition of crude cottonseed oil.—A summary, G. S. JAMIESON and W. F. BAUGHMAN (*Jour. Oil and Fat Indus., 3 (1926), No. 10, pp. 347-355*).—A summary of data reported in the literature on the physical and chemical constants and chemical composition of crude cottonseed oil.

Physical chemistry of the cells and tissues, R. HÖBER (*Physikalische Chemie der Zelle und der Gewebe. Leipzig: Wilhelm Engelmann, 1926, 6. ed., rev., pp. XVI+955, figs. 125*).—The subject matter of this reference book is arranged in two parts, the first dealing with the physical chemistry of homogeneous and heterogeneous systems and the second with the physical chemistry of body juices, cells, and tissues.

A chemical study of cystine from kidney stones, R. A. GORTNER and W. F. HOFFMAN (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 8, pp. 691-693).—The results obtained in an examination of purified cystine isolated from kidney stones have been compared with data reported in the literature for protein cystine and other samples of stone cystine.

Some of the properties were identical with those previously reported for stone cystine, others for protein cystine, and still others were distinct from both. The possible explanation of these differences is that "cystine is an extremely labile compound and possibly occurs in more than one form, so that persons working with cystine are probably working with a mixture of substances, and that this mixture varies in composition depending at least upon (1) the source of the biological material from which the cystine is prepared, and (2) the method of preparation which is used for the isolation and purification of this amino acid."

The effect of molecular complexity on the end-products formed by *Clostridium thermocellum*, W. H. PETERSON, E. B. FRED, and E. A. MARTEN (*Jour. Biol. Chem.* 70 (1926), No. 2, pp. 309-317).—The fermentative powers of the thermophilic microorganism *C. thermocellum* (E. S. R., 55, p. 203) have been tested on various sugars and related compounds.

In the fermentation of the monosaccharides, lactic acid was the product formed in largest amounts from all but two, rhamnose and galactose. More than 75 per cent of the fructose was converted into lactic acid, while galactose yielded little or no lactic acid, behaving more like cellulose in its fermentation. The polysaccharides derived from two or more sugar molecules behaved more like galactose than like the other monosaccharides. Salicin and mannitol resembled the simple sugars. The type of fermentation is considered to be determined by the complexity of the molecule. An exception to this was malic acid, which was not attacked. The lactic acid consisted almost entirely of the dextro form. The volatile acid was almost entirely acetic acid and the alcohol chiefly ethyl.

The effect of dihydroxyacetone on insulin hypoglycemia, W. R. CAMPBELL and J. HEPBURN (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 575-583, fig. 1).—Clinical and experimental evidence is reported indicating that dihydroxyacetone is capable of curing insulin hypoglycemia. Since previous evidence has shown that no substance inconvertible into glucose, mannose, or maltose can cure insulin hypoglycemia, it is considered to have been proved that dihydroxyacetone is a precursor of glucose.

The relation between peroxidation and antirachitic vitamin, L. YODER (*Jour. Biol. Chem.*, 70 (1926), No. 2, pp. 297-307).—This contribution from the Iowa Experiment Station consists of a report of a systematic examination for peroxidation of a large number of substances previously examined for antirachitic potency. The test employed for peroxidation was the starch and hydriodic acid reaction with peroxides. One gm. of the substance to be tested was shaken with a mixture of 0.5 cc. of a fresh 2 per cent solution of soluble starch, neutral or faintly acid in reaction, and 1 cc. of 2.5 per cent hydrogen iodide. Under these conditions a faint blue color appears after 1 or 2 minutes in highly peroxidized, and in 10 minutes in faintly peroxidized, oils.

With a few exceptions in each group there appeared to be a correlation between antirachitic potency and peroxidation in the untreated and in the irradiated samples, but no correlation in excessively irradiated samples. Fresh mineral oils, which do not acquire antirachitic properties on irradiation, responded positively to the peroxidation test for a short time after irradiation, but lost this property after a day, while irradiated olive oil and cottonseed oil retained it after 14 days.

The author is of the opinion that the capacity to peroxidize is a function of the antirachitic potency of a compound.

The action of light on cod-liver oil, P. R. PEACOCK (*Lancet [London]*, 1926, II, No. 7, pp. 328-330, fig. 1).—A study of the possible relation of loss of fluorescence in cod-liver oil on exposure to light to the content of vitamins A and D in the oil is reported.

The results indicate that there is no association between fluorescence and antirachitic value, but that loss of fluorescence and destruction of vitamin A parallel each other to a certain extent. That the phenomena are not identical, however, was demonstrated by the observation that the destruction of vitamin A is complete before the fluorescence has been entirely destroyed and, furthermore, that fluorescence is gradually restored on keeping the oil in the dark, while there is no corresponding recovery of vitamin A. The changes in fluorescence were found to be accompanied by changes in the absorption spectrum of the oil.

It is emphasized in closing that "light is a variable factor which must be taken into account in all quantitative experiments concerning the growth-promoting properties of cod-liver oil and the manner in which such oil is stored."

Further proof of the "bios" character of crystalline bios 223, R. W. KERR, W. H. EDDY, and R. R. WILLIAMS (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 6, pp. 416-419).—Further proof that the activity of bios, isolated as previously described (*E. S. R.*, 52, p. 110), resides in the pure crystals themselves is afforded by the demonstration that the activity of these crystals is lost by the formation of the crystalline benzene sulfonamide by the action of benzene sulfonchloride, and is restored by the hydrolysis of this inactive crystalline product. Since the reaction takes place at the NH_2 group, it is assumed that this group is concerned in the activity of bios.

Enzymes: Properties, distribution, methods, and applications, S. A. WAKSMAN and W. C. DAVISON (*Baltimore: Williams & Wilkins Co.*, 1926, pp. XII+364, figs. 10).—In this monograph the extensive literature on enzymes, both of plant and animal origin, has been summarized under four main headings—properties of enzymes, distribution of enzymes, methods for the preparation and study of enzymes, and practical applications of enzyme activity. Especial attention has been paid to the occurrence and preparation of enzymes, to the methods of measurement, and to the practical application of enzymatic activity. A bibliography of over 1,300 titles is appended.

Allen's commercial organic analysis, edited by S. S. SADTLER, E. C. LATHROP, and C. A. MITCHELL (*Philadelphia: P. Blakiston's Son & Co.*, 1925, 5. ed., rewritten and rev., vol 4, pp. [4]+X+648, figs. 9).—The corresponding edition of the first three volumes of this well-known reference book has been noted previously (*E. S. R.*, 53, p. 503).

Adsorption from solution by ash-free adsorbent charcoals, I, II, E. J. MILLER (*Jour. Phys. Chem.*, 30 (1926), Nos. 8, pp. 1031-1036; 9, pp. 1163-1169).—Two papers are presented.

I. A method for the purification of adsorbent charcoals.—A method is described by which it is said to be possible to reduce the ash content of adsorbent charcoals of both animal and vegetable origin to a few hundredths or less of 1 per cent.

The method consists of a preliminary extraction with hydrofluoric acid either alone or in mixture with other suitable acids such as hydrochloric or sulfuric, followed by two extractions with concentrated hydrochloric acid, boiling with distilled water to remove the hydrochloric acid, drying, and

igniting at a temperature of from 900 to 1,200° C. in silica vessels from which the air is excluded. The process is repeated until the charcoal is of the desired purity, after which it is ignited to drive off adsorbed acid, boiled in conductivity water to which has been added approximately 1 cc. of N/50 sodium or potassium hydroxide per gram of charcoal, and finally boiled and filtered three or four times.

Data are reported on the ash content of samples of blood charcoal, norit, and activated sugar charcoal before and after several successive treatments with hydrochloric acid and of blood charcoal after successive treatments with a mixture of hydrochloric and hydrofluoric acids.

II. *Properties of purified adsorbent charcoals.*—The theory advanced in previous papers (E. S. R., 52, p. 110) that all charcoals would show the same behavior in adsorption from solution of acids, bases, and salts provided they could be freed from ash and adsorbed substances has been tested with charcoals of animal, vegetable, and carbohydrate origin purified by the method noted above, with results confirming this hypothesis.

All of the charcoals after purification had the same properties of selective adsorption from solutions of electrolytes, adsorbing acids but not inorganic hydroxides and adsorbing salts hydrolytically.

Methods are described for determining the activity and purity of adsorbent charcoals. The activity test consists in determining the adsorption capacity for benzoic acid. The presence or absence of adsorbed acids and alkaline inorganic matter is determined by two tests, based on the fact that inorganic acids adsorbed on charcoal may be quantitatively removed and estimated by treatment with alkali and that charcoal free from adsorbed acids has no effect on the strong inorganic bases.

The pH with quinhydrone electrode, L. E. DAWSON (*Sugar [New York]*, 28 (1926), Nos. 5, pp. 211-214; 6, pp. 262-264, fig. 1; 7, pp. 310-312, fig. 1; 8, pp. 369, 370).—This paper consists of a comprehensive review of the literature on the theory, construction, and operation of the quinhydrone electrode, the advantages and limitations in its use, and its application to H-ion concentration determinations in sugar solutions. A bibliography of 103 titles is appended.

On the presence of amines in the distillate from Kjeldahl-Gunning nitrogen determinations.—Preliminary paper, R. A. GORTNER and W. F. HOFFMAN (*Jour. Biol. Chem.*, 70 (1926), No. 2, pp. 457-459).—Data are presented showing that amines are present in the distillate from a normal Kjeldahl-Gunning digest to the extent of approximately 7 per cent of the nitrogen. The amount of amines is greatly increased by the presence of salts of the dibasic metals magnesium, calcium, strontium, and barium. In the presence of magnesium sulfate, nearly one-fifth of the total nitrogen in the distillate is in the form of amines.

A new factor for converting the percentage of nitrogen in wheat into that of protein, D. B. JONES (*Cereal Chem.*, 3 (1926), No. 3, pp. 194-198).—"In the light of results recently obtained from a study of the proteins of wheat bran [E. S. R., 54, p. 309], a new factor for the conversion of the percentage of nitrogen in wheat into terms of protein has been calculated. The conversion factors for the nitrogen in the three parts of the kernel are bran 6.31, endosperm 5.70, embryo 5.80. By basing the calculation on the percentages of nitrogen in the individual proteins of the endosperm, embryo, and bran, and on the relative proportions in which these proteins are present, the conversion factor 5.83 is obtained for the nitrogen of the whole kernel, instead of 5.7, the factor generally used."

A rapid method for determination of the free and hydrolyzable sugar content of foodstuff, G. W. PUCHER (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926),

No. 6, pp. 470-472).—The method developed by Thomas and Dutcher for analyzing the free sugar content of plant material (E. S. R., 53, p. 108) has been adapted to the analysis of the free carbohydrates in foodstuffs. Data are given on the percentage of free and hydrolyzable sugars in various fruits and vegetables, cereal products, and diabetic preparations.

The sugar in urine and in blood, O. FOLIN and A. SVEDBERG (*Jour. Biol. Chem.*, 70 (1926), No. 2, pp. 405-426).—This paper, which should be consulted in the original for descriptions of technique, consists of a revision of the recently described method of determining sugar in normal urine (E. S. R., 55, p. 613) necessitated by the source of error described by Benedict (E. S. R., 55, p. 805), specifications as to the conditions which must be observed in using the method for the determination of sugar in blood, a description of a fermentation method for the determination of sugar in blood said to be simple, convenient, and dependable, data on the nonglucose sugar of the blood under varying conditions, and a preliminary description of a class of alkaline copper reagents which are reduced by the ordinary nitrogenous products, having distinct reducing properties, but are unaffected by reducing sugars.

Fearon's "pyrogallol" test as a possible basis for the estimation of vitamin A, S. G. WILLIMOTT and T. MOORE (*Biochem. Jour.*, 20 (1926), No. 4, pp. 869-872).—A critical examination of the Fearon pyrogallol test for vitamin A (E. S. R., 55, p. 712) leading to certain modifications in the test is reported.

The principal changes introduced were the use of resorcinol in place of pyrogallol and of benzoyl peroxide to hasten the color development. The absolute exclusion of water was found to be unnecessary when sufficient acid was present. Proper adjustment of the resorcinol concentration was found to be most essential, the transition from blue to red being most rapid at a concentration about 0.5 per cent that of the oil being tested. The quantitative technique finally adopted consisted in dropping various quantities of the oil into test tubes and adding to each an amount of an ethereal solution of resorcinol equivalent to 0.5 per cent of the oil, and then with thorough vertical shaking 5 cc. of 10 per cent trichloroacetic acid in toluene and 0.5 cc. of benzoyl peroxide in toluene. After about 2 hours the colors are compared against a solution of magenta toned with methylene blue. Data are reported showing that under these conditions the color developed is fairly proportional to the amount of oil taken.

In qualitative tests positive results were obtained with all cod-liver oils, beef suet, butterfat, and egg yolk fat, and negative with olive oil, linseed oil, palm kernel oil, and "ostelin" (a preparation rich in vitamin D).

The relation of storage to the quality of sweet potatoes for canning purposes, C. W. CULPEPPER and C. A. MAGOON (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 627-643, figs. 4).—The observation in a previous study (E. S. R., 47, p. 613) that if sweet potatoes are canned immediately after digging the product is firmer than if they are subjected to the usual curing treatment before canning has led to a comparison with a large number of varieties of sweet potatoes of the quality and composition of the product canned before and after the usual curing treatment and storage for a month. Uniform canning methods were used throughout for two types of product—whole potatoes in No. 3 cans and pulp or pie stock in No. 2 cans. The methods of analysis were the same as in the previous study, and the products were examined for quality by practical cooking tests.

With all of the 36 varieties and strains tested, the freshly dug potatoes yielded a firm product and the cured and stored stock a product varying all the way from a medium to a very soft consistency. The chemical changes

responsible for the differences in consistency were the transformation of starch to dextrin and sucrose and, during cooking, a splitting of a portion of the starch to maltose. The ratio of starch to moisture determined the consistency of the product. The varieties yielding the most attractive product in the can were Nancy Hall, Gold Skin, Vineless Pumpkin Yam, and Porto Rico.

In the cooking experiments the products from the freshly dug sweet potatoes gave better results in all cases than from the cured stock, particularly in the preparation of sautéd and candied sweet potatoes. Gold Skin was given first place in the cooking tests, with Vineless Pumpkin Yam and Porto Rico tying for second place.

"As a result of these combined studies it is apparent that by judicious handling of the raw stock the sweet potato canner is able to put on the market products suited to every demand which the sweet potato supplies as a table commodity, and which for certain culinary uses is equal if not superior to the fresh vegetable."

METEOROLOGY

Meteorology and agriculture (*Jour. Min. Agr. [Gt. Brit.]*, 33 (1926), Nos. 8, pp. 747-753; 9, pp. 814-824).—Abstracts are given of eight papers presented at a conference on the effect of weather on crop growth, as follows:

The influence of summer rainfall on the fruiting of apples, A. H. Lees.—The following correlations between previous crop, previous rainfall, and succeeding crop of apples have been found to hold for adult trees provided that excessive frosts or continuous cold winds do not interfere in the spring:

Relation of previous crop and rainfall to succeeding crop

Previous crop	Previous rainfall	Succeeding crop	Previous crop	Previous rainfall	Succeeding crop
Heavy.....	Wet.....	Very poor.	Light.....	Wet.....	Medium.
Heavy.....	Medium.....	Poor.	Light.....	Medium.....	Good.
Heavy.....	Dry.....	Medium.	Light.....	Dry.....	Very good.
Medium.....	Wet.....	Poor.	None.....	Wet.....	Good.
Medium.....	Medium.....	Medium.	None.....	Medium.....	Very good.
Medium.....	Dry.....	Good.	None.....	Dry.....	Very good.

A rainfall under 6 in. during June, July, and August is classed as dry, 6 to 9 in. medium, and over 9 in. wet.

Meteorological conditions and the growth of barley, F. G. Gregory.—Pot experiments with pure lines of barley under controlled moisture with quantitative measures of plant growth showed that carbon assimilation is almost completely controlled by climatic factors, especially light intensity. Rate of leaf growth increases with increased day temperature and decreases with increased night temperature. The increase in dry weight, or the efficiency index, increases with higher day temperature and decreases with higher night temperature. In other words, increase in temperature accelerated leaf growth and carbon production, which determine yield. Bright sunshine showed an opposite effect on both processes.

Essentials of theory and points of practice in crop weather work, F. L. Engledow.—The difficulties encountered in a study of the effect of weather on crops are discussed.

Technique of crop observations, T. Eden.—The importance of getting as many measurements in the field as possible is emphasized, and the following are recommended as characters giving the best measure of performance of

oats: The capacity of the plant to tiller, the character of the leaf, and the total height of the plant.

Solar radiation, R. Corless.—Conditions which modify the intensity of solar radiation and methods of measuring it are discussed, attention being called particularly to the Callendar radiograph.

Solar radiation and plant growth, V. H. Blackman.—The relation of solar radiation to form of growth and carbon assimilation is briefly discussed. Studies of the effect of increasing the carbon dioxide content of the surrounding air are referred to. Emphasis is placed upon the importance of working with the crop as a whole and not with detached leaves. It is suggested that "differences of crop-yield of different varieties may be partly due to their different efficiencies in the utilization of solar radiation."

The value of coordination in phenological observations, J. E. Clark.—Progress in coordinating and establishing systematic observations in England, United States, Holland, Belgium, and Germany is reviewed, and attention is called to the plan of the Royal Meteorological Society for observations at 300 stations in England, as well as the work of 12 centers on the Continent. Confirmation of the general applicability of the bioclimatic law of Hopkins is noted.

The value of phenological observations in practical agriculture, A. Roebuck.—Periodicity in plant growth as determined by natural conditions and modified by culture is discussed, as is the general applicability of the bioclimatic law. Attention is called to the use of index plants to indicate the state of the season. It is stated that "oats sown when the purple plum (*Prunus pissardi*) commences to flower have yielded well and been free from frit fly attack, the pest most feared by growers. The flowering of the elder (*Sambucus nigra*) has also coincided with seeding of swedes to obtain good crops. The best time for seeding of winter oats appears to be between the flowering of ivy (*Hedera helix*) and the ripening of holly berries (*Ilex aquifolium*)." Reference is made to a plan proposed by the Ministry of Agriculture for testing the possibilities of this idea.

Climatological data for the United States by sections, [July–August, 1926] (*U. S. Dept. Agr., Weather Bur. Climat. Data, 13 (1926), Nos. 7, pp. [195], pls. 3, figs. 3; 8, pp. [193], pls. 4, fig. 1*).—These numbers contain brief summaries and detailed tabular statements of climatological data for each State for July and August, 1926.

Meteorological summaries for the year 1925 (Kentucky Sta. Rpt. 1925, pt. 1, pp. 32–34).—Data compiled from records of the United States Weather Bureau Station at Lexington, Ky., on temperature, precipitation, wind, and cloudiness are summarized in tables. The data for temperature and precipitation cover the years 1872–1925.

Meteorological report for the year 1925 (Montana Sta. Rpt. 1925, pp. 50–52).—Observations at Bozeman, Mont., on temperature, precipitation, evaporation, cloudiness, and wind are summarized. The mean temperature for the year was 43.5° F.; the highest 96°, July 14; the lowest –2°, January 26 and March 13. The total precipitation was 19.48 in. The first killing frost in autumn occurred October 1, the last in spring May 10. The number of clear days was 145. The evaporation for the months of April to October, inclusive, was 35.02 in. The mean temperature for the three months January to March, inclusive, was the highest ever recorded at this place, 30.9°, and the minimum for these months, –2°, was the highest ever recorded. September and October were unusually rainy, and this retarded harvesting and threshing grain.

Climatological summary for State College, Pennsylvania, 1925 (Pennsylvania Sta. Bul. 204 (1926), p. 40).—A summary is given of monthly and

annual temperature, precipitation, and cloudiness. The annual temperature was 49.6° F., 1.6° above the 41-year normal. The extremes of temperature were 95° June 5 and -14° January 28. The precipitation for the year was 33.95 in., 5.64 in. below the normal. The snowfall was 44.5 in. There were 127 clear days.

SOILS—FERTILIZERS

Electrodialysis of the colloidal soil material and the exchangeable bases, S. MATTSON (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 553-567, fig. 1).—In studies conducted by the U. S. D. A. Bureau of Soils two soil colloids, representative of widely different groups of colloidal soil materials, were electro-dialyzed in order to determine what part of the bases can be removed by this process.

Preliminary work showed that the quantity of bases that can be removed by electro-dialysis is fairly definite, and that the order in which the different bases appear in the cathode chamber is about as follows: Calcium, potassium, sodium, magnesium, aluminum, manganese, and iron. It is pointed out, however, that this may not represent the order in which the cations are released from the colloid particles, since the appearance of the bases in the cathode chamber is largely affected by the H-ion concentration in the compartment containing the colloid.

The total quantity of bases removed by electro-dialysis from one colloid was about five times that removed from the other. While the percentages of the calcium or sodium in the colloid that were removable did not agree closely in the case of the two colloids, it was evident that the various bases are characterized by different degrees of removability. The proportion of the total lime or manganese removable by electro-dialysis was much greater than the proportion of magnesium, potassium, or sodium, and the proportion of total aluminum or iron removable was still less. Extraction of the two colloids with normal ammonium chloride or N/20 hydrochloric acid yielded quantities of the mono-valent and divalent bases that were almost identical with those obtained by electro-dialysis.

Treatment of the electro-dialyzed colloids with a calcium chloride solution developed quantities of acidity that approximated the base exchange capacities of the untreated colloids. It appeared that in the process of electro-dialysis there is a substitution of hydrogen ions from the water for most of the mono-valent and divalent cations removed by the electric current. It was evident that each of the mono-valent and divalent bases in the colloid is present in two conditions which might be defined simply as exchangeable and nonexchangeable.

It is pointed out that if the deductions involved in formulas connecting electrical migration with electrokinetic potential and charge of the particles are correct, only a part of the exchangeable bases in the colloid are present in the dissociated condition.

Ion exchange in relation to soil acidity, W. P. KELLEY and S. M. BROWN (*Soil Sci.*, 21 (1926), No. 4, pp. 289-302).—Studies conducted at the California Experiment Station are reported which showed that dilute acids react with soil in much the same manner as neutral salts, the reaction involving an exchange of ions. When reacted on by acids the exchange complex gives up base in exchange for H ions. The soil then becomes unsaturated with base and therefore acidic. H ions are energetic replacing ions. Weak acids, such as carbonic acid, are capable of effecting an exchange of H ions for soil bases. The H ions may in turn be displaced from the soil, in part at least, by the base of a neutral salt, with the resulting formation of an acid solution.

Dialysis experiments indicated that the exchange complex ionizes to some extent. The ionization products of a base-saturated soil are composed largely of the replaceable bases as cations and aluminosilicate particles as anions.

The replaceable bases of mineral soils are believed to be chemically combined as salts of one or more of the aluminosilicic acids, and when displaced by H ions the compounds become acid silicates. It is suggested that the electro-negative character of soils, their cataphoretic property, etc., are due, in part at least, to the ionization of true chemical compounds rather than to the influence of adsorbed ions.

It was found that when a soil is treated with aluminum chloride a replacement of soil bases takes place. The H ion formed as a result of hydrolysis, and not the aluminum ion, is responsible for the replacement. It is considered probable that the trivalent bases which are removed from an acid soil by extraction with a neutral salt solution are probably brought into solution as a result of the solvent power of the solution, which is materially increased by the H ions that are displaced from the exchange complex by the neutral salt.

A considerable number of acid soils were found to contain subnormal amounts of replaceable calcium. It is considered probable that this condition will prove to be a general characteristic of acid soils.

Other results of the work are presented in detail.

Some comparisons of the properties of humid-tropical and humid-temperate American soils, with special reference to indicated relations between chemical composition and physical properties, H. H. BENNETT (*Soil Sci.*, 21 (1926), No. 5, pp. 349-375, figs. 4).—Reconnaissance studies by the U. S. D. A. Bureau of Soils in humid Central America are reported in which two distinct classes of upland clay were found, with properties not explainable by their relative content of sands, silt, and clay. Soil with as much as 99.3 per cent of silt and clay, of which 71 per cent was colloids, were exceedingly friable, highly permeable, very resistant to erosion, and so lacking in stickiness as to plow to a crumbled condition immediately after heavy rains. Clay of the opposite group with as much as 97.4 per cent of silt and clay, of which 82 per cent was colloids, possessed extreme plasticity and stickiness and absorbed very little water. Those clays grouped on the basis of a molecular ratio of $\frac{\text{SiO}_2}{\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3} =$ less than 2 were usually much more friable than those having a corresponding ratio greater than 2, and in parts of their profile those of the former group were more friable and permeable than most upland clays of the humid United States.

The evidence obtained points toward more advanced weathering in the material of the more friable soils, this giving an end product of relatively low contents of silica and of the bases CaO, MgO, Na₂O, and K₂O, and relatively high contents of iron and alumina. The unusual permeability and resistance to dispersion in water seemed to be due to a flocculation of the colloids of such strong character as to make it exceedingly difficult for water to separate the grains.

The data are taken to indicate that degree of weathering rather than type of weathering explains the differences between the two groups of soils. The constantly warm temperature of the Tropics probably accounts for the very much larger proportion of friable clay soils in humid tropical than in humid temperate zones.

On the composition of the fractions separated by mechanical analysis from some Transvaal soils, B. DE C. MARCHAND and C. R. VAN DER MERWE (*So. African Jour. Sci.*, 22 (1925), pp. 104-118).—Data from chemical studies of

sandy soils, red clay soils and heavy red loams, and black clay soils are presented, together with information on weathering and on the physical properties and composition of clay.

Saline County soils, R. S. SMITH, E. A. NORTON, E. E. DETURK, F. C. BAUER, and L. H. SMITH (*Illinois Sta. Soil Rpt. 33 (1926), pp. 53, pl. 1, figs. 7*).—This survey deals with the soils of an area of 247,488 acres in southeastern Illinois which lies within the lower extremity of the glaciated region of the State. The county has extremes in topography which are due primarily to the rugged hilly character of the Ozark highlands. The area is generally well drained.

The soils are grouped as upland timber, terrace, swamp and bottomland, and residual soils. Eleven soil types are mapped, of which the yellow-gray and yellow silt loam upland timber soils and the deep gray silt loam swamp and bottomland soils cover 30.88, 23.68, and 18.15 per cent of the area, respectively. The results of analyses of the prevailing soil types are summarized, indicating that the phosphorus content of the soils of the county is low. The amounts of calcium are also rather low.

An appendix is included giving explanations for interpreting the soil survey and outlining the principles of soil fertility, together with a supplement of field data from five experimental fields.

Soil survey of Merrick County, Nebraska, F. A. HAYES ET AL. (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1922, pp. III+871-919, fig. 1, map 1*).—This survey, made in cooperation with the University of Nebraska, deals with the soils of an area of 304,640 acres in east-central Nebraska. The topography of the small upland area is for the most part rough and dissected, while the alluvial lands have a generally flat to gently undulating relief. The county is said to be as a whole well drained, although there are extensive areas throughout the bottom lands which are either subject to overflow or in which the water table often rises too near the surface.

The soils of the county are classed as loessial, alluvial, and aeolian soils. Including dunesand and riverwash, 26 soil types of 9 series are mapped, of which the Cass fine sandy loam covers 14.3 per cent of the area.

Soil temperature records during 1923 (*Egypt Min. Agr., Cotton Research Bd. Ann. Rpt., 4 (1923), pp. 107-119*).—Soil temperature studies of Egyptian soils are reported, the results of which are taken to indicate that the maintenance of the fertility of Egyptian soils is directly dependent upon the sharaqi period. The fact that the yield of cotton following a summer fallow is greater than that following no fallow or a short fallow is considered to be strong evidence that the decline in the yield of cotton is directly attributable to the elimination of the fallow period beyond the point necessary for the maintenance of soil fertility. A heavy dressing of Nile silt had no effect upon the cotton crop. This is taken to indicate that the decline in the yield of cotton can not be attributed to a reduction in the amount of Nile silt received by the land under perennial irrigation.

Drainage waters at Cawnpore, H. N. BATHAM (*India Dept. Agr. Mem., Chem. Ser., 8 (1926), No. 8, pp. 127-152, figs. 5*).—Data from 13 years' observations on the amount and composition of the rain and drainage waters of Cawnpore are reported (E. S. R., 27, p. 19).

It was found that the heavier the rainfall the greater is the drainage of any particular place. The difference in the quantities of water percolating through gauges of the same size always varies, but it generally remains below 2 in. The variations are greater in the case of 3-ft. gauges than in the case of 6-ft. Shallow gauges give greater quantities of drainage water than the deeper ones.

Cropping was found to reduce the drainage considerably, and the heavier the crop the less was the drainage and the greater was the evaporation. The maximum amount of drainage was found to take place during the months of August and September. Evaporation was found to decrease when the rainfall increased. The evaporation was usually greater from a cropped gauge than from a fallow one, and nearly always greater from a deep gauge than from a shallow one.

The content of nitrate in drainage waters appeared to decrease rapidly with time. The fallow gauges of different sizes gave nearly the same quantities of nitrogen in their drainage waters. This is taken to indicate, therefore, that the nitrate comes only from the surface soil. Fallow gauges were found to lose about seven times more nitrogen in their drainage waters than the cropped ones, and the maximum loss of nitrate in drainage took place during the month of August.

The loss of soluble salts in runoff water, F. L. DULEY (*Soil Sci.*, 21 (1926), No. 5, pp. 401-409).—Studies conducted at the Missouri Experiment Station are reported in which the run-off water from the soil erosion plats at the station was sampled and analyzed for a period of one year.

The total amount of dry salts lost varied from 166.8 lbs. from the plat in wheat and clover to 380.1 lbs. per acre from the plat which was spaded 4 in. deep in the spring and fallowed throughout the season. Calcium and sulfur were lost in larger amounts than any of the other elements determined. The loss of potassium was relatively small, but amounted to considerably more than would ordinarily be applied in commercial fertilizer in several cases. The losses of magnesium, sodium, and phosphorus were too small to be of much practical importance.

The results indicated further that the surface run-off water is not a great source of nitrogen loss. The soluble salts from the fallow plats showed a higher percentage of inorganic material than did the soluble material coming from land carrying a crop.

The reclamation of land containing sodium chloride and sodium carbonate (*Egypt Min. Agr., Cotton Research Bd. Ann. Rpt.*, 4 (1923), pp. 120-128).—Experiments are reported which indicated that the reclamation of land containing sodium chloride may be considerably hastened and rendered independent of the summer water supply by the use of sodium bisulfate, and that land containing sodium carbonate may also be reclaimed.

Soil treatment with various disinfectants, T. G. MAJOR (*Sci. Agr.*, 6 (1926), No. 8, pp. 283-285).—The preliminary results of experiments in progress at the Central Experimental Farm, Ottawa, on a number of preparations for the disinfection of tobacco seed bed soils are reported.

Dust treatment of the soil was of no value. In the liquid treatments the formaldehyde preparations did not appear to injure the plants as much as did the mercuric compounds. Data taken on weed control showed that none of the preparations will check the development of weeds without also injuring the tobacco.

Some protozoa found in certain South African soils, V. H. B. FANTHAM and N. F. PATERSON (*So. African Jour. Sci.*, 22 (1925), pp. 355-399).—In the fifth contribution to the subject from the University of Witwatersrand (E. S. R., 53, p. 618), data on protozoa from soils of the Cape Province, Natal, and the Transvaal are reported.

Frost seemed to cause a decrease in the number of protozoa. Veld burning was found to be injurious to protozoal cysts in some soils. Soils examined in cultures before and after the addition of fertilizer showed in some cases a

reduction in the number of species of protozoa, confirming the previous finding that certain protozoa are affected selectively by certain fertilizers.

A comparison of the protozoa from banana soils from two different districts showed that about half of the species observed were common to both soils, and that a greater number of the species occurred in the moister and more acid soils.

Effect of the summer fallow upon Egyptian soil protozoa (*Egypt Min. Agr., Cotton Research Bd. Ann. Rpt., 4 (1923), pp. 119, 120*).—Studies are briefly reported which indicated conclusively that cyst forms of protozoa are being dealt with in sharaqi soils, and that as the temperatures of these soils are not high enough to kill cyst forms the protozoa of sharaqi soils are not suppressed. This is taken to indicate, therefore, that Egyptian soils can exhibit the characteristics of partially sterilized soils without the protozoa being suppressed. An investigation of the effect of heat upon the physical properties of the soil has shown that heating results in a modification of the colloidal properties of the soil and its behavior toward water.

[**Soil fertility studies by the Indiana Station at Moses Fell Annex Farm**], H. J. REED and E. W. MOORE (*Indiana Sta. Circ. 135 (1926), pp. 2-7, fig. 1*).—The progress results of general soil fertility studies are briefly summarized.

[**Soil fertility studies at the Pennsylvania Station**] (*Pennsylvania Sta. Bul. 204 (1926), pp. 9-11*).—The progress results of work on the subject are briefly summarized.

Rebuilding soil cropped continuously to grain (*Montana Sta. Rpt. 1925, pp. 25, 26, fig. 1*).—Data are briefly reported indicating that a serious deficiency of the experimental soil is in available nitrogen, and that the nitrogen in alfalfa brings about greater soil improvement than does commercial fertilizer.

The use of oat straw in a system of soil fertility, R. P. THOMAS and H. J. HARPER (*Soil Sci., 21 (1926), No. 5, pp. 393-400*).—Studies conducted at the Iowa Experiment Station are reported in which the effects of applications of oat straw on the accumulation of nitrate in soils when applied alone and in combination with red clover, Hubam clover, sodium nitrate, and ammonium sulfate were studied under greenhouse conditions.

The results showed that the addition of oat straw did not appreciably affect the accumulation of nitrates in Webster silt loam and Carrington loam soils. Soil treated with straw alone yielded less than untreated soil. Where oat straw was applied and turned under with the second growth of red clover, Hubam clover, and alfalfa no retardation of nitrate occurred except in that portion of the soil immediately in contact with straw which was not mixed with the legume. Additions of oat straw alone and in combination with red clover and Hubam clover to Carrington loam had no retarding effect on the growth and yield of corn.

The conclusion is drawn that straw can be returned to many Corn Belt soils by spreading it on the second growth of red clover, on Hubam clover, or on biennial sweet clover, and by plowing in the fall wherever possible, without causing any injury to crop growth and yield.

Geometrical calculation of ternary fertilizer mixtures using triangular coordinates, B. COLBJÖRNSEN (*Indus. and Engin. Chem., 18 (1926), No. 7, pp. 724-726, figs. 6*).—This method of calculation is outlined in some detail and compared with the algebraic method.

Nitrogen and cultivated plants [trans. title], O. ARRHENIUS (*Meddel. Centralanst. Försöksv. Jordbruksområdet [Sweden], No. 299 (1926), pp. 27. pl. 1, figs. 2; Eng. abs., pp. 24-26*).—Preliminary experiments are reported on the influence of the concentration of nitrate nitrogen in the development and yield of cultivated plants such as oats, barley, red clover, and sugar beets.

The results indicated that the three plants which did not assimilate nitrogen behaved in about the same manner. At the zero concentration they did not yield anything. The weight of the plants increased rapidly with increasing nitrate concentration. For sugar beets there was a decrease in yield from the 9 to 32 concentration. Clover behaved differently. It grew fairly well at the zero concentration, reaching a maximum at 3, decreased to 9, and then increased at 32. Nodule formation was strongly influenced by the nitrate concentration.

It was found that if the nitrate concentration is kept at the optimum for 6 weeks, it may then decrease considerably without any serious effect on the yield. After three weeks, however, the influence of a drop is quite marked. The results are taken to indicate that 9.5 mg. of nitrate nitrogen per kilogram of soil is the optimum concentration, and that this concentration need be kept only during the first stages of growth.

Maps showing the distribution of nitrates in the soils of two Swedish farms are given. Fallow soils contained a very high nitrate concentration. On the other hand, grass and corn soils contained no nitrates. The nitrate content was increased as soon as cultivation of the soil was begun.

The nitrogen compounds in rain and snow, F. T. SHUTT (*Canada Expt Farms, Div. Chem. Rpt., 1925, pp. 68-74*).—A summary is presented of the data obtained during the past 17 years' observations of the amount and character of the nitrogen compounds in rain and snow. The progress of these observations has been previously noted (*E. S. R., 54, p. 422*).

The Chilean nitrate industry, B. D. OSSA (*Internatl. Rev. Sci. and Pract. Agr. [Rome], n. ser., 3 (1925), No. 4, pp. 942-971, pls. 13, figs. 18*).—A profusely illustrated description of the Chilean nitrate industry is presented in a contribution from the University of Chile.

Nitrifying power of pozzuolana [trans. title], C. SEBONO and L. GUERCI (*Ann. Chim. Appl. [Rome], 15 (1925), No. 7, pp. 309-316*).—Studies on the manner of formation of nitrates occurring in volcanic soils showed that the transformation into nitrate of ammonia, probably of volcanic origin, is due to the catalytic action of the pozzuolana in the presence of moisture and atmospheric oxygen. This does not appear to be a superficial action, but one characteristic of pozzuolana which takes place at a temperature not exceeding 100° C. (212° F.).

Phosphoric-acid content of crops grown upon peat soils as an index of the fertilization received or required, F. J. ALWAY, W. M. SHAW, and W. J. METHLEY (*Jour. Agr. Research [U. S.], 33 (1926), No. 8, pp. 701-740, figs. 8*).—Studies conducted at the Minnesota Experiment Station are reported of the ash and phosphoric acid contents of crops from fertilized and unfertilized peat soils and of hay from black prairie soils.

The phosphoric acid contents of hays, straws, and even grains grown on peat soils deficient in phosphate were greatly increased by phosphate fertilization, except where the application was very light, and greatly increased yields resulted. With the straws the increase in some cases amounted to several hundred per cent, with the hays from 20 to 50 per cent and even higher, and with the grains usually between 10 and 60 per cent. The results are taken to indicate that the phosphoric acid determination has the most significance when comparisons are made between fields or plats of a crop in the same locality and in the same season and with hay crops of the same cutting, using the separated important plants rather than mixed samples.

The analysis of crops is said to be very useful in detecting mistakes in the application of fertilizers. It is considered difficult, however, to place either

upper or lower limiting values for the phosphoric acid requirement of any crop. Crop analysis is not considered a practical method of detecting phosphate deficiencies in black prairie soils.

The literature on the palatability and nutritive value of tame hay from peat lands is reviewed, and the possible bearing of the phosphoric acid content upon these properties is discussed. It is pointed out that certain minimum contents of phosphoric acid in hay may be secured, if desired, by heavy initial phosphate applications.

The relative availability of phosphatic fertilisers on acid and non-acid soils, G. INGHAM (*So. African Jour. Sci.*, 22 (1925), pp. 122-134).—Studies are reported which indicated that the availability of a phosphatic fertilizer in a soil depends more upon the nature of the soil than upon the water or citrate solubility of the fertilizer. The availability of superphosphate in 28 soils varied from 21 per cent of the total phosphoric acid for very acid soil to 96 per cent for a soil free from acidity. The availability of air-floated Egyptian rock phosphate was generally very little less than that of superphosphate except in the case of soils containing 0.5 per cent or more of calcium carbonate. In these cases the availability of rock phosphate was considerably less.

Little difference was found between the availability of superphosphate and of other forms of phosphatic fertilizers when equal amounts of phosphoric acid were applied to the soil. The availability was found to be closely related to the iron and aluminum contents, the amount of organic matter present, and the reaction of the soil.

Phosphates of iron and aluminum obtained by precipitation when an extract of superphosphate was added to soluble iron and aluminum salts were readily soluble in 1 per cent citric acid. It is suggested that low availability of a phosphatic fertilizer is due to the absorptive power of the organic and inorganic colloids. Acid soils were found to have a high absorptive capacity for phosphoric acid as well as for lime. Flocculation of the inorganic soil colloids is suggested as a means of reducing their excessive absorptive capacity.

It was found that the absorptive capacity for phosphoric acid of soil containing a large amount of iron and aluminum was doubled and the citrate solubility of the fertilizer was reduced to half by removing the calcium carbonate. The addition of calcium carbonate to an acid soil had no perceptible effect on the availability of superphosphate after a month, but gave a definite increase after 12 months.

The physiological value of phosphoric acid in superphosphate and other phosphates, J. STOKLASA (*Internatl. Rev. Sci. and Pract. Agr. [Rome]*, n. ser., 3 (1925), No. 4, pp. 921-941).—Experiments carried on over a number of years at the State Experiment Station for Plant Production of Czechoslovakia on manuring with the different forms of phosphoric acid are reported.

The form in which water-soluble phosphoric acid appears in superphosphate was found to be important. Free phosphoric acid had a decidedly better effect than monocalcium phosphate when used on sandy loam and chalk soils. On the other hand, the water-soluble form of the acid stood the test better on humus soil. This is taken to indicate that fertilizer factories should manufacture a superphosphate for use on sandy loam and chalk soils in which the phosphoric acid is chiefly available in free form. It was found that the phosphoric acid insoluble in water in any form of the different types of phosphates now on the market has less physiological value than the water-soluble forms in superphosphate.

Effect of dressings of basic slag on the lime status of soils, R. WILLIAMS (*Jour. Agr. Sci. [England]*, 16 (1926), No. 2, pp. 196-204).—Studies conducted

at the University College of North Wales are reported which showed that the addition of basic slag to moist base-unsaturated soils under laboratory conditions caused an increase in their content of exchangeable calcium, degree of saturation, pH, and amount of calcium soluble in an aqueous solution of carbon dioxide.

Slag seemed to be almost as effective as calcium carbonate or lime in increasing the exchangeable calcium and the degree of saturation of soils, but its action on pH was not so marked. The effect of dressings of slag on the lime status of soils from experimental plats was still evident after eight years. The exchangeable calcium of samples of soil taken from the same fields after an interval of six years showed a considerable decrease due to leaching.

It is suggested that the addition of low grade basic slag to unsaturated soils may tend to maintain or improve their lime status and will to some extent compensate for the losses of calcium due to drainage and crops.

Greensand as a source of potassium for green plants, J. R. SKEEN (*Amer. Jour. Bot.*, 12 (1925), No. 10, pp. 607-616, figs. 4).—This experimentation is said to be a continuation of that reported by True and Geise (*E. S. R.*, 40, p. 423).

It is held that greensands offer a physiologically available source of potassium for plant growth. The percentage of potassium used for plant growth depends upon the quantity of greensand added, such percentage increasing in a sharply linear curve probably to 2 per cent and falling away sharply upon further addition of more greensand. No loss of potassium results from the addition of large amounts of greensand, but plants apparently absorb up to a definite maximum, the unabsorbed portion remaining as a reserve in the soil. It is claimed that the average soil deficient in potassium should show marked improvement for several years after the addition of from 5 to 15 tons of greensand per acre. It is thought best to have considerable calcium present in the soil or composted with the greensand.

Gypsum or copi, P. R. SCOTT and W. C. ROBERTSON (*Jour. Dept. Agr. Victoria*, 24 (1926), No. 2, pp. 65-74, figs. 9).—Information on the mining and use of gypsum in Victoria is presented, together with data from experiments on the effect of gypsum on soil. It was found to liberate potash from minerals containing potash and, to a lesser extent, phosphoric acid, magnesia, and silica. It also encouraged the growth of legumes, increased the rate of ammonification, and flocculated the finer particles in soils.

The effect of sulfur on the microflora of the soil, J. M. FIFE (*Soil Sci.*, 21 (1926), No. 4, pp. 245-252, figs. 5).—Studies conducted at the Utah Experiment Station are reported on the influence of varying amounts of sulfur on the soil microflora as measured by numbers, ammonification, nitrification, nitrogen fixation, and the rate of sulfur oxidation. Three soils were used which were composed primarily of coarse and medium silt and fine sand.

Depending upon the soil and upon the amount of sulfur applied, the results showed that the addition of sulfur to soil increased the ammonifying power from 50 to over 100 per cent, and the nitrification over 100 per cent in some instances. Sulfur was without effect on nitrogen fixation in soil during the short period of the observations. The bacterial counts decreased as the incubation period increased. Relative to the untreated soil the bacterial numbers increased as the amount of sulfur increased in the soil containing a large amount of organic matter, whereas the bacterial numbers of soils deficient in organic matter decreased as the sulfur increased. From 36 to 89 per cent of the sulfur was oxidized to sulfates in 30 days, depending on the soil and its porosity.

Effect of sulphur on alfalfa and clover (*Montana Sta. Rpt. 1925, pp. 24, 25, fig. 1*).—Data are briefly reported which show that sulfur gave an average increase of 1.92 tons of alfalfa per acre and gypsum an increase of 1.35 tons per acre. The increase of protein in the crop was also quite marked.

AGRICULTURAL BOTANY

Plants and man, F. O. BOWER (*London: Macmillan & Co., 1925, pp. XII+365, pl. 1, figs. 148*).—"The present aim is to explain for the general reader, in very general terms, how plants fabricate for their own life commodities that man finds so useful in his. . . . A number of the later chapters are devoted to the conjoint life, so common among plants, which is promoted by crowding and close contact . . . all the varied grades of mechanical dependence, mutualism, parasitism, disease, death, and decay. These subjects have been broadly treated, rather from the point of view of plant-biology than from any other."

Studies of the rate of growth of leaves by a photographic method.—I, The determinants of the rate of growth of first leaves of *Phaseolus vulgaris*, M. C. VYVYAN (*Ann. Bot. [London], 38 (1924), No. 149, pp. 59-103, figs. 14*).—A photographic method is described for recording daily area increments in a leaf during growth, the sources of error not exceeding 1 per cent. An account is given of two experiments applying this in a series to be further reported. Results and their interpretation are detailed in comparative form.

"The form of the curve of percentage increments in area is shown to be approximately of a descending logarithmic type, but it is pointed out that as in its earlier portion this curve can be shown to be of a compound nature, the apparently logarithmic form, in this portion at any rate, is probably of little significance."

Contributions to an investigation of the chemical nature of the cellulose membrane, F. M. WOOD (*Ann. Bot. [London], 38 (1924), No. 150, pp. 273-298*).—The state of the cellulose, either naturally or artificially produced, was studied with a view to determining whether oxidation or hydration had occurred. The optimum conditions for distinguishing between cellulose and pectin after the use of a double stain are those causing minimum oxidation and maximum hydration without disintegration. Particulars are given.

The viability of the nodule bacteria of legumes outside of the plant, I-V, M. M. ALICANTE (*Soil Sci., 21 (1926), Nos. 1, pp. 27-52; 2, pp. 93-110, pls. 4*).—In experimentation treating inoculated seeds with soil, glue, and sugar, alone or in combination, some legumes remained viable, nodule production occurring after storage during 60 days in small seed bags under ordinary conditions. Sugar gave uniformly large, evenly distributed nodules. Soil with sugar gave no better results than did sugar alone.

Soils containing 10 per cent sugar developed acidity unfavorable to *Bacillus radicicola*. Cloth seed bags are better than glass containers for storing purposes.

B. radiobacter and *Azotobacter chroococcum* showed no unfavorable effects upon the life and infecting capability of nodule bacteria. Soy bean, sweet clover, cowpea, and garden pea bacteria, when grown together, showed no harmful effect upon each other. The activity of pea bacteria when grown in milk was not impaired by the presence of any one of the organisms tested, including *B. prodigiosus*, *B. capsulatus*, *B. subtilis*, *B. mesentericus*, pink yeast, and molds.

The multiplication rate was greater in high dilution than in low dilution. *B. radiculicola* of garden pea lived in solution 142 days. Oxygen was a limiting factor during the whole growth of nodule bacteria in solution. Shaking gave increased growth. Calcium carbonate stimulated growth better than did tricalcium phosphate. The heat resistance of *B. radiculicola* of garden pea and sweet clover and of *Pseudomonas radiculicola* of cowpea and soy bean was lower than the heat resistance of *B. radiobacter* and *A. chroococcum*.

Peat maintained the life of nodule bacteria at a much higher temperature than brown silt loam. Acid soil lowered the thermal death point of legume organisms, and the organisms died in such soil after a short period of storage. The addition of calcium carbonate raised the thermal death point and the keeping quality of legume organisms. Abnormal media favored changes in the forms of nodule bacteria. The absence of phosphate or carbonate in the media resulted in the formation of bacteroids. Aluminum chloride and hydrochloric acid had similar effects on the form of legume bacteria. The presence of acetic, nitric, and sulfuric acids in media changed the legume bacteria into bacteroids, and each of these acids affected the form of the organisms specifically.

Lack of nodule-formation in a subfamily of the Leguminosae. L. T. LEONARD (*Soil Sci.*, 20 (1925), No. 2, pp. 165-167).—In the subfamily Mimosaceae, examinations were made for root nodules in 24 species of the genus *Acacia* and the closely related genera *Albizzia* and *Prosopis*. *Acacia baileyana* alone failed to show root nodules. This exception is discussed.

A further contribution to the morphology and physiology of the genus *Eidamia*. A. S. HORNE and G. H. JONES (*Ann. Bot.* [London], 38 (1924), No. 150, pp. 351-359, figs. 4).—In a previous investigation, apparently one that has already been reported and noted (E. S. R., 52, p. 215), Jones isolated a fungus which on further study appeared to be a new species of *Eidamia* and which has been described as *E. tuberculata*. The identity of *Monopodium urcdopsis* and *E. acremonioides* is regarded as established.

A description of *Colletotrichum biologicum* nov. sp., and observations on the occurrence of a saltation in the species. H. CHAUDHURI (*Ann. Bot.* [London], 38 (1924), No. 152, pp. 735-744, pl. 1, figs. 7).—A description is given of *C. biologicum* n. sp., as collected in Dahlem, near Berlin, October, 1921, from dying stalks of potatoes, with an account and summary of studies of the cultural characteristics of the fungus as developed on different media and under various conditions. The production of different colors by the saltant has been found to be entirely dependent on temperature.

Growth-inhibiting and growth-stimulating substances. W. F. GERICKE (*Bot. Gaz.*, 78 (1924), No. 4, pp. 440-445).—"When pots containing fertile soils are seeded to wheat or barley for continuous seasons, and successive short-period crops of four to six weeks' growth are removed from such soils, it is found that the first crop is usually the largest, the immediately succeeding crops are much smaller, but some of the latter crops may be larger than some of the preceding ones. Thus instead of soils becoming progressively poorer by continuous cropping due to progressive diminution of its supply of plant food, they may become better at certain times than they were before, through certain processes and agencies concerned in the growth of plants." The results obtained with soils led the author to conduct experiments with culture solutions and to employ a method that would provide a number of successively grown crops under the same climatic complex. The results of this work are tabulated with discussion.

"The growth of plants is not only a complex of many processes, but is in a sense the result of the succession of processes. Some of these processes are de-

pendent on certain salts which supply necessary inorganic elements to plants." Experimental data show that a constantly maintained supply of nutrients in culture media is not as favorable to the growth (entire life cycle) of cereal plants as is a changing supply. This may indicate that any subsequent stage of growth may be beneficially affected by secretions from previous growth phases. Plants may thus be similar to animals in that they have a physiology which is subject to growth inhibiting, growth stimulating, and sensitizing agencies produced by the organism itself.

Effect of methyl and ethyl alcohol on the growth of barley plants, A. N. PURI (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 745-752, figs. 3).—Ethyl alcohol is more toxic to barley plants than is methyl alcohol, the difference in the toxicity of the two being of kind as well as of degree. Ethyl alcohol favors the growth of ear shoots and the suppression of vegetative leaves, methyl alcohol favoring the growth of leaves and not that of the ear shoots. Plants in the later stages of growth can withstand the toxic action of ethyl alcohol much better than in the earlier stages.

The influence on vegetation of some cyanogen compounds [trans. title], A. PETIT (*Jour. Agr. Pract., n. ser.*, 45 (1926), No. 25, pp. 490, 491).—Experimentation is outlined in which small proportions of cyanogen compounds (potassium cyanide, potassium ferrocyanide, potassium ferricyanide, potassium cyanate, and potassium sulfocyanide) were furnished to certain plants in pots, which in most cases showed increase in weight over the controls.

The effect of general anaesthetics on the respiration of cereals.—I, Carbon dioxide production, E. P. SMITH (*Ann. Bot. [London]*, 38 (1924), No. 150, pp. 261-272, figs. 9).—The effects of chloroform, ether, and ethyl alcohol concentrations on the carbon dioxide output of wheat, rice, and oats were found to be similar. With chloroform, recovery (defined as return to a completely responsive state) occurs only after very short exposure, whether continuous or intermittent. With ether, recovery occurs after exposure for six hours, if respiration is not allowed to fall below 60 per cent. The difference in toxicity is supposed to result from the formation of a more stable combination with some cell constituent by chloroform than by ether. Experiments with *Ipomoea* indicate that the effect of the anesthetic upon the permeability of the plasma membrane to carbon dioxide must be taken into account in the interpretation of these results.

The antagonism between dyes and inorganic salts in their absorption by storage tissue, C. E. T. MANN (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 753-777, figs. 8).—The absorption of methylene blue, of neutral red, and of orange G, respectively, has been followed in simple solution and in solutions containing chlorides of ammonium, magnesium, aluminum, and lanthanum, and the results are detailed.

The colloid precipitation theory of the plasma membrane receives support from the phenomena of antagonism investigated and affords a possible explanation of the relationship existing between the degree of antagonism and the valency of the cation of the antagonizing salt. The results here reported are thought to be not inconsistent with the view that the plasma membrane carries an electrical charge.

Effect of light on growth of excised root tips under sterile conditions, W. J. ROBBINS and W. E. MANEVAL (*Bot. Gaz.*, 78 (1924), No. 4, pp. 424-432, figs. 2).—Continuing experimentation on growth of excised cornroot tips under sterile conditions (E. S. R., 53, p. 123), diffuse light was found to be favorable to the continued growth of root tips in a modified Pfeffer solution containing 2 per cent glucose, or the same solution to which 80 parts per million or 400

parts per million of autolized yeast were added. Anthocyan developed in some of the excised corn roots in the light, but in none in the dark. It was present in the rootcap, at points where secondary roots were to emerge or had emerged, and at the base of the root, but not in the meristematic region. The longest period during which a root tip was grown was 149 days, through 10 periods of transfer, in diffuse light in the modified Pfeffer solution containing 2 per cent of glucose and 400 parts per million of autolized yeast. "Roots which remained attached to the grain during the first two weeks grew for a longer time than those grown under excised conditions from the start. One such root was grown in the dark for 133 days, 119 in excised condition."

Further experiments on the conduction of tropic excitation, R. SNOW (*Ann. Bot. [London]*, 38 (1924), No. 149, pp. 163-174, figs. 6).—The author has shown previously (*E. S. R.*, 52, p. 217) that the tip of a decapitated root, if stuck in place with gelatin, becomes again capable of curving down in response to gravity, though it could not then be certainly known that the effective excitation was transmitted past the gelatin, since the stimulus of gravity can not be applied to the tip alone. It was therefore decided to make tests with traumatic stimulus, and to compare quantitatively the effects of excitations on the convex and on the concave side of the root. Also other experiments, for which the root is not suitable, have been carried on with cotyledons of *Avena*.

It is claimed that the traumatic excitation can pass through the gelatin layer and produce a negative curvature in the stump. Tropic excitation due to traumatic stimulus or gravity stimulus can be conducted back along either side of the root alone. In *Avena* cotyledons, if the tip is removed and replaced in an anomalous position so that its far side (with reference to the light) is in connection with the near side of the stump, then, on illumination of the tip alone, phototropic curvature away from the light follows. Simply relative expansion is here regarded as causal. The excitation conducted down the far side of the *Avena* cotyledon can cross a gap filled with moisture.

Water content, a factor in photosynthesis, R. H. DASTUR (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 779-788, fig. 1).—It is concluded from this investigation that photosynthesis is dependent upon water content, and that under normal conditions it is inadequate water supply which terminates photosynthetic activity of leaves and ultimately causes their decay.

Evaporation in wind, W. STILES (*Ann. Bot. [London]*, 38 (1924), No. 150, pp. 299-304).—A critical examination is made of the contribution on the physics of transpiration by Sierp and Noack previously noted (*E. S. R.*, 49, p. 127).

GENETICS

"Pluripotenz" phenomena: Synthetic contributions to the science of heredity and descent, V. HAECCKER (*Pluripotenzerscheinungen. Synthetische Beiträge zur Vererbungs- und Abstammungslehre. Jena: Gustav Fischer, 1925, pp. 213, figs. 26*).—There are assembled in this book a large number of obscure phenomena related to variation which deal especially with the physiological and environmental influences. The term "pluripotenz" is taken to include the numerous possibilities for development possessed by organisms which are not externally evident.

A portion of the work deals with an attack on the linear arrangement of genes in the chromosome and other linkage relations.

The standard errors of chromosome distances and coincidence, H. J. MULLER and J. M. JACOBS-MULLER (*Genetics*, 10 (1925), No. 6, pp. 509-524).—Theoretical formulas have been calculated for determining standard errors of

chromosome distances and coincidence. The latter is defined as the ratio of the proportion of double crossovers which actually occur in two regions to the proportion of double crossovers which would occur there if crossings over in the two regions were independent of each other. The application of the formulas is discussed, and it is pointed out that the standard error of coincidence is not finally determinate but may be approached within narrow limits.

A formula is also given for calculating the maximum and minimum possible true values of a proportion of crossovers which might occur in a random sample.

The chromosome numbers of the principal cereals, with general consideration of plant chromosomes and their number and size, K. V. STOLZE (*Die Chromosomenzahlen der Hauptsächlichsten Getreidearten nebst Allgemeinen Betrachtungen über Chromosomen, Chromosomenzahl und Chromosomen-grösse im Pflanzenreich*. Leipzig: Borntraeger Bros., 1925, pp. [1]+71, figs. 54).—Cytological studies concerned with the chromosomes in *Secale*, *Triticum*, *Hordeum*, and *Avena* are reviewed, with a résumé of research by the author in these genera. Significant findings in important studies on chromosome number and size in other plants are pointed out. More than 150 titles are listed in the bibliography.

Pollen abortion in chromosomal types of *Datura*, A. F. BLAKESLEE and J. L. CARTLEDGE (*Natl. Acad. Sci. Proc.*, 12 (1926), No. 5, pp. 315-323).—The present paper presents the results of a study of the proportion of abortive grains in the pollen of different chromosomal types of *Datura*.

The meiotic phase in certain mammals, C. E. WALKER (*Roy. Soc. [London], Proc., Ser. B*, 99 (1926), No. B 698, pp. 366-374, pls. 3).—From studies of meiosis in material from guinea pigs, rats, mice, rabbits, and a monkey at the University of Liverpool, the author discusses the meiotic phase in these animals as follows:

"The daughter chromosomes elongate and divide longitudinally, filling the nucleus with irregularly distributed semivalent threads. During this process of unraveling of the chromosomes into semivalent threads an appearance very similar to that seen during synapsis is evident. These threads rejoin laterally in pairs, forming univalent filaments. These filaments join laterally in pairs. They again separate, excepting at their ends which remain joined until the first meiotic division takes place. The longitudinal split of the filament into semivalent threads reappears at the telophase, and is consummated at the second meiotic division."

The development of the ovum of the white mouse, Z. FRANKENBERGER (*Biol. Gen.*, 2 (1926), No. 1-2, pp. 21-62, pls. 3, figs. 4).—The results of a study of oogenesis in the white mouse are reported, based on sections of ovaries taken from mice varying in age from fetuses 12 mm. in length to full-grown individuals. The different stages in the growth and divisions are described and illustrated. The diploid chromosome number appeared to be 24, but the presence of various nucleoli is also noted in the formation of the mature ova.

The genus *Epilobium* [trans. title], E. LEHMANN (In *Bibliographia Genetica. The Hague: Martinus Nijhoff, 1925, vol. 1, pp. 363-418*).—The systematic, morphological, and anatomical bases for employing plants pertaining to *Epilobium* in genetic research is discussed, with extensive comment on hybrids in *Epilobium* and on significant results in inheritance studies in the genus. The bibliography includes 177 titles.

Genetic investigations with mosses [trans. title], F. VON WETTSTEIN (In *Bibliographia Genetica. The Hague: Martinus Nijhoff, 1925, vol. 1, pp. 1-38*).—Genetic studies on Musci and Hepaticae are reviewed under the topics of de-

velopmental history, genetic investigations, hybridization experiments, and sexuality of mosses, and a bibliography of 128 titles is appended.

Present-day problems of corn breeding, H. K. HAYES (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 4, pp. 344-363).—Experimental results indicating the value of present methods of corn breeding are reviewed. Some questions of a research nature which remain to be solved are discussed.

Bud mutation in potato and its agricultural significance [trans. title], J. C. DORST (*Genetica [The Hague]*, 6 (1924), No. 1, pp. 1-123, pl. 1, figs. 20; *Eng. abs.*, pp. 114-118).—The author during 7 years collected bud mutations numbering 21 for the variety Eigenheimer, 12 for Red Star, 5 for Bravo, and 15 for all other varieties collectively. In case of several bud mutants reversion was found. As regards degeneration, further investigation is regarded as desirable. No good reason appears for the believing that bud mutation is limited to a few characters only. Deterioration of a given variety is considered as entirely possible without the agency of degenerative diseases. The action of a bud mutation may cause a variety to undergo a gradual change.

Bud sports in sweet potatoes, E. L. HARTER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 523-525, pl. 1, fig. 1).—Three yellow and three red roots were found on a plant of the Haiti sweet potato, normally a red variety marked with small oval or elongated whitish to yellow spots. Two generations from each strain bred true as to color, but the progenies were similar in size and shape of roots, growth habits, and leaves.

Heritability of different rates of shedding in cotton, T. H. KEARNEY and R. H. PEEBLES (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 651-661, fig. 1).—An interspecific cotton hybrid, Pima Egyptian \times Acala, was studied to ascertain whether genetic factors are involved in the shedding of the flower buds and the young bolls (abscission before and after anthesis). Practically no difference was observed in the mean percentage of bud shedding, whereas boll shedding was at a much higher rate in Acala than in Pima.

In both the F_1 and F_2 generations the hybrid gave much lower mean percentages of bud shedding than either parental population, while the mean percentage of boll shedding by both hybrid generations was between the parental types. The mean shedding percentage both of buds and bolls was about twice as great in F_2 as in F_1 , and the differences were very significant. Eliminating the soil variation did not void this difference. While the frequency distributions of the F_1 population for percentage of bud shedding and percentage of boll shedding gave no indication of segregation in definite ratios, the behavior may be interpreted on the theory that three or more genetic factors are involved. The much greater variation in F_2 than in F_1 suggested that Mendelian segregation occurred. Further evidence of genetic factors in shedding was shown by the significant differences obtained by comparing the shedding percentages of pairs of adjacent F_2 plants, which practically eliminated the influence of soil heterogeneity, and also by the great disparity between the sizes of observed and expected standard deviations of the hybrid. This investigation is held to have supplied evidence that there are genetic factors for shedding which segregate and recombine in the usual manner.

Inheritance of white plumage in pigeons, J. R. WALKER (*Genetics*, 10 (1925), No. 6, pp. 593-604).—The results of various crosses in pigeons are reported which have been concerned with the behavior of four genetic factors related to white plumage. A factor, dominant white, in the homozygous condition produces practically self-white birds, and in the heterozygous nearly white birds. In the latter case part of the individual feathers are white and part are colored. A factor for recessive white spotting shows considerable

range in its expression, varying from no white to self-white. The individual feathers, however, are wholly white or wholly colored. In the heterozygous condition some feathers show white and coloring. This factor is also associated with dark brown irises in the homozygous condition. Mottle white is a recessive factor, producing a varying amount of white on and under the wings and on the rump after the first molt. It is apparent only in recessive-red birds. Mottle black, a dominant factor, behaves similar to mottle white except that it is apparent from birth. Genetically black birds never show mottle white, but mottle black appears in both blacks and reds.

The inheritance of hair color in Dachshunds, including observations on the inheritance of hair form [trans. title], J. ANKER (*K. Danske Vidensk. Selsk., Biol. Meddel.*, 4 (1925), No. 6, pp. 72).—From studies mainly of Danish Dachshund breeding records of individuals and societies the author found that in short-haired dogs the colors were explained by four dominant factors: *A* (black), *B* (red), *C* (tigering), and *D* (black cross stripes on red animals). Both *B* and *C* are epistatic to *A*. The theoretical proportions of the different types expected from the various crosses were tabulated and found to agree closely with the observed results.

In addition to *A* and *B* a gene *G* causes gray color in rough-haired Dachshunds. *G* is epistatic to *A* and *B*. In long-haired dogs a gene *F* for the extension of color is present, which in the recessive condition causes red.

The hair forms, short, long, and rough, are due to the action of two genes, *R* and *K*. The presence of *R* causes rough hair. *K* without *R* produces short hair, and when both factors are recessive the individuals are long haired. The factors *K* and *E* appear to be linked.

On the occurrence in the house mouse of a Mendelizing structural defect of the retina producing blindness, C. E. KEELER (*Natl. Acad. Sci. Proc.*, 12 (1926), No. 4, pp. 255-258, fig. 1).—The results of further studies of the hereditary retinal abnormality in mice (*E. S. R.*, 55, p. 821) are reported. It has been established that the external nuclear layer is not entirely absent, though the rods and external molecular layer are absent. This condition results in total blindness. It is due to a recessive character which does not appear to be linked with sex, albinism, dilution, brown, pink-eye, recessive spotting, agouti, short ears, kinky tail, waltzing, or dominant spotting. It has no lethal action and can not be determined until about 13 days after the birth of the animal.

A study of hernia in swine, B. L. WARWICK (*Wisconsin Sta. Research Bul.* 69 (1926), pp. 27, figs. 7).—The anatomy of the inguinal region of the pig is reviewed, including descriptions of the changes from the normal associated with inguinal and umbilical hernias.

The physical causes of inguinal hernias appeared to be large vaginal rings and a low degree of tensility of the tunica vaginalis. The importance of inguinal hernias was estimated from data obtained from various sources. In experiment station herds from which records were obtained inguinal hernia affected 1.68 per cent and umbilical hernia 0.60 per cent of the male pigs born, while 1.16 per cent of the females were herniated, practically all of which were umbilical. Inguinal hernias may appear at any time during the first month of age, but were found to occur more frequently on the left than on the right side.

Three generations of pigs were produced from mating a bilaterally herniated boar to females related to herniated boars. Of the first generation boars produced 14.28 per cent had hernias. The F_2 males produced by breeding F_1 sows and herniated boars were 45.90 per cent herniated, and 43.18 per cent of the males in the third generation similarly produced had inguinal hernias.

These results indicated that the condition of inguinal hernia is definitely inherited, and a 2-factor hypothesis was tentatively suggested to account for the mode of inheritance, the double recessive males being herniated while the females were normal. A minor influence of environmental effects is suggested.

The dependence of secondary sex-characters upon testicular hormones in *Lebistes reticulatus*, L. J. BLACHER (*Biol. Bul. Mar. Biol. Lab., Woods Hole, 50* (1926), No. 5, pp. 374-381, figs. 13).—In experimental work with *Lebistes reticulatus* at the Biological Laboratory of the Zoological Garden at Moscow six male fish were observed which gradually lost their male secondary characteristics, such as size and the black, red, and yellow pigment spots. Dissection of these individuals showed that the testicles were either absent or were greatly atrophied. It is, therefore, concluded that with the disappearance of the male sex hormones the sex characters approach the female type.

In another fish, which in external appearance bore certain resemblances to both sexes, the gonad was found on sectioning to possess a well-developed ovary with embryos nearly ready to be born and with a well-developed testicle adjacent. The colors of the hermaphrodite were those carried in the X chromosome, but none of those common to the Y chromosome of Winge (*E. S. R.*, 48, p. 765) were present, indicating that the hermaphrodite lacked the Y chromosome and was, therefore, genetically a female.

A sex difference in linkage in rats and mice, W. E. CASTLE (*Genetics, 10* (1925), No. 6, pp. 580-582).—Data are cited from ten experiments, nine being from Detlefsen (*E. S. R.*, 53, p. 523), with rats and mice in which not less than 1,000 young were produced in each, which showed that the amount of crossing over between the dark-eye and color genes was always greater in females. The excess of crossovers exceeded the probable error by 1 to 2 times in 5 experiments, 2 to 3 times in 2 experiments, 5 times in 1 experiment, and was 7 times greater than the probable error in another experiment. It is also pointed out that the probable errors were larger than those calculated by the usual methods. It is, therefore, concluded that crossing over in this region is more frequent in female than in male rats and mice, though the differences as found in individual experiments might not be considered significant.

The third linkage group in *Oenothera*, G. H. SHULL (*Natl. Acad. Sci. Proc., 11* (1925), No. 12, pp. 715-718).—In 1921 the author found, it is stated, in cultures of *O. lamarckiana* a new flower color which was designated as old gold (vetaurea) and which is here treated as the first discovered factor of a third linkage group in *Oenothera*. The discovery of this third linkage group in *Oenothera* is expected to be valuable in rationalizing interpretations of genetical phenomena in this genus, and may prove a most important factor in determining the validity of the suggestion, credited to R. E. Cleland, that chromosome cohesions may constitute a cytological basis of linkage and crossing over in this group of plants, and offered as an alternative to the hypothesis favored by Shull that linkage in the *Oenotheras* results, as in other organisms, from the inclusion of the linked genes within a single chromosome pair. "Coordinated genetical and cytological studies on material characterized by three groups of linked genes will present a number of critical tests which should make it possible to decide promptly which of the two rival hypotheses is correct."

The linkage of pubescent node and beard factors as evidenced by a cross between two varieties of wheat, E. F. GAINES and A. CARSTENS (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 8, pp. 753-755).—Observations in the F₁, F₂, and F₃ generations of a cross, Hybrid 128×Velvet Node wheat, grown at the Washington Experiment Station, led to the conclusion that linkage exists between the beard and pubescent node factors and in such degree that about 5 per cent of crossing over occurs.

Hybrid vigor in rice, J. W. JONES (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 5, pp. 423-428).—F₁ rice hybrids at the Biggs, Calif., Rice Field Station exhibited heterosis in height of plants, number of culms per plant, and yield per plant, whereas little evidence of hybrid vigor was seen in length of panicle.

Studies in twin resemblance, C. E. LAUTERBACH (*Genetics*, 10 (1925), No. 6, pp. 525-568, pls. 5, figs. 3).—The author has made studies of the relation between various body measurements and characteristics, including intelligence tests, of 212 pairs of twins, varying in age from 90 to 238 months. Among the twins there were 71 pairs in which both were boys, 78 pairs in which both were girls, and 63 pairs consisting of one girl and one boy.

The results of the study, which are discussed in relation to the findings of other investigators, have led to the conclusion that twins resemble each other more closely than other sibs, and that those of like sex show a greater resemblance than those of unlike sex. The resemblance between the latter was similar to that found among single sibs. Age did not appear to affect the degree of resemblance between twins. Certain characteristics showed variations in the resemblance. A considerable proportion of the monozygotic twins showed symmetry reversal in handedness, head-hair whorls, etc., and variability in the palm pattern. Similar conditions were observed in dizygotic twins, and in certain cases similar palm patterns were observed in the latter type.

The resemblance between twins, a statistical examination of Lauterbach's measurements, R. A. FISHER (*Genetics*, 10 (1925), No. 6, pp. 569-579).—The author has made a statistical study of the significance of the relation between the standing and sitting height, weight, and cephalic index of the pairs of twins on which the data are presented in the above paper, from which similar conclusions have been reached.

The correlations for the various measurements of unlike twins ranged from 0.38 to 0.54, but for like twins they ranged from 0.57 to 0.74. A study of the heterogeneity of the pairs classified as monozygotic indicated that there were some dizygotic twins in this group, since they were divisible into at least two groups on the basis of resemblance, and only about 59 per cent were thus classified as monozygotic. If this assumption is true the correlation between the identical pairs must be approximately 0.9.

Sole patterns of twins, R. B. MONTGOMERY (*Biol. Bul. Mar. Biol. Lab., Woods Hole*, 50 (1926), No. 4, pp. 293-300, fig. 1).—An analysis has been made of the sole patterns of 87 pairs of twins living in the vicinity of Madison, Wis., to see if monozygotic twins may be identified by this means. The patterns, which were classified by the Wilder method, were identical in 13 sets of twins, of which 12 sets were of the same sex. Of 38 pairs of sibs studied in addition to the twins, only one pair of sisters had similar patterns. The author concludes that the presence of identical sole patterns points toward a monozygotic origin in twins, but that their absence does not disprove it.

FIELD CROPS

New methods with check plats, C. K. McCLELLAND (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 7, pp. 566-575, figs. 2).—The author describes and illustrates the application of methods for adjustment of yields termed "the weighted check" method and "the average percentage value" method.

[Forage crops experiments in Florida, 1920], J. M. SCOTT (*Florida Sta. Rpt. 1920*, pp. 16-19, fig. 1).—Experimental activities are reported on these pages continuing previous investigations (E. S. R., 54, p. 230) and preceding work already reported (E. S. R., 48, p. 298; 49, p. 823).

Cultural and pasturing studies demonstrated that Bahia grass (E. S. R., 43, p. 528) will spread and make a complete sod under pasture conditions, and that cattle like it. Bahia grass seems best adapted to a rather moist soil but may not be of value when planted on dry, sandy land or successful on land subject to overflow. It is rather sensitive to cold, but the roots do not appear to be injured by frosts or light freezes. Fertilizer tests with sweet potatoes demonstrated the need for potash if maximum yields are to be expected. The response of Japanese cane to different fertilizer mixtures is shown.

[Crop experiments at the Moses Fell Annex Farm, Bedford, Ind.], H. J. REED and E. W. MOORE (*Indiana Sta. Circ. 135 (1926), pp. 7-10*).—Seeding tests with clover and sweet clover, and fertilizer trials on pastures are described as heretofore (E. S. R., 53, p. 431). The crop varieties averaging highest in yields included Purkoff, Michigan Amber, and Fultz wheat, Mammoth Winter and a local rye, Purdue 21 barley, Johnson County White and Alexander Gold Standard corn, and Minota, Swedish Select, and Iowa 103 oats.

[Field crops experiments in Kentucky, 1925] (*Kentucky Sta. Rpt. 1925, pt. 1, pp. 13, 14*).—While average field applications of fertilizer salts carrying chlorine increase the chlorine content of Burley tobacco, this did not seem an important factor affecting the quality of the tobacco.

Wheat averaged 20 bu. per acre where limestone and phosphate were applied and 7 bu. on untreated soil, and similarly treated clover yielded 2,350 lbs. and 300 lbs., respectively. Certain clover selections have exhibited a high degree of resistance to mildew.

Close cutting second year growth of sweet clover after the stand had attained enough growth for hay continued to result in the death of practically all plants. Cutting high, 5 to 10 in., allowed more or less branch development, which was found to vary inversely with the seeding rate and maturity stage and directly with the height of stubble left. If correctly handled, the crop may be made to yield both hay and pasture, or pasture and seed, or pasture, hay, and seed the second year. Pasturing tests with milk cows suggested that each acre of sweet clover (allowed a good start before being pastured) nearly equaled 3 acres of blue grass during a dry summer.

For soy bean hay heavy seedlings appeared advisable, the stems being finer and the hay curing more readily and being more palatable. The forage cured much more readily if cut soon after pod formation. The most practical way of curing hay for home use is to permit it to lie in the swath, as it cures more rapidly and the quality is not seriously injured. Under average conditions, curing will require at least a week. Soil known to be well supplied with bacteria was found to be equal, if not superior, to the commercial cultures for inoculating soy beans.

[Crop experiments in Maryland] (*Maryland Sta. Rpt. 1925, pp. VIII, IX*).—Varietal studies during from 20 to 34 years recommend smooth wheats, such as Currell, Leap, and Fultz, for the Piedmont Plateau region, and the Fulcaster type, such as Mammoth Red, Bearded Purplestraw, and Miracle, for the Coastal Plains and limestone valleys. Wheat after corn seemed the most practical rotation on most farms, and with proper culture and fertilization, need not result in low yields. On farms where considerable manure is used on corn a fertilizer high in phosphoric acid and potash has proven most efficient. On typical wheat soils a 2-12-4 fertilizer has produced the best yields. Wheat after soy beans for hay has outyielded wheat after corn.

Virginia and Wilson soy beans continued to lead about 50 varieties as best adapted to Maryland conditions. For seed, planting in rows 28 in. apart and giving some cultivation was preferable, but where cultivation is not feasible

rows 14 in. apart are indicated. In a comparison of soy beans seeded with cowpeas, millet, or Sudan grass for hay, results favored the Sudan grass mixture, as the yield was higher and the seeding cost much less.

Hay, pasture, and lawn grass tests gave results indicating that for pastures on the hilly land orchard grass, tall meadow oat grass, red fescue, and sweet vernal may be considered satisfactory; on the slopes and mountain valleys white clover and lespedeza (Japan clover) may be added. At the station Kentucky blue grass and orchard grass have proven best for pastures. For hay a combination of alsike clover, alfalfa, and timothy seemed much more profitable for yield and quality than the growing of clover and timothy alone. Top-dressing with 20 to 30 tons of ground limestone may stimulate blue grass enough to crowd out crab grass.

[**Agronomic experiments in Montana**] (*Montana Sta. Rpt. 1925, pp. 8-12, 22-24, 28-30, 33-35, 38-44, 47-49, figs. 15*).—The leading varieties (E. S. R., 54, p. 327) of winter and spring wheat, barley, oats, corn, and alfalfa are indicated from test results at the station and substations. Sunflowers surpassed corn for silage in the mountain valleys. The best flax-wheat mixture, 14 and 30 lbs., respectively, per acre, produced more than these crops grown alone. Hoary cress (*Lepidium draba*) and Russian knapweed, potentially troublesome weeds, were reported from several localities in the State, and control methods are suggested.

Seed potatoes, 2 oz. or larger, yielded decidedly better than smaller seed and resulted in more stalks, more tubers per hill, and more tubers weighing from 2 to 12 oz. By a method outlined, the 2-man potato planter can be used in planting tuber units.

Germination tests of wheat kernels frozen at different development stages (E. S. R., 54, p. 737), made in comparison with similar but nonfrozen wheat, gave evidence that very immature wheat under favorable conditions germinates nearly 100 per cent. Freezing, however, practically kills the germs in such wheat and reduces germination to about 50 per cent or less in kernels containing 43 to 50 per cent of moisture. Moreover, this germination seemed to decrease as the frozen kernels aged. Baking tests made with this wheat showed that when wheat kernels 21 to 25 days from fertilization, containing 50 to 56 per cent of moisture, were frozen, the flour made therefrom was markedly reduced in quality. At 38 days from fertilization, however, and containing 34 per cent of moisture, frozen wheat gave a flour as good as that from nonfrozen wheat at the same development stage. The immature wheat did not yield as good flour as that from the more mature.

Application of manure or the inclusion of alfalfa in the rotations was followed by enhanced yields of sugar beets and potatoes at the Huntley Substation (E. S. R., 55, p. 132). Corn has been a good crop on irrigated land and on the dry lands in the Yellowstone Valley. Investigations under the latter conditions proved that corn fits readily into the cropping systems of farms with enough livestock to utilize the crop. Small grain and flax on disked corn land returned yields about midway between those from continuous cropping and those after fallow. Rotations including corn produced more total grain and a higher average acre yield of grain than similar rotations without corn.

Wild oats heavily infested those plats at the Judith Basin Substation continuously cropped to small grain or in manured rotations with only one cultivated crop in 3 years, whereas few or no weeds appeared in plats summer fallowed every second year in a 3-year rotation with a cultivated crop omitting manure, or in 5- and 6-year rotations including legumes or grass for 2 or more years. Delaying spring seeding until after the early weed growth is destroyed

by cultivating with such an implement as the duckfoot cultivator was found to permit a practically weed-free crop to be grown that season. Seeding early and with the ordinary drill brought the largest returns from spring grain, while winter wheat produced much better when furrow drilled. Spring harrowing did not increase yields of either spring or winter wheat but does destroy weeds in furrow-drilled winter wheat. Seeding rates are indicated for wheat, oats, barley, and flax. Manure and heavy straw mulch has increased alfalfa yields.

Delaying seeding until May 1 and destroying all weeds that start by thorough surface cultivation has controlled Russian thistle at the North Montana Substation. Wheat so grown yielded higher, and the grain averaged superior in quality.

[Agronomic experiments in Pennsylvania], D. E. HALEY, O. OLSON, C. F. NOLL, ET AL. (*Pennsylvania Sta. Bul.* 204 (1926), pp. 6, 11, 12).—Applications of 300 lbs. of ammonium sulfate tended to increase the nicotine content of *Nicotiana rustica* (E. S. R., 54, p. 328) grown on light soils somewhat acid. A further 300 lbs. added 3 weeks after the first resulted in a lowered nicotine content. An increase in nicotine content always followed an increase in the application of sodium nitrate. Strains of Pennsylvania Broadleaf or Seedleaf tobacco developed at the Ephrata Substation yielded from 1,850 to 2,050 lbs. per acre and contained from 4.85 to 6.25 per cent of nicotine, whereas yields of strains obtained from farmers produced from 1,400 to 1,800 lbs. and contained from 5.04 to 5.75 per cent of nicotine.

Hardy alfalfas averaged 480 lbs. more hay per acre annually than common alfalfa from different parts of the United States. Northwestern common did not surpass common from Kansas, Arizona, and Utah. Chilean and Peruvian alfalfas suffered more winter injury than other sorts, and these and Turkestan gave low average yields.

Wyoming forage plants and their chemical composition.—Studies No. 7, Effect of altitude, seasonal variation, and shading experiments, E. N. ROBERTS (*Wyoming Sta. Bul.* 146 (1926), pp. 35–89, figs. 25).—Continued investigations (E. S. R., 41, p. 333; 52, p. 368) were concerned with the effects of altitude, seasonal variation, and shading on the composition of grasses and other forage plants.

Increase in altitude generally caused a marked increase in crude protein, increase in N-free extract, and a gradual increase in caloric value, while the crude fiber decreased and the contents of ether extract and ash were apparently not affected. The crude protein:N-free extract ratio seemed to be maintained at an approximately constant level or decreased slightly.

As the season advanced the forage plants showed in general a decrease in crude protein, an increase in N-free extract, ether extract, and the crude protein:N-free extract ratio. While fiber and ash contents varied somewhat with the species, about two-thirds of the samples showed an increase in ash with advance of season.

Shading markedly affected the forage grasses in causing an increase in crude protein, a decrease in N-free extract, and in most cases an increase in ether extract and ash content. The effect on crude fiber was not so consistent. Shaded grasses showed a narrower crude protein:N-free extract ratio than unshaded grasses.

Conclusions of practical importance are that western forage plants increase in feeding value with increase in the altitude at which they are grown, that the forage plants studied are generally less valuable for hay when cut unduly late in the season, that the introduced grasses, timothy and red top, suffer the most rapid loss in feeding value as the season advances, and that the native

sorts, such as wire grass and *Carex* spp. suffer the least loss in feeding value from late cutting.

[**Agronomic and plant breeding investigations in Bombay, 1924-25**], G. B. PATWARDHAN (*Bombay Dept. Agr. Ann. Rpt. 1924-25, pp. 139-147*).—This research has dealt with practically the same projects as noted earlier (*E. S. R.*, 54, p. 231).

Corn experiments, 1925, South Mississippi Branch Experiment Station, E. B. FERRIS (*Mississippi Sta. Circ. 64 (1925), pp. 6*).—Experiments with corn reported on for 1925 comprised fertilizer trials, study of the residual effect on corn from fertilizers applied to cotton for 5 years, the effects on yields of corn and legumes (*E. S. R.*, 55, p. 228) grown alone and in combination, variety tests, and rotations.

Relation of breaking strength and other cob characters to yield of corn, F. L. WINTER (*Jour. Amer. Soc. Agron., 18 (1926), No. 7, pp. 592-596*).—The relation between cob-breaking strength and the yield of corn was studied in five strains of corn at the Illinois Experiment Station. The data obtained indicated that each strain has a distinct average cob-breaking strength, and that a positive relationship exists between this breaking strength and the yield when strains are compared. A positive correlation seemed apparent between either pink or red coloration of the ligneous part of seed-ear cobs and average yield and a negative correlation between brown coloration of the ligneous part of seed-ear cobs and average yield. Such relationships might be of a certain value in choosing seed for planting.

Correlations of seed, fiber, and boll characters in cotton, T. H. KEARNEY (*Jour. Agr. Research [U. S.], 33 (1926), No. 8, pp. 781-796, figs. 2*).—This contribution from the Bureau of Plant Industry, U. S. D. A., presents information in regard to the correlations existing among the characters of the bolls, seeds, and fiber of cotton. Numerous determinations were made at Sacaton, Ariz., on Pima and other varieties of the Egyptian type and on an F_2 population of an upland \times Egyptian hybrid. Published data of other investigators working chiefly with upland cottons are also cited.

Study of off-type plants of Acala cotton, R. D. MARTIN (*U. S. Dept. Agr., Dept. Circ. 390 (1926), pp. 11, pls. 5*).—Studies of progenies grown at Sacaton, Ariz., from Acala cotton plants off-type in leaf, stalk, and fruiting branch characters and also in a series of progenies from Acala plants that were typical except for small bolls, short and sparse lint, and seed characters such as dark fuzz, green fuzz, and naked seeds with little or no fuzz, seemed to show that the divergent characters were inherited. The information is presented to emphasize the need of careful and continued selection in cotton and to assist in the recognition of off-type plants in the roguing of fields where seed is grown for planting.

Cotton experiments, 1925, South Mississippi Branch Experiment Station, E. B. FERRIS (*Mississippi Sta. Circ. 63 (1925), pp. 7*).—Varietal leaders according to acre value in 1925 included D. & P. L. No. 4 and No. 5, Delfos 911, Delfos 631, and Lone Star 65. Lone Star, Trice, and Delfos have led in average acre value during the period 1921-1925. The progress of fertilizer trials and boll weevil control methods with cotton is reported. Unthinned and 11-in. spacing and April 4 and 11 plantings resulted in the highest yields of seed cotton.

[**Report of the Administrative Council of the Empire Cotton Growing Corporation**] ([London]: *Empire Cotton Growing Corp., 1926, pp. 32*).—The activities of the organization in furthering cotton production and research in various divisions of the British Empire are summarized for the year ended March 31, 1926.

A chemical and physiological study of maturity in potatoes, C. O. APPLEMAN and E. V. MILLER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 569-577, fig. 1).—Observations at the Maryland Experiment Station on Irish Cobbler tubers dug at six growth stages from full bloom to vines brown and dry indicated that the ripening and maturing processes in potatoes may continue during storage, so that by the end of the rest period immature potatoes large enough for seed have practically the same percentage composition and respiratory response as potatoes allowed to mature on the vine, if both are stored under the same conditions. No chemical or physiological basis for the superiority of immature potatoes for seed was apparent. Reported cases of immature seed surpassing mature seed may have been due to greater freedom from degeneration diseases in the immature seed.

Germination of rice seed as affected by temperature, fungicides, and age, J. W. JONES (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 7, pp. 576-592).—Information on the germination of rice under water and as affected by different temperature and other conditions, as derived from the experiments here reported, largely conducted at the University of California in 1923 and 1924, is of practical interest, since in California (E. S. R., 55, p. 34) a considerable rice acreage is sown broadcast and immediately submerged.

Seeds of certain rice varieties seemed more resistant to deterioration during long exposure under water at low temperatures than seed of other sorts, Colusa, Wataribune, and Early Prolific appearing the most resistant of the 8 varieties tested. Exposure of 8 hours under water at from 100 to 118° F. in each 24-hour day greatly reduced the germination of Caloro seed, while 2, 4, and 6 hours' exposure each day did not affect germination noticeably. Exposure of moist rice seed for 1 and 2 hours at 122 and 130° had no appreciable effect on germination. Exposure for 1 hour at 152° materially reduced the germination of seed of both Caloro and Colusa, a 2-hour exposure practically killed all seeds of both sorts, and a 3-hour exposure entirely killed all seeds of both varieties.

Exposure of dry rice seed for 1 hour at 122, 130, 140, 150, and 158° did not affect germination, whereas a 1-hour exposure at 170° appeared to reduce the germination of Caloro seed, a 1-hour exposure at 190° greatly reduced the germination of both Caloro and Colusa rice, and at 205° all seeds were killed. Rice seed germinated very well when subjected to a temperature range of from 42 to 117° or from 65 to 71° during the germination period. Some varieties were observed to germinate sooner than others and all varieties to germinate quicker at high than at low temperatures. Rice seed germinated about equally well at constant temperatures of about 61, 68, 86, 88, 93, and 100°, but at 108° no seeds of Colusa and only few of Caloro germinated, and at 122° all seeds of both varieties were killed.

Treatment of seed with copper carbonate dust, a 1:40 solution of copper sulfate, or a 1:400 solution of Uspulun prevented the growth of fungi and in some cases appeared to stimulate the germination of rice seed submerged in Petri dishes. Seed treated with these fungicides made better stands under field conditions, but such stands may have been due to factors other than seed treatment. Copper carbonate appeared toxic to some seedlings after germination.

The seeds of some rice varieties appeared to deteriorate with age faster than others. Three-year-old seed of 5 varieties tested ranged in germination from 85 to 99 per cent, while 3 other sorts ranged from 19 to 72 per cent. The vitality of rice seed more than 3 years old is likely to be low. The percentage of germination of rice seed harvested at different development stages increased with advance in maturity from the milk to the dead-ripe stages. Brown hulled

and dehulled kernels and dehulled and hulled half kernels of rice appeared to germinate well under favorable conditions, whereas immature seed usually is low in vitality.

Metrical attributes and the physiology of hardy varieties of winter wheat, K. H. KLAGES (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 7, pp. 529-566, figs. 8).—Certain physical and physiological properties of winter wheat were studied at the University of Illinois to determine the degree of association existing between them and winter hardiness. Factors involved in the development of winter wheat and the relative behavior of spring and winter varieties were also considered.

Measurement showed that most hardy varieties of winter wheat have a comparatively small leaf area in autumn. While leaf area is not an absolute index to hardiness at Urbana, it appeared to be worthy of consideration in selecting hardy types. Close and constant correlations were found to exist between area of the seed leaf, width of the seed leaf, width of widest foliage leaf, and total leaf area of the plant. Since width of seed leaf is most easily and accurately determined, it was considered the best criterion of leaf area. The correlation of the width of the seed leaf and total leaf area in the tillering stage in greenhouse plants was $r=0.843\pm 0.015$ and for field-grown plants $r=0.8\pm 0.012$.

Measurements of widths of seed leaves did not seem of value in the selection of hardy types of winter wheat in so far as the magnitude of the leaf area exposed by plants stands in relationship to hardiness. Variations in growth habits do not stand in absolute relationship to hardiness. An erect habit of growth apparently better indicated lack of resistance than a recumbent growth habit indicated hardiness. The data showed that the amount of tillering of a variety in autumn is not indicative of its hardiness.

Hardy varieties of winter wheat showed a slower growth rate in the field in autumn than nonhardy varieties. However, due to varietal characteristics, the amount of material produced by the several varieties is not in direct proportion to their degrees of hardiness. Since the weight of a plant in autumn is closely associated with the extent of its leaf area, the conclusions relative to the connection of leaf area to hardiness also seemed to apply here.

The rhythm in the development, as ordinarily observed in the growth of winter wheat, is apparently an enforced rhythm. Low temperatures and low intensities of light constitute the limiting factors in the growth of winter wheat in autumn. The behavior of winter wheat grown in the greenhouse and especially that of plants grown in the greenhouse with the aid of electrical illumination seemed to preclude the autogenous explanation for the occurrence of a period of dormancy. Exposure to low temperatures did not seem essential to the normal development of winter wheat. Winter as well as spring wheats quickly responded to the application of artificial (electrical) illumination, spring wheats being more exacting in their light requirements than winter wheats.

Trumbull and Fulhio wheat best for Ohio farms, L. E. THATCHER (*Ohio Sta. Bim. Bul.*, 11 (1926), No. 5, pp. 172-177, fig. 1).—Results obtained at the station and on experimental farms in Ohio indicate that Trumbull and Fulhio wheats (*E. S. R.*, 49, p. 738) have surpassed other wheats generally grown in the State, and the rapid increase in acreage shows them to be satisfactory to Ohio farmers.

Trumbull is noted for stiffness of straw, early maturity, freedom from loose smut, comparative freedom from stinking smut and scab, nonshattering of grain, high quality of grain and flour, and good average yields. Its tendency

to winterkill in unfavorable situations, where drainage is poor and when seeded late on thin land, can be reduced decidedly by timely seeding and by liberal use of fertilizer or manure on spots where winter injury is probable. Fulhio is somewhat more winter hardy, stools better, and averages a little higher in yield than Trumbull and will succeed where Trumbull winterkills. It equals Trumbull in time of maturity, nonshattering of grain, and quality of grain and flour, but is slightly inferior in strength of straw and disease resistance.

Fertilizers for wheat, R. M. SALTER (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, pp. 163-171, fig. 1).—Field experiments (E. S. R., 49, p. 738) involving the use of fertilizers on wheat in 14 counties in Ohio during from 7 to 32 years showed that acid phosphate used alone returned a profit in each test. On many soils profits yet larger may be expected from either potash-phosphoric acid mixtures or complete fertilizers. In most of the tests the return from the phosphoric acid was higher than for the same investment in potash and nitrogen. Increasing the relative amount of phosphoric acid and reducing the nitrogen and potash seemed to increase the profit from the fertilizer combinations. Wheat could receive about two-thirds of the total fertilizer for the rotation and corn the remainder. A good standard acre application for wheat seems to be about 400 to 500 lbs. of a fertilizer containing about 16 per cent total plant food or its equivalent. On livestock farms producing manure enough to apply 10 to 12 tons per acre in a 4-year rotation, acid phosphate alone should supply the commercial fertilizer for the wheat. Ohio standard fertilizers are indicated for wheat on several soil types.

HORTICULTURE

[**Horticultural investigations at the Montana Station**] (*Montana Sta. Rpt.* 1925, pp. 30, 31, 35, 36, 44-46, figs. 3).—Observations upon celery plants grown under warm, medium, and cool temperature conditions showed approximately 50 per cent of premature seeding in plants grown in cool environment with none in the warm and medium temperature lots. Early transplanting to the field, May 21, as compared with June 16, did not induce seeding in the warm and medium temperature lots. Lettuce set in the field as early as the weather permitted was of better quality and made firmer heads than later plantings.

Long continued soil-management studies at the Horticultural Substation at Victor further demonstrated the inadvisability of maintaining continuous clean culture in orchards. Red clover proved an excellent crop for building up the soil, but should be followed by a perennial such as alfalfa, alsike, or Dutch clover rather than by an intervening year of clean tillage. Nitrate of soda proved beneficial to clean cultivated orchards and aided in establishing cover crops. Cultural tests with lettuce indicated the possibility of growing two commercial crops each year. Staking and pruning proved beneficial in tomato production.

Shelter belt tests at the Judith Basin Substation showed that Caragana, box elder, and green ash are hardy and vigorous growers. Northwestern poplar, although short lived, is considered a valuable ingredient of the shelter belt on account of its very rapid growth. Pruning of any kind decreased the efficacy of the shelter belt plantation.

[**Horticultural investigations at the Pennsylvania Station**] (*Pennsylvania Sta. Bul.* 204 (1926), pp. 5, 6, 15, 27-32, figs. 3).—Studies by D. E. Haley and W. S. Clark on stored apples grown under different fertilizer treatments showed that in a single variety red fruit had greater acidity than green fruit, the acidity being greater in the flesh just below the red coloration. Baldwin apples fer-

tilized with muriate of potash failed to keep as well as those treated with sulfate of potash. The permeability of the cells of the muriate lot was lower than that of the sulfate lot. Baldwins grown under good fertility conditions showed a greater acidity and permeability of cells than did those grown under poor conditions. In general, acidity decreased with the length of the storage period.

Comparisons by J. B. Hill of the ovule and pollen fertility in F_1 species hybrids of *Digitalis* showed that both pollen and ovules are relatively sterile in cases of high sterility. In combinations in which the F_1 showed some fertility there was little correlation found between the degree of ovule and pollen fertility.

Orchard management studies by R. D. Anthony emphasized the need of applying nitrogen to sod orchards. Nitrates applied at the time of bud swelling were quickly taken up by the tree and also stimulated a heavy grass cover crop. In certain mature sod orchards the use of 10 lbs. of nitrate of soda proved profitable. A good growth in the orchard cover crop is deemed necessary to the maintenance of sustained production in mature orchards. Studies by L. M. Marble and Anthony of above-ground and bank cellar storages showed that both can keep apples successfully through their usual commercial season.

As reported by W. Thomas and Anthony, applications of complete fertilizer to apple trees grown in iron cylinders, under carefully controlled conditions, showed much greater effect on sod than on tilled trees, the increases in the season's growth above check sod and check tillage being 117 and 23 per cent, respectively. There was, however, relatively little difference in the average season's growth between fertilized trees in tillage and in sod. The ratios of starch to total nitrogen and of total carbohydrates to nitrogen indicate that the nitrogen supply is decidedly too low in the check sod trees to utilize properly the stored carbohydrates. Tillage alone increased the nitrogen supply, but not sufficiently to utilize carbohydrates advantageously. The ratios of total carbohydrates to total nitrogen for check sod, check tillage, N P K sod, and N P K tillage, in one-year wood were 276, 122, 71, and 85; in one-year bark 49, 34, 32, and 26; and in leaves 23, 19.3, 15.9, and 15.6, respectively. The ratios of total nitrogen to phosphoric acid in check sod, check tillage, N P K sod, and N P K tillage were in wood 6.7, 10.9, 19, and 16, and in bark 25.3, 26, 31.4, and 30, showing the lack of a physiological balance in the unfertilized trees and indicating that nitrogen is supplied at a rate lower than is required for the utilization of available phosphoric acid. Apparently the C/N and N/P₂O₅ ratios are a valuable index as to the relative excess or deficiency of nitrogen and phosphoric acid. It is deemed likely that a determination of the composition of the leaves alone may be sufficient evidence. Finding no correlation between the potash content of leaves, wood, or bark and growth, the authors concluded that the soil used contains sufficient potash for young apple trees. No advantage was gained by studying 2-year-old wood, as the composition is of the same relative order.

Studies by F. N. Fagan indicated that the selection of framework branches by disbudding undesirable shoots is a valuable practice in the apple, but of no particular advantage in the peach.

In vegetable breeding studies by C. E. Myers, self pollination of individual cabbage plants failed in practically every case to yield seed. Observation of the progeny of tomato crosses indicated that, in respect to fruit size, Yellow Cherry, Red Currant, and Yellow Plum are dominant over large fruited varieties. Crosses made by M. T. Lewis between Golden Yellow Stonehead and Mignonette lettuces yielded seedlings in which the color was more intense than in either parent. Observations by W. B. Mack upon cabbage replants showed

that many of these failed to mature or made small, inferior heads. A statistical study of the value of check plats for correcting plat yields for soil variability showed no consistent reduction of variability after correction by the yields of the nearest checks. As compared with other fertilizers, phosphorus gave consistent gains for all vegetables, particularly tomatoes. The largest yields were, however, produced on the barnyard manure plats.

An experiment on the winter-killing of vegetable crops in market gardens, T. WALLACE (*Jour. Pomol. and Hort. Sci.*, 5 (1926), No. 3, pp. 205-209, pl. 1).—Difficulty in wintering over vegetables in market garden soils which had been in use for several years was overcome by the liberal application of potassic fertilizers. The author believes that the excessive use of animal manures year after year had brought about an unbalanced nutrient ratio, namely, too much nitrogen in proportion to potassium.

The mica ink-cap or glistening Coprinus, F. C. STEWART (*New York State Sta. Bul.* 535 (1926), pp. 3-30, pls. 3).—Information of a popular nature is offered upon the mushroom species *C. micaceus*, found rather common about old stumps or buried wood and considered of real merit as an edible form. Experiments showed that from 72 to 74 per cent of liquid is produced by a given weight of mushrooms during autodigestion. The pure liquid is reddish brown, but usually appears black due to the admixture of spores and particles of the undigested residue.

Effect of nutrition on the number of blossoms per cluster and the dropping of blossoms in the tomato, H. R. KRAYBILL (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 371-374).—Records taken at Arlington Farm, Virginia, upon the performance of the first and second flower clusters of Stone tomato plants set April 17, 1918, in pots of soil obtained from a Maryland field in which considerable dropping of blossoms had occurred the preceding season showed that modifications in fertilizer treatment may materially affect the number of blossoms, the number of developing fruits, and the number of abscising blossoms per cluster. The highest average number of blossoms per cluster in the unfertilized plants was 3.5, while none of the fertilized plants averaged less than 5. Control plants in one case dropped 73.3 per cent of their blooms, as compared with a maximum of 20 per cent in the fertilized plants.

An experiment in propagating apple trees on their own roots, E. C. AUCHTER (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 205-211, pl. 1).—Marked success was obtained at the University of Maryland in an attempt to propagate own-rooted apple trees. In all cases long scion (16 to 20 in.) and very short roots (2 to 3 in.) were used, and the grafts, after storing in sand, were planted very deep. Of 400 Stayman Winesap, 250 York Imperial, and 100 Yellow Transparent grafts planted in the spring of 1922, 300, 130, and 40, respectively, produced excellent scion roots. Quite favorable results were obtained with Wealthy, Delicious, Stayman Winesap, and York Imperial in 1924. Where fine copper wire was twisted above the graft union with the hope that this might check the growth of seedling roots and encourage root formation from the scion, the results were inconsistent, being apparently beneficial only in the case of Wealthy and York Imperial.

The use of burr-knots in the vegetative propagation of apple varieties, C. F. SWINGLE (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 228-230).—In again reporting the successful asexual propagation of apples normally producing burrknots (E. S. R., 54, p. 538), the author adds that histological studies have shown a close relationship between burrknots and vascular rays and the leaf and branch traces of the bud. Chemical analysis of 1-year-old shoots of mound-layered seedling apple trees showed little difference in the composi-

tion of those kept defoliated from June on and those with leaves intact, although there was a striking difference in the top and root growth in favor of the untreated shoots. The author concludes that root growth is dependent on top growth rather than on any differences in chemical composition. The possibility is suggested of hormone activity.

Some results of bending the branches of young apple and pear trees, L. H. MACDANIELS and A. J. HEINICKE (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 201-204).—Studies carried on in the experimental orchard at Cornell University upon the effect of tying down the limbs of young, vigorous Northern Spy apple and Kieffer pear trees showed a marked stimulation in early fruiting, thus bearing out the results secured in California, by Caldwell (*E. S. R.*, 46, p. 736), with pears and plums. In the case of moderately pruned Northern Spy trees which up to the time of treatment had borne practically no fruit, the yield per tree the season following treatment was 68 ± 10 lbs. as compared with 8.5 ± 2.7 lbs. for pruned trees and 35.2 ± 6.7 lbs. for lightly pruned trees. These results show (1) that pruning delayed fruiting, and (2) that tying down the side branches more than counteracted the retarding effect of pruning. In respect to trunk growth the treated trees showed a slightly greater increment than the others. In the case of Kieffer trees, the tied branches were more resistant to breaking under the load of fruit than were normal branches. A search of the literature shows a reference to a similar practice in a treatise by Langley, published in 1729.

Effect of pruning upon fruit production (*Kentucky Sta. Rpt. 1925, pt. 1, pp. 15, 16*).—Lightly pruned apple trees yielded 45 per cent more fruit than did neighboring heavily pruned trees.

Further evidence of uncongeniality in disease-resistant stocks, J. A. McCLINTOCK (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 231, 232).—The death during the summer of 1925 at the Tennessee Experiment Station and the West Tennessee Substation of peach trees worked on Marianna plum roots is deemed to be further evidence of the low value of the Marianna plum as a peach stock. Marianna plums and peach trees planted in the holes from which the dying trees were removed made a vigorous, healthy growth, indicating the absence of destructive pathological organisms.

[Peach varieties at the Moses Fell Annex Farm] (*Indiana Sta. Circ. 135 (1926), pp. 10, 11*).—Brief notes are given on the productivity and bud hardiness in 14 varieties of peaches planted in 1920 and fruiting for the first time in 1923.

The cold storage behavior of cherries, E. L. OVERHOLSER (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 54-58).—Records taken on 51 varieties of cherries picked before, at, and succeeding the commercial harvest showed the following average optimum storage periods, namely, 14, 12, 8, and 4 days at temperatures of 32, 36, 45, and 67-75° F., respectively. At these temperatures the maximum storage periods were 22, 19, 14, and 7 days, respectively. Little difference was noted between the three picking dates in relation to keeping. However, the fruits of the second and third harvest were superior in quality and appearance. Individual data are presented for 23 varieties of cherries. In general the sour cherries did not store as well as the better keeping sweet varieties.

Some effects of pruning on grape production, J. H. CLARK (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 80-84).—Pruning studies at the New Jersey Experiment Stations upon Concord and Brighton grapevines showed that canes from 7 to 9 ft. in original length were the most productive, with those from 5 to 7 ft. next in order. The 7 to 9 ft. group was also most productive in respect to average yield per node. Although in 1925 the most productive

type of cane on Concord vines pruned to from 12 to 20 buds per cane apparently included those having an original length of over 9 ft., the author does not believe that a different type of cane should be chosen according to the severity of the pruning. Fairly consistent correlations between cane length and diameter and between cane length and internode length were recorded. Very little difference was found in the comparative percentages of developing buds on long and short canes.

Growth and yield of Concord grapevines, N. L. PARTRIDGE (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 84-87).—An analysis of data obtained by the Michigan Experiment Station in two experimental vineyards in Van Buren County shows a distinct correlation between yield and vine vigor as measured in the weight of prunings annually removed. That the character of the soil has a direct bearing on this correlation is shown in correlation coefficients of 0.52 ± 0.01 , 0.45 ± 0.01 , and 0.59 ± 0.01 for the years 1922, 1923, and 1924 in a fertile, loam vineyard and 0.74 ± 0.01 , 0.76 ± 0.01 , and 0.67 ± 0.01 for the years 1923, 1924, and 1925 in a less fertile, sandy vineyard. The data emphasize the importance of increasing the vigor of the less thrifty vines, and the author points out that smaller returns may be expected from increases in the higher growth classes. The weight of prunings alone is not an infallible index to productivity, for fruitfulness is associated with other factors, such as the size of the preceding crop, soil conditions, etc.

Fruit-bud differentiation and subsequent development of the flowers in the Hicoria pecan, J. G. and N. C. WOODROOF (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 677-685, figs. 7).—Cytological studies at the Georgia Experiment Station upon pecan buds collected during the winter and early spring showed that differentiation of pistillate flowers occurs in terminal buds from February 15 to March 1. If the terminal bud has been destroyed before this time, one or more of the lateral buds may differentiate pistillate blooms. Pistillate blooms were found to develop rapidly and to reach a receptive condition in about 2 months after differentiation. Undeveloped pistillate flowers occurring at the time of pollination dropped without attaining a receptive condition. As the embryo sac is not mature at the time of pollination, it is concluded that fertilization does not take place immediately. Although varieties exhibited differences in the size, color, and shape of the stigmas, these could not be associated with any characters in the nuts. Staminate blooms were found to be differentiated in lateral buds from 6 to 12 months before the pollen was ripe.

Trees for roadside planting, F. L. MULFORD (*U. S. Dept. Agr., Farmers' Bul. 1482* (1926), pp. II+50, figs. 29).—Supplemental to an earlier publication (E. S. R., 55, p. 442) which discussed the location and the care of roadside trees, this paper presents information upon the kinds of trees suitable for the roadside, regions of adaptability, trees for special purposes, and detailed descriptions of various species useful for roadside planting.

FORESTRY

[Forestry investigations by the Pennsylvania Station], J. A. FERGUSON (*Pennsylvania Sta. Bul. 204* (1926), p. 27, fig. 1).—Cuttings in experimental plantations of black locust and catalpa planted in 1908 yielded 1,064 black locust and 340 catalpa posts per acre, thus establishing the superiority of the locust to the catalpa as a farm crop.

Age classes of western white pine planting stock in relation to aspect of planting site in northern Idaho, W. G. WAHLENBERG (*Jour. Agr. Research*

[*U. S.*], 33 (1926), No. 7, pp. 611-619, figs. 2).—Planting investigations conducted on barren, burned-over slopes of from 25 to 30 per cent gradient and at an elevation of from 3,350 to 3,700 ft. with nursery stock of different ages showed the best survival in the older stock, namely, that which had been two years in the seed bed and two years in the nursery. The aspect of the site was quite as important as the kind of stock, the mortality being greatest on the western exposure. Sliding soil had a tendency to cover and kill trees, especially those in the youngest age classes. Height growth was, like survival, greatest in 4-year-old stock. On the basis of net cost of surviving trees, 2-year seedlings were most economical on moderate sites, and 4- and 3-year-old stock on less favorable sites.

Tables for determining contents of standing timber in Minnesota, Michigan, and Wisconsin (*Minnesota Sta. Tech. Bul. 39* (1926), pp. 99).—This bulletin contains 93 volume tables covering 25 forest species growing in the Lake States region. Of these tables, 31 are published for the first time and 15 are based upon data assembled by the Cloquet Forest Station of the Minnesota Station and the U. S. D. A. Lake States Forest Station. For certain species volume tables prepared in other regions are offered as temporary substitutes, in full realization of their inadequacy.

DISEASES OF PLANTS

Report of the plant pathologist, H. E. STEVENS (*Florida Sta. Rpt. 1920*, pp. 29-39).—The work reported consists in the main of investigations of avocado diseases and their control.

Descriptions are given of black spot caused by *Colletotrichum* sp. and blotch due to *Cercospora* sp. It is claimed that both diseases can be controlled by the use of Bordeaux mixture, and apparently two applications are sufficient.

For the control of scab, three or four applications of Bordeaux mixture, one of which should be made when the trees are in bloom, are suggested.

Report of truck pathologist, C. D. SHERBAKOFF (*Florida Sta. Rpt. 1920*, pp. 40-45).—Tests are reported of six varieties of potatoes made to determine their resistance to brown rot, *Bacterium solanacearum*. In one series selections from Spaulding Rose did not show any rot, but in a second test none of the six varieties showed any resistance to the disease.

Experiments on the control of damping-off of celery in seed beds by treating the beds with a 0.5 per cent solution of copper sulfate showed that the disease was controlled, but some injury followed if the treatment was made during the warmer part of the day. When the treatment was made in the evening and the plants thoroughly sprinkled with water early the next morning, no injury resulted.

Studies were made of the *Phytophthora* which causes buckeye fruit rot of tomatoes and related species from other host plants. It was found that they would all attack tomato and castor bean plants, but with varying degrees of virulence. Some morphological differences between the species were also noted.

Observations by C. M. Tucker are said to show that seed treatment prevented watermelon wilt in the field, and that spraying with Bordeaux mixture controlled anthracnose. A leaf spot of watermelon caused by *Alternaria* is said to have been severe in several localities.

[Plant disease investigations at the Kentucky Station] (*Kentucky Sta. Rpt. 1925*, pt. 1, pp. 12, 13, 14, 15).—The results from tests made during the year are said to suggest that corn root rot and tobacco brown root rot may be caused by identical organisms. An examination of rotting tobacco roots

showed the presence of a Pythium-like fungus similar to that found in the roots of corn.

Studies on the longevity of the causal organisms of bacterial leaf spots of tobacco indicate that they die in the course of about 12 months. Tests with seed 18 months old gave results far more promising than seed treatment.

The eradication of perennial weeds capable of carrying mosaic disease from the permanent tobacco bed did not result in a reduction of initial mosaic infection in the field. Tests to determine whether or not chewing tobacco, which is used extensively by most tobacco men, is a source of mosaic infection at planting time suggest strongly that it is the important source of infection. Certain brands of commercial tobacco were found to carry mosaic, and tobacco as old as five years may still retain the virus in a virulent form.

A study of corn root rot has shown two distinct types of injury, seedling blights, due to seed-borne organisms, and true corn root rot, which may be produced experimentally by using old corn soil or by adding rotted roots from a continuous corn plat to sand cultures of fungus-free plants. The results of the experiments are said to indicate that *Gibberella saubinetii*, *Fusarium* spp., and probably *Diplodia zeae* are not concerned in the true corn root rot, and suggest strongly that the cause of this disease is a fungus of the Pythium type. A method is said to have been developed for producing corn seedlings, for pot culture work, that are entirely free from seed-borne fungi.

Observations to determine the relative susceptibility of varieties of apple to blight are said to show that the degree of infection is clearly correlated with severe pruning. The most severely infected varieties in 1925 were Domine, Lowell, Maiden Blush, Milam, Pewaukee, Rhode Island Greening, and Tolman.

Botany and plant pathology (*Pennsylvania Sta. Bul. 204 (1926)*, pp. 14, 15, 15-18).—A summary account is given of investigations by E. L. Nixon on fire blight of the apple, a more detailed report of which has been noted (E. S. R., 55, p. 549). It is said that as a result of his investigations methods for propagating apple trees on their own roots and rapid determination of their immunity to fire blight have been discovered.

Investigations by R. C. Walton on the cause of frog-eye of apple are briefly reported, in which an attempt was made to produce the disease through leaf inoculations with every organism found associated with the disease. While no definite results were obtained from the artificial inoculations, the disease appeared abundantly under natural conditions and almost totally defoliated the trees by midsummer.

As a result of further studies by Walton, the perfect stage of the disease causing apple fruit spot is said to be a *Mycosphaerella*. Additional points about the life history of the organism were found. Among them, some leaf infection, and probably a high percentage, takes place while the foliage is still on the trees, the spots being overlooked in the fall because of the natural coloring of the leaves at that time of the year. It was found that fruit infection could take place much earlier in the spring and later in the fall than was formerly supposed, and humidity is believed to be a decided factor in producing fruit infection with conidia. The part that the ascospores played in producing infection of foliage and fruit has not been definitely determined.

A survey by W. S. Beach showed that probably the most important fungus parasite of mushrooms in Pennsylvania is *Mycogone perniciosus*. Soil sterilized with formaldehyde by a sprinkling method, and used for casing, gave good yields of mushrooms and apparently prevented *Mycogone* infection of the mushrooms. Sprinkling the bearing beds with various disinfectants usually prevented the further production of mushrooms.

Continuing his studies on the crown rot of rhubarb, Beach found additional evidence to justify the use of selected roots from diseased fields when roots from a disease-free source were not obtainable. Copper lime dust was found to check the spread of crown rot and was more convenient to apply than Bordeaux mixture.

Experiments with formaldehyde and other disinfectants for the control of lettuce diseases are briefly summarized, and it is stated that there was no evidence that fertilizers increased resistance or enabled seedlings to undergo transplanting with less loss. Seed bed treatments with 0.25 per cent solutions of Uspulun and Bayer compound and 0.5 per cent solution of Semesan gave only slight improvements in lettuce, the difference being too small to justify their use. Observations upon growth and weather factors with relation to *Botrytis* are said to indicate that the temperature extremes combined with rapid succulent growth are the most important factors in predisposing lettuce to an attack of this fungus in coldframes.

A brief report is given on infection experiments carried out with two bacterial organisms parasitic on Lima beans. The infections were readily secured with and without wounds. The organism producing red spots is said to agree with *Bacterium viridifaciens* in most of its cultural characteristics, while the one producing brown spreading spots appears to be *B. phaseoli*.

[Plant disease investigations], J. A. McCLINTOCK (*Tennessee Sta. Rpt. 1925*, pp. 16, 17, 18, 19, figs. 2).—The results obtained from growing apple grafts in steam-sterilized soil are said to indicate that crown gall bacteria in nursery soils are an important source of plant infection. Studies on aerial galls of both apples and quinces indicate that they are not of pathological origin but are abortive attempts at root formation. Western apple seedlings lined out at the station and budded in 1924 were dug and examined in the fall of 1925, and practically no crown gall had developed.

Inoculation tests with pure cultures of the fire blight organism are said to indicate that practically immune varieties of blight-resistant pears, apples, and quinces have been obtained.

Tests are said to have shown that nematode-resistant species of *Prunus* are available, but the practical use of these as stocks is complicated by a lack of congeniality between the resistant stocks and the commercial peach varieties which it was desirable to propagate.

Spraying experiments have shown that apple blotch and scab can be readily controlled by a 2-4-50 Bordeaux mixture, applied at 2-week intervals, three or four applications being made, depending upon varieties. Apple blotch producing twig canker in orchards was observed to be less serious where the trees had been sprayed for two seasons with Bordeaux mixture.

Tests in two commercial orchards in 1925 are said to indicate that cherry leaf spot may be held in check by thorough applications of 2-4-50 Bordeaux mixture, without injury to fruit or foliage.

A leaf spot of cruciferous plants caused by *Alternaria herculea*, J. L. WEIMER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 645-650, pls. 2, fig. 1).—A leaf spot of cruciferous plants caused by *A. herculea*, which is reported to be quite prevalent in the vegetable-growing section south of San Francisco, Calif., is described. The disease is said to be quite similar to that caused by *A. brassicae*, and is probably frequently confused with it. The parasitism of the fungus was demonstrated on cabbage, cauliflower, Chinese cabbage, and rutabaga.

Ozonium root rot, G. L. PELTIER ET AL. (*U. S. Dept. Agr. Bul. 1417* (1926), pp. 28, pls. 11, figs. 2).—The results are given of a study of the root rot of

cotton, alfalfa, and other plants in the southwestern portion of the United States.

I. *Studies of Ozonium root rot in Arizona and Texas*, G. L. Peltier and C. J. King.—The authors state that *O. omnivorum* appears to be indigenous in the soils of certain regions of the southwest section of the United States and yearly causes large economic losses, principally to cotton, alfalfa, and fruit trees in Texas and in certain irrigated valleys of New Mexico, Arizona, and southeastern California. A study of exhumed root systems of susceptible plants at various stages of infection is said to have given no evidence that the mycelium of the fungus spreads from plant to plant by underground contact of diseased with healthy roots, but rather indicates that the fungus usually progresses radially from a center through the soil, irrespective of the root systems, and attacks the plants in the line of the advancing mycelium. The plants are said to be generally attacked on the taproot within the first foot of soil, and the laterals usually rot from the point of attachment with the taproot.

The actual agent in the penetration of the roots is said to be the strand hyphae, which are found approximately from 38 to 75 cm. in advance of the wilting zone of plants. The hyphae composing the mycelial web found on wilting plants appear to complete the breaking down of the roots and act as a reserve food supply for the advancing strand hyphae.

At the close of the growing season the only active mycelium is slightly in advance of the periphery of the root-rot spots, and it is at this point that new centers of infection usually occur the following year. The organism is believed to be not commonly spread by any aboveground agency, including the spores of the conidial stage. Because of the extremely erratic behavior of the fungus in the field, no correlation could be made with certainty with regard to environmental factors, the only one which seemed to have any influence being the amount of precipitation occurring during July, August, and September, and this appeared to be of little influence in the irrigated region.

II. *The pathological anatomy of Ozonium root rot*, G. L. Peltier and R. W. Samson.—Studies of material representing various stages of root rot on alfalfa and cotton roots, together with Ozonium strands on mesquite roots, are said to show that the strand hyphae are composed of a large central hypha around which are bands of smaller hyphae. The central hypha of the strands branches profusely to form a dense web of large, irregular-shaped, thin-walled, many-nucleated hyphae. Entrance to cotton roots is said to be effected by the hyphae of these wefts through the lenticels, through wounds of various kinds, and by direct penetration of the fungus between the cork cells. In the case of alfalfa, entrance can also be made through the small fibrous rootlets where they are attached to the taproot.

Entrance is effected by the formation of a hyphal wedge, which pushes its way between the cord and lenticel cells until the cork cambium is reached. The invading hyphae advance in all directions through the cork cambium and into the cortex. The hyphae are present in and between the cells, and in a short time enough of the parenchyma cells are broken down to form a depression in the bark. Many such depressions are found on the roots, and this is believed to indicate why the death of an alfalfa or cotton plant under optimum conditions for the disease is effected within a week.

Oospore-like bodies in cultures of *Phytophthora infestans*, H. R. ANGELL (*Quebec Soc. Protect. Plants Ann. Rpt.*, 17 (1924-25), pp. 79-81, figs. 2).—Certain bodies found in material associated with the growth of *P. infestans* have been studied and described.

The preparation and effectiveness of basic copper sulphates for fungicidal purposes, E. B. HOLLAND, C. O. DUNBAR, and G. M. GILLIGAN (*Jour. Agr.*

Research [U. S.], 33 (1926), No. 8, pp. 741-751.—The authors describe a method for producing a basic copper sulfate that may be substituted either as a spray or powder for Bordeaux mixture. The preparation is described as a light, bulky powder, of good flow, free from grit, and adapted for use either as a spray or dust. The copper content is said to be similar to that of copper sulfate, and it is thought would be applied at the same concentration as Bordeaux mixture. Laboratory experiments with conidia of the apple scab fungus and field tests for the control of anthracnose and downy mildew of cucumbers and both early and late blight of celery showed that basic copper sulfate is an effective fungicide, easily applied, fairly indicative of the leaf surface covered, and of reasonable suspension, distribution, and adhesiveness.

Oat smut control experiments in 1923, B. T. DICKSON (*Quebec Soc. Protect. Plants Ann. Rpt., 16 (1923-24), pp. 77-79*).—A continuation, by the author, of work formerly recorded as done by him in connection with others (E. S. R., 50, p. 549) tabulates data so far as yet obtained in work, a further contribution to which is noted below.

Oat smut control in 1924, B. T. DICKSON (*Quebec Soc. Protect. Plants Ann. Rpt., 17 (1924-25), pp. 35, 36*).—Experimentation continued during 1924 at Macdonald College using Liberty oats and both smuts inoculated and handled as previously (see above) showed the best results from dust treatments as tabulated, the percentages of smut running for no treatment from 55.4 to 60, nickel hydrate from 1.7 to 2.5, nickel carbonate 1.66, nickel sulfide 0.8, and copper carbonate 2.1 per cent.

Studies concerning injury to seed oats after smut disinfection, W. L. GORDON (*Quebec Soc. Protect. Plants Ann. Rpt., 16 (1923-24), pp. 79-94, pls. 4*).—An investigation to determine the factors responsible for injury as regards germinability to seed oats during or after disinfection and remedies therefor is set forth in detail and in tabular form with discussion.

The treatment phases considered included effect of varying strength (formalin solution), of duration, temperature, carbon dioxide, presoaking, soil moisture (limed and unlimed seed), dry storage (after treatment), and comparison of different smut treatments.

Work done on three hulled varieties and one hull-less variety of oats to determine the effects on germination of formalin, copper carbonate, and Uspulun showed that hulled oat seed can be effectively treated for smut with use of formalin without injury, even if the seed are stored (dry) for several months after such treatment. Different methods of formalin treatment for smut seriously injured Liberty oats, and this injury was increased by dry storage, temperature proving also to be a factor in producing such injury, which was, on the other hand, reduced by soaking before treatment with formalin.

The characteristic type of formalin disadvantage was retardation or killing of the radicle rather than plumule injury. Distinct reduction of formalin injury was obtained by dipping the seed in milk of lime after the formalin treatment.

Copper carbonate did not reduce germination in hulled oats or in Liberty oats, also such seed stored for several months retained its germinability.

Uspulun was harmless to hulled oats and appeared stimulating to Liberty oats, as regards germination. Storage for one month after this treatment did not reduce germinability.

A bacterial wilt and root rot of alfalfa caused by *Aplanobacter insidiosum* L. McC., F. R. JONES and L. McCULLOCH (*Jour. Agr. Research [U. S.], 33 (1926), No. 6, pp. 493-521, pls. 6*).—An account is given of a serious disease of alfalfa

which is said to occur in certain irrigated districts and the more humid areas of the United States where alfalfa is grown. The disease has been reported in various localities from New Jersey to Idaho and south to Mississippi.

The disease is said to be chiefly vascular in character, the bacteria passing from the taproot to each succeeding weakened crop of stems until the plant is killed. The most conspicuous symptom is a dwarfing of severely diseased plants and pale color of foliage, and small, narrow leaflets yellowed and curled at the margins. The taproot when cut shows yellow or brown discoloration beneath the bark. Artificial inoculation of alfalfa plants was accomplished only through wounds, introducing the parasite directly into the vascular system through cut stems, or into cortical tissue of roots whence it makes its way into the vessels. Symptoms of disease and the death of infected plants appeared to be hastened by retardation of root growth brought about by high soil temperature or frequent cutting of tops.

The parasite was also found to produce a wilt disease on sweet clover (*Melilotus alba*).

The cultural and morphological characters of the causal organism (*A. insidiosum*) are described and a technical description given of the organism by the second author.

Physiological specialization of *Colletotrichum lindemuthianum* in eastern Canada. K. A. HARRISON (*Quebec Soc. Protect. Plants Ann. Rpt.*, 17 (1924-25), pp. 45-62, pls. 2, figs. 2).—A study is described as applied to bean pod spot, or anthracnose, a very serious bean disease, ranging as widely as Alaska, the Tropics, and Australia. This work was carried out largely along the lines of physiological study of the causal organism, *C. lindemuthianum*, in eastern Canada. A total of 21 cultures was used in a series of inoculation studies on 16 bean varieties, and results from 13 of these are given as limited each to one pure line strain.

The only variety found resistant to all the cultures used was Wells Red Kidney. Varieties proving resistant to all Canadian cultures were Navy, Minnesota 73, Davis White Wax, Yellow Six Weeks, Robust, and Fordhook Favorite.

A comparison of the infection results of the cultures isolated during the course of the work with their growth weights on mannitol showed that cultures grouped from slight differences in infection also gave different average weights. In an attempt to secure the perfect stage from any of the isolations by growing several cultures in one plate so that the colonies would run together, no sign of a perfect stage was found.

Preliminary report on a disease of common bean. K. A. HARRISON (*Quebec Soc. Protect. Plants Ann. Rpt.*, 17 (1924-25), pp. 62-69, pl. 1).—An organism isolated from a bean pod from Annapolis County, Nova Scotia, apparently infected with *Colletotrichum lindemuthianum* is temporarily considered as being *Phyllosticta phaseolina* and distinct from the conidial stage of *Diaporthe phaseolorum* (*Phoma subcircinata*), primarily causing a pod spot of Lima beans. The organism seems to agree closely with the description given by Smith of *P. phaseolina* (E. S. R., 17, p. 47), but further work is needed.

Foreign clovers subject to disease (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, p. 207).—Tests of red clover seed from various sources have shown that Canadian, Wisconsin, and Ohio strains have very little anthracnose, while some foreign strains have as high as 60 per cent infection. Italian clover is said to be particularly susceptible to the anthracnose fungus.

Cultural characteristics of certain *Colletotrichum* species. G. A. SCOTT (*Quebec Soc. Protect. Plants Ann. Rpt.*, 16 (1923-24), pp. 123-137, pls. 5,

figs. 7).—This article, said to be an abridgment of a master's thesis at Macdonald College, deals with cultural and morphological characters of organisms found in association with certain potato diseases as cultured for comparative study.

In these experiments six organisms were used, all causing potato disease, but growing also on solid or liquid media. The results to date are detailed.

Potato degeneration diseases: Natural spread and effect upon yield, D. FOLSOM, E. S. SCHULTZ, and R. BONDE (*Maine Sta. Bul.* 331 (1926), pp. 57-112).—In continuation of a previous publication on the importance and natural spread of potato degeneration diseases (*E. S. R.*, 52, p. 246) a report is given of studies of samples of potatoes of the crop of 1923, grown in 1924 and in 1925, in which the increase of disease and the effect on yield are shown. Spindle tuber in Green Mountain and Irish Cobbler varieties reduced the yield rate of completely infected stocks to 20 per cent below the yield rate of healthy stocks of the same strains. Mild mosaic in similar comparisons in Green Mountain strains reduced the yield rate to from 8 to 15 per cent below that of healthy stocks. Rugose mosaic reduced the yield rate by 50 per cent. Mild mosaic was found to reduce the yield about the same in the third year of apparent infection as in the second. When the disease was present to the extent of 50 per cent or less the yield was not reduced in proportion to the reduction by a 100 per cent infection, and this did not reduce the yield rate more than uncontrolled differences in soil and other environmental conditions.

Tests made in 1925 of Green Mountain potatoes showed that spindle tuber reduced the yield rate of a completely infected stock to 25 per cent below the yield of a healthy stock. Mild mosaic reduced the yield rate to the same extent as spindle tuber, while rugose mosaic reduced the yield rate by about 60 per cent. Giant hill stock yielded slightly better than healthy. With spindle tuber or mosaic present in only part of the stock, the yield was reduced more than was proportional to the reduction in the completely diseased lots.

In a study of the amount and distance of spread of mosaic and spindle tuber from diseased to healthy fields, potatoes grown in 1924 showed that in 1923 one or both diseases had spread, in some places infecting a third of the plants in the first 5 healthy rows next to the diseased ones, while in some cases the disease spread across the field as far as the fiftieth row. A general increase of disease due to spread from one hill to another in partly diseased stock was found to be more frequent and probably greater in effect than the spread from one field to another. Therefore, the secondary effects of field-to-field spread may be worse than the immediate effects.

Although spindle tuber seemed to increase about as rapidly as mild mosaic when no tuber selection was attempted, it was found easier to reduce by roguing tuber unit seed plants than was mild mosaic. Some evidence was secured that is believed to indicate that other insects in addition to aphids are able to transmit these diseases, and that they probably do not transmit them similarly. Other degeneration diseases such as leaf roll and rugose mosaic are considered easier to eliminate than mild mosaic. Incompleteness of tuber infection was found to present a difficulty in attempting to rogue early, as it was often accompanied by a delayed appearance of symptoms. Contact between hills was found to increase the spread of the disease but was not necessary for its dissemination. Parts of a strain of potatoes may become different from each other through unequal contamination by disease.

Mosaic of rhubarb, B. T. DICKSON (*Quebec Soc. Protect. Plants Ann. Rpt.*, 17 (1924-25), pp. 36, 37, fig. 1).—In 1922-1925 observations were made on the appearance and spread of what is thought to be mosaic in rhubarb near

Montreal. Inoculation by rubbing or injection failed as did also attempts to transfer aphids.

Seed treatments for sweet-corn diseases, C. S. REDDY, J. R. HOLBERT, and A. T. ERWIN (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 8, pp. 769-779, figs. 4).—The results are reported of experiments in the treatment of sweet corn with several organic mercury compounds for the control of seed-borne diseases.

No practical control of bacterial blight was obtained by treating the seed. When nearly disease-free seed was used, the field stands and yields were affected but little by seed treatments with organic mercury compounds. When seed diseased with *Diplodia zeae* or *Gibberella saubinetii* was used, the field stands and yields nearly always were materially increased by seed treatments with the compounds. The yields from nearly disease-free seed were slightly higher than those from treated *Diplodia*-infected seed, and considerably higher than those from treated *Gibberella*-infected seed. The authors state that when only diseased seed is available for planting, certain treatments will have distinct value, and such treatments do not injure the seed.

Infection and temperature relations of black rot of sweet potatoes in storage, J. I. LAURITZEN (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 663-676, figs. 4).—A study was made of the method of infection, influence of temperature on infection, development of black rot of sweet potatoes, and on the growth of the causal organism (*Ceratostomella fimbriatum*).

Infection was found to occur through the normal skin of the sweet potato, but usually there was evidence of tissue disturbances at the point of infection in the form of raised areas, slight abrasions, and small rootlets. Wounding is not considered necessary in order for infection to occur, although evidence was obtained to indicate that wounding will aggravate infection and the development of the disease.

The fungus was found to grow in cultures over a range of temperatures extending from 9 to 36° C., and this range corresponds very closely with the limiting temperatures for infection. The optimum temperatures for infection and development of the disease are said to be from 23 to 27°. The temperature range for enlargement of the lesions was found to be from 6 to 33.5°.

The rate of enlargement of the lesions is said to be very slow at temperatures between 6 and 14°, and it is believed possible to practically eliminate the spread and development of black rot if sweet potatoes are stored at temperatures of from 10 to 12°, with a relative humidity below 90 per cent.

The relation of humidity to infection of the sweet potato by *Rhizopus*, J. I. LAURITZEN and L. L. HARTER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 527-539, figs. 2).—The results are given of a study of the effects of air moisture on the infection of the sweet potato by *R. nigricans* and *R. tritici*.

Sweet potatoes of three varieties were cut in half and inoculated by dipping them in suspensions of spores of the fungi, after which the pieces were placed under controlled temperature and moisture conditions.

Evidence was obtained to show that infection of sweet potatoes by *Rhizopus* occurs almost exclusively through fresh wounds. The optimum relative humidities at a temperature of 23° C. for the infection were found to range from 75 to 84 per cent, the percentage of infection decreasing rapidly as the humidity was raised above or lowered below the optimum humidities. Very few infections occurred at relative humidities of from 93 to 99 per cent. Very few halved roots which had been subjected to relative humidities of from 89 to 97 per cent at a temperature of 23° for a period of from 4 to 12 days became infected when they were retained at these humidities for another period or were placed at humidities of from 48 to 89 per cent. On the other hand, a high

percentage of the halved roots which were subjected to relative humidities of from 51 to 73 per cent for a period of from 4 to 12 days became infected when they were placed later at relative humidities of from 84 to 95 per cent. Roots exposed to relative humidities of from 51 to 52 per cent for a period of from 9 to 12 days did not become infected when they were subsequently placed at relative humidities of from 48 to 73 per cent. A resistance to infection was developed in the roots that had been held at relative humidities of from 89 to 97 per cent. This resistance is said to be located in the surface layers of the wounded areas and has a possible relation to cork formation.

Apple spraying and dusting experiments in 1925, D. FOLSON (*Maine Sta. Bul.* 333 (1926), pp. 145-204, pls. 8).—Studies were made of the spore discharge of the fungus in relation to infection by apple scab as bearing on time of spraying or dusting. Copper-lime dust, lime sulfur sprays with and without a spreader, and lime sulfur and sulfur dusts were compared for the control of scab and injury to fruit and foliage of the variety Ben Davis, the data being compared with those previously published (E. S. R., 54, p. 749).

Scab spots were found to appear early on the leaves of all plats, but the spread of the disease was checked by spraying. The spread of the fungus on trees representing the dusted plats was not significantly different from the spread in the control ones. As compared with the untreated control trees, those receiving copper lime dust showed more leaf spotting, apparently due to burning. Lime sulfur caused less burning than in 1924. In percentage of fruits affected, scab was significantly more abundant in one copper dusted plat, one plat sprayed 4 times, and two plats dusted 5 times with Pomodust than in three plats sprayed 5 times and one plat dusted 6 times with sulfur and sprayed once.

The most fruit russeting was associated with copper dusting, and the least was found in the controls. With more spraying there was more russeting, with no effect apparent from adding a casein spreader or from substituting dry for liquid lime sulfur. With more numerous applications of sulfur dust there was more russeting, but there was less injury than from the same number of applications of spray. The total yield of fruit was not appreciably affected by any fungicidal treatment, although there were some differences in the proportion of the better grades resulting from the amount of scab and russeting.

The author claims that the amount of scab on the fruit in any plat was determined by the current season's fungicidal schedule rather than by the amount of scab present on the fruit in the preceding year. The cost per tree of treatment is said to have been for 4 sprayings with liquid lime sulfur, 41 cts.; 4 sprayings with dry lime sulfur, 45 cts.; 5 sprayings with dry lime sulfur, 54 cts.; 4 sulfur dustings, 40 cts.; 6 sulfur dustings, 53 cts.; and 6 copper dustings, 54 cts.

From the small proportion of leaves found to contain mature ascospores, together with the time required for examination of the leaves, the author concludes that it is doubtful whether technical advice can be given that will permit a modification of spray schedules to fit seasonal and local variation in the time and severity of the first scab infection.

A study was made of the development of scab on fruit while in storage, and it was found that new spots may develop that at packing time were not detected or could only have been recognized by very careful examination. Temperature and humidity influenced the rapidity of development of the storage form of scab. The most important cause or difference in storage behavior was the source of the fruit, much less storage scab developing on fruit from sprayed trees than on fruit from unsprayed ones.

The brown-pocket heart rot of stone-fruit trees caused by *Trametes subrosea* Weir, S. M. ZELLER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 687-693, figs. 2).—The author reports that *T. subrosea* causes a brown-pocket heart rot of peach and prune trees in orchard districts from central California to British Columbia. A survey in prune orchards showed that 73 per cent of the heart rot was produced by *T. subrosea*, and it was demonstrated that the presence of this heart rot is related to large, unprotected pruning cuts. Preventive measures recommended are the proper pruning to facilitate healing, treating the wounds with an antiseptic dressing, and preferably the use of a system of pruning such that large cuts are unnecessary or are reduced to a minimum.

Progress report on red plant of strawberries, A. H. LEES and L. N. STANLAND (*Univ. Bristol, Agr. and Hort. Research Sta. Ann. Rpt. 1924*, pp. 66-69).—Examinations by the present authors subsequent to the report by Ballard and Peren (*E. S. R.*, 52, p. 748) showed that in the summer of 1924 the nematode *Aphelenchus fragariae* could be found in comparatively large numbers in strawberry plants which appeared to be normal. A number of such observations are detailed.

The relation of the nematodes to water was also studied. The facts set forth suggest a distribution of nematodes other than that hitherto accepted. For an explanation of the different manifestations of the disease, other factors must also be investigated. The authors still accept the presence of nematodes as a necessary hypothesis for the moment, but suggest that this alone is not sufficient.

The perfect stage of the fungus which causes melanose of citrus, F. A. WOLF (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 621-625, figs. 2).—The author reports that the perfect stage of the organism which causes melanose and stem-end rot of citrus has been found to occur upon decaying twigs of lime, grapefruit, sweet orange, and tangerine. Its connection with *Phomopsis citri* has been established by growth of both the pycnidial and ascogenous stages in culture from isolations from ascospores.

The ascigerous stage is said to belong to the genus *Diaporthe*, and the name *D. citri* is proposed for it. A technical description of the new combination is given.

Wintering over and infection of *Puccinia malvacearum* Mont., H. HILL (*Quebec Soc. Protect. Plants Ann. Rpt.*, 17 (1924-25), pp. 81-84).—This paper presents a brief report of germination tests and inoculations made with the teliospores of *P. malvacearum* which had overwintered outdoors in Quebec on the stems and leaves of the hollyhocks, the purpose of this work being to determine the possibility of the organism overwintering as a teliospore and germinating the following spring so as to cause infection of healthy plants. It is stated that the immature teliospores can overwinter and infect healthy plants, though the percentage of these teliospores is so small that this can not be considered the chief means of spring infection in Quebec.

ECONOMIC ZOOLOGY—ENTOMOLOGY

Report of the entomologist, J. R. WATSON (*Florida Sta. Rpt. 1920*, pp. 20-28).—In this report on the work of the year ended June 30, 1920, the author considers the camphor and other thrips; the velvet bean caterpillar and the winter weather; nematodes and control by the use of calcium cyanamide, the sodium cyanide-ammonium sulfate treatment, sulfur, and the summer fallow and cultivated cowpeas and velvet beans; the whitefly-eating *Delphastus*; some other insects of the year; and the insects of pigeon peas.

[Entomological work at the Montana Station] (*Montana Sta. Rpt. 1925*, pp. 26-28).—In a discussion of the cause of the increase in numbers of grasshoppers some years, general observations have shown that temperature has considerable effect on their activity. When reared in cabinets kept at 70, 80, 90, and 100° F., it was found that the total amount of food required to carry the young grasshoppers from the egg to the adult stage was the same at all the temperatures, but the time required was 94 days at 70° and 25 days at 100°. The grasshoppers ate nearly four times as much in a day and grew nearly four times as fast at 100° as at 70°. The adult grasshopper was found to eat from 50 to 75 per cent more than the last nymphal stage, and at 100° they ate 2.5 times as much as when kept at 80°. At temperatures ranging from 80 to 100°, one adult grasshopper ate 1 mg. of dry food per hour and ate its own weight in green food every 15 to 18 hours. These figures indicate that it is not alone the number of grasshoppers but also the temperature conditions that determine the damage done to the crops by grasshoppers. Thus at Bozeman in 1918, from July 10 to October 1 there were 193 hours when the range of temperature was favorable to active feeding by the grasshoppers, whereas in 1919 there were 418 such favorable hours, and the food consumed by each grasshopper during the summer of 1919 was 2.2 times that consumed in 1918.

The study has also shown that with continued warm weather the grasshoppers lay more eggs, and that with favorable temperatures from 11 to 15 egg pods per season may be deposited. Confined in control cabinets kept at from 80 to 100°, the female grasshopper of one species was found to lay 1 egg mass every 80 hours, while, under field conditions when the air temperatures 4 ft. from the ground ranged from 70 to 90°, it was noted that no egg laying takes place below 70° and only in shaded ground when the air temperature is above 80°. Applying these facts to temperature conditions in the vicinity of Bozeman, in 1918, from July 10 to October 1 there were 264 hours when the air temperature at 4 ft. above the ground ranged between 70 and 90°, which made possible the laying of 3 egg masses, or 75 eggs, by each female, whereas in 1919 there were 640 hours of favorable temperature, making possible the laying of 8 egg masses, or 200 eggs, by each female. Thus 2½ times as many eggs could have been laid in 1919 as in 1918.

In investigations made in an effort to lower the cost of controlling insect pests, it was found in work with the fruit tree leaf roller that, by using calcium caseinate "spreader" instead of soap as an emulsifier, as effective results can be obtained with 4 per cent of oil in the spray as with 6 per cent and with no checking of the foliage in the spring. The study also showed that the stock emulsion can be made locally at a cost of about \$2.50 for a 200-gal. tank of dilute spray mixture, whereas the best price on commercial oil emulsions would be \$6 per tank. By thus lowering the cost while maintaining its efficiency, it is deemed probable that the oil spray will take the place of the lime sulfur now generally used to control oyster-shell scale and the blister mite, since it is both cheaper and easier to handle and equally as effective in the control of these orchard pests.

[Work in zoology and entomology at the Pennsylvania Station] (*Pennsylvania Sta. Bul. 204 (1926)*, pp. 35-38, fig. 1).—In life history studies of the oriental fruit moth by S. W. Frost at Arendtsville, where four broods were reared, it was found that emergence commenced on May 5 in 1926, more than two weeks later than in the preceding year. In work with the bait pail, infestation under orchard conditions was reduced 50 per cent and infested fruit nearly 25 per cent. Best results were secured with a bait consisting of 1 part of molasses to 10 parts of water. A more detailed report of this method

of control has been made from another source (E. S. R., 55, p. 557). Reference is made to leaf-roller investigations by Frost. A bulletin relating to the red-banded leaf roller (*Eulia velutinana* Wlk.) has been noted (E. S. R., 54, p. 458), and one dealing with *Amorbia humerosana* Clem. is noted on page 156. *E. quadrifasciana* Fern. and *Pandermis limatata* were also under observation.

In control work with millepedes by C. A. Thomas, late fall treatments with granular calcium cyanide were applied to the soil in lettuce coldframes 12 days before planting the seed, and it was found that 400 lbs. per acre gave satisfactory control, whether drilled in with a seed drill or broadcast on the soil and thoroughly raked in. Treatment of a soil strip 2 ft. wide along the inside of the backboard gave as good control as did treatment of the whole bed.

Biological and control experiments were started by Thomas with the flies, springtails, and mites which affect cultivated mushrooms. A good control of the mites was obtained by the use of Kreso sheep dip, 1 part to 30 parts of water. However, this kills the mushrooms and retards the growth of the spawn and should be used only on beds where the mites are very abundant, to check their spreading. The flies can be held in check by dusting pyrethrum powder in the houses at the rate of about 2 lbs. to each 60-ft. house. Shallow pans filled with kerosene and placed just under electric lights in the house attracted and killed a large percentage of the flies. When the springtails gather in the aisles they can be killed by spraying them with kerosene, gasoline, or a nicotine solution. Fumigation of the houses when the manure is at its highest temperature (130 to 140° F.) will kill most of the insects and mites therein. Calcium cyanide has proved to be the very best fumigant tried thus far, but the best dosage has not been worked out.

In the early spring, when various species of wireworms that affect truck crops were beginning to move up toward the surface of the soil, excellent control was obtained by Thomas by first drilling in rows of corn 2 ft. apart and about two weeks later, when diggings showed about all the wireworms feeding on the corn, drilling in 150 lbs. of granular calcium cyanide per acre close to the rows and at least as deep as the grains of corn. In another two weeks the cyanide gas was out of the soil, and the regular crop was then planted. Another method, slightly less effective, was the broadcasting of the cyanide over the soil at the rate of 250 lbs. per acre in the late spring, when the wireworms have reached the upper 4 or 5 in. of soil, and plowing it under at once. Spring treatments are of considerably more value than treatment in the summer, when there is danger of burning the plants with cyanide, or in late fall after crop removal, when a large percentage of the wireworms are several inches below the plow line.

[Work in entomology at the Tennessee Station], S. MARCOVITCH (*Tennessee Sta. Rpt. 1925, pp. 15, 16*).—Reference is made to the use of fluosilicates as insecticides, accounts of which have been noted from other sources (E. S. R., 55, pp. 152, 157) and on page 157. It is pointed out that in tests conducted sodium fluosilicate has been fully as toxic to certain insects as arsenic, whereas against man the latter is 300 times as poisonous. The use of corn as a trap crop for the corn ear or boll worm on tomatoes did not give adequate protection, as previously noted from a more extended account (E. S. R., 55, p. 154).

Laboratory and field tests with the woolly aphid again showed paranitrochlorobenzene to be the most toxic material tested, amounts as small as $\frac{1}{8}$ oz. being sufficient to rid 1-year-old trees of the woolly aphid underground. Due to various conditions, such as high temperature, the material evaporated too quickly and injured the trees. Further experiments with coal tar indicate that it is toxic enough to kill without any apparent injury to the trees.

Insecticide tests show that weevils can be readily killed with sodium fluosilicate, but further work is necessary to determine its actual value for the boll weevil.

An important outbreak of insects infesting soy beans in lower South Carolina, C. B. NICKELS (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 614-618).—This is a contribution from the South Carolina Experiment Station, reporting upon a severe outbreak of leaf-devouring caterpillars which occurred during the late summer and autumn of 1925 in fields of soy beans in the southern counties of the State. The lepidopterous species conspicuous in the outbreak included the velvet bean caterpillar (*Anticarsia gemmatilis* Hubn.), corn ear worm, fall army worm, bean leaf roller, and *Prodenia* sp.

Insect enemies of sugarcane in western Mexico, R. H. VAN ZWALUWENBURG (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 664-669).—In this contribution from the Hawaiian Sugar Planters' Station, the author reports that the major sugar cane pests in western Mexico are two moth borers, *Chilo loftini* Dyar and *Diatraea lineolata* Wlk. Neither is held in check by parasites, although the latter is fairly well parasitized by *Trichogramma* late in the summer and is of secondary importance after the first crop. *Leptodictya tabida* H. S. is everywhere common but is of slight economic importance. A noctuid larva, *Saccharaphagos mochisa* Schauss, is sometimes numerous in ratoon fields, where two species of *Cirphis* also occur. *Tomaspis posticata* Wlk. has lately become a pest of some importance.

Toxicity of dipyriddyds and certain other organic compounds as contact insecticides, C. H. RICHARDSON and C. R. SMITH (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 7, pp. 597-609, figs. 5).—This paper reports on the chemical relationships of the dipyriddyds, preliminary experiments on the toxicity of crude dipyriddyd oil, methods of application of crude dipyriddyd oil, insects used in the experiments, spraying experiments with aphids, submergence tests with other insects, effects of sprays on plants, insecticidal properties of the constituents of crude dipyriddyd oil, and insecticidal properties of other compounds.

It is pointed out that a crude oil containing several isomeric dipyriddyds and other substances has been prepared from pyridine and sodium, which was found to be highly toxic in spraying experiments with six species of aphids, though surpassed in this respect by nicotine. In submergence experiments the crude oil was more toxic than nicotine to the larvae of two species of Coleoptera and one species of Lepidoptera, and less toxic than nicotine to the adult of one species of Coleoptera and to silkworm larvae.

"Crude dipyriddyd oil, in the present experiments, was not injurious to plants infested with aphids at concentrations sufficient to kill the aphids. $\alpha\alpha$, $\beta\beta$, $\beta\gamma$, and $\gamma\gamma$ dipyriddyds, which occur in the crude dipyriddyd oil used in these tests, were not so toxic to *Aphis rumicis* as the crude oil itself; $\gamma\gamma$ dipyriddyd is much less toxic than the other three compounds. Several preparations from the crude oil proved to be highly toxic to *A. rumicis* on nasturtium plants. Although unquestionably impure, they approached closely the toxicity of nicotine for this aphid. Work is being continued on these preparations. The toxicities of 16 other organic compounds tested during this investigation are given also. Several of these are related to the dipyriddyds or to nicotine. As compared with dipyriddyd oil, they showed no appreciable toxicity. Crude dipyriddyd oil was more toxic than nicotine to certain insects used in this investigation, and it is possible that it may also prove more effective for the practical control of some injurious insects."

The possibilities of sodium fluosilicate as a poison in grasshopper baits, G. S. LANGFORD (*Jour. Econ. Ent.*, 19 (1926), No. 4, p. 670).—In an attempt to

determine the efficiency of sodium fluosilicate against the common injurious species of grasshoppers in Colorado, a 4-acre plat of freshly cut alfalfa was poisoned, and excellent results were obtained. A series of laboratory experiments were then undertaken, using mostly the red-legged grasshopper. Compared with other insecticides tested in the same way, the percentage of kill after six days was sodium fluosilicate 100 (4 days), Paris green 98.7, white arsenic 98.2, sodium arsenite 96.5, sodium fluoride 92, and control 30.3 per cent.

Preliminary report on sodium fluoride as a control for cattle lice, F. E. GUYTON (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 602, 603).—In experiments conducted, sodium fluoride applied to the neck, shoulders, and rump of cattle by means of a small tin shaker and rubbed into the hair by the naked hand gave perfect control of three species of biting lice with no ill effects to the cattle. Five cattle treated with nicotine dust all showed infestation eight days after treatment.

Survival expectancies of two aphids, A. C. BAKER (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 648-650, fig. 1).—The author presents a graph showing the survival expectancies of two common species, namely, the apple aphid and the "green bug" of the grain fields (*Toxoptera graminum* Rond.).

The spruce gall-aphid (*Adelges abietis* Kaltenbach), G. W. HERRICK and T. TANAKA (*New York Cornell Sta. Bul.* 454 (1926), pp. 17, figs. 6).—The authors discuss the history, distribution, and injury, and the scientific and common names of *A. abietis*, describe the forms, and deal with the life history, parthenogenetic development, and control of this insect, which is a source of injury particularly in New York, Pennsylvania, and the New England States.

It is reported that in control work a 550-ft. hedge which had been abundantly infested with the aphid was thoroughly sprayed on both sides on April 9, 1924, with powdered lime sulfur at the rate of 16.5 lbs. to 50 gal. of water, with the result that not a single developing fresh gall was found throughout the season. On April 21, 1924, another hedge was sprayed with Sunoco oil at the rate of 1 part to 20 parts of warm water, and very satisfactory results were obtained from the readily emulsified oil. The thorough application of 1 qt. of Scalecide to 20 qt. of water on April 6 gave very satisfactory results, not a single new gall having been observed on the trees during the summer and fall. There was no evidence of any injury to the tree when applied during the spring of the year at this strength. The author considers the evidence obtained to indicate that this miscible oil is nearly a specific in destroying the spruce gall aphid.

An apparently new sugar-cane mealybug, H. MORRISON (*Jour. Agr. Research* [U. S.], 33 (1926), No. 8, pp. 757-759, fig. 1).—Under the name *Ripersia radiccicola* the author describes a new species of mealybug injurious to sugar cane in certain localities in Cuba through its attack upon the roots. It has also been taken on the roots of *Echinochloa colonum* at Baragua, Camaguey, Cuba.

The dusky leaf roller [*Amorbia humerosana* Clem.], S. W. FROST (*Pennsylvania Sta. Bul.* 205 (1926), pp. 15, figs. 11).—This is an account of a lepidopteran which has of recent years caused considerable injury to apples in Pennsylvania. It feeds upon a number of plants, but the apple seems to be the only host on which it inflicts serious injury. Records show it to be generally distributed throughout the eastern United States. The larvae roll the leaves and feed on both foliage and fruit, the deep cavities eaten in the fruit seriously affecting its quality. It has but one brood a year, and hibernates in the pupal stage. Three hymenopterous parasites, namely, *Epirhysalus atriceps* Ashm., *Glypta phoxopteridis* Weed, and *Glypta* n. sp., have been reared from the

larvae. Late summer and early fall applications of an arsenical poison seem to offer the best means of control.

The seasonal history and food habits of the tobacco budworm, *Heliothis virescens* Fab., in the southern tobacco-growing region, F. S. CHAMBERLIN and J. N. TENHET (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 611-614, fig. 1).—This is an account of the seasonal history and food habits of *H. virescens* in the southern tobacco-growing region. The pest is usually present from the first of April until the middle of October, during which period there are four broods. Tobacco and beggarweed are the food plants of major importance. Control measures have been reported in an earlier noted publication by Morgan and McDonough (*E. S. R.*, 37, p. 663). *H. obsoleta* is said to be only rarely found on tobacco in the southern tobacco-growing region.

[Insecticide tests at the Kentucky Station] (*Kentucky Sta. Rpt. 1925, pt. 1, p. 15*).—Of various insecticides tested for control of the Mexican bean beetle, the best results were obtained from calcium arsenate 1 part and hydrated lime 9 parts, only 2.85 per cent of the plants being injured when finally examined.

Fluorides versus fluosilicates as insecticides, S. MARCOVITCH (*Science*, 64 (1926), No. 1650, p. 159).—Referring to an article by Roark, previously noted (*E. S. R.*, 55, p. 658), it is maintained that the author's early investigation included the first scientifically planned experiment with the fluosilicates for the control of the Mexican bean beetle by dusting.

The squash beetle in Arizona, occurrence and probable manner of introduction, J. R. DOUGLASS (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 632-635).—During 1921 the squash beetle appeared in the vicinity of Douglas, Ariz., and slowly extended its range until 1924, when it covered about 65 square miles. During 1925 the insect was not found within the previously infested area, and it is believed that a deficiency in precipitation combined with an increase in the mean temperature, may have been responsible for the disappearance of the pest. The beetle differs from the northern or eastern form.

Metal barriers as protective devices against the saw-toothed grain beetle, J. C. HAMLIN and W. D. REED (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 618-624, pl. 1).—Laboratory experiments reported upon indicate that, under certain conditions, certain types of metal barriers may afford to raisins a high degree of protection from the saw-toothed grain beetle. A preliminary report has been noted (*E. S. R.*, 54, p. 662).

The Acalypha flea beetle (*Crepidodera atriventris* Melsh.), W. V. BALDUF (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 624-632).—This flea beetle, which has long been known to eat wild Acalypha, recently did marked damage to ornamental species of the genus at the University of Illinois. The first three stages are spent in the ground about the plants, the larva feeding on the roots. Two generations are believed to develop each year at Urbana, Ill., the winter being passed in the adult stage. A small hymenopterous parasite was obtained from the adults.

The concentration of wireworms by baits before soil fumigation with calcium cyanide, R. E. CAMPBELL (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 636-642).—In this further report on the use of calcium cyanide (*E. S. R.*, 52, p. 856), the author finds that applications of from 200 to 300 lbs. of the granular form to the acre with a grain drill under certain conditions will kill a high percentage of the wireworms, but that ordinarily this treatment is too expensive for commercial use. Therefore, advantage was taken of the fact that wireworms will collect in rows or hills of seeds, and several kinds of seeds were planted as baits to concentrate the wireworms in rows. It was found that by this method a fairly heavy dosage can be applied to the baited rows, and the

amount required to the acre will be considerably less than in broadcast treatment. Considering the lethal effect and the cost, from 5 to 5.5 lbs. per 1,000-ft. row was found to be the most satisfactory amount of calcium cyanide. The percentage of wireworms attracted to the baits decreased as the width of the rows increased, being 96 per cent for 2-ft. rows and 80 per cent for 4-ft. rows.

The clover root borer, L. P. ROCKWOOD (*U. S. Dept. Agr. Bul. 1426 (1926), pp. 48, figs. 15*).—This is a report of studies of *Hylastinus obscurus*, which has been under observation for the last several years at the field station of the Cereal and Forage Insect Division of the Bureau of Entomology at Forest Grove, Oreg. In the course of the investigation many new data on the bionomics of the insect have been accumulated and are here presented in an attempt to correlate them with previously published records and with unpublished notes from the bureau files. The author deals with the synonymy, habits of related species, economic history, distribution, seasonal history, life history, sexual development, number of generations, rate of reproduction, ecology, damage, natural enemies, and control, and gives descriptions of the several stages in the life of the borer. A list of 50 references to the literature is included.

Recommendations regarding boll weevil work, J. E. MILLS (*Abs. in Jour. Econ. Ent., 19 (1926), No. 4, pp. 601, 602*).—This is an abstract of recommendations presented at the annual convention of the Cotton States Entomologists, held at Atlanta, Ga., in February, 1926.

Cotton boll growth in relation to boll weevil injury, E. W. DUNNAM (*Jour. Econ. Ent., 19 (1926), No. 4, pp. 589-593*).—While studying the boll weevil, the author found that as cotton bolls grow older they are less susceptible to injury. Of the varieties of cotton used, namely, Dixie Triumph, Webber 49, and Humco Cleveland, the first mentioned was the most and the last the least susceptible. There was no correlation between the number of feeding punctures or the number of egg punctures and the percentage of cotton loss; nor was there any relation between the thickness of hull and susceptibility to weevil damage, in spite of the fact that the weevils lay fewer eggs in the thick-hulled varieties. The determining factor appears to be the hardness of bolls, because varieties with the hardest bolls, as determined by the number of grams pressure required to puncture them, show also the smallest percentage of cotton loss.

The breeding of boll weevils from infested cotton squares, B. GEHAUF (*Jour. Econ. Ent., 19 (1926), No. 4, pp. 593-599, figs. 2*).—This is a report on the rearing of boll weevils for use in toxicity work of the Chemical Warfare Service of the U. S. Army.

Comparative tests with sodium fluosilicate and calcium arsenate for the control of the cotton boll weevil (*Anthonomus grandis*), M. R. OSBURN (*Jour. Econ. Ent., 19 (1926), No. 4, pp. 643, 644*).—In field and cage tests conducted at the Upper Coastal Plain Substation, Rocky Mount, N. C., sodium fluosilicate was more effective against the boll weevil than calcium arsenate, and reached its effectiveness in less than half the time. An average control of 80 per cent was attained in 24 hours, when maximum effect was reached, while 48 hours were necessary for a control of 69 per cent with calcium arsenate. Sodium fluosilicate appeared to act as a repellent as well as an insecticide.

Progress report of work of the Chemical Warfare Service on the boll weevil (*Anthonomus grandis*), H. W. WALKER and J. E. MILLS (*Abs. in Jour. Econ. Ent., 19 (1926), No. 4, pp. 600, 601*).—This is an abstract of a paper presented by the authors at the annual convention of the Cotton States Entomologists, held at Atlanta, Ga., in February, 1926. They report that preliminary tests were made of some 1,000 poisons or poisonous mixtures, in which a total

of over 100,000 weevils were used. About 50 of the materials showed a toxicity equal to or greater than calcium arsenate, and of these above 20 showed little or no injury to the cotton plant. Barium, lead, zinc, mercury, and to a less extent iron showed some measure of toxicity to the boll weevil when combined with other chemical groups in themselves harmless, and the toxicity of these metals seemed, in general, to be retained when combined with arsenic and to increase the toxicity of the resulting arsenical. Sodium fluosilicate, barium fluoride, and cryolite seemed to be equally as effective as calcium arsenate on a volume for volume basis. Every effort should be made to decrease the specific gravities of these compounds so as to give them the same covering power as the calcium arsenate. The authors believe that an advantage is gained in reducing the percentage of arsenic in calcium arsenate and using a larger amount per acre. It is pointed out that high concentrations of toxic gases are ineffective against the weevil, due to its apparent ability to suspend breathing more or less at will.

The "cloud drift" versus the regular method of dusting, W. E. HINDS (*Abs. in Jour. Econ. Ent., 19 (1926), No. 4, pp. 607, 608*).—This is an abstract of a paper, reporting upon a test made at the Louisiana Experiment Stations in 1925, which indicated that the cloud-drift method will be limited in usefulness by the narrow range of atmospheric conditions within which it can be applied, but that when these conditions do occur and the direction of the drift is across the rows, advantage may be taken of the cloud-drift method to save at least one-half the time required for making the application by the usual every-row treatment.

Water-carriers versus nectar-carriers, O. W. PARK (*Jour. Econ. Ent., 19 (1926), No. 4, pp. 656-664, figs. 5*).—In this contribution from the Iowa Experiment Station, it is pointed out that water carriers may be distinguished from nectar carriers by gently pressing on the abdomen of the loaded bee while it is held fast on a sheet of filter paper. If the disgorged honey-sac contents is nectar a translucent spot will be produced on the filter paper, whereas, if it is only water no such spot will remain upon drying. No suitable chemical test was found. Individuals selected by means of this test showed that nectar carriers working on white sweet clover required on the average one-half to three-quarters of an hour to make a round trip, while water carriers, obtaining their loads within 50 yds. of the apiary, completed their round trips in five minutes on the average.

A brief history of the sticktight flea and the fowl tick in the United States, D. C. PARMAN (*Jour. Econ. Ent., 19 (1926), No. 4, pp. 644-648*).—The author discusses the probable origin and spread of these two pests, and presents a list of host animals for each species together with the most important biological data relating to each.

ANIMAL PRODUCTION

The mutual influence of the proportion of the several nutrients in feeds on their digestibility.—I, Crude fiber—the digestibility of rations containing varying amounts of alfalfa and paper pulp, H. W. TYRUS (*New Mexico Sta. Bul. 153 (1926), pp. 52, figs. 3*).—The complete results of the investigation of the effect of fiber on the digestibility of alfalfa hay previously noted (*E. S. R., 55, p. 465*) are presented.

Rations consisting of first cutting alfalfa hay, and alfalfa with a high-grade filter paper pulp known as Cellomass making up 15, 30, 45, and 60 per

cent of the ration were each fed to 5 steers in two 10-day digestion periods. The following table shows the average apparent digestibility of the different rations, excluding the results which appeared to be erroneous:

Apparent digestibility of rations containing various amounts of alfalfa and paper pulp

Ration	Ingredients		Coefficients of digestibility								
	Alfalfa	Cello-mass	Dry matter	Organic matter	Total nitrogen	Protein	Non-protein	Ether extract	Nitrogen-free extract	Crude fiber	Ash
	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>
1-----	100	0	59.72	60.86	71.97	70.71	78.00	34.27	72.91	41.76	50.41
2-----	85	15	61.85	62.97	68.12	67.22	72.59	28.68	71.81	54.67	50.83
3-----	70	30	66.12	67.62	64.19	62.41	71.57	26.59	71.26	66.62	47.97
4-----	55	45	67.84	69.66	53.55	54.61	48.38	13.70	69.83	71.88	40.96
5-----	40	60	69.20	70.98	38.40	41.98	21.56	7.21	68.31	74.43	34.92

A study of the effect of the Cellomass on the apparent digestibility of the constituents of the alfalfa indicated that Cellomass up to 45 per cent of the total ration had no significant effect on the apparent digestibility of the dry matter, organic matter, and nitrogen-free extract of the alfalfa. When Cellomass made up 60 per cent of the ration, the digestibility of the organic matter appeared to be depressed.

When over 30 per cent of the ration consisted of Cellomass the apparent digestibility of the ash was lowered. As the percentage of Cellomass was increased the digestibility of the ether extract of the alfalfa was rather uniformly depressed, though it is suggested that this may not have been directly caused by the Cellomass. The results with the crude fiber showed some irregularity, as did the total carbohydrates of the alfalfa. Increasing the percentage of Cellomass in the ration decreased the digestibility of the fiber at first, then increased it, and finally decreased it. The apparent digestibility of the total nitrogen of the alfalfa dropped from approximately 72 per cent to approximately 38.4 per cent as the amount of the fibrous substance was increased from 0 to 60 per cent, but when corrected for metabolic nitrogen the true digestibility appears not to have been very much affected. In general the apparent digestibility of the total nutrients increased as the nutritive ratio changed from 1:3.37 to 1:7.92 and decreased as the nutritive ratio became greater.

The apparent digestibility of the organic matter, crude fiber, and nitrogen-free extract of the mixed feeds was approximately the same as was calculated for these nutrients, but as the amount of fiber in the ration was increased the digestibility of the ash, ether extract, and crude protein of the mixed feeds became less than was calculated. The optimum nutritive ratio for digestibility of the several ingredients of the mixed feeds was found to be approximately 1:7.9.

The retention of nitrogen by the steers increased as the percentage of Cellomass was increased up to 45 per cent, but when greater than 45 per cent there was a decrease in the amount of nitrogen retained.

From the results of the investigation it is concluded that the substitution of up to 45 per cent of lignin-free cellulose for an equal weight of alfalfa in a ration consisting solely of alfalfa does not affect the apparent digestibility of the carbohydrate portion of the mixed feed to any marked degree. It very greatly decreases the apparent though not the true digestibility of the crude

protein of the mixed feed, and causes a greater retention of nitrogen from a given weight of feed, resulting in a mixed feed producing larger gains in live weight per unit of feed eaten.

The composition of the gains in weight and the utilization of food energy in growing rats, H. H. MITCHELL and G. G. CARMAN (*Amer. Jour. Physiol.*, 76 (1926), No. 2, pp. 398-410).—In studying the composition of the gains made by rats, the composition of the carcass (minus the contents of the intestinal tract) of individuals from the different litters selected from experiments previously noted (E. S. R., 55, p. 794) was compared with the analyses of the experimental animals at the conclusion of the feeding period. The results for the individual animals are tabulated, showing the sex, age, live and empty weights, and percentage composition and calculated amounts of dry matter, ether extract, ash, total nitrogen, and energy in the empty carcass and in the gains of each. The analyses of the check animals agreed fairly well except for ether extract and gross energy, which showed considerable variability in rats from different litters. The composition of the gains appeared to vary widely, even though the same ration was consumed and the rates of gain were similar. Individuals from the same litter showed wide differences. In one case 2 rats gained 156 and 158 gm. in the same time and with approximately the same food consumption, but the energy value per gram of gain of one was 3.04 calories and of the other 1.65 calories.

The percentage of the total metabolizable energy of the ration that was accounted for as used in basal heat production and as body increases is tabulated for each rat fed. The utilization of the energy by individuals within the same litter generally showed good agreement, though there was considerable variation between the litters. In general, from 60 to 75 per cent of the metabolizable energy was accounted for. The energy stored in the body constituted only from 6 to 10 per cent of the metabolizable energy consumed. In all the litters except one the females consistently stored the lowest percentages, indicating that the females' voluntary activity was greater than that of the males.

The specific dynamic effect of food in the growing rat appears to be small. Data from another experiment are presented to show that while on a maintenance ration this effect is probably inappreciable.

Growth and development with special reference to domestic animals.—II, A new method for measuring surface area and its utilization to determine the relation between growth in surface area and growth in weight and skeletal growth in dairy cattle, S. BRODY and E. C. ELTING (*Missouri Sta. Research Bul.* 89 (1926), pp. 5-18, figs. 12).—This bulletin presents essentially the same material as was previously published by the junior author (E. S. R., 55, p. 675) with the addition of data showing the relation between surface area and weight and linear dimensions. The formula $SA = CW^n$, in which SA is the surface area, W is weight or linear dimensions, and C and n are constants, was found to represent accurately the relation between area and weight when $n=0.56$; area and height at withers when $n=0.24$; area and heart girth when $n=1.6$; and area and length of body when $n=1.7$.

The influence of the environmental temperature on the heat production of cattle, E. B. FORBES, W. W. BRAMAN, M. KRISS, ET AL. (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 579-589).—Since a review and recalculation of the energy metabolism work at the Pennsylvania Institute of Animal Nutrition indicated that a steer which had been sheared produced more heat as measured in the calorimeter at 13.5° C. than at 19.0° in 3 repetitions at these temperatures, an experiment was conducted with one shorn and one unshorn steer, both of which were fasting.

At temperatures of 13.68, 15.70, 18.26, and 22.06° the 24-hour heat production corrected to the standard day for the shorn steer was 8,243, 7,989, 7,519, and 6,806 calories, respectively. At temperatures of 15.54, 18.46, 21.51, and 14.16°, the 24-hour heat production of the steer carrying a full coat of hair was 6,322, 6,430, 6,453, and 6,180 calories, respectively. The results indicate that the 3 temperatures below 22.06° were below the critical temperatures for the shorn animal, while at least all those above 15.54° were above the critical temperature for the haired animal, though the data suggests that there may have been a slight expenditure of energy resulting from an effort to keep cool.

With both animals the relative amount of heat given off as latent heat of water vapor increased as the temperature rose, but was much more pronounced with the steer having the full coat of hair.

The average heat production of a fasting steer with its full winter coat was 18.01 calories per kilogram of live weight and 1,457 calories per square meter of body surface. The decrease of heat production per degree centigrade of rise in temperature below the critical was 36 calories per square meter of body surface, or approximately 2.5 per cent of the fasting katabolism.

The fasting katabolism of dry cows, E. B. FORBES, J. A. FRIES, W. W. BRAMAN, and M. KRISS (*Jour. Agr. Research* [U. S.], 33 (1926), No. 6, pp. 591-595).—Data are presented giving the heat production as determined in the calorimeter at the Pennsylvania Institute of Animal Nutrition of dry cows which were fasted for from 3 to 8.5 days. Other data presented include the total and empty live weights of the animals, surface area, heat production per unit of weight and per unit of body surface, latent heat of water vapor, and temperature of the chamber.

Although 4 of the 5 experiments were conducted with different individuals, and the heat production depends on both the basal metabolism and the normal activity in the stall, nevertheless the heat production per standard day per unit of body surface was relatively uniform.

Beef cattle on the ranch (*Montana Sta. Rpt. 1925, p. 49*).—Experiments conducted at the substation at Havre have indicated that such feeds as corn fodder, silage, and straw fed in combination would maintain breeding cows during the winter in as good condition as the more expensive ration of alfalfa hay and cottonseed cake. Cows maintained on the cheaper ration have also produced as many and as large calves. In these tests, which have been conducted over a number of years, cows 8 to 9 years old have produced calves which are heavier at weaning than have younger or older cows.

Steer feeding: Substituting a legume hay for corn silage toward the end of the feeding period, E. S. GOOD and L. J. HORLACHER (*Kentucky Sta. Bul. 264* (1926), pp. 3-27).—The results of the 3 years' experiments in which clover or alfalfa hay replaced the corn silage in the ration of fattening 2-year-old steers toward the end of the feeding period (*E. S. R.*, 54, p. 359) are brought together and summarized. The combined results show that in cases where silage gives out before the steers are fat a legume hay may be substituted for the silage with satisfactory results, though steers receiving silage throughout the entire feeding period showed somewhat greater returns than when legume hay was substituted during the latter part of the feeding period. In two of the three experiments legume hay produced more rapid gains and slightly fatter animals which brought a higher selling price, but the relatively high price of hay resulted in smaller net returns.

Wintering steers with and without corn silage preparatory to finishing on grass without grain, E. S. GOOD (*Kentucky Sta. Bul. 267* (1926), pp. 73-93).—The results are given of three tests of the ability of steers to gain on

blue grass pasture without grain after being wintered on grain and hay rations with and without corn silage, a brief account of which was previously noted (E. S. R., 39, p. 475).

In the two experiments in which 2-year-old feeders were used and sold for slaughter off pasture, those which received corn silage made 20 and 66 per cent larger gains, respectively, on grass the following summer than those which were wintered without silage. In the third experiment, in which yearlings were wintered and sold as feeders off pasture, the steers receiving silage made 20.4 per cent less gain on pasture than those not receiving silage.

In the first experiment the combined winter and summer gains were practically the same for both lots, but in the other two experiments the combined gains were 16.6 and 4.5 per cent greater for those receiving silage. The calculated costs of gain were greater on the rations not including silage in all lots. It proved more profitable to feed a heavy silage ration with little or no corn than to allow a heavy feed of corn and a minimum amount of silage for wintering.

Effect of winter rations on gains of calves marketed as 3-year-old steers, E. W. SHEETS and R. H. TUCKWILLER (*U. S. Dept. Agr. Bul. 1431 (1926), pp. 11, figs. 5*).—In continuing the studies of beef production problems in the Appalachian region in cooperation with the West Virginia Experiment Station (E. S. R., 51, p. 772), three lots of 30 calves each were kept from the time of weaning until marketing at 3 years of age. The rations during the first winter consisted of clover hay, corn silage, and wheat straw; cottonseed meal, corn silage, and wheat straw; and mixed hay and grain. At the end of the first year's pasturing season each of the 3 lots was again divided into 3 sublots and was wintered on rations of clover hay, corn silage, and wheat straw; cottonseed meal, corn silage, and wheat straw; and mixed hay, corn silage, and wheat straw. All were finished on cottonseed meal, corn silage, and wheat straw with grass.

The results showed that there were relatively small differences in the gains made by the steers in the 9 different lots, but all showed a pronounced loss in weight from about October 10, when frost occurred, until the cattle were placed in winter quarters. This loss of weight in the yearlings was not made up until the end of the following winter feeding period.

Baby-beef feeding and grazing experiment, M. JACOB (*Tennessee Sta. Rpt. 1925, p. 14*).—The results of this project, which was started in the fall of 1923 and completed in the summer of 1925, with 50 native (Tennessee) calves and 50 Texas calves, indicated that oat straw and corn stover when fed with corn silage and cottonseed meal to calves and yearlings were as satisfactory as alfalfa hay for producing gains and were much more economical. The alfalfa-fed cattle produced the largest gains during the winter, but those receiving oat straw and corn stover made the greatest gains during the summer.

An analysis of the results indicated that it is better to finish calves for baby beef the first summer after wintering than to carry them through the second winter and finish on grass.

[Experiments with sheep at the Kentucky Station] (*Kentucky Sta. Rpt. 1925, pt. 1, pp. 18, 19*).—The results of the following experiments are briefly reported:

Fattening spring lambs on pasture.—In a comparison of blue grass pasture and a mixture of oats and rape for fattening spring lambs, 22 spring lambs were divided into 2 lots. Both lots received a supplemental grain mixture of rolled oats, bran, and linseed oil meal. Both lots of lambs made average gains of 3.5 lbs. each in 28 days.

Comparison of gains in sheared and unsheared lambs.—In this comparison 13 sheared lambs made an average gain of 3.5 lbs. in 28 days, while 7 unsheared lambs made an average gain of 6 lbs. in the same period.

Fattening late native lambs.—In a feeding period from July 9 to August 18, 36 lambs drenched with copper sulfate for stomach worms made an average gain of 12.2 lbs., as compared with 7 lbs. as the average gain of an equal number of undrenched lambs.

Culling the flock to improve wool production (Montana Sta. Rpt. 1925, pp. 16, 17).—The correlations of the first, second, and third fleeces with the fourth fleece of range ewes have been calculated as 0.29 ± 0.060 , 0.69 ± 0.023 , and 0.82 ± 0.014 , respectively, which indicate that the first fleece is an unreliable indicator of the fourth fleece, but that the second and third fleeces furnish much more satisfactory indicators of a ewe's ability as a wool producer.

Crossbreeding Merino ewes and Dorset \times Merino F_1 ewes with mutton rams, W. L. HENNING (Pennsylvania Sta. Bul. 204 (1926), p. 13, fig. 1).—In a test of the desirability of purebred and grade Merino ewes when mated with a Dorset ram and Dorset \times Merino F_1 ewes mated with a purebred Southdown ram for the production of hothouse lambs, it was found that the crossbred lambs were very suitable for this purpose from the standpoint of conformation, quick fattening, and desirable quality.

Pig feeding experiments, J. M. SCOTT (Florida Sta. Rpt. 1920, pp. 13, 14).—Four lots of 4 pigs, fed for 130 days on rations of ground corn only, ground corn and tankage 10:1 self-fed, ground corn and peanut meal without hulls 2:1, and ground corn and peanut meal 1:1, made average daily gains of 0.58, 1.35, 0.84, and 0.90 lbs., respectively. The carcasses were examined for hardness at the conclusion of the experiments, but the results were somewhat conflicting.

Similar results were obtained in another experiment in which 4 pigs were fed on corn and peanut meal with a little skim milk.

[Experiments with swine at the Kentucky Station] (Kentucky Sta. Rpt. 1925, pt. 1, p. 17).—No advantage was apparent in the rate of gain of pigs receiving the worm treatment as compared with pigs receiving no such treatment. Creamery buttermilk produced more economical and more rapid gains than semisolid buttermilk or water as a supplement to a grain mixture. Semisolid buttermilk was not as effective as the worm capsule in expelling roundworms from pigs.

The results of another experiment indicated that mineral mixtures were desirable as supplements to corn alone or corn and soy beans hogged down. A bone meal mixture was found to produce more rapid and more economical gains than a phosphate mineral mixture. Salt likewise stimulated the rate of gain made by pigs hogging down corn as compared with lots receiving no supplement, but tankage was not benefited by the addition of salt and limestone, though a good mineral supplement was almost equal to tankage when fed to hogs hogging down corn.

[Swine feeding experiments at the Montana Station] (Montana Sta. Rpt. 1925, pp. 18, 19).—The results of two experiments are briefly reported.

Value of supplements in feeding swine.—The addition of various supplements to a basal ration of ground barley and alfalfa hay indicated that the basal ration was deficient in protein and vitamins and probably in calcium and phosphorus.

In another experiment bone meal added to the basal ration produced very satisfactory results, as the feeding of 1 lb. of this substance saved 17.25 lbs. of barley as calculated from the feed required to produce a unit of gain.

In another experiment hull-less barley fed with alfalfa hay seemed to be 20 per cent more valuable for the production of gains than hull barley.

An economical method of feeding pigs on alfalfa pasture.—Spring pigs fed a limited grain ration during the pasture season were found to require less grain to attain a weight of 200 lbs. than when fed a full grain ration on pasture, or when no grain was fed during the pasturing season. A limited amount of tankage during the finishing period increased the rate and economy of gain. The recommended grain ration to be fed with pasture was 1 to 1.5 lbs. per head daily.

[Experiments in swine feeding at the Pennsylvania Station], M. F. GRIMES (*Pennsylvania Sta. Bul.* 204 (1926), pp. 13, 14, fig. 1).—The results of the following experiments are briefly reported:

Forage crops for pigs.—In a comparison of rape, oats and peas, alfalfa, and Sudan grass, 1-acre plats supplemented with a 2.5 per cent ration of corn and tankage 10:1 provided sufficient feed for 20 pigs over a period of 78 days in the rape, alfalfa, and Sudan grass groups. Oats and peas, however, only lasted 57 days. The groups ranked in the following order in the rate and economy at which gains were produced: Rape, alfalfa, Sudan grass, and oats and peas. White pigs in all lots showed some sun scald except for those on alfalfa.

By-products for fattening swine.—In continuing the studies of bakery by-products (E. S. R., 52, p. 270), bread and mixed crackers were compared with rations of corn and tankage, and corn, tankage, and minerals, with rape pasture in all lots. The rate of gain in the different lots was very similar.

Fattening rations for swine (dry lot).—The results of this test, which is a duplicate of that previously noted (E. S. R., 54, p. 366) do not entirely agree with the previous trial as to the value of minerals. Barley and middlings produced gains at a higher cost than combinations of corn with tankage, fish meal, or pea-size oil cake.

Winter rations for brood sows.—Sows made satisfactory gains and were kept in good condition with no apparent difference in the strength or size of the pigs in the litters produced when fed on rations of ear corn and fish meal, ear corn and alfalfa hay; ear corn, fish meal, and wheat bran; and ear corn, fish meal, and ground oats.

The endogenous nitrogen of hens as affected by molting, C. W. ACKERSON, M. J. BLISH, and F. E. MUSSEHL (*Poultry Sci.*, 5 (1926), No. 4, pp. 153-161).—This and the following papers give more detailed results of the incomplete experiments previously noted from the Nebraska Experiment Station (E. S. R., 54, p. 368). The methods and plan of the experiments dealing with the utilization of proteins were previously outlined (E. S. R., 50, p. 576).

Detailed data showing the body weight, daily nitrogen excreted, and other information are tabulated for each of the 60 experiments with 25 nonmolting birds, and for each of the 35 experiments with 26 molting birds. The average nitrogen excretion daily on the nitrogen-free diets is also tabulated for each group according to the month in which the experiment was conducted. The daily endogenous nitrogen produced was relatively uniform in the different individuals and throughout the different months of the year in both groups with few exceptions, but during molting the nitrogen excreted per unit of body weight was 60 per cent higher than for nonmolting birds. The average figures were 144 mg. for nonmolting birds and 219 mg. for molting birds per kilogram of body weight daily.

The effect of cystine on the endogenous metabolism of molting hens, C. W. ACKERSON and M. J. BLISH (*Poultry Sci.*, 5 (1926), No. 4, pp. 162-165).—In studying the effect of cystine on the endogenous nitrogen of molting birds,

3 series of experiments were conducted, using 4 molting birds in each. Two of the birds received small amounts of cystine in addition to the nitrogen-free diet. In the 3 experiments the molting birds not receiving cystine excreted an average of 239 mg. of nitrogen per kilogram of body weight daily, while the nitrogen excretion was reduced to 137 mg. per kilogram of body weight by the feeding of small amounts of cystine, which supplied from 15 to 19 mg. of nitrogen daily. The loss of body weight was also less when cystine was fed. The cystine thus exerted a protein-sparing effect entirely out of proportion to its nitrogen content.

The utilization of the proteins of corn by hens, C. W. ACKERSON and M. J. BLISH (*Poultry Sci.*, 5 (1926), No. 5, pp. 226-232).—The average utilization of the proteins of corn was 68 per cent when the ration consisted of whole yellow corn and sugar together with minerals and filter paper for bulk. This determination was obtained by averaging the results of 43 trials with 25 mature nonmolting hens. On making a proper correction for the increased endogenous nitrogen metabolism of 12 molting birds on this ration the calculated protein utilization was identical.

The antiscorbutic vitamin in poultry nutrition, S. M. HAUGE and C. W. CARRICK (*Poultry Sci.*, 5 (1926), No. 4, pp. 166-172, figs. 2).—The results of experiments at the Indiana Experiment Station are presented, which show that as much as 20 cc. of egg white or 15 cc. of egg yolk daily would not cure or prevent the occurrence of scurvy in guinea pigs receiving diets otherwise deficient in the antiscorbutic vitamin. Chicks, however, grew normally on scorbutic rations, and the livers and kidneys of such chicks contained abundant supplies of the antiscorbutic substance. The authors interpret these results to indicate that the chick requires the antiscorbutic vitamin but that it is able to synthesize this vitamin within its own body.

Concerning the growth of chickens raised without grit, G. D. BUCKNER, J. H. MARTIN, and A. M. PETER (*Poultry Sci.*, 5 (1926), No. 5, pp. 203-208).—Two lots of 10 chicks each were kept confined from May 2, 1925, to January 1, 1926, at the Kentucky Experiment Station, for making a study of the need of growing chicks for grit. The feeds of the two lots, which were similar, included buttermilk, a grain mixture, mash, green feed, and cod-liver oil. Sand at first and later gravel was supplied as grit to one lot. The biweekly weights of the individual chicks showed that there was no significant difference in the growth rate of the males and females in the two lots or in the egg production of the pullets.

Analyses of the droppings for ash and residue insoluble in hydrochloric acid showed that larger amounts of both were present in the droppings from the birds receiving grit. The nature of the hydrochloric acid-insoluble residue showed that considerable sand was passing through the birds receiving it. Ash determinations of the contents of the gizzards at the conclusion of the experiment showed that there was a very small amount of ash present and nothing which could have served as a grinder in the gizzards of the birds which had received no sand. The gizzards of this lot were also slightly heavier than those of the other lot, indicating a possible enlargement to overcome the lack of grit for grinding. It thus seems that grit is not essential to the growth and egg production of White Leghorn chicks up to 8 months of age.

Does the growing chick require grit? R. M. BETHKE and D. C. KENNARD (*Poultry Sci.*, 5 (1926), No. 6, pp. 285-293).—The results of 3 experiments are reported from the Ohio Experiment Station in which chicks were successfully raised for from 12 to 28 weeks without access to grit.

In the first experiment 2 lots of 18-day-old chicks, receiving coarse ground and fine ground feed, respectively, but without access to grit, averaged 346.6

and 395.3 gm. in weight at the end of the 12 weeks. Two comparative lots having free access to granite grit averaged 353.0 and 373.5 gm., respectively, at the same age. No abnormalities or nutritional disorders were observed aside from the fact that all birds showed a tendency toward constipation.

In a second experiment 2 lots of chicks were used for comparing liquid skim milk fed ad libitum with 15 per cent dried buttermilk added to the basal ration, but no grit was fed to either group. At the age of 12 weeks, up to which time growth had been particularly successful on the liquid skim milk ration, all birds from both lots were divided into 2 groups, one of which was allowed access to grit up to 23 weeks of age. It is reported that both lots made normal growth with no signs of digestive or nutritional disturbances, and that laying was started between the eighteenth and nineteenth week in each lot. At the conclusion of the experiment the birds were killed and the digestive tracts examined. No differences were apparent except that the gizzards of the grit-fed birds were from one-fourth to one-third filled with grit, while from 2 to 10 particles of hard granular material were present in the gizzards of the other birds.

In a third experiment 2 lots of chicks were fed on muslin cloth during the first 2 weeks and on 0.5 in. mesh hardware cloth up to 28 weeks of age. Grit was furnished to one lot but not to the other. A coarse ground mixture of yellow corn and whole wheat was fed during the greater part of this experiment. The rate of growth and mortality was similar in the 2 lots, and the pullets started laying in both lots between the nineteenth and twentieth weeks. No grit was found in the gizzards of cockerels killed at the end of the sixteenth week which had received no grit during the experiment, and there was no apparent variation in the thickness or firmness of the gizzard musculature.

From the results of these experiments the authors conclude that grit is of no benefit to the birds for grinding purposes, the natural craving being due to the chickens' desire for minerals. These results are in agreement with those of Buckner, Martin, and Peter noted above.

Grit requirements of the growing chick, R. M. BETHKE and D. C. KENNARD (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, pp. 188-193).—This is another account of the experiment noted above.

The influence of certain feeds upon the production of spermatozoa by the domestic chicken, W. A. CRAFT, C. H. M'ELROY, and R. PENQUITE (*Poultry Sci.*, 5 (1926), No. 4, pp. 187-198).—In experiments conducted at the Oklahoma Experiment Station, 18 White Leghorn males were given rations containing a basal mash plus supplements in different lots of cubed white corn, cubed yellow corn, cubed white corn plus sprouted oats, and cubed white corn plus 4 per cent of cod-liver oil mixed with the mash.

Semen was collected from the cloaca of females after copulation with these males and placed in physiological salt solution. The numbers of spermatozoa and the percentage of motile spermatozoa were recorded. In the 116 samples of semen collected the numbers of spermatozoa per cubic millimeter of semen ranged from 2,000 to 4,000,000, and the percentage of motile spermatozoa from 1 to 100 in the different individuals. The males receiving the most deficient rations produced fewer sperm, but differences in the sexual activity of individuals were not entirely associated with variations in the ration. The males which were more active sexually produced a larger percentage of weak and dead sperm.

The weights of the testicles of each bird are also given as determined at the conclusion of the experiment.

The relation of the date of sexual maturity to egg production, H. L. KEMPSTER (*Missouri Sta. Research Bul.* 88 (1926), pp. 3-12, figs. 3).—This is a

complete report of the studies previously noted (E. S. R., 54, p. 762), dealing with the relation between the date on which laying starts to the seasonal and annual egg production of 1,110 White Leghorns, trap nested over a period of 7 years. The distribution of the birds according to the season of production including calculations of the usual statistical constants are presented. A third degree parabola was calculated to show the relation between the date of laying the first egg and the number or value of the eggs produced during the year. The correlation coefficients calculated with the date of maturity were annual egg production -0.2853 ± 0.0198 , winter egg production -0.3315 ± 0.0158 , summer egg production -0.16239 ± 0.021 , rate of laying -0.1255 ± 0.021 , and date production ceased -0.10688 ± 0.021 .

It is concluded that the optimum date of sexual maturity is approximately November 1, but in order that an optimum mean date of maturity be obtained it is necessary that a considerable number of the birds of a flock start laying as early as September.

The all-mash method of feeding for egg production, D. C. KENNARD and R. M. BETHKE (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, pp. 180-187, figs. 3).—Directions for feeding layers by the all-mash method, including suggested rations.

Supplements that improve the ration for layers, D. C. KENNARD and R. M. BETHKE (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, pp. 194-197).—A series of tests of the comparative value of various supplements to a ration of grains and meat scrap indicated that the basal ration was deficient in certain supplements, but was improved by allowing exposure to the sunlight or by furnishing green forage. Green legumes improved the hatchability of the eggs, whereas cod-liver oil did not, though the latter substance lowered mortality and increased egg production in one of the two experiments.

[Broiler production at the Pennsylvania Station], M. H. BRIGHTMAN and P. H. MARGOLF (*Pennsylvania Sta. Bul.* 204 (1926), pp. 34, 35, fig. 1).—Data presented indicate that broilers can be fattened as satisfactorily under good average range conditions as by crate fattening and with less labor.

In another test of the feasibility of broiler production for the Easter trade it was indicated that in order to make winter broiler production profitable good hatches must be secured and brooder facilities must be adequate to prevent high mortality.

Turkey production, F. E. MUSSEHL (*Nebraska Sta. Circ.* 34 (1926), pp. 19, figs. 7).—Directions for turkey raising, including suggestions for the feeding, management, breeding, and control of diseases.

Fur rabbits for profit, E. B. SMITH (*London: The City & South London Ptg. & Pub. Co.*, [1925], pp. [6]+46, pls. 11).—Directions are given for the feeding, breeding, and management of fur rabbits, with suggestions on varieties, exhibiting, and the preparation of the pelts.

DAIRY FARMING—DAIRYING

[Experiments with dairy cattle at the Pennsylvania Station], S. I. BECHDEL and H. E. HONEYWELL (*Pennsylvania Sta. Bul.* 204 (1926), pp. 18-21, fig. 1).—The results of the following experiments are briefly reported:

The vitamin B requirement of the calf.—In continuing this study (E. S. R., 54, p. 373), 11 animals have received a ration deficient in vitamin B until they have been on the experiment in some cases over 2 years. The calves have grown normally to maturity, conceived, and 5 have dropped strong, healthy calves. The evidence indicates that calves do not have a requirement for

vitamin B unless the substance is synthesized by bacteria and other microorganisms in the digestive tract. The ration as used proved inadequate for lactation. The heifers went off feed in from 1 to 3 weeks after freshening and became very weak and emaciated, but the exact cause of the trouble was not definitely determined.

Ground whole buckwheat as a substitute for corn meal in the ration.—Grain rations containing one-third ground whole buckwheat and one-third corn meal were compared by the double reversal method in 3 20-day periods, using 10 Holstein cows. The buckwheat mixture proved to be somewhat inferior to the corn-meal mixture for milk production, but it is concluded that ground whole buckwheat may be used to take the place of corn meal in the dairy ration without seriously affecting milk production.

Is the vitamin B potency of milk dependent on the presence of vitamin B in the ration of the cow?—Milk from the heifers which freshened on the vitamin B rations noted above was fed at the rate of 8, 10, 12, 16, and 20 cc. per day to rats receiving an otherwise vitamin B deficient ration in order to test the potency of such milk in this substance. Such milk was found as potent in vitamin B as milk from cows fed on the usual winter ration of silage, grain, and leguminous hay. This points toward the conclusion that ruminants have the ability to synthesize vitamins through bacterial action in the digestive tract.

Soybean hay and soybean silage, C. C. HAYDEN and A. E. PERKINS (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 5, pp. 178, 179, fig. 1).—Soy bean hay fed with corn silage was compared with corn and soy bean silage for milk production by the double reversal method in an experiment running from November 28, 1923, to April 18, 1924. The results indicated practically no difference in the feed value of the soy bean hay and the silage, though the cows refused the coarse stems which constituted 13 per cent of the hay.

Sunflower silage for dairy cows (*Montana Sta. Rpt. 1925, p. 17*).—In a comparison of oat and pea silage with sunflower silage, 2 lots of 4 Jersey cows each were fed experimentally for 42 days. The results showed that 100 lbs. of dry matter of oat and pea silage, with hay and grain added, produced 273 lbs. of milk and 12.5 lbs. of butterfat, while an equal amount of dry matter from sunflower silage produced 402 lbs. of milk and 19.23 lbs. of fat. The sunflower silage is also more productive in the higher valleys.

The rôle of vitamin A in the nutrition of calves, I. R. JONES, C. H. ECKLES, and L. S. PALMER (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 119-139, figs. 11).—This paper reports studies of the vitamin A requirements of Holstein calves conducted at the Minnesota Experiment Station. Six experimental and three control animals, of which the dams' feeding during gestation was known, were used in the investigation. With some modifications the experimental animals were fed vitamin A deficient diets, beginning soon after birth, which were composed of oxidized whole milk or skim milk, and later skim milk powder, white corn, wheat straw, lemon juice, calcium carbonate, and calcium phosphate. The control animals received cod-liver oil as a source of vitamin A. The vitamin A deficiency of the individual feeds was checked in experiments with rats. The feeding, growth record, and condition of each calf are reported.

The combined results show that calves require vitamin A the same as other species of animals. Cod-liver oil in amounts of 20 cc. daily protected two calves from evidence of vitamin A deficiency, though the necessary amount might have been less. One calf receiving 40 per cent of wheat straw in the ration made normal growth, while another calf on the same ration but consuming less wheat straw showed symptoms of vitamin A deficiency, probably

due to differences in vitamin A storage at birth. Calves suffering from a deficiency of this vitamin in the ration improved almost immediately when cod-liver oil was administered.

The livers of calves receiving rations containing vitamin A were rich in this substance, but it was absent from the livers of calves receiving the deficient diets.

Calves raised on whole and skim milk plus a roughage containing vitamin A are not likely to suffer from a lack of this substance, but where cows receive mainly dry feed and calves are raised on milk substitutes such troubles may occur.

Genetics of breeding better dairy stock, J. W. GOWEN (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 153-170, figs. 4).—This is largely a discussion of the relation between the milk production and the butterfat percentage of the milk from related animals as obtained from other studies at the Maine Experiment Station of Holstein and Guernsey Advanced Registry records.

Increased producing ability in dairy cows due to test conditions, M. H. FOHRMAN (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 215-218).—A comparison of the effect of age on the butterfat production of Jersey and Guernsey cows as determined by initial and reentry records showed that the reentry records indicated greater increases than were to be attributed to age. The difference is considered as due to the development resulting from the first test, and amounted to 12.2 per cent of the reentry records for the Guernseys and 11 per cent for the Jerseys.

A quantitative form of expressing persistency of milk or fat secretion, C. W. TURNER (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 203-214, fig. 1).—In previous studies (*E. S. R.*, 51, p. 379) it has been shown that the monthly milk and fat production of cows declines as a constant percentage of the preceding month's production after the maximum is reached and when not complicated by unusual conditions or pregnancy. Indexes for persistency of production were derived as the average monthly decline during a lactation period and as the ratio between the total production and the highest month's production. The latter approaches a maximum of 12 in yearly records, and a maximum of 10 in 305-day records. The ratios associated with various rates of decline in fat production are tabulated and charted. From these the annual production may be estimated from the decline during the first few months after the maximum of production by multiplying the equivalent ratio by the maximum month's production.

The variation in the relation between the maximum month's and total production is shown among 5,396 Guernsey cows in which the coefficient of correlation was 0.761 ± 0.004 .

Practical uses in the selection and breeding of dairy cattle of this quantitative index of persistency are pointed out.

The effect of environmental temperature on the percentage of fat in cow's milk, W. P. HAYS (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 219-235).—In studying the effect of temperature on the fat percentage of milk the percentage of fat of the milk of the Missouri Experiment Station herd was determined for 258 days and compared with the average daily temperature when the cows were in and out of doors. With decreases in the average temperature from 86.5 to 49.7° F. the fat percentage gradually increased from 3.171 to 3.505 per cent, but there was a decrease to 3.463 per cent at 40.1° which was unexplainable.

In another experiment two Jersey cows were kept at constant temperatures of approximately 30, 40, 50, 60, 70, 80, and 90° until the fat percentage of the milk became relatively constant. The periods varied in length from 4 to 8

days. In each of the tests the fat percentage was distinctly different on the first day. The average results of these tests are summarized in the following table:

The effect of control of temperature on fat percentage of milk

Trial	Period	Average temperature for entire trial	Average milk per day	Average fat content for entire trial	Trial	Period	Average temperature for entire trial	Average milk per day	Average fat content for entire trial
	<i>Days</i>	<i>° F.</i>	<i>Pounds</i>	<i>Per cent</i>		<i>Days</i>	<i>° F.</i>	<i>Pounds</i>	<i>Per cent</i>
1.....	8.0	92.7	20.8	5.388	4.....	5.0	52.3	21.3	5.646
6.....	4.0	80.0	21.6	5.227	3.....	6.5	39.9	20.2	6.099
2.....	6.0	72.5	20.5	5.149	7.....	5.0	27.0	18.4	6.012
5.....	4.0	60.9	21.0	5.424					

The physiology of temperature regulation in animals is discussed, and it is pointed out from these results that the lowest fat test occurs between 70 and 90°, while variations either way increase the fat percentage, probably due to increased metabolism. Between 70 and 30° the fat percentage increases approximately 0.2 per cent for each 10° reduction in temperature.

The Babcock test for fat in milk and cream, A. D. BURKE (*Oklahoma Sta. Circ. 65 (1926), pp. 14, figs. 12*).—This includes directions for testing milk and cream for butterfat and the text of the Oklahoma law.

[**Experiments with dairy products at the Pennsylvania Station**], F. J. DOAN, C. D. DAHLE, W. J. CAULFIELD, H. B. PIERCE, ET AL. (*Pennsylvania Sta. Bul. 204 (1926), pp. 21-25*).—The results of the following experiments are briefly reported:

Methods of processing chocolate milk and their effect on cocoa separation, cream separation, and general quality.—The preparation of chocolate milk from raw or pasteurized milk was unsatisfactory because of the unsightly cream layer and the presence of sediment. Homogenization prevented the formation of the cream layer, and when two valves were used at low pressure the smallest amount of sediment was deposited. The use of gelatin was of no benefit, but the plain condensed skim milk or fluid skim milk replacing all or a portion of the water used in the sirup was advantageous, since it increased the viscosity of the finished product.

Studies in "cream line" formation.—The temperature of pasteurization did not appear to affect the creaming ability unless it was higher than 212° F. Additions of solids-not-fat in the form of plain condensed skim milk or skim milk powder did not increase the creaming ability, while clarification of raw milk decreased creaming, and clarification of hot milk intensified the effect, though milk held at a low temperature for several hours and clarified at 85° F. showed an increase in the creaming ability. Mixing fresh raw cream and skim milk had only a slight but variable effect on the amount of cream rising, but the mixing of pasteurized skim milk with raw cream produced a considerable loss in creaming. Homogenization of the milk reduced the volume of cream at all pressures, but when the cream only was homogenized an enormous increase in the cream volume was observed.

Factors affecting time, temperature, and overrun in freezing ice cream.—In this study the addition of ingredients which lowered the freezing point increased the time of freezing and whipping. Those ingredients lowering the freezing point were serum solids, cane and corn sugar, and various flavors.

Overrun was obtained more quickly with brine at low temperatures than with brine at high temperatures.

One of the most important factors influencing overrun was the temperature of the mix when the brine was shut off. Aging from 4 to 24 hours did not affect the time required to produce a 100 per cent overrun, though aging improves the texture of finished ice cream, but those mixes aged for 4 hours only were very satisfactory.

Relation between "gold number" and other tests in selection of gelatin in ice cream manufacture.—Irregularities observed in the relation of the gold number to the jellying value of gelatins for ice cream making indicate that the knowledge of the gold number is of little use in denoting the merits of a gelatin for ice cream making.

Factors affecting the freezing point of ice cream.—The results of comparative tests in which corn sugar replaced cane sugar on a dry-weight basis or on an actual-weight basis indicated that the substitution of corn sugar for part or all of the cane sugar considerably lowered the freezing point. Flavors such as strawberries, orange-pineapple, and chocolate were found to lower the freezing point and increase the time of freezing before the brine was shut off, as well as the total time required to freeze the mix and obtain the desired overrun.

Some factors affecting the growth of certain strains of *P. roqueforti* blue mold, H. N. S. GOLDING (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 236-242, figs. 2).—The influence of salt on the rate of growth in milk and in standard media of four strains of *Penicillium roqueforti* has been investigated in continuing this series (E. S. R., 55, p. 873).

Salt was added to each type of media in amounts of 4, 8, 12, and 16 per cent. The relative ability of the different strains to grow in different concentrations of salt showed that salt concentrations as usually found in Roquefort cheese would retard the growth of these strains, but that the amount of salt in Wensleydale cheese would not be an inhibiting factor.

An algebraic method of proportioning ice cream mixes, W. V. PRICE (*Jour. Dairy Sci.*, 9 (1926), No. 2, pp. 243-250).—An algebraic method of proportioning the ice cream mix for the production of a standard type of ice cream is described which has proved satisfactory at Cornell University. The amounts of materials other than milk to be used are first determined directly, and then the amounts of milk products are found by solving suitable equations.

VETERINARY MEDICINE

[Work in veterinary medicine at the Kentucky Station] (*Kentucky Sta. Rpt. 1925, pt. 1, pp. 16, 17*).—In work with sterility in mares it was found that by not breeding mares with genital infections, by the proper handling of mares with functional disturbances, and by the correct application of even the simplest forms of cleanliness during the breeding season the percentage of foals in a number of studs was raised from 50 and 60 per cent to 75 and 80 per cent.

Reporting on vaccination work, it is stated that, of the 1,786 mares vaccinated in 47 different herds in 1924, 15 aborted, but the *Bacterium abortivo equinus* was not incriminated as the causal agent, 2 of the abortions being caused by *Streptococcus genitalium*, 7 by bad feed, 1 mare aborted twins, and no cause could be assigned for the remaining 5 abortions. During the fall of 1925 the *Streptococcus* was found in the internal organs of 5 aborted fetuses, indicating that this organism is the cause of some abortions among mares. Vaccination work was also conducted with cows and sows.

[**Work with livestock diseases at the Montana Station**] (*Montana Sta. Rpt. 1925, pp. 31, 32*).—Tests made by the station have demonstrated that small doses of potassium iodide fed to pregnant animals will prevent goiter in the young. The expense of feeding the potassium iodide can be reduced approximately to 1 ct. per sheep per year by mixing 1 oz. with 100 lbs. of stock salt. This method was tried out with several large bands of sheep and proved most effective and economical for controlling goiter in newborn lambs, the lambs not only being free from goiter but better and stronger as a whole.

Experiments in 1921 with blackleg, which is increasing among the sheep of the State, indicated that 2.5 cc. of vaccine, which is one-half the standard dose of vaccine for cattle, was sufficient to protect sheep, but this dosage produced material depression and shock in the sheep for several hours after the vaccination. Several experiments conducted have shown that 2 cc. of aggressin is the smallest safe dose for sheep. The experiments showed that 12 days should elapse before the sheep are exposed in pens and corrals known to be infected. The apparent depression or shock from vaccination was found by close observation to be only temporary in character, having no bad effect on the sheep after from 18 to 24 hours.

[**Annual reports of the chief veterinary officer of Kenya Colony for the years 1924 and 1925**], A. G. DOHERTY (*Kenya Colony Dept. Agr. Ann. Rpts. 1924, pp. 48-62; 1925, pp. 43-67, pl. 1*).—The occurrence of and work with infectious diseases of livestock are reported for 1924 and 1925.

Report of the chief veterinary research officer, J. WALKER (*Kenya Colony Dept. Agr. Ann. Rpts. 1925, pp. 68-124, pls. 2*).—The research work of the year 1925 with infectious diseases of livestock is reported upon.

The precipitin reactions of extracts of various animal parasites, L. HEKTOEN (*Jour. Infect. Diseases, 39 (1926), No. 4, pp. 342-344*).—Experiments here reported indicate that the precipitin reactions of materials derived from animal parasites follow the general law of species-specificity. The only exception to this rule seems to be the reaction of extract of *Setaria equina*, which in its classification is far removed from the ascarids, with precipitin serum against *Ascaris albumin*.

The X-ray diagnosis of animal parasites (helminths) in man, J. F. BRAILSFORD (*Vet. Jour., 82 (1926), No. 615, pp. 451-466, figs. 9*).—It is pointed out that the possibility of X-ray diagnosis depends on the calcification of the parasites or their location in the body.

Growing plants as possible carriers of anthrax, H. MORRIS and H. K. RILEY (*Louisiana Stas. Bul. 196 (1926), pp. 4-16*).—This is a report of investigations, based upon a series of experiments started in 1924 with a view to obtaining definite information as to possible forage contamination with anthrax spores.

The results indicate that under laboratory conditions anthrax spores were carried from artificially inoculated soil by germinating and growing plants, including corn, oats, rice, and beans. A few tests showed that the spores were also carried from the soil by Bermuda grass and bull grass. The spores were carried from the soil on the surface of the plant and not in the plant tissue. Washing the plants with water for three consecutive days removed only a portion of the anthrax spores. The findings emphasize the importance of sanitation in the control of this disease, and especially the necessity for complete destruction of anthrax carcasses to prevent soil inoculation and subsequent spread of the disease through forage contamination.

Cultivation of Rickettsia-like microorganisms from the Rocky Mountain spotted fever tick, *Dermacentor andersoni*, H. NOGUCHI (*Jour. Expt. Med.,*

43 (1926), No. 4, pp. 515-532, pls. 4).—A systematic study made by the author of 74 ticks of the species *D. andersoni* (= *D. venustus* Banks), the infectivity or noninfectivity of which was determined by biting experiments, inoculation of emulsions, and specific immunity tests, showed the presence in some instances of several types of microorganisms morphologically resembling the inciting microorganisms of spotted fever. Descriptions are given of these organisms, of which *Bacillus rickettsiformis* n. sp. was most frequently isolated and *B. pseudoxerosis* n. sp. and *B. equidistans* n. sp. less commonly encountered. These organisms are nonpathogenic for the guinea pig, rabbit, and *Macacus rhesus*.

Undulant fever from *Brucella abortus*, C. M. CARPENTER and H. E. MERRIAM (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 16, pp. 1269-1271, fig. 1).—This is a detailed report of two cases of infection in students at Cornell University in 1925 due to *B. abortus*, previously referred to by Moore and Carpenter (*E. S. R.*, 55, p. 575). Recent reports of infection in man with *B. abortus* by Keefer (*E. S. R.*, 50, p. 684) and Evans (*E. S. R.*, 54, p. 872) have been noted. L. J. Orpen is said to have described cases in Rhodesia.¹

A study of the value of the living vaccine in the control of bovine infectious abortion, R. E. LUBBEHUSEN, C. P. FIRCH, and W. L. BOYD (*Cornell Vet.*, 16 (1926), No. 3, pp. 166-185; also *Minnesota Sta. Tech. Bul.* 43 (1926), pp. 166-185).—This is a report of experimental work projected during the summer of 1922 and of a detailed observation on the efficiency of the living vaccine under farm conditions and natural infection. An earlier report has been noted (*E. S. R.*, 51, p. 783).

The work has led to the conclusion that although some degree of immunity toward *Bacterium abortum* Bang is induced by the use of the vaccine, it does not reduce the abortion rate to a desirable minimum and should never be used in other than badly infected herds. Individual susceptibility to *B. abortum* infection was found to be extremely variable. The use of the living vaccine did not increase the number of animals which eliminated *B. abortum*. Some animals eliminated *B. abortum* without showing serologic evidence of infection. The authors were unable to demonstrate that vaccination retards conception, nor that increased sterility is directly associated with the use of the living vaccine. Clinical data on vaccinated and control groups are given in four infolded tables that are appended.

An experimental study on the pathology of the black-leg, H. MORITA (*Jour. Japan. Soc. Vet. Sci.*, 5 (1926), No. 1, pp. 1-10; *Jap. abs.*, pp. 7-10).—This abstract of the author's original paper in Japanese² has been previously noted from another source (*E. S. R.*, 55, p. 70).

A study of contagious pleuropneumonia in imported cattle [trans. title], S. ONO (*Jour. Japan. Soc. Vet. Sci.*, 4 (1925), No. 1, pp. 9-48, pls. 4; *Eng. abs.*, pp. 45-48).—It is pointed out that, while this disease is widespread in Asia, particularly in Russia and India, Japan was quite free from it until September, 1924, when three cases were discovered by the author at the Yokohama quarantine station among 42 head of cattle imported from Dairen, China. Pathological studies of the three cases are reported upon.

Further notes on contagious pleuropneumonia in imported cattle [trans. title], S. ONO (*Jour. Japan. Soc. Vet. Sci.*, 4 (1925), No. 3, pp. 245-258, pl. 1; *Eng. abs.*, pp. 257, 258).—The author reports that in May, 1925, eight months after the first occurrence of pleuropneumonia among cattle imported from China to Japan, as above noted, the disease again broke out in the city of

¹ So. African Med. Rec., 22 (1924), p. 75.

² Japan. Jour. Expt. Med., 8 (1924), No. 10.

Osaka and rapidly spread to the five neighboring prefectures, 124 cows being found affected and 656 treated as exposed to infection. A brief account is given of cultural and inoculation studies of the organism.

Appearance of contagious pleuropneumonia in cattle in Japan [trans. title], (*Jour. Japan. Soc. Vet. Sci.*, 4 (1925), No. 3, pp. 329, 330).—An account is given of the appearance of this disease in Japan in September, 1924, and May, 1925, as noted above. The work of eradication is briefly reported upon, and the belief is expressed that the disease will soon be stamped out.

Lameness in lambs, H. R. SEDDON (*Agr. Gaz. N. S. Wales*, 37 (1926), No. 8, pp. 563-567).—This is a review of the present knowledge of lameness in lambs.

New cases of contagious pustulous dermatitis of swine, H. FUTAMURA (*Jour. Japan. Soc. Vet. Sci.*, 5 (1926), No. 1, pp. 11-13; *Jap. abs.*, p. 13).—A pustulous skin disease long recognized as an epizootic disease among swine in Japan, severe outbreaks of which have occurred since 1917, has been found to be due to a streptococcus isolated from the pustules. It is thought that natural infection in swine is probably favored by injury of the epidermis caused by the bite of insects such as mosquitoes, flies, etc.

Contribution to the biological and serological study of *B. abortus equi*, S. FUJIMURA, T. TOYOSHIMA, and T. SUENAGA (*Jour. Japan. Soc. Vet. Sci.*, 5 (1926), No. 1, pp. 15-20; *Jap. abs.*, pp. 19, 20).—In investigations at the veterinary laboratory of the Ministry of Agriculture and Forestry, Nishigahara, Tokyo, it was found that *Bacillus abortus equi* can be separated from the various members of the paratyphoid-enteritidis group as a specific bacillus and is perhaps the only organism causing abortion in mares.

Ultraviolet radiation as a therapeutic agent in veterinary medicine, J. W. PATTON (*Jour. Amer. Vet. Med. Assoc.*, 69 (1926), No. 6, pp. 734-758, figs. 3).—The author discusses the subject at length, much of the data being presented in tabular form, and reports upon experiments with dogs suffering from distemper and chorea, in which he used the mercury vapor quartz lamp.

From the results obtained he concludes that ultra-violet radiation apparently has no direct beneficial therapeutic value in the treatment of so-called distemper in dogs. It does not appear to prevent those suffering from the disease from later developing chorea. Chorea apparently is little benefited by radiation. The antigen-antibody phenomenon would appear to be slightly assisted by radiation. The hemoglobin content of the blood appears to be raised by radiation, as are also the cellular constituents, with the exception of the polymorphonuclear leucocytes, which show an actual decrease. The hair coat, at least in the heavier and long-hair breeds, appears to retard penetration of the rays to the skin of dogs.

Internal parasites in poultry, M. H. BRIGHTMAN (*Pennsylvania Sta. Bul.* 204 (1926), pp. 33, 34).—Reference is made to the treatment of poultry with many of the known anthelmintics, none of which were 100 per cent effective. It was found that in a fowl nearing maturity there was slight chance of complete recovery even though the parasites were removed. Preventive measures are recommended.

On the intermediate host of *Fasciola hepatica* in Japan, M. SHIRAI (*Tokyo Imp. Univ., Govt. Inst. Infect. Diseases Sci. Rpts.*, 4 (1925), pp. 441-446).—The author reports that the miracidia of the liver fluke were found to fairly penetrate into *Lymnaea peruvia*, which has not been known as the intermediate host in Japan, gradually grow in it, and in a period of from 45 to 70 days become mature cercariae. If rabbits and guinea pigs were fed with encysted cercariae developed in *L. peruvia*, they were well infested, having the young worms in the liver and other organs. Regarding the migrating route of young worms, the

author confirms Ssinitzin's finding (E. S. R., 31, p. 758) that the young worms penetrate through the intestinal wall and come into the peritoneal cavity in order to get into the liver.

Cecal abligation in fowls, A. J. DURANT (*Vet. Med.*, 21 (1926), No. 8, pp. 392-395, figs. 2).—In this contribution from the Missouri Experiment Station the author reports having found cecectomy in chickens and turkeys for the removal of the cecal habitat of coccidia and *Heterakis papillosa* to be a difficult and unsatisfactory operation. The difficulties encountered led to the development of a comparatively simple operation, merely that of tying off the cecal pouches at their junction with the main gut, leaving the ceca in place without any surgical disturbance to the mesenteric attachments and blood supply. The author uses the term abligation to differentiate this operation from cecectomy. The ligation ultimately effects a complete severance of the ceca from the main gut, and the stumps produced by the ligature wounds heal over in most cases so perfectly as to prevent any leakage from the functional gut or from the detached ceca.

The operation has been performed successfully on fowls varying in age from chicks three weeks old to adult birds, both male and female. Birds most suitable in size, however, are those that weigh from 20 to 30 oz. In the case of turkeys five weeks old poults have been operated upon with good results. The limits of size and age that will be safe for turkeys have not been determined. —The technique is described.

Poultry disease control, F. A. LAIRD (*Jour. Amer. Vet. Med. Assoc.*, 69 (1926), No. 6, pp. 717-723).—In this account the author deals with sanitation and hygiene, bacillary white diarrhea, and avian tuberculosis.

The relationship between the amount of electrical charge and the agglutination capacity of bacteria, M. W. LISSE (*Pennsylvania Sta. Bul.* 204 (1926), p. 6).—Sufficient work is said to have been done by the author, in cooperation with R. P. Tittsler, on the problem of measuring the rate of cataphoresis and the agglutination capacity of strains of *Salmonella pullora* bacteria which cause bacillary white diarrhea in chicks to show (1) that the methods being used are suitable and accurate, (2) that there are large differences in charge and agglutination capacity for the 24 strains studied, and (3) that a positive answer will probably be obtained. This means that strains carrying a slight charge, and which, therefore, are already near the isoelectric point, are easily agglutinated, whereas those carrying a high charge are agglutinated with difficulty.

Technical studies upon bacillary white diarrhea, R. P. TITTSLER (*Pennsylvania Sta. Bul.* 204 (1926), p. 26).—Brief reference is made to studies of variations existing between strains of *Salmonella pullora*, 90 of which strains were used. It was found that the agglutinability is the most important variation, as some strains were encountered which agglutinated so poorly that if used in the agglutination test for carriers of bacillary white diarrhea the test would be worthless. These variations existed when the medium was uniform. No correlation was found between the agglutinability and the length of time the strains were carried in stock on artificial media. Reference is made to the electrophoretic studies being made cooperatively, as noted above.

Fowl pest in geese [trans. title], H. MIESSNER and R. BERGE (*Deut. Tierärztl. Wehnschr.*, 34 (1926), No. 21, pp. 385-393, figs. 10; abs. in *Trop. Vet. Bul.*, 14 (1926), No. 3, pp. 116, 117).—This is a report of investigations of fowl pest, which disease appeared in two shipments of geese from northern Italy. It resulted in the death of 81 of 210 geese in the first shipment and of 40 of 96 geese in the second shipment. Clinical and bacteriological studies are reported upon. Pigeons were infected by the virus from hens, geese, and pigeons. The

filtrability of the organism was established by inoculation experiments with the hen. In contact experiments negative results were obtained. A list of references to the literature is included.

AGRICULTURAL ENGINEERING

Research in agricultural engineering, 1925, R. W. TRULLINGER (*Agr. Engin.*, 7 (1926), Nos. 8, pp. 279-282; 9, pp. 312-317).—A critical analysis of typical research in agricultural engineering during 1925 is presented, together with a brief review of the more important results, the purpose being to indicate the type of work which was done during the year, to show something of its scope, and to draw attention to important lines of inquiry requiring further consideration. The general subjects dealt with are machinery, structures, irrigation, drainage, power, sewage disposal and water supply, materials, land clearing, and soil erosion.

The conclusion is drawn that the character of the research in agricultural engineering is improving. A great deal of comparative experimenting and testing of a local nature is still going on, but the tendency is to recognize the importance of establishing the broadly applicable fundamental principles governing the performance of agricultural operations.

The engineer and the soil—an orientation for reclamation, R. W. TRULLINGER (*Agr. Engin.*, 7 (1926), No. 7, pp. 243-245).—In a contribution from the U. S. D. A. Office of Experiment Stations a brief analysis is presented of the engineering features of soil moisture control which require fundamental study. A list of 99 references to literature bearing on the subject is included.

Relation of water to yield of crop (*Montana Sta. Rpt. 1925*, pp. 19, 21).—Data are briefly reported which showed that the largest number of irrigations and the maximum amount of water applied gave the largest acre yield of alfalfa, but the yields were in no way proportionate to the amount of water applied. The time of application of the water was also an important factor. The yield of wheat was found to have little relation to the amount of water applied.

Character of the groundwater resources of Arizona, C. N. CATLIN (*Arizona Sta. Bul. 114* (1926), pp. 173-293).—Analyses of a large number of samples of the ground waters of Arizona are presented and discussed, with particular reference to their value for sanitary and irrigation purposes.

Surface water supply of Pacific slope basins in Washington and upper Columbia River basin, 1924 (*U. S. Geol. Survey, Water-Supply Paper 592* (1926), pp. V+178, pls. 3).—This report, prepared in cooperation with the States of Washington, Montana, and Idaho, presents the results of measurements of flow made on streams in these basins during the year ended September 30, 1924.

Daily river stages at river gage stations on the principal rivers of the United States, H. C. FRANKENFIELD (*U. S. Dept. Agr., Weather Bur., Daily River Stages*, 23 (1925), pp. II+279).—This volume, containing the daily river stages for 1925, constitutes the twenty-third of a series of reports on the subject (*E. S. R.*, 53, p. 788).

Public Roads, [October, 1926] (*U. S. Dept. Agr., Public Roads*, 7 (1926), No. 8, pp. 153-176+[2], figs. 26).—This number of this periodical contains the status of Federal-aid highway construction as of September 30, 1926, together with the following articles: Simplified Soil Tests for Subgrades and Their Physical Significance, by C. Terzaghi; Direct Production Costs of Broken Stone, by G. E. Ladd; Concrete Compared with Timber for Highway Bridge Floors, by O. L. Grover; and The Strength of Mortar and Concrete as Influenced by the Grading of the Sand, by T. C. Powers.

A preliminary experiment on the supporting strength of culvert pipes in an actual embankment, M. G. SPANGLER (*Iowa Engin. Expt. Sta. Bul. 76 (1926), pp. 31, figs. 23*).—The results are reported of a preliminary study conducted in cooperation with the U. S. D. A. Bureau of Public Roads to determine, for different kinds of culvert pipe, embankment materials, and field conditions, the ratios between the supporting strengths which culvert pipe can safely be counted upon to develop in actual use and the laboratory strengths of such pipes when tested by standard methods. Ten sections, each 23.5 in. long, of practically unreinforced 36-in. concrete culvert pipe with shields 3 in. thick, were tested in an embankment which was built up gradually to a height of 10 ft. above the top of the pipe. The measurements of side pressures were made by the use of 6 earth pressure cells. Laboratory tests were also made of 5 similar pipes using 3-edge bearings.

The culvert pipes cracked under heights of embankment ranging from 4 to 8.5 ft. above the top of the culvert, but none of the pipes collapsed or deformed extensively under the loads imposed by an embankment 10 ft. high above the top of the culvert. The settlement of the rigid culvert pipes was many times greater than any lowering of their tops from shortening of their vertical diameters under the loads. The ratio of actual supporting strength to 3-edge bearing laboratory test strength was approximately 2.6 at first crack in this experiment. Without the help of the active side pressure the ratio would have been about 1.9. The side pressure varied widely, showing a range equal to 158 per cent of the smallest result. However, the results confirmed the conclusion previously reached by the station that the active horizontal pressure in a mass of granular materials can be computed with fair accuracy by Rankine's formula for horizontal earth pressures.

These results alone are considered inadequate to warrant the drawing of general conclusions as to the safe ratio between the field supporting strengths and the laboratory test strengths of culvert pipe.

Laboratory investigations of the influence of curing conditions and various admixtures on the life of concrete stored in sulfate solutions as indicated by physical changes, D. G. MILLER (*Amer. Soc. Testing Materials Proc., 24 (1924), pt. 2, pp. 847-861, figs. 8*).—Studies conducted by the University of Minnesota in cooperation with the U. S. Department of Agriculture and the Minnesota Department of Drainage and Waters are reported (*E. S. R., 55, p. 880*).

The results indicate that concrete, regardless of how well cured in water, must subsequently be allowed to dry thoroughly and harden before being exposed to the action of sulfate bearing waters if great resistance to attack is to be expected. Since no evident physical deterioration had taken place in one year in concrete cylinders cured in water vapor at or near the normal boiling temperature for water, the resistance of concrete so cured to sulfate bearing waters is deemed markedly greater than that of water cured cylinders.

The addition of powdered blast furnace slag to concrete up to 40 per cent of the weight of the concrete apparently had little or no influence on the strength and absorption, although the resistance to sulfate waters was increased to a degree closely proportional to the quantity of slag added. Ironite added to concrete up to 10 per cent of the weight of the cement had but slight influence on the strength and absorption, although the life in the sulfate solutions increased with the amount of ironite added. The life of specimens in sulfate solutions was also increased about 20 per cent by adding 4 per cent of calcium chloride or 4 per cent of Cal.

The use of a siliceous material in the form of volcanic ash as an admixture increased the life of specimens nearly 70 per cent when as much as 20 per

cent by weight of the cement was added. The results were negative for amounts less than 20 per cent, and the resulting loss in strength was about 30 per cent, so that it is considered probable that the utility of this material as a means of developing resistance to sulfates is very limited.

Both high calcium and high magnesium hydrated lime gave negative results on the life of concrete in sulfate solutions when used in proportions of 5 and 10 per cent. Alkagel A in the proportions of 1.5 and 3 per cent also gave negative results, as did water-gas tar in the proportion of 5 per cent.

Twenty per cent of water-gas tar caused more than 50 per cent of loss in the strength of concrete cylinders. Although the life of the specimens in the sulfate waters was about 50 per cent above that of normal cylinders, due to the water repellent qualities, the results are taken to indicate that the use of water-gas tar is not feasible.

Research in mechanical farm equipment, J. B. DAVIDSON (*U. S. Dept. Agr., Bur. Pub. Roads, 1926, pp. [2]+93*).—This report is discussed editorially on page 101.

The development of the disk plow, R. C. INGERSOLL (*Agr. Engin., 7 (1926), No. 5, pp. 172-175, figs. 3*).—A brief history of the development of the disk plow is presented, together with some data on factors involved in design.

Control of the corn borer by machinery, C. O. REED (*Agr. Engin., 7 (1926), No. 9, pp. 305-308, figs. 7*).—The preliminary results of studies conducted at the Ohio State University on the control of the corn borer by machinery are briefly reported, and 11 methods which are to be tried out are outlined.

It has been found that in areas where it has been the practice to leave cornstalks standing the corn borer can be effectively controlled by machinery which simply combines machine elements now used in independent operations, without a material increase in cost of harvesting over present methods. Although some of the proposed 2-row harvesters compare very favorably in cost of operation with the 1-row outfits, their higher initial cost has been found to handicap their introduction. While the cutter head or combination cutting and shredding head type of machine seemed to have a slight advantage, the number of experiments was too small to permit the drawing of conclusions.

After the stalks are cut close to the ground and removed from the field, practically all of the larvae therein must be destroyed. Such stalks may be fed whole and the residue carefully segregated and burned in the spring prior to the emergence of the larvae. It has been found more practical and effective, however, to shred the stalks, leaves, and husks prior to feeding.

Preliminary data from incomplete experiments with both the cutting and shredding types of husker-shredder indicate that the borer mortality computed early in the following spring ranges from 95 to 100 per cent. Notwithstanding the fact that extremely high pressures were employed, the destruction of borers by crushing stalks between two large corrugated rollers was not nearly complete enough. Plowing under of crop residues was also unsuccessful, since many borers were found to crawl to the surface when buried a foot deep.

The conclusion is drawn that if any trash appears, even after weathering or harrowing, plowing under is a failure as a control measure.

A new machine to combat the grape leaf hopper, J. P. FAIRBANK (*Agr. Engin., 7 (1926), No. 7, p. 240, figs. 4*).—A machine is briefly described and illustrated which blows calcium cyanide dust in and through four nozzles placed to direct the dust upward, downward, and sidewise. The dust is carried by air blasts through flexible metal tubes which come from a standard make of dusting machine. The whole outfit is carried on framework built upon a tractor which carries the assembly and drives the duster. Two tents are

carried by the framework, each astride a vine row. The tents are 18 ft. long and arranged with flaps at either end, which closely surround the vines. The tractor travels at a rate such that each vine is under the fume-filled tent for about 8 seconds.

Preliminary report of an investigation into the artificial drying of crops in the stack (*Oxford Univ., Inst. Agr. Engin. Bul. 2 (1926), pp. 104, pls. 8, figs. 32*).—Studies conducted by the Institute of Agricultural Engineering of the University of Oxford, England, are reported.

In the first series of experiments air at atmospheric temperature was successfully used for the drying in the stack of peas, beans, and cereals, but it is considered highly questionable whether any dependence can be placed on the method, since under adverse weather conditions the results have been a failure. In cold, damp weather or under conditions where the natural heat of a stack was low the method proved totally inadequate.

The second series of experiments dealt with the use of heated air. The average air temperature was 67° F. at 85 per cent relative humidity, and the temperature of the heated air at the duct was 97°. The volume of air used was 2,800 cu. ft. per minute. The number of stacks dried successfully demonstrated the practicability of the system. During the course of the experiments the volume of air supply was increased to 5,000 cu. ft. per minute.

A third series of experiments showed that, when there was sufficient heat and the volume of air was so regulated as to obtain the necessary heat reaction inside the material, the drying was successful.

Laboratory studies on the development of the drying apparatus showed that with cylindrical and conical center chambers the slope of the center chamber did not influence the formation of eddy currents if the blast of air was previously allowed to spread gradually in the duct without losing its stream line motion, and provided the velocity of the air was low. The penetrability of a stack was found to vary according to its height. With an equal thickness of stack around a cylindrical center chamber the penetrability at the bottom was less than at any point higher up. The design of the center chamber was found to be influenced by the fact that the action of rapid drying caused a stack to consolidate quickly and decrease in height within a few hours. It was therefore necessary to design the center chamber so as to insure equal distribution of the air after consolidation had taken place.

With the sloping trench opposite the duct outlet there was a considerable amount of turbulence inside the center chamber. When the sharp angles of the trench were rounded off a satisfactory distribution was obtained. Within certain limits an increase in the velocity of the air delivery appeared to have little effect on turbulence.

During the drying of sugar beet cosettes the resistance gradually decreased as the moisture content was reduced, and the dried material had a resistance approximately equal to 25 per cent of that of the original wet material. The shrinkage during drying was approximately 50 per cent. Wet and dried cosettes obeyed the same laws with regard to air velocity and thickness of material.

Experiments on the porosity of hay showed that to avoid undue resistance to the passage of air the average velocity of the air through the material must not exceed 20 ft. per minute. This fact definitely fixes the size of the center chamber for a given mass of hay.

It was further found that a temperature of 150° with any quantity of moisture present will effectively kill germination in seeds, and that a temperature of 140° in the presence of moisture will greatly reduce germination, re-

dering the grain unfit for malting purposes. However, when a temperature of 120° is reached in a moist state there is an increased speed of germination and a more uniform sample is produced. Heating in a dry state appeared to cause little actual damage to the seeds, aside from a slight retardation of germination. It was found that in practice if the duct temperature is 160° the cooling effect due to evaporation considerably reduces the air temperature, and not until the material has a reduced moisture content does the stack temperature approach that of the ingoing air. Therefore a duct temperature of 140° is considered to be perfectly safe for crops grown for seed.

Several appendixes relating to supplementary experiments and to the mechanical details of the apparatus used are included.

Grain storage, drying, and shrinkage problems, E. W. LEHMANN (*Agr. Engin.*, 7 (1926), No. 8, pp. 269, 270, fig. 1).—The results of studies conducted at the Illinois Experiment Station are briefly reported, from which the conclusion is drawn that for quick drying and a minimum loss of grain forced heated air is the most effective. Very good results may also be secured with a well designed crib and good natural ventilation, provided by an aerator and some sort of ventilating ducts to draw the air through the corn.

Results from artificial lighting of laying houses, G. W. KABLE (*Agr. Engin.*, 7 (1926), No. 9, p. 304, fig. 1).—The results of studies conducted at the Oregon Experiment Station are reported graphically. The conclusion is drawn that lighting intelligently applied has the effect of smoothing out the egg production curve, transferring enough eggs from the low-price seasons to those of high price to pay all costs and yield a good profit.

An economical fire-heated hotbed, J. C. C. PRICE (*Mississippi Sta. Circ.* 65 (1926), pp. 7, figs. 5).—A flue-heated hotbed is described, and working drawings are presented.

RURAL ECONOMICS AND SOCIOLOGY

[Investigations in agricultural economics at the Kentucky Station] (*Kentucky Sta. Rpt.* 1925, pt. 1, pp. 6-12).—A number of projects are reported upon.

Costs, returns, and profits for tobacco.—The study, covering 6 years in the Burley region and 5 years in the dark tobacco region, gave the following data, respectively, for the farms studied in the 2 sections: Acres of tobacco per farm 7.7 and 9.4, yield per acre 1,064 and 794 lbs., man labor per acre 330.4 and 252 hours, and horse labor per acre 97.6 and 84.3 hours. Tables are given showing for each kind of tobacco the percentage each cost item was of the total cost and the percentage of the total man labor hours expended in different operations. Man labor, horse work, barn and sticks, and use of land constituted 38.27, 7.14, 11.87, and 36.66 per cent, respectively, of the total cost of producing Burley tobacco; and 49.21, 13.02, 8.49, and 15.88 per cent, respectively, in the case of dark fire-cured tobacco. Of the man labor 35.45, 17.69, and 12.82 per cent, respectively, were required for stripping, cutting and housing, and worming, topping, suckering, and spraying in the case of Burley tobacco; and 22.48, 11.10, and 21.48 per cent, respectively, for dark fire-cured tobacco. Curing of the dark fire-cured tobacco required 9.66 per cent of the man labor.

Effect of yield on cost of producing wheat.—Data gathered from 19 farms in the Purchase region show the average yield of wheat and the cost of production per bushel to be 14.8 bu. and \$1.22, respectively. The average yield and cost per bushel on the 5 farms having the highest yields and the 5 having the lowest yields were 23.2 bu. and 92 cts., and 8 bu. and \$1.93, respectively.

Complete farm cost studies in Christian County.—The results of a three years' study show a wide variation on the different farms in the various items

of cost of producing an acre or a given quantity of product. The time at which, and the efficiency with which, the different operations were performed were found to be largely responsible for the differences both in the amount of labor used and the quality of the crop.

Business analysis of farms in Union and Henderson Counties.—A study of 270 farms shows the chief factors affecting farm profits to be efficiency of labor utilization, ratio of expenses and cost of production to receipts from farm sales, volume of sales, crop yields, and the ratio of returns from livestock to the value of feed fed.

Poultry and egg marketing.—The results of this study show that the outstanding problem is quality improvement, involving production, handling, and marketing; that satisfactory results in such improvement will not be possible until producers are paid on a definite grade basis; that the problem of distribution is one of getting the products into larger consuming centers; and that the price of Kentucky eggs averages higher than that for Tennessee and Missouri eggs, but lower than that for Indiana and Ohio eggs.

Tobacco marketing.—The study of the data on the production and stocks of tobacco indicate that the consumption of Burley tobacco in recent years has been slightly below 250,000,000 lbs. annually, while the production in 1922, 1923, and 1924 was considerably in excess of that amount. The production and consumption of dark tobacco in western Kentucky have been more nearly equal.

Statistical studies.—These studies show that the long-time trend of land in Kentucky farms has been upward, that the proportion of rural population in the State is higher than in the country as a whole, that the trend has been and is toward smaller farms, and that tobacco has been growing in importance.

[*Investigations in agricultural economics at the Montana Station*] (*Montana Sta. Rpt. 1925, pp. 15, 16*).—Eighty-nine irrigated farms in the vicinity of Billings having sugar beet yields of from 10 to 14 tons per acre returned 12.2 per cent on the investment, as compared with 4.1 per cent for 52 farms with yields of from 7 to 10 tons. The study indicates that sugar beets and winter feeding should be the basic sources of farm income for this section.

[*Rural economics investigations at the Ohio Station*] (*Ohio Sta. Bimo. Bul., 11 (1926), No. 5, pp. 198-207*).—The results of work in rural economics are given.

Ohio farm expenses, J. I. Falconer.—A table is given showing the index number (1909-1913=100) for labor, machinery, feed, taxes, fertilizer, building, clothing, furniture, groceries, fuel, and miscellaneous, and the weighted index for the total expenditures for April of 1923, 1924, 1925, and 1926, together with the weight assigned each item in computing the weighted index. The weighted indexes for the four years were 164, 162, 168, and 161, respectively.

Freight rates on Ohio livestock, G. F. Henning.—Tables are given showing the freight rates prior to 1915, between 1915 and 1922, and the present rates from different shipping points within the State to Cleveland, Pittsburgh, Cincinnati, Baltimore, and Jersey City. The freight from Columbus to Cleveland amounted to 1.5 and 1.9 per cent, respectively, of the farm price of hogs and cattle in 1914, and averaged 1.9 and 3.2 per cent, respectively, for the first six months of 1926.

Index number of freight rates on Ohio farm products, G. F. Henning.—Index numbers of freight rates for farm products (rates prior to 1915=100) were found to be 105 from January 4, 1915, to June 26, 1917; 120.7 from June 27, 1917, to June 24, 1918; 150.9 from June 25, 1918, to August 25, 1920; 211.3 from August 26, 1920, to December 31, 1921; and 190.2 from January 1, 1922, to the present time. The present rates are relatively high as compared with the

prices of commodities, and especially with the prices of farm products, the indexes for which have been 156, 152, and 162, and 134, 133, and 159, respectively, for 1923, 1924, and 1925. It is pointed out that with the relatively high freight rates, Ohio farmers enjoy a better market outlet owing to their nearness to the markets.

Index numbers of production, wages, and prices, J. I. Falconer.—Index numbers previously noted (*E. S. R.*, 55, p. 684) are continued through July, 1926.

A food survey of Lima, B. A. Wallace.—A table is given showing the annual per capita consumption of farm products produced locally and commodities competing with such products. The figures are based upon records secured from transportation agencies as to the amount of food products shipped into and out of the city.

Range and ranch studies in Wyoming, A. F. Vass (*Wyoming Sta. Bul.* 147 (1926), pp. 93-151, figs. 13).—This is part of a study of the cattle industry in the Northern Great Plains area of the United States made in 1925 by the agricultural experiment stations of Wyoming, Montana, North Dakota, and South Dakota in cooperation with the Bureau of Agricultural Economics and the Bureau of Animal Industry, U. S. D. A., to determine the factors and methods of management best for the area. This report is based on data from 60 ranches in Crook and Campbell Counties, Wyo., of which the average size was 7,115 acres and the average investment \$53,777 per ranch. Of the land included, 45.6 per cent was owned by the operators, and 70 per cent of the remainder was leased from private owners. Cattle represented 31.3 per cent of the total investment, there being an average per ranch of 430 head, with an average investment of \$39.18 per head, besides 114 calves. The annual cost of carrying per head was \$15.42 for 1-, 2-, and 3-year-olds, \$21.18 for cows, and an average of \$18.14 for all classes, excluding calves. The average return on the investment per ranch was \$3,044, equal to 5.66 per cent, but of this amount \$1,658 was due to increase in the inventory. Taxes equaled 12.7 per cent and interest paid 18.4 per cent of the ranch income.

High land values, \$8.13 per acre, without buildings or improvements, and a land tax of 10 cts. per acre made leasing more conducive to profits than ownership. Only one ranch of 21 having less than 20 per cent of the total capital invested in cattle showed any return on the investment, while 75 per cent of the ranches having 40 per cent or more of their capital in cattle showed returns of from 1 to 8 per cent on the investment. The turnover was 21.8 per cent, where calves were sold, as compared with 22.7 per cent where 3-year-old steers and 2-year-old heifers were sold. Where calves were sold, 68 per cent more cows were required to make possible the same total amount of sales. The cost of producing a 6-month-old calf was \$37.06, or 10.2 cts. per pound. The cost of production after the 6-month period was 7.76 cts. per pound. The cost of producing calves was very high due to the very low calf crop, which averaged only 57.15 per cent as compared with 75 per cent for the best managed herds. The percentage of the calf crop increased as the number of cows per bull decreased, being 76 per cent where there was at least 1 bull for 20 cows. The labor cost was \$4.32 per animal, and the running of 250 head was necessary for the most efficient handling of the labor. Of the total receipts, 35 per cent came from 3-year-old steers, 20 from cows, 17 from 2-year-old steers, and 9 per cent each from the sale of 1 and 4-year-old steers. Calves represented only 2 per cent.

The possibilities of Brazil as a competitor of the United States in cotton growing, B. YOUNGBLOOD (*Texas Sta. Bul.* 345 (1926), pp. 59, figs. 27).—The short crops during the past few years and the increasing consumption of American cotton by American spinners have given impetus to a movement to

develop the cotton-growing possibilities of the British possessions and other countries, notably Brazil. This bulletin gives a general description of the present development of and possibilities for agriculture and stock growing in Brazil and more detailed information regarding the status of cotton growing and the factors affecting it.

The acreage and production in 1924-25 in Brazil were 1,573,000 acres and 605,000 bales, respectively, as compared with 40,115,000 acres and 13,153,000 bales in the United States. About 20 per cent of the Brazilian crop is exported at the present time. That country probably has more agricultural lands than the United States, and it is possible to grow cotton in practically every State. The soils and climate seem favorable to both quality and quantity production, the average yield per acre of lint cotton in 1920-1924 being 188 lbs. as compared with 150.5 lbs. in the United States. It is thought that Brazil will grow increasing crops of cotton of the American upland, medium staple type, much of which will be of superior quality, but greater quantities will be consumed at home due to the growing population and the increasing per capita consumption.

How soon, if ever, Brazil may increase her cotton exports to the point of becoming a serious competitor of the United States is problematical, depending upon whether the world supply materially exceeds the world demand as the cotton-growing possibilities of Brazil are developed.

Factors affecting the price of hogs, G. C. HAAS and M. EZEKIEL (*U. S. Dept. Agr. Bul. 1440 (1926), pp. 68, figs. 30*).—This is a statistical study, based on the prices for heavy hogs at Chicago from January, 1896, through December, 1925, made to determine a means of forecasting hog prices. The supply of hogs on the market and expected to arrive within a few months, the quantity of hog products in storage, the general price level, general business conditions, and the prices of alternative products were the dominant influences in the hog market. The general levels of demand at home and abroad are important, but ordinarily change only slowly.

Exhaustive trials of the different available series of data showed the ones best suited in constructing an index of future prices to be (1) the corn-hog ratio, reflecting conditions most likely to cause changes in breeding plans; (2) the price of corn, indicating the weight to which hogs are likely to be fattened; (3) the weight of hogs, indicating the current balance between corn prices, hog prices, and breeding animals; and (4) the prices of industrial stocks, indicating what the speculative community thinks of the outlook for general business conditions.

The statistical technique is presented by which formulas were arrived at for forecasting hog prices (1) in deviations from trend, considering the corn-hog differential, live weight of hogs, index of prices of industrial stocks, and price of corn; (2) by percentage changes, considering corn-hog differential and the index of prices of industrial stocks; and (3) future prices for hog products—short ribs and lard.

The deviation from trend method gave estimates for the pre-war period that covered 88 per cent of the variation in the monthly averages of the actual prices and 94 per cent of the variation, if only general movements of prices were considered. For the period July, 1924, to January, 1926, 65 per cent of the variation was covered. The errors in estimated prices obtained by use of the future hog-product method averaged about twice as great as with the deviation from trend method. Post-war trend of demand as yet has not become sufficiently stable to permit of estimates of its future course. The semiannual pig survey reports of the Department have made the market more responsive to future

changes in receipts and have changed the relative importance of the different factors in determining prices.

Crops and Markets, [data for October, 1926] (*U. S. Dept. Agr., Crops and Markets*, 6 (1926), Nos. 16, pp. 241-256; 17, pp. 257-272; 18, pp. 273-288; 19, pp. 289-304).—The usual market information, tabulations, summaries, and notes are given for the period October 4-30, 1926.

Monthly Supplement to Crops and Markets, [October, 1926] (*U. S. Dept. Agr., Crops and Markets*, 3 (1926), *Sup. 10*, pp. 305-344, figs. 8).—The usual tabulations, summaries, and notes regarding crops, livestock and livestock products, dairy products, fruit and vegetable shipments, prices and price movements of agricultural products, cold-storage holdings, seeds, exports of grain, etc., are given, together with reports for cotton as of September 16 and October 1 and a special report for tobacco as of October 1. Special articles and tabulations are included on the number of persons employed on farms, October, 1923, to October, 1926; farm wages and index numbers, 1910-1926, and farm wages by States for October, 1924-1926; the percentages of reduction from full yields per acre for different causes for 11 leading crops, 1909-1925, and for 4 States for corn for 1916-1925; the effect of the supply of potatoes on farm prices and crop values; and the monthly money income of farmers and business conditions, July, 1919, to June, 1926, inclusive.

The farmers' standard of living, E. L. KIRKPATRICK (*U. S. Dept. Agr. Bul. 1466* (1926), pp. 64, figs. 7).—This is a socio-economic study of 2,886 white farm families of selected localities in 11 States. It includes 317 families in the New England States, 1,130 families in the Southern States, and 1,439 families in the North Central States, and covers the period 1922-1924. The studies were carried on by this Department in cooperation with 12 colleges and universities.

A table is given and analyzed showing for each State and group of States, by owners, tenants, and hired men, the size of family and household, the average value of goods used during one year, and the distribution of this value among the principal groups of goods furnished by the farm and purchased. The average size of family and household for the 2,886 farms was 4.4 and 4.8 persons, respectively. The total value of all goods used was \$1,597.50 divided into food, \$658.80; clothing, \$234.90; house rent, \$199.60; furniture and furnishings, \$40.20; operation goods, \$213.10; health, \$61.60; advancement, \$104.80; personal, \$41.00; insurance, \$40.80; and unclassified, \$2.70. Of the total value of goods, \$440.70 worth of food, \$199.60 worth of rent, and \$43.20 worth of fuel were furnished by the farm.

A table is given showing the distribution of the average value of goods among different groups of articles, proportions of total family living and of food furnished by the farm, and size of house, by steps of increase in the total value of goods used during one year. Comparisons are made between families of owners, tenants, and hired men in this study, between farm families of this study and farm families of other studies, and of farm families with workingmen's families.

A study is made of (1) the number and ages of children per family, the ages and formal education of the operator and the home maker, and isolation, in terms of distances from the local trading center, church, and high school, as factors influencing the demands and desires of the family; (2) the length of the work day, hours of rest, vacations, etc., as aspects of the standard of living; and (3) acres operated per farm, the period the operator has been a farm owner, mortgage indebtedness, and income from other sources as factors indica-

tive of ability to provide economic goods. The number and ages of children had a direct relation to the standard of living. The formal schooling of the operator and home maker, especially the latter, had a significant relation. The relation of the use of time to the value of goods and the distribution among the different groups of goods was insignificant. The relation between the standard of living and the size of farm was direct. A fairly significant relation existed between years of ownership and the standard of living. Mortgage indebtedness seemed to have no relation. Income from outside sources had a fairly significant relation.

Standard of living on Iowa farms, J. F. THADEN (*Iowa Sta. Bul.* 238 (1926), pp. 81-140, figs. 8).—This study analyzes the standard of living of farm families of 212 owners and 239 tenants in Boone, Story, and Sac Counties for the year ended July 1, 1923, and is a sequel to the bulletin previously noted (E. S. R., 56, p. 82). The cost consumptive powers or weights to be ascribed to the different individuals in determining household or family-size indexes for the different items of consumption are derived from the actual expenditures and activities shown by the survey schedules. Tables are given showing the relation to the standard of living of population, various economic factors, education, home library and reading matter, membership and participation in organizations, and various social factors.

The percentage of the total expenditures of the family devoted to advancement—formal education, reading matter, organization dues, church contributions, vacations, etc.—is taken as the index of the standard of living. This percentage increased slightly with the number of children up to 5, owners' families with 5 or more children at home spending 2 to 2½ times as large a percentage as families with few or no children. The cost consumption per unit was less and the percentage devoted to advancement greater where operators and farmers' wives were over 41 and 45 years old, respectively. The percentage of the total expenditures devoted to miscellaneous purposes increased from 17.2 in families with total expenditures less than \$900 to 36.9 per cent in families with expenditures over \$2,500. The size of the farm, value of land per acre, value of farm, value of house, and the ratio of the value of the house to the value of the farm had rather close relationship to one another, but none of them seemed to bear any relationship to the average cost consumption per unit or to the percentage of the total expenditures for advancement. The standard of living rose with better education of the parents, membership and active participation in social, fraternal, and economic organizations, and attendance at church and financial support to religious organizations. The extent of the education of the children was the best single factor indicating the family's standard of living. The total expenditures for advancement rose with increased expenditures for vacations and trips, the shortening of the work day, and the modernness of the house. Former residence in town or city, employment of hired help, and the carrying of life and health insurance had but slight effect.

An increase in the percentage of the total expenditure for advancement was accompanied by an increase in the average total household expenditures, both per family and per cost consumption unit. The percentage for clothing, furnishings, and personal expenses increased, but those for food, rent, and maintenance of health decreased and those for operating expenses and insurance remained practically the same. The percentage of food, fuel, and shelter furnished by the farm also decreased as the total expenditures increased.

AGRICULTURAL AND HOME ECONOMICS EDUCATION

Report on agricultural education in the financial year 1924-25 (*Jour. Min. Agr. [Gt. Brit.], 33 (1926), No. 8, pp. 711-729*).—A general report of the activities of the Ministry of Agriculture of Great Britain in connection with agricultural education during the year 1924-25.

The book of rural life, edited by J. A. BELLOWS, E. M. TUTTLE, J. H. GRISDALE, ET AL. (*Chicago: Bellows-Durham Co., 1925, vols. 1-10, pp. XXXVIII+6210, illus.*).—A reference book on rural life for schools and homes, consisting of one or more signed articles by 250 men and women, a large number of whom are connected with the leading agricultural institutions of the United States and Canada. The articles are arranged alphabetically and cover different phases of the subjects of agriculture, home economics, health, education and culture, science, and civic and business relationships. The volumes are profusely illustrated, there being 35 full page color plates, 19 colored maps occupying one or two pages, 128 full page sepia plates, and approximately as many halftone and line drawing text figures as pages. A classified arrangement of the articles is given in a readers' research guide at the end of the tenth volume.

Laboratory manual in general microbiology, W. GILTNER ET AL. (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, 3. ed., pp. XXVI+472, pls. 6, figs. [82]*).—This is a third edition of the work previously noted (E. S. R., 35, p. 593).

Laboratory experiments in dairy chemistry, L. S. PALMER (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, pp. XIII+84*).—This laboratory manual has been developed to supplement the lectures in the course in dairy chemistry given by the division of agricultural biochemistry of the University of Minnesota. Thirty-seven experiments are given under eight topics as follows: Physical and chemical properties of milk, isolation and properties of milk constituents, chemical and physicochemical state of milk constituents, butter, rennet coagulation, qualitative analysis of Cheddar cheese, qualitative examination of milk powder, and quantitative analysis of milk. Selected references for supplementary reading, classified by the experiments upon which they have a bearing, and several tables are appended.

Agricultural surveying, including mensuration, road construction, and drainage, J. MALCOLM (*London: Univ. Tutorial Press, 1926, pp. VII+313, figs. 187*).—An elementary textbook on surveying for agricultural students and farmers.

A history of economic progress in the United States, W. W. JENNINGS (*New York: Thomas Y. Crowell Co., 1926, pp. XVI+819, pl. 1*).—This is a college textbook. The history is divided into five periods, with a chapter on agriculture included for each period.

Readings in marketing principles, I. WRIGHT and C. A. LANDON (*New York: Prentice-Hall, 1926, pp. [XI]+799, figs. 29*).—A collection of readings covering the subjects ordinarily included in a basic college or university course in marketing. Chapters are included on assembling county products, cooperative marketing in agriculture, and cooperative marketing by commodities, besides numerous articles pertaining to agricultural products in other chapters.

Community organization, J. F. STEINER (*New York and London: Century Co., 1925, pp. X+395*).—This text for colleges, universities, and schools of social work is "a comparative study of various types of organization based upon a sociological analysis of the community." It is divided into three parts dealing with the community movement and social progress, typical experiments in community organization, and theories and principles of community organization. A selected bibliography is given for each chapter.

FOODS—HUMAN NUTRITION

The biological value of the nitrogen of mixtures of patent white flour and animal foods, H. H. MITCHELL and G. G. CARMAN (*Jour. Biol. Chem.*, 68 (1926), No. 1, pp. 183-215).—The method previously noted (E. S. R., 51, p. 407) has been applied to the determination of the biological values of the nitrogen of white flour and various animal proteins and of mixtures of the white flour with the animal foods in the proportion of one part of nitrogen from the animal food to two parts from the white flour. The purpose of testing the various combinations was to obtain an estimate of the supplementing action of the various animal proteins for the deficient flour protein. The data were obtained in general on two groups of five rats each.

The average biological values of the nitrogen of the foods tested separately were white flour 52, whole egg 94, egg albumin 83, milk 85, veal 62, and beef 69. The values obtained for the various combinations and the calculated values of the same combination on the assumption of no supplementary relationship were, respectively, as follows: Flour and whole egg 75 and 66, flour and milk 71 and 62, flour and egg albumin 66 and 64, flour and veal 62 and 53, and flour and beef 73 and 60. According to these figures the supplementary relationship was greatest between flour and beef and least between flour and egg albumin.

Proteins of wheat bran.—III, The nutritive properties of the proteins of wheat bran, J. C. MURPHY and D. B. JONES (*Jour. Biol. Chem.*, 69 (1926), No. 1, pp. 85-99, figs. 4).—The conclusion drawn in the previous paper of the series (E. S. R., 54, p. 309), that the proteins of wheat bran are of a high nutritive value as judged by their amino acid make-up, has been substantiated in the present biological study.

When fed to young rats as the sole source of protein to the extent of 70 per cent of the ration, commercial wheat bran promoted growth at better than normal rates for 15 or 16 weeks. On washed bran growth was not so rapid. On patent flour as the sole source of protein in a similar ration, growth was much less rapid, the gain of weight per gram of protein eaten being only 0.88 gm. as compared with 1.83 gm. for the bran. After the first 16 weeks, however, growth was at a standstill on the bran ration and progressed at about the same rate on the flour. Fecundity was low on the bran ration, and but few of the young born were raised.

In discussing the results obtained, the authors advance the opinion that "wheat bran contains in abundance the factors which meet the animal's nutritional requirements during the period of its most active growth, but is deficient in some other factor or factors which are required for the animal's normal development after it has reached maturity. The white flour diet, on the other hand, although inadequate to meet the requirements of early growth satisfied to a better degree the requirements of the more mature animal. Whether these differences in the nutritive properties of the bran and flour diets are to be ascribed to the protein, or amino acid factor, or whether they are due to some nutritionally essential nonprotein constituent must for the present remain undecided."

The use of sodium nitrite in the curing of meat, R. H. KERR, C. T. N. MARSH, W. F. SCHROEDER, and E. A. BOYER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 6, pp. 541-551).—This is a general discussion, with selected data, of the cooperative project conducted by Federally inspected meat establishments to determine the feasibility of the substitution of sodium nitrite for sodium or potassium nitrate in the curing of meat. The experiments along this line

conducted by the Institute of American Meat Packers have been noted previously from a report by Lewis and Vose (E. S. R., 55, p. 591).

The general conclusions drawn from the entire series of studies are that sodium nitrite can be successfully substituted for sodium or potassium nitrate in the curing of meat, with a shortening of the customary curing process, and that meats thus cured need contain no more nitrites than meats cured with nitrates and have the advantage of being free from unconverted nitrates regularly present in nitrate-cured meats. It has been found that from 0.25 to 1 oz. of sodium nitrite is sufficient to fix the color in 100 lbs. of meat, the exact quantity depending on the meat to be cured and the process to be employed.

As a result of this investigation the use of sodium nitrite in meat curing in Federally inspected establishments has been formally authorized by the U. S. Department of Agriculture, subject to meat-inspection regulations.

A contribution to the bacteriological study of ham souring, E. A. BOYER (*Jour. Agr. Research [U. S.], 33 (1926), No. 8, pp. 761-768*).—"Hams from dressed hog carcasses taken from the killing floor 45 minutes after slaughter were found to harbor microorganisms in the interior musculature, synovial fluid, and bone marrow. Similar organisms were found in hams from carcasses scalded in a steam cooker and scraped by hand, and in hams taken from the carcasses as soon as bleeding had been completed. Five species of anaerobes, namely, *Bacillus putrefaciens*, *B. histolyticus*, *B. sporogenes*, *B. tertius*, and an unidentified organism resembling *B. oedematiens* in some respects, were isolated from such hams. There were also present numerous and varied aerobic organisms. No organisms of the *B. coli* group were found, although a special search was made for them. It is concluded, therefore, that this group is rarely, if ever, present in the bacterial flora of fresh hams. There is no evidence that any of the organisms found gained access through killing-floor operations.

"From the foregoing data it is concluded that the organisms responsible for ham souring are disseminated throughout the carcass from the moment of slaughter and possibly are present in the blood and tissues of the living animal. It is evident, therefore, that access of these organisms can not be prevented by any alteration of killing-floor operations or practices. Prevention of ham souring depends, therefore, on preventing the development of the causative organisms which are known to be present. Prompt handling and prompt and efficient chilling resulting in early attainment of the low temperatures required to check the development of *B. putrefaciens* and similar organisms, and maintenance of uniform low temperatures until sufficient salt has been taken up by the ham to hold these organisms in permanent check, are the means of prevention indicated. The effectiveness of these methods is shown in a practical way by the low rate of spoilage attained by those establishments at which they are consistently practiced."

A study of the manufacture of water ices and sherbets, A. C. DAHLBERG (*New York State Sta. Bul. 536 (1926), pp. 3-30, figs. 2*).—This study was undertaken for the purpose of devising methods of preparing water ices and sherbets which would overcome some of the difficulties at present encountered in their manufacture. The terms water ice and sherbet are defined as follows: "A water ice is a semifrozen product made of water, sugar, and fruit juice which may or may not contain added color, flavor, fruit acid, and stabilizer. A sherbet is a semifrozen product made of the same ingredients as a water ice except that it also contains milk or milk products." The chief difficulty to overcome was the tendency for the unfrozen sirup to drain out of the semi-

frozen product during storage, with the result that the ice is exceedingly hard in the upper part of the container and soft or mushy in the lower part.

The first point studied was the influence of the sugar concentration and the percentage of overrun upon the hardness of the product. A sugar concentration of from 30 to 33 per cent and an overrun of 20 to 30 per cent were established as optimum for obtaining products comparable in hardness to ice cream at the same temperature.

Of various materials tested alone and in combination as stabilizers, India gum of good quality prevented most of the sirup from draining out, but did not overcome the tendency of the frozen product to crumble. Gelatin made a smooth product, but it was impossible to reduce the overrun to the desired amount. Gelatin and low-grade India gum were precipitated by each other, and a mixture of gelatin and gum tragacanth or high-grade India gum could not be whipped readily. This difficulty in whipping was also true of agar in a concentration of about 0.2 per cent. The most satisfactory results were obtained with a combination of agar with milk proteins, gelatin, gum tragacanth, or high-grade India gum. The substitution of corn sugar for 20 or 25 per cent of the sucrose still further improved the quality of the product by preventing the crystallization of the sucrose and the formation of ice particles. A satisfactory formula for water ice embodying all the recommendations is given as follows: Cane sugar 25, corn sugar 7, agar 0.2, gum tragacanth or high-grade India gum 0.4, and water, fruit, fruit acid, flavor, and color 67.4 lbs. This is said to give an overrun of 20 to 25 per cent and a total yield of 13 gal. For sherbets the same amounts of the first three ingredients are recommended, with 0.2 lb. of gum tragacanth, 50 lbs. of whole milk, and 17.6 lbs. of water, fruit, etc. This gives an overrun of from 25 to 30 per cent and a yield of 13.5 gal. In place of the whole milk ice cream mix without sugar or gelatin can be used, the directions calling for 10 lbs. of the mix and 57.6 lbs. of the water, fruit, etc.

Vitamin studies.—XIII, Vitamin B in evaporated milks made by vacuum and aeration processes, R. A. DUTCHER and E. FRANCIS (*Jour. Dairy Sci.*, 9 (1926), No. 4, pp. 379-387, figs. 2).—This continuation of the series of vitamin studies at the Pennsylvania Experiment Station, the preceding number of which by Souba, Knandel, and Dutcher has been noted (*E. S. R.*, 54, p. 670) has been noted essentially from a progress report (*E. S. R.*, 52, p. 201).

The general conclusion drawn is that "vitamin B is not readily destroyed by the evaporation methods described, and only under unusual conditions would we expect the vitamin B deficiency of commercial evaporated milks to be due to methods of manufacture." In the control tests with raw milk, fairly normal growth was secured with 12 cc. of milk daily. This would indicate that the Pennsylvania herd milk used was slightly superior in its vitamin B content to that described by Osborne, Mendel, et al. (*E. S. R.*, 39, p. 570) and slightly inferior to the Minnesota milk described by Kennedy and Dutcher (*E. S. R.*, 47, p. 78).

Vitamin studies.—XIV, The influence of ultra-violet light on the anti-rachitic properties of purified rations used in the study of vitamin A, R. A. DUTCHER and J. H. KRUGER (*Jour. Biol. Chem.*, 69 (1926), No. 2, pp. 277-282).—The authors have attempted to discover which constituent of the basal ration used in their vitamin A studies responds most readily to irradiation, for the purpose of securing an abundance of the antirachitic vitamin now considered to be an essential ingredient in basal diets to be used for vitamin A studies.

The basal ration used consisted of purified casein 18, agar 2, salt mixture 3, and dextrin 77 parts. A comparison of the growth of nonirradiated rats re-

ceiving this ration untreated and irradiated and of irradiated rats receiving the nonirradiated ration showed that loss in weight was delayed by irradiation of either the ration or the animals themselves. The separate ingredients of the ration were then irradiated, one at a time, and the extent of increase in anti-rachitic properties was tested by determinations of the ash content of the femur and humerus of the rats on the fourteenth day of feeding. No change was made in the constituents of the ration, except that of one group in which 2 per cent of corn oil replaced 2 per cent of dextrin. The percentage of bone ash was markedly increased by irradiation of the dextrin and corn oil, but not to any extent by irradiation of the other ingredients of the ration. Since irradiation of 2 gm. of corn oil brought about the same degree of calcification as that of 77 parts of dextrin, it was concluded that irradiated corn oil is at least 38 times as potent as irradiated dextrin. The addition of irradiated corn or olive oil to basal vitamin A-free rations is recommended.

Studies upon the inorganic composition of bones, J. HOWLAND, W. McK. MARRIOTT, and B. KRAMER (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 721-728).—From bone analyses by the methods previously described (E. S. R., 56, p. 14), it is concluded that the calcium phosphate compound in all bones, rachitic or nonrachitic, is tricalcium phosphate, that different bones of the same individual have the same inorganic composition, and that the ratio of calcium phosphate to calcium carbonate is higher in the bones of normal than of rachitic animals. Precipitates made from solutions comparable in their inorganic composition to the serum of normal and rachitic animals were found to contain essentially the same calcium phosphate compound as bone. The ratio of calcium phosphate to calcium carbonate in these precipitates was found to vary directly with the inorganic phosphorus content of the solution.

The relation of the rate of growth to diet, I, T. B. OSBORNE and L. B. MENDEL (*Jour. Biol. Chem.*, 69 (1926), No. 2, pp. 661-673, figs. 5).—In this investigation, which has been noted briefly from a progress report (E. S. R., 55, p. 189), the authors with the cooperation of H. C. Cannon have attempted to prepare single food mixtures for their stock rats which would be more convenient and efficient than the dog biscuit-green food ration hitherto used in their colony. In the course of this work combinations were secured on which growth has been accelerated far beyond the Donaldson standards.

On a biscuit prepared from red dog flour 65, meat scrap 12, commercial casein 12, alfalfa 10, and sodium chloride 1 per cent, with 1 mg. of potassium iodide for each kilogram of the mixture, the average time required for making the gain in weight from 60 to 200 gm. was 38 days as compared with 43 days, the maximum rate of gain reported by King, and 65 days by Greenman and Duhring. Several other efficient food combinations are summarized, with the time required to make gains in body weight from 60 to 200 and 300 gm., respectively. These, together with graphic records and photographs, show the marked increase in growth which can be brought about by selective feeding. It is noted, moreover, that the increase in rate of growth can also be initiated when the change in ration is made considerably later than in most of the experiments reported.

No definite conclusions have been drawn as yet in explanation of the acceleration of growth, although it is suggested that hitherto unappreciated cell constituents may be partly responsible. Whether the rapid initial growth will result in definitely larger adults and whether it is truly normal from a morphological and physiological standpoint have yet to be determined.

The effect of light on creatinine and creatine excretion and basal metabolism, M. EICHELBERGER (*Jour. Biol. Chem.*, 69 (1926), No. 1, pp. 17-23).—Expo-

sure for an hour to direct sunlight or for 50 minutes to the light of a carbon arc lamp is reported to have increased the creatinine excretion during the period of irradiation and decreased it for several hours thereafter in a group of young women subjects and also in two young girls. The creatine excretion was not affected. Creatinine excretion was also increased by exercise, in some cases to a higher degree than by irradiation. No significant alterations in basal metabolism resulted from irradiation.

Intestinal chemistry, IV-VII, O. BERGEIM (*Jour. Biol. Chem.*, 70 (1926), No. 1, pp. 29-58, figs. 7).—In continuation of the series of studies previously noted (*E. S. R.*, 55, p. 190), four papers are presented.

IV. *A method for the study of food utilization or digestibility*.—The method described is an adaptation of the one described in the first paper of the series (*E. S. R.*, 52, p. 862), involving the incorporation of ferric oxide in the food. In the present case, the percentage utilization of any food is calculated by determining the ratio of the amount of the food substance ingested to the amount of iron in the food and in the feces. The method is said to be applicable to studies on small animals, such as white rats, and to have the advantage over the usual method in not requiring the separation and complete collection of the feces.

V. *Carbohydrates and calcium and phosphorus absorption*.—The method noted above has been applied in a study of the effect upon calcium and phosphorus absorption from the intestines of the addition of various carbohydrates to the ration. The experiments were conducted on young rats on a basal diet of whole wheat 33, gelatin 15, wheat gluten 15, whole yellow corn 33, sodium chloride 1, calcium carbonate 3, agar 0.5, and ferric oxide 0.2 per cent. The calcium and phosphorus absorption on the control diet was determined for each rat during two successive 4-day periods, and on the modified diets on successive 4-day periods, with 2 days' interval between.

Starch, glucose, fructose, and maltose were without effect on the calcium and phosphorus absorption when fed at a 25 per cent level, but caused a small increase at 50 per cent. Dextrin had little effect in the smaller amounts but a more marked effect in the larger. Lactose even at a 25 per cent level caused a marked increase in the calcium and phosphorus absorption, particularly the former. The effect of these carbohydrates is considered to be due to increased lactic acid fermentation in the intestines, with resulting increased acidity of the intestinal contents which would be more marked with lactose than with the other carbohydrates.

VI. *A method for the study of absorption in different parts of the gastrointestinal tract*.—In this application of the method outlined in Part IV, the food in question is fed to the experimental animals for 24 hours or more, or until all residues of the preceding diet have left the intestines, and is then given in small amounts at frequent intervals. After several feedings the animal is killed and the contents of various parts of the intestinal tract examined. As an alternative several animals may be fed a single meal and killed at different times, or an animal with a series of fistulas may be used.

VII. *The absorption of calcium and phosphorus in the small and large intestines*.—Using the method outlined in the preceding paper, a study was made of the effect of cod-liver oil as the source of the antirachitic vitamin on the absorption of calcium and phosphorus from different parts of the intestinal tract of rats on a high-calcium-low-phosphorus diet. Three rats were fed this diet supplemented by 10 drops daily of inactive olive oil and three by the same amount of cod-liver oil. Three others received a high-calcium-high-phosphorus diet consisting of equal parts of powdered milk and cornstarch.

In all groups there was a considerable degree of calcium absorption from the small intestine, indicating that the rachitic condition could not be due to a failure of absorption. In all groups there was a marked excretion of phosphate into the small intestines. The normal animals showed normal calcium and phosphorus balances throughout the intestines. In the rachitic animals the excretion of calcium into the lower intestine was more marked than the absorption, thus leading to a negative balance. This was accompanied by a failure of phosphate to be reabsorbed.

"The failure of absorbed calcium to be used in calcification is believed to be due to the low phosphate concentration of the blood. Antirachitic substance may act by elevating blood phosphate by promoting the breakdown of organic tissue phosphates, thus leading to increased deposition of calcium with lessened excretion into the gut and consequent better absorption of phosphate therefrom."

Studies of the metabolism of women.—II, Cyclic variations in uric acid and total nonprotein nitrogen content of blood, R. OKEY and S. E. ERIKSON (*Jour. Biol. Chem.*, 68 (1926), No. 3, pp. 687-709, fig. 1).—The investigation previously noted (*E. S. R.*, 54, p. 592) has been extended to a study of the blood uric acid levels and nonprotein nitrogen content of the blood during the menstrual period in college women, many of them subjects of the previous study. In all 271 samples covering 37 monthly periods in 22 subjects were analyzed. On the basis of the data obtained, the conclusion is drawn that in most normal women there is a tendency for the blood uric acid to reach a high level immediately preceding menstruation. This is followed by a decrease during menstruation and a second increase shortly after the close of the period. The average values at these periods in terms of intermenstrual values were 105.8, 86.4, and 105 per cent. The values obtained in 92 observations of the blood uric acid levels of 9 men showed no greater variations than those observed in the women subjects during the intermenstrual period.

Observations on the total nonprotein content of the blood showed a tendency toward high levels during or just after the menstrual period. Preliminary observations of the nitrogen partition showed no consistent cyclic changes in the levels of creatine, creatinine, urea, and amino acids. This is thought to indicate that the rest nitrogen fraction alone is involved.

Various theories in explanation of the fluctuations in nitrogen distribution are discussed.

TEXTILES AND CLOTHING

Fibres, textiles, cellulose, and paper, D. J. NORMAN (*Soc. Chem. Indus. [London], Ann. Rpts. Prog. Appl. Chem.*, 10 (1925), pp. 137-164).—A review of technical research in 1925 on cellulose, cotton, and allied fibers, silk, wool, nitrocellulose, rayon, and paper-making materials.

New method of depicting fiber cross sections [trans. title], A. HERZOG (*Melliand Textilber.*, 7 (1926), No. 11, pp. 925-927, figs. 7).—The details of the method are set forth, with illustrations of the apparatus employed.

Spinning tests of leading varieties of Texas cotton (crop of 1924), H. H. WILLIS (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1926, pp. 20, figs. 3).—A preliminary report of tests in cooperation with Clemson Agricultural College on Acala, Lone Star, Kekchi, Mebane, Rowden, Kasch, and Hoground (mixed) cotton grown in Texas in 1924 gives environmental and field data, grades, staple, and the usual spinning test data.

The test results on the 1924 crop, which tend to substantiate those of the 1923 crop, indicate that all of these varieties may be spun into satisfactory

22s and 28s yarn; that Acala, Lone Star, Kekchi, Mebane, and Rowden may be spun into satisfactory 36s yarn; and that Acala, Lone Star, and Kekchi may be made into 44s yarn for some purposes.

Spinning tests of leading varieties of North Carolina cottons (crop of 1925), H. H. WILLIS (*U. S. Dept. Agr., Bur. Agr. Econ., 1926, pp. 28*).—This is a preliminary report of spinning tests made in cooperation with Clemson Agricultural College on the Trice, Sugar Loaf, Cleveland, Acala varieties, and strains of the Mexican variety of cotton grown in several localities in North Carolina. Environmental and yield data are given in addition to the usual spinning test data and a formula which has been devised for estimating the breaking strength of 28s yarn.

The breaking of yarns and single cotton hairs, G. G. CLEGG (*Brit. Cotton Indus. Research Assoc., Shirley Inst. Mem., 5 (1926), No. 18, pp. 223-233, figs. 11*).—The Congo Red staining method (E. S. R., 55, p. 695) has made it possible to determine the number and character of all the fiber present at the point of breakage, the average number of fibers ending naturally in the portion of yarn in which the break occurs, and the number of fibers actually broken. The average number of fibers in the yarn cross section is found by counting those at a cut end.

Use of this technique on a number of yarns broken on a single-thread tester or a ballistic instrument gave evidence that yarn does not usually break by slipping of the individual hairs. In reality a considerable proportion of the hairs are actually broken, as many as 70 per cent in a Sakel 36's weft. No definite relation was apparent between the breaking load of a raw cotton and that of the yarn itself. This seemed largely due to the indefiniteness of the quantity determined as the single fiber-breaking load, and the effects of two contributing factors, presence of abnormal hairs and length of test specimen, were examined. No direct relation was shown between the single fiber-breaking load and the wall thickness of the fibers.

Variations in damped knitting yarns, W. DAVIS (*Wool Rec. [Bradford], 30 (1926), No. 916, pp. 1524-1527, figs. 10*).—Experiments showed that after damping wool yarns there is a rapid alteration in the tensile and stretch properties, which reaches its maximum intensity about 4 hours after lubrication. After this time there is a gradual return toward normal conditions. This return, however, is in no case complete before 24 hours have elapsed, during which period all of the yarn wound is supposed to be worked up on the frame; otherwise the effects of lubrication must be maintained by placing the wound yarns in a damp atmosphere. In tests on 18's and 2/18's worsted hosiery yarns, which were damped with different lubricating substances and the effects noted at various periods, the general behavior was similar in each case.

The effect of atmospheric influences on wool and cloth [trans. title], A. KERTESS (*Melliand Textilber., 7 (1926), No. 11, pp. 928, 929*).—Microscopic study of natural white wool and samples of gray army cloth that had been exposed to the action of the atmosphere for about a year did not show an appreciable change in appearance of the fibers, but they were exceedingly brittle and easily broken into short fragments. Conclusions which confirmed earlier investigations are that the action of the atmosphere, especially light, causes a chemical deterioration with a considerable concurrent reduction in quality.

Bleaching, dyeing, printing, and finishing, A. J. HALL (*Soc. Chem. Indus. [London], Ann. Rpts. Prog. Appl. Chem., 10 (1925), pp. 165-187*).—Activities of the bleaching, dyeing, printing, and finishing industries are reviewed for 1925, and summaries are given of the patent and research publications brought forth during the year.

MISCELLANEOUS

National problems for cooperation, agricultural experiment stations and U. S. Department of Agriculture (*U. S. Dept. Agr., Off. Expt. Stas., 1927, p. [3]+41*).—This revision is referred to editorially on page 101.

Report [of Florida Station] for the fiscal year ending June 30, 1920, P. H. ROLFS ET AL. (*Florida Sta. Rpt. 1920, pp. 45+II, figs. 2*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1920, a list of the publications of the year, a general review of the work of the station during the year, and departmental reports, the experimental features of which are for the most part abstracted elsewhere in this issue.

Report of Moses Fell Annex, Bedford, Indiana, June, 1926, H. J. REED and E. W. MOORE (*Indiana Sta. Circ. 135 (1926), pp. 15, figs. 5*).—The experimental work summarized in this report is for the most part abstracted elsewhere in this issue.

Thirty-eighth Annual Report of [Kentucky Station, 1925, I], T. P. COOPER (*Kentucky Sta. Rpt. 1925, pt. 1, pp. 34*).—Part 1 of this report contains the organization list, a financial statement as to the Federal funds for the fiscal year ended June 30, 1925, a report of the director on the work and publications of the year, and meteorological data. The experimental work reported and not previously noted is for the most part abstracted elsewhere in this issue.

The Thirty-eighth Annual Report of the Maryland Agricultural Experiment Station, [1925], H. J. PATTERSON (*Maryland Sta. Rpt. 1925, pp. XX+189, figs. 79*).—This contains the organization list, a report by the director on the work and publications of the station, a financial statement for the fiscal year ended June 30, 1925, and reprints of Bulletins 268-273, all of which have been previously noted. Experimental work with field crops is noted on page 132.

Some new facts from the Montana Experiment Station: Thirty-second Annual Report, July 1, 1924, to June 30, 1925, F. B. LINFIELD (*Montana Sta. Rpt. 1925, pp. 60, figs. 22*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1925, and a report of the director on the work of the station. The experimental work reported and not previously noted is for the most part abstracted elsewhere in this issue.

Thirty-ninth Annual Report of the Pennsylvania Agricultural Experiment Station, [1926], [R. L. WATTS] (*Pennsylvania Sta. Bul. 204 (1926), pp. 47, figs. 10*).—This bulletin discusses briefly the work of the station for the year ended June 30, 1926, including a financial statement for this period. The experimental work recorded and not previously noted is for the most part abstracted elsewhere in this issue.

Thirty-eighth Annual Report [of Tennessee Station], 1925, C. A. MOOERS ET AL. (*Tennessee Sta. Rpt. 1925, pp. 24, figs. 2*).—This contains the organization list, an account of the work of the station, and a financial statement for the fiscal year ended June 30, 1925. The experimental work reported and not previously noted is for the most part abstracted elsewhere in this issue.

Bimonthly Bulletin of the Ohio Agricultural Experiment Station, [September-October, 1926] (*Ohio Sta. Bimo. Bul., 11 (1926), No. 5, pp. 161-208, figs. 7*).—This number contains, in addition to several articles abstracted elsewhere in this issue, the following: Ohio Sportsmen Plant 45,000 Forest Trees, Orchard Trees Need Nitrogen, and Feeding Dairy Cows.

NOTES

Arizona University.—President C. H. Marvin, the chancellor of the board of regents, and three other members of the board have tendered their resignations.

California University and Station.—L. J. Fletcher, head of the agricultural engineering division, resigned December 30, 1926, to engage in commercial work.

Colorado Station.—A wooden building used to house the work of the station in animal husbandry, dairy husbandry, veterinary science, and poultry was burned January 28, together with the R. O. T. C. building and the Government arsenal. The loss is estimated at \$200,000.

Connecticut College.—Approximately \$500,000 is being requested from the General Assembly for new construction. The largest item is that of \$435,720 for a classroom building to replace a frame structure erected in 1890. Other items in the estimates include \$19,920 for equipment for fruit storage, \$47,622 for enlargement of the filter beds, and \$32,000 for four faculty cottages.

Massachusetts Station.—The resignations are noted of Gerald M. Gilligan and Orman E. Street, investigators in chemistry and agronomy, respectively. Recent appointments include Miss Esther S. Davies and Linus H. Jones, assistant research professors of home economics and botany, respectively, and the following investigators: Robert S. Horne, agronomy; Joseph L. Kelley, cranberry studies; Ronald L. Mighell, farm management; Paul R. Nelson, chemistry; and Ray G. Smiley, pomology.

Michigan College and Station.—Edward D. Devereaux has been appointed assistant professor and research assistant in bacteriology. R. V. Gunn has been appointed extension specialist in economics.

Minnesota University.—Work has been begun on a plant industry building, which, with equipment, is to cost \$250,000. This building will house the division of agricultural biochemistry and will furnish much needed laboratory equipment for the entire plant industry group. It will be a three-story and basement structure of brick and limestone, 154 by 65 ft. in size, and is expected to be ready for occupancy September 1.

Missouri University.—The total attendance at Farmers' Week held from January 17 to 21 was 1,263, of whom 383 were women. There were represented 96 Missouri counties and 12 other States.

A new marketing course of three days' duration was held from February 8 to 10 for officers, managers, and members of cooperative marketing associations in cooperation with farmers' organizations of the State and the U. S. Department of Agriculture.

Montana College.—Miss Florence Fallgatter, acting head of the home economics department, has been appointed field agent for home economics in the central and Pacific coast regions by the Federal Board for Vocational Education, succeeding Miss Mabel V. Campbell, who has resigned to become chairman of the department of home economics of the University of Missouri.

Nebraska University.—A new dairy building costing \$50,000 was dedicated October 21, 1926. It is a brick building with asbestos shingles, 131 by 197 ft. It includes a milk house, accommodates 52 cows in stanchions, together with box stalls for 4 cows, and is equipped with many labor-saving devices.

Rutgers University.—A week's marketing institute was held beginning January 24.

New Mexico College and Station.—Work was recently begun by the station and the extension division on a Purnell project entitled *The Determination of the Economic Possibilities of the Storage and Keeping Qualities of New Mexico Eggs.*

New York State Station.—The addition of plaster of Paris to dust mixtures used in fighting the pear psylla, one of the most troublesome pear pests in New York, has proved quite effective in controlling this insect in the Hudson River Valley. The new dust mixture is harmless to pear foliage and costs only about 3 cts. a pound, this amount being sufficient to cover the average-sized pear tree. The treatment is useful chiefly in the early stages of the insect's development, when the moist bodies of the young psyllas cause the plaster of Paris to set in a hard case, thus causing suffocation. The dust mixture suggested for these stages contains four parts of freshly hydrated lime to one part of high-grade plaster of Paris. For later use, nicotine sulfate may be added, and sulfur or copper dust or lead arsenate may be substituted for a part of the lime for special purposes. It is thought that the plaster of Paris dust may also prove effective against other orchard pests, and tests are now in progress to discover how they may be used to the best advantage.

As a result of recent station tests, in which such varieties as Delaware, Campbell, Niagara, Concord, Iona, and Catawba were grafted on rootstocks of Clinton, Riparis Gloire, and Rupestris St. George and grown beside own-rooted vines propagated in the usual way, it is believed that American grapes can be materially improved in quality, that yields can be increased, and that more vigorous vines can be obtained by bench grafting desirable varieties on suitable stocks. While at present the cost of grafted stock will probably be too great for use in commercial plantings, improved methods of grafting may lower this cost and eventually prove practicable. For home planting, the immediate benefits to be secured from grafted stock are believed to justify the slightly greater cost both in the production of better fruit and the greater assurance of success.

Pennsylvania College and Station.—R. B. Maxwell resigned December 1, 1926, as instructor in storage research. Recent appointments include J. M. Huffington as assistant professor of vegetable gardening extension, Howard O. Triebold as instructor in agricultural chemistry, and Arthur C. McIntyre as research assistant in forestry.

South Dakota College and Station.—Guy H. Harvey of Yankton and W. S. Dolan of Milbank have been appointed regents of education, and Alvin Wagner of Philip has been reappointed to the position. Turner R. H. Wright, livestock specialist in the extension service, was transferred January 1 to the department of animal husbandry as associate professor of animal husbandry.

Texas Station.—Dr. P. C. Mangelsdorf, assistant geneticist at the Connecticut State Station, has been appointed agronomist in charge of corn and small grain investigations and entered upon his new duties January 1.

Vermont University.—The Ira Allen Chapel, named in honor of the founder of the university and the gift of Hon. James B. Wilbur of Manchester, was dedicated January 14. It is a brick colonial structure, 135 by 90 ft. in size,

with a 170-ft. campanile. The seating capacity of the auditorium is 1,000. Special attention has been given to its acoustics, and a three-manual grand concert organ has been installed.

West Virginia University and Station.—Dr. J. H. Rietz, professor of veterinary medicine and advisory veterinarian in the station, has been appointed veterinarian in the department of animal husbandry, beginning January 1, thereby filling a vacancy which has existed since the resignation of Dr. C. A. Lueder in September, 1924. E. C. Stillwell, assistant professor in the College of Agriculture and junior animal husbandman in the station, resigned January 1.

Wisconsin University and Station.—At the request of the Wisconsin Utilities Association the first short course in tree trimming for line foremen was offered by the department of horticulture from February 8 to 12.

The radio committee of the College of Agriculture has cooperated with the university committee in a series of farm and home radio programs given weekly during January.

Walter H. Ebling has resigned as assistant to the dean and director, effective January 1, to accept the position of State agricultural statistician. Reid F. Murray has resigned as secretary of the Wisconsin Livestock Breeders' Association and extension specialist in animal husbandry, and has been succeeded by Arlie M. Mucks, county agent of Barron County.

Office of Experiment Stations.—H. W. Marston, instructor in animal husbandry and assistant animal husbandman in the Kansas College and Station, has been appointed associate animal husbandman. He will have charge of the abstracting for *Experiment Station Record* in the sections of animal production and dairying and dairy farming, relieving George Haines, who while retaining his connection with the section of genetics will devote the greater part of his time to the work of the Office dealing with its direct relations with the experiment stations.

Survey of Land-Grant Colleges and Universities.—Under a provision of the act signed January 12 making appropriations for the support of the Department of the Interior for the fiscal year ending June 30, 1928, the Bureau of Education is granted \$61,000 to make a study of the organization, administration, and work of the land-grant institutions. The total cost of the survey is expected to be \$117,000. The survey is the result of discussion and action in the Association of Land-Grant Colleges and Universities and received the indorsement of the association in 1925 and 1926. It is expected that special attention will be given to agricultural and home economics education.

National Agricultural College Student Council.—According to a note in *Agricultural Student*, this organization was formed at a meeting held in Chicago November 26, 1926, with representatives of the agricultural colleges of Alabama, Iowa, Missouri, New York, Ohio, Pennsylvania, and Tennessee in attendance. It is expected to hold annual meetings to consider problems confronting councils, clubs, and societies in these institutions dealing with student government and similar matters.

California Forest Experiment Station.—This station, located at the University of California, has begun operations with E. I. Kotok as director and a scientific staff of five other foresters. For the present its activities will be confined to the pine region and southern California watersheds, but later it will take up the problems of the redwood regions. Substations have been located at Devil's Canyon in the San Bernardino Mountains, Feather River on the Plumas National Forest, and Cow Creek on the Stanislaus National Forest, and at least two others and an experimental forest are contemplated.

Agricultural Education in South Africa.—The Department of Agriculture of the Union of South Africa is contemplating the establishment of a sub-

tropical experiment station and is seeking a suitable site. Orchard management is to be featured, together with pathological, entomological, and plant physiological studies. A part of the work will also be devoted to subtropical field crops, such as cotton, tobacco, and coffee, and to studies of the suitability of certain varieties of deciduous fruits for the low veld.

The department has definitely decided to establish a maize experiment station in the Orange Free State. A site has been selected near Kroonstad, and operations will be begun as soon as the property has been taken over.

The Government has decided to increase the number of agricultural scholarships for study overseas from 15 to 27. The new scholarships are valued at not to exceed £200 and include 4 in agricultural economics, 3 in sheep and wool, 2 in entomology, 2 in botany, and 1 in field husbandry.

A two-year diploma course at the Potchefstroom School of Agriculture was replaced January 1 by a one-year course. A year's practical experience on a farm is required for admission. The curriculum includes animal husbandry, poultry, field crops, veterinary science, horticulture, agricultural chemistry, agricultural engineering, agricultural economics and law, entomology, book-keeping, and agricultural botany, as well as practical work in blacksmithing, saddlery, carpentry, and farm management. Short courses in eight lines are also offered. The school has a farm of about 2,800 acres, of which about one-fourth is under cultivation, as well as a ranch of about 4,000 acres.

Rubber Research Institute of Malaya.—This institute incorporated by the Legislature of the Federated Malay States has recently been established with G. Bryce as director. The institute is financed by Government funds, but is controlled by a board representing both the Government and the rubber growing industries. While its work will be primarily for the advancement of the rubber industry, it is realized that many fundamental questions of concern to tropical agriculture will necessarily be gone into. It is hoped that an early start may be made in chemical and physical work on soils, latex and preparation of rubber, plant nutrition and the physiology of growth, genetics, pathology, and statistical methods in field methods.

Fellowship for Textile Research.—A fellowship of \$300 has been offered for the academic year 1927-28 by the American Home Economics Association through its committee on research. The work provided for is to be done at a college or university of recognized standing and under the direction of a member of the staff who has carried on textile research either personally or through students. Candidates are restricted to women holding at least one college or university degree and who have specialized in either textiles and in chemistry or in physics with some training in textiles. Applications close April 1, 1927. Additional information may be obtained from Miss Ruth O'Brien of the Bureau of Home Economics, U. S. Department of Agriculture.

New Journals.—*Entomologica Americana*, published by the Brooklyn Entomological Society, has resumed issue after an interval of 36 years. The intention is to utilize its columns for papers from authors not connected with institutions which publish the results of the research of their staffs, and which are too long or specialized for existing journals and too short for a book. The initial number consists of a thesis submitted for the D. Sc. degree at Radcliffe College by Priscilla B. Hussey and entitled Studies on the Pleuropodia of *Belostoma flumineum* Say and *Ranatra fusca* Palisot de Beauvois, with a Discussion of These Organs in Other Insects.

Western Dietitian, "a modern journal of dietetics and nutrition," is being issued monthly. The initial number contains several original articles, including What We Can Expect to Accomplish through Scientific Nutrition, by E. V.

McCollum; Sunlight and Nutrition, by R. E. Ramsay; Dietetic Value of the Avocado, by M. E. Jaffa; Acidosis, by W. D. Sansum; Isabel Bevier: Her Contribution to Home Economics, by H. B. Thompson; and How the New Science of Nutrition Has Revolutionized the Food Industries, by R. H. Shaw.

Boletín de los Servicios Agrícolas is being published quarterly by the Director General of the Agricultural Service of Chile. The initial number discusses the organization and work of the Department of Agriculture and Industry and presents contributions on The Economic Concept in National Agriculture, by J. Schneider Labbé; Paratyphoid in Hogs, by J. Descazeaux; and An Insect Injurious to Grapes, by C. E. Porter; together with economic data, statistics, news notes, decrees, etc.

Bulletin of Hygiene is being issued as a monthly by the Bureau of Hygiene and Tropical Diseases of Great Britain. It will consist of summaries and reviews of publications on all branches of public health and preventive medicine from the special point of view of overseas Britain. A section on hygiene in the Tropics will deal with publications in various languages, but the remainder of the journal will for the present be mainly restricted to publications in English. A feature of the initial number is the reproduction of numerous illustrations.

The Belgrade Economic Review is a monthly journal published in English and devoted to the economic, commercial, and industrial problems of the Kingdom of the Serbs, Croats, and Slovenes. The initial number contains among other material an article on Agricultural Credit in Jugoslavia, by M. K. Djordjević, and provisional statistics on the 1926 harvest of the chief crops in the Kingdom.

The North Western Naturalist is being issued quarterly as a scientific and educational journal for the district in Great Britain covered by Lancashire, Cheshire, Shropshire, Staffordshire, Derbyshire, North Wales, Cumberland, Westmorland, and the Isle of Man. The initial number contains several original articles, one of which deals with The Craneflies of Carnarvonshire, by H. F. Barnes.

Fortschritte der Landwirtschaft is being published semimonthly by the agricultural department of the High School for Soil Culture of Vienna and the Austrian Agricultural Experiment Stations. The initial number contains several original articles, as well as shorter contributions, abstracts, notes, etc.

The Economic Record has been established as a semiannual journal of the Economic Society of Australia and New Zealand. The initial number contains numerous original articles, reviews, and notes. Among the reviews is one entitled The Story of Australian Land Settlement, by H. Heaton.

Montana is to be issued by the State Department of Agriculture, Labor, and Industry six times per year. The initial number contains a large amount of data regarding the agricultural and other resources of the State. Subsequent issues are to be smaller in size and mainly statistical in scope.

Il Notiziario Chimico-Industriale is being published monthly at Turin, Italy, with a number of members of the staffs of Italian experiment stations on its corps of collaborators. The initial number contains several articles of agricultural interest, including one on the Preservation of Lemon Juice, by G. Romeo.

Farming in South Africa is being issued monthly by the Department of Agriculture, Union of South Africa. It is published primarily in the interests of the farmer, and consists largely of practical articles.

CONTENTS OF VOL. 56, NO. 3

	Page.
Recent work in agricultural science-----	201
Notes-----	300

SUBJECT LIST OF ABSTRACTS

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Colloid and capillary chemistry, Freundlich, trans. by Hatfield-----	201
Textbook of microchemistry, Emich-----	201
Textbook of food chemistry, Röttger-----	201
The essential oils, Finnmere-----	201
Experiments on sunflower seed oil, French and Humphrey-----	201
On the chemical composition of poisonous beechnut cake, Van Kampen---	202
Improved method for preparation of wheat gliadin, Blish and Sandstedt---	202
The antirachitic value of irradiated cholesterol, VI, Hess et al-----	202
Anti-rachitic properties of irradiated sterols, Rosenheim and Webster---	202
Fractionation of irradiated cholesterol, I, II-----	203
The pigeon and rat methods of testing for antineuritic vitamin, Seidell---	203
Note on colorimeter correction curves, Wright-----	204
Influence of NaCl on determination of pH, Parsons and Douglas-----	204
A rapid electrometric method for the measurement of hydrion concentration of flour-water suspensions, Denham and Blair-----	204
Determination of H-ion concentration of crackers, Bohn and Martz-----	204
Control of diastatic activity in wheat flour, II, Sherwood and Bailey-----	204
Gasoline color value of several classes of wheat, Coleman and Christie---	205
Miscibility tests in the detection of adulterated butter, Atkinson-----	205

	Page
Dehydration of fruits in California, Christie-----	205
Cultures and yeast foods tested for vinegar making-----	206
The effect of pickle scum on the pickle brine, Joslyn-----	206
A causative factor of "floaters" during the curing of olives, Alvarez---	206
Methods of preserving sardines, Beard-----	206
The principal tanning materials of Australia, Welch and Coombs-----	206

METEOROLOGY

The high cost of weather, Huntington-----	207
The influence of weather factors on yield, Holdefleiss-----	207
Climates of California, Russell-----	207
Meteorological observations, [Stevens]-----	207
Meteorological records, 1883-1925-----	207
Climatology and meteorology of Pinheiro, State of Rio, Cavalcanti-----	207
Report for 1924 of the German Phenological Service, Werth-----	207
Meteorological observations, 1924-25-----	207

SOILS—FERTILIZERS

Properties of the colloidal soil material, Anderson and Mattson-----	208
Do colloids exist as a coating around the soil grains? Bouyoucos-----	208
The moisture equivalent of soils, Thomas and Harris-----	208
Some soil and plant relationships, McCool and Romaine-----	209
Some effects of mulching paper on Hawaiian soils, Stewart et al-----	209
Concentration of carbonates in two Minnesota soil types, McMiller-----	210
Contribution to the theory of the origin of alkali soils, De'Sigmond-----	210
The soils of the glacial region of northwestern Ohio, Conrey-----	210
Origin and nature of the soil organic matter or "humus," I, Waksman--	210
The carbon-nitrogen ratio in soils, Waterman-----	210
Sweet clover in relation to the nitrates in soil, Whiting and Richmond--	210
Microorganisms in decomposition of celluloses, Waksman and Skinner--	211
Profiles of peat deposits in New England, Dachnowski-----	212
Factors and problems in the selection of peat lands, Dachnowski-----	212
[Soil studies at the Illinois Station]-----	212
Effect of different methods of fertilizer application, Beaumont-----	212
Studies of certain physiological and chemical aspects of cereal straw--	212
Analyses of rainfall from a protected and an exposed gage, Johnson-----	212
The rate of absorption of nitrate of soda, Appleton and Helms-----	213
Potash: A review, estimate, and forecast, Turrentine-----	213
The availability of phosphates in soils, Breazeale and Burgess-----	213
Influence of lime and phosphatic fertilizers on the phosphorus content of the soil solution and of soil extracts, Parker and Tidmore-----	213
Influence of form, soil-zone, and fineness of lime and magnesia incorpora- tions upon outgo of calcium and magnesium, MacIntire-----	213
Influence of form, soil-zone, and fineness of lime and magnesia incorpora- tions upon outgo of sulfates and nitrates, MacIntire-----	214
Fixation of calcium-magnesium, MacIntire and Shaw-----	214
Synthetic calcium silicates as a source of lime, II, Barnette-----	215
Relation of fineness of grinding to sulfur oxidation in soils, Stephenson--	216
Rabbit's foot oil and organic ammoniate fertilizer, Walton-----	216
Analyses of commercial fertilizers, Curtis et al-----	216
Commercial fertilizers-----	216
Analyses of commercial fertilizers sold in New York State, 1925-----	216
Commercial fertilizers in 1925-26 and their uses, Fraps and Asbury-----	216

AGRICULTURAL BOTANY

The plant cuticle, I, Lee and Priestley-----	216
Experimental vegetation: Tree seedlings as phytometers, Phillips-----	217
Duration of light and growth, Adams-----	217
Respiration in plants, Popoff-----	218
Relation of temperature to growth in the potato plant, Bushnell-----	218
Absorption and exudation pressures of sap in plants, MacDougal-----	218
The absorption of salts by storage tissues, Stiles-----	219

	Page
The absorption of ions by citrus and walnut seedlings, Haas and Reed.....	219
Testing corn stalks chemically to determine plant food needs, Hoffer.....	220
Observations on the nitrate-reducing properties of plants, Anderson.....	220
Formation of growth-promoting substances, Mockridge.....	220
The root-tubercles in <i>Arbutus unedo</i> , Rivett.....	221
The staling of fungal cultures, I, II, Pratt.....	221
On the theory of "age and area," Schonland.....	221

GENETICS

The neurogenic theory of karyokinesis, Mühlmann.....	221
A cytological investigation of the genus <i>Saccharum</i> , Bremer.....	221
The cytology of the sugarcane, Bremer.....	221
Hereditary doubling suggesting anomalous chromatin, Danforth.....	222
A genetic and cytological study of dwarfing in wheat and oats, Goulden.....	222
Quadruple allelomorphs affecting eye color, Whiting and Burton.....	223
Two wing mutations in <i>Habrobracon</i> and their inheritance, Whiting.....	223
The occurrence of pigmented facets in white eyes in <i>Drosophila</i> , Spencer.....	223
Marking of black-spotted Holstein cattle and its inheritance, Lauprecht.....	223
Inheritance of horns, wattles, and color in grade Toggenburg goats, Lush.....	224
Genetic analysis of temperament of rats, Sadovnikova-Koltzova.....	224
Abnormal sexuality in animals.—I, Genotypical, Crew.....	224
Offspring from immature females hampered.....	224
Heredity involved in hairlessness of animals.....	225
Hyperglycaemia as a recessive character, Cammidge and Howard.....	225
Genetic studies on the nature of cancer, Strong.....	225
A genetic study of the growth of a transplantable tumor, Strong.....	225
The question of xenia occurrence in horticultural plants, Höstermann.....	225
An experimental study on xenia in the domestic fowl, Kopeć.....	225
The appearance of xenia in the domestic fowl, Kopeć.....	226
The ovarian follicular hormone, Allen.....	226
Standardization of ovarian follicular hormone, Bugbee and Simond.....	226
The time of ovulation in the menstrual cycle of the monkey, Allen.....	227
Alcohol and the sex ratio in mice, Danforth.....	227

FIELD CROPS

Artificial plats for field experiments, Lyon and Leland.....	227
A census of an acre of corn (by sampling), Engledow.....	227
Grazing and forage on national forests, Sampson and Malmsten.....	227
[Agronomic experiments in Guam, 1925], Guerrero.....	228
[Field crops experiments in Illinois].....	229
Number of nodes of culms in barley, wheat, and rice plants, Yamasaki.....	230
The preservation of the pollen of cereals, Sasaki.....	230
[Experiments with legumes in Illinois].....	230
Alfalfa and red-clover seed tests.....	231
Alfalfa seed production in southern Idaho, McClymonds.....	231
Effect of immaturity on seed corn, Alberts.....	231
Experiments on the manuring of mangels, 1892-1925, Roberts.....	231
Influence of external conditions on blooming of rice flowers, Kobayasi.....	232
[Investigations with soy beans in Illinois].....	232
Influence of adjacent rows of soy beans, Garber and Odland.....	233
Sugar cane experiments in Lesser Antilles and British Guiana, Williams.....	233
Investigations on high-nicotine tobacco.....	233
Rate, date, and depth of seeding winter wheat, Moss.....	233
A sow thistle survey of Ontario.....	233

HORTICULTURE

[Horticultural investigations at the Illinois Station].....	233
[Horticultural investigations at the New York State Station].....	235
Sprays and spraying materials, Talbert.....	235
Factors influencing the quality of fresh asparagus, Blsson et al.....	235
[Copa meal as a fertilizer], Guerrero.....	236
Cantaloupe production in California, Rosa and Garthwaite.....	236
Ginger.....	236

	Page
Breeding new varieties of canning peas, Delwiche and Renard.....	236
Has ringing any place in commercial orchard practice? Howlett.....	236
The effect of ringing filler trees in an apple orchard, Fagan.....	236
Starting the apple orchard, Burkholder.....	237
Experiments in cool storage of apples, Adam and Harrison.....	237
The growth of the fruit of the Elberta peach, Blake.....	237
Fruiting habit of the grape, Swartwout.....	237
Effects of fruiting on the growth of grape vines, Chandler and Heinicke..	238
The influence of pruning on <i>Vitis vinifera</i> , Winkler.....	238
Propagation of the date palm, Crider.....	239

FORESTRY

World forestry number.....	239
The forest resoures of Canada, Craig.....	239
Danger of frosts studied at Wind River Nursery.....	239
Factors which influence forest fires, Hawley.....	239
Harvesting timber in the national forests of the East and South, Evans..	239
Predicting the second cut in national forest management plans, Dunning..	240
Yield, stand, and volume tables for white fir in California, Schumacher..	240
Field manual of trees, Schaffner.....	240
The commercial woods of the South.....	240
A universal index to wood, Swain.....	240

DISEASES OF PLANTS

[Plant disease investigations at the Illinois Station].....	240
[Plant disease investigations at the New York State Station].....	241
Diseases of crops in England and Wales, 1922-1924, Pethybridge.....	242
Plant diseases in relation to certification of seeds, Gussow.....	242
A review of immunity and resistance in plants, Howitt.....	242
Influence of time and temperature on growth of certain fungi, Fawcett..	243
Recent advances in dusting methods, Smith.....	243
<i>Botrytis cinerea</i> in Alaska, Anderson.....	243
The growth of <i>Ophiobolus graminis</i> Sacc., Webb and Fellows.....	243
Production of substances toxic to plants by <i>Penicillium expansum</i> , Barnum..	243
Spore germination of <i>Ustilago striaeformis</i> , Davis.....	244
Reactions of selfed lines of maize to <i>Ustilago zaeae</i> , Hayes et al.....	244
Notes on the climatic conditions influencing the 1923 epidemic of stem rust on wheat in Illinois, Tehon and Young.....	244
Anthraxnose as a cause of red clover failure, Pieters and Monteith.....	244
The rust of cowpeas, Fromme.....	245
Control of diseases of cucurbits, Guerrero.....	245
Flax rust and its control, Henry.....	245
Immunity to mildew and its inheritance in lettuce, Jagger.....	245
Bacterial slime disease of lettuce, Smith.....	245
Species of <i>Fusarium</i> isolated from onion roots, Sideris.....	246
Mosaic and leaf roll of potatoes in Idaho, Hungerford and Raeder.....	246
<i>Alternaria solani</i> as a cause of tuber rot in potatoes, Folsom and Bonde..	246
Resistance of sorghum to loose and cover smuts, Kulkarni.....	246
Studies of a new <i>Fusarium</i> wilt of spinach in Texas, Taubenhaus.....	246
Curly leaf transmission experiments, Severin.....	247
Progress report on curly-top of the sugar beet, Carsner and Stahl.....	247
Environment and western yellow blight of tomatoes, Shapovalov.....	247
The behavior of certain varieties of tomatoes towards <i>Fusarium</i> -wilt in- fection in California, Shapovalov and Lesley.....	247
Relation of temperature and humidity to leaf spot, Pritchard and Porte..	247
The stripe or streak disease of tomatoes in Quebec, Vanterpool.....	248
Host plants of <i>Bacterium tabacum</i> , Johnson et al.....	248
Overwintering of tobacco wildfire bacteria in New England, Anderson.....	248
Tobacco wildfire and tobacco seed treatment, Thomas.....	248
Decay of xylem of apple caused by <i>Polystictus versicolor</i> , Smith.....	248
The study of resistance to crown-gall in <i>Prunus</i> , Smith.....	248
Biological and cultural studies of <i>Ewoascus deformans</i> , Mix.....	249
Notes on cranberry fungi in Massachusetts, Stevens.....	249
Mosaic disease of loganberry, Zeller.....	249

	Page
Grape rust in Florida, Shear.....	249
Alternaria rot of lemons, Bartholomew.....	249
The life history of the snapdragon rust, <i>Puccinia antirrhini</i> , Mains.....	250
Herpetomonad flagellates in the latex of milkweed in Maryland, Holmes.....	250
Decay of Douglas fir due to <i>Poria incrassata</i> , Zeller.....	250
Hypoxylon poplar canker, Povah.....	250

ECONOMIC ZOOLOGY—ENTOMOLOGY

Animal ecology, with especial reference to insects, Chapman.....	250
The value of life history studies to systematic entomology, Van Dyke.....	250
Importance of life-history data in biological control work, Smith.....	250
The natural "cleaning up" habit of insects, Mote et al.....	251
Hippelates flies and other pests of Coachella Valley, California, Herms.....	251
[Entomological work at the Guam Station], Vandenberg.....	251
[Report of the New York State Station division of entomology].....	251
[Economic insects in Pennsylvania].....	253
[Reports of the economic biologist of British Guiana], Cleare.....	253
Recent introductions of beneficial insects in Hawaii, Swezey.....	253
The aphiscidal properties of tobacco dust, Huckett.....	253
Airplane dusting for the control of vegetable pests, Morrill.....	254
Technical aspects of petroleum oils and oil sprays, De Ong.....	254
The use of oil spray on citrus trees, Woglum.....	254
Fumigation with hydrocyanic acid gas, Smit and Naude.....	254
Paradichlorobenzene as a soil fumigant, Essig.....	255
Naphthalene fumigation of greenhouses, Hartzell.....	256
The control of grasshoppers by airplane dusting, Granovsky.....	256
Control experiments on the Surinam cockroach, Doucette and Smith.....	256
Notes on the recent outbreak of <i>Toxoptera graminum</i> , Ainslie.....	256
Crepe myrtle plant louse, Doziér.....	256
The pea aphid as an alfalfa pest in California, Packard and Campbell.....	257
The peach cottony scale, Parrott and Harman.....	257
Notes on some Lepidoptera from eastern Texas, Bottimer.....	257
The biology of the Lepidoptera, Hering.....	258
The peach and prune root-borer injurious to cherries, Thompson.....	258
Some possibilities in codling moth control, List.....	258
Codling moth attacks cherries, Mote.....	258
The oriental peach moth, Peterson and Haeussler.....	258
Observations on injury caused by Lima bean pod borer, Larson.....	258
Tobacco cutworms and their control, Crumb.....	258
The use of powdered larvicides in combating mosquitoes, Roubaud.....	258
The horse bots and their control, Bishopp and Dove.....	259
The lesser bulb fly, <i>Eumerus strigatus</i> Fallen, in Oregon, Wilcox.....	259
The cherry fruit fly, Glasgow and Gambrell.....	259
Water and water solutions of organic compounds as dips for the soil of potted plants infested with the Japanese beetle, Fleming.....	259
A contact spray for the control of the Japanese beetle, Van Leeuwen.....	259
The cadelle, Back and Cotton.....	259
The Arizona cotton boll weevil problem, Cassidy.....	259
The problem of insects injurious to alfalfa, Doten.....	259
The collection and utilization of pollen by the honeybee, Parker.....	260
Reappearance of <i>Harmolita grandis</i> and <i>H. vaginicola</i> in Utah, Doane.....	260
<i>Habrobracon brevicornis</i> Wesm., Genieys, trans. by Howard.....	260
Some hymenopterous parasites of aphidophagous Syrphidae, Kamal.....	260
Hereditary transmission of tularaemia infection by the wood tick, Parker.....	261

ANIMAL PRODUCTION

Digestibility of dried orange pulp and raisin pulp, Mead and Gilbert.....	261
Commercial feeding stuffs in Kentucky in 1925, Turner et al.....	261
The effect of feeding cellulose on the pulse rate of steers, Titus.....	261
Fattening steer calves: Corn and oilmeal in dry-lot rations, Bohstedt.....	261
Stanchion-feeding compared with group-feeding of baby heaves, Bohstedt.....	262
[Experiments with beef cattle at the Illinois Station].....	262
Feeding bone meal to cattle on the Coastal Plains of Texas, Schmidt.....	263

	Page
[Nutrition studies with sheep at the Illinois Station]-----	263
[Experiments with sheep at the Nevada Station], Fleming-----	263
Progress of reindeer grazing investigations in Alaska, Palmer-----	264
[Experiments with swine at the Illinois Station]-----	264
Crossbreds versus purebreds in producing market hogs, Shearer et al.---	265
[Swine feeding experiments at the Guam Station], Edwards-----	265
Corn Belt rations for fattening spring pigs, Evvard et al.-----	266
Corn gluten feed, enzymes, oat feed, minerals, and water supply for fattening spring pigs, Culbertson et al.-----	266
Protein supplements, mineral mixtures, outdoor sunshine, and water supply for fall pigs, Evvard et al.-----	267
Protein supplements to corn for fattening pigs, Godbey and DuRant.---	268
Wyoming corn for pork, Quayle-----	269
Fattening pigs with rye, Morgan and Arnett-----	269
Fillies made good growth on soybean ration-----	270
[Feeding and nutrition experiments with poultry at the Illinois Station]_	270
Annual persistency in relation to egg production, Hays and Sanborn.---	270
The litter problem, Kennard and Nettleton-----	271
Poultry keeping in back yards, Jull and Lee-----	271

DAIRY FARMING—DAIRYING

[Feeding experiments with dairy cattle at the Illinois Station]-----	271
Feeding dairy animals, Corbett-----	271
Liberality and economy in feeding dairy cows, Perkins-----	271
Experimental disturbances in the milk secretion of the cow, Davidson---	272
Official records as material for studying inheritance of milk and butter- fat production, Fohrman-----	272
Good bulls and foundation cows the source of better cattle, Fairchild---	272
[Experiments in dairying at the Illinois Station]-----	272
Cells in cream, skim milk, and separator and centrifuge slimes, Breed---	274
Produce clean milk, Shepardson-----	274
Practical dairy tests, Burke-----	274
Some factors influencing the keeping quality of butter, Retief-----	274
Peroxidase as a factor in butter deterioration, Palmer and Miller-----	274
Microscopy of cheese, Laxa-----	275
Cottage cheese, Lucas-----	275

VETERINARY MEDICINE

A text-book of pathology, Delafield and Prudden, rev. by Wood-----	275
Chemical pathology, Wells-----	275
The National Formulary-----	275
The dispensary of the United States of America, Wood et al.-----	275
[Livestock disease investigations]-----	275
[Work of the veterinary division], Freeman-----	277
Proceedings in Northern Ireland under Disease of Animals Acts, Emery--	277
Report of the veterinary officer for the year 1924, Turbet-----	277
Animal diseases regulations with notes on diagnoses, Lionnet-----	277
Does the flesh of animals suspected to be infected by foot-and-mouth disease form a source of danger for the spreading of virus? Lourens--	277
A case of typhus-like fever following tick bite, Spencer-----	277
The toxic action of sarcosporidiotoxin and its serological study, Sato.---	277
Tumors of domestic animals, Formad-----	278
A promising treatment for infectious abortion, Edwards and Coffman.--	278
An obscure hemorrhagic disease in cattle, Records and Vawter-----	278
Etiology of tuberculosis in relation to immunisation in cattle, Thomson--	279
The chemotherapy of surra of horses and cattle in India, Edwards-----	279
Training the dog, Blair-----	279
Researches on the variolous, diphtheric affection of fowls, Verge-----	279
Studies of fowl pest, I, Pfenninger and Metzger-----	279
Studies of fowl pest, II, Pfenninger and Finik-----	279
A coryne-bacillus as a cause of abscess in the feet of hens, Kawamura---	280

AGRICULTURAL ENGINEERING

	Page
[Agricultural engineering studies at the Illinois Station]-----	280
Effect of size of soil columns on capillary rise of water, Wadsworth--	280
Centrifugal pump tests, Murdock-----	280
Water works practice-----	280
Action of sodium and magnesium sulfates on Portland cement, Shelton--	281
The weight and lateral pressure of sunflower silage, Murdock-----	281
Turn the switch—let electricity do the work, Hienton and McMahon----	281
Tractor lug studies on sandy soil, Randolph-----	282
Plows and plowing, Smith-----	282
Summer tillage implements, Ogaard-----	282
Some results of tests of the operation of combines in Illinois, Blauser--	282
Stationary spray plants in California, Moses and Duruz-----	283
The farmer's shop book, Roehl-----	283
A method of studying farm fires, Lantz-----	283

RURAL ECONOMICS AND SOCIOLOGY

[Investigations in agricultural economics at the Illinois Station, 1925]--	284
[Rural economics investigations at the Ohio Station]-----	285
Irrigated farming in Twin Falls County, Idaho, Hunter and Nuckols----	285
Farming for profits: South Carolina, Jensen-----	286
Economic studies of dairy farming in New York, VI, VII, Misner-----	287
Factors in the cost of producing beef in Kansas, Wilcox et al-----	288
Methods and practices of retailing meat, Davis-----	288
Margins, expenses, and profits in retailing meat, Gardner-----	288
Crops and Markets [for November, 1926]-----	289
Monthly Supplement to Crops and Markets, [November, 1926]-----	289

FOODS—HUMAN NUTRITION

Nutritional physiology, Stiles-----	289
Food selection in a college community, Kramer and Grundmeier-----	289
Feeding problems in college communities, Raitt-----	290
A square meal, Plimmer-----	290
Nutritive value of protein in beef extract, ox blood, ox palates, calf lungs, hog snouts, and cracklings, Hoagland and Snider-----	290
The biological value of bread-protein, Hindhede-----	290
A study of the laxative action of wheat bran, Williams-----	291
Peas in the diet, Marlatt-----	291
Cellulose sausage casings, Henderson and Dietrich-----	291
Studies on the effect of heat on milk, I, II, Magee and Harvey-----	291
Peptic digestion of cow's milk, Hess, Koch, and Sennewald-----	292
The production and handling of human milk, Chapin-----	292
The nutritive value of inorganic substances, I, Fairhall-----	293
The value of egg yolk in supplementing diets deficient in calcium, Tso---	293
The relation of anemia to vitamin A deficiency, Koessler et al-----	293
Treatment of pernicious anemia by a special diet, Minot and Murphy--	294
A differentiation between the water-soluble growth-promoting and anti- neuritic substances, Hauge and Carrick-----	294
The production of antirachitic properties in human milk, Hess et al-----	295
Effect of irradiation of the environment on rats, II, Hume and Smith-----	295
Production by irradiation with ultra-violet light of antirachitic properties in sterols derived from <i>Palaquium burckii</i> , Hume and Smith-----	295
Puffer fish oil; a very potent antirachitic, Hess and Weinstock-----	296
Studies on experimental rickets, XXVII, McCollum et al-----	296
Concentrated orange juice, source of vitamine C, Wilson-----	296
Present status of knowledge of the etiology of pellagra, Goldberger-----	296
Simple goiter and its prevention, Marine-----	296

TEXTILES AND CLOTHING

Collecting the literature of textiles, Goldthwait-----	297
The flax, hemp, and jute year book, compiled by Carter-----	297
Application of X-rays in the textile industry, Clark-----	297
Molecular structure of plant fibers determined by X-rays, Sponsler-----	297

	Page
The bacterial decomposition of textile fibres, IV, Thaysen and Bunker-----	297
The swelling of cotton fibres, Hall-----	297
A test for mercerised cotton, Mennell-----	297
The standardisation of wool in international wool statistics, Henseler-----	298
Dyes not fast to ironing, Haller-----	298
Principles of window curtaining, Davis-----	298

HOME MANAGEMENT AND EQUIPMENT

Convenient kitchens, Gray-----	298
--------------------------------	-----

MISCELLANEOUS

Report of the Guam Experiment Station, 1925, Edwards et al-----	299
Thirty-eighth Report [of Illinois Station, 1925], Keilholz-----	299
Abstracts of papers, finances, meteorology, index-----	299
Annual Report of [Nevada Station], 1925, [Doten]-----	299
Forty-fifth Report of the New York State Station [1926], Thatcher-----	299
Bimonthly Bulletin of the Ohio Station, [November-December, 1926]-----	299

LIST OF EXPERIMENT STATION AND DEPARTMENT PUBLICATIONS ABSTRACTED

<i>Stations in the United States</i>	
Arizona Station:	Page
Bul. 115.....	239
Tech. Bul. 10.....	213
California Station:	
Bul. 406.....	283
Bul. 407.....	240

RECENT WORK IN AGRICULTURAL SCIENCE

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Colloid and capillary chemistry, H. FREUNDLICH, trans. by H. S. HATFIELD (*London: Methuen & Co., 1926, pp. XV+883, pls. 7, figs. [136]*).—This is a translation of the third German edition of this well-known text. A translation of the less technical abridged edition has been noted previously (*E. S. R.*, 54, p. 407).

Textbook of microchemistry, F. EMICH (*Lehrbuch der Mikrochemie. Munich: J. F. BERGMANN, 1926, 2. ed., rev., pp. XI+273, figs. [82]*).—A revision of the text previously noted (*E. S. R.*, 29, p. 801).

Textbook of food chemistry, H. RÖTTGER (*Lehrbuch der Nahrungsmittel-Chemie. Leipzig: J. A. Barth, 1926, 5. ed., rev., vols. 1, pp. X+1028, insert pp. 8, pl. 1, figs. 27; 2, pp. VII+1029-2182, figs. 33*).—The fifth edition of this text, the third edition of which has been noted (*E. S. R.*, 19, p. 669).

The essential oils, H. FINNEMORE (*London: Ernest Benn, 1926, pp. XV+880, pls. 11, fig. 1*).—An extensive compilation of information on the production, chemical constituents (with methods for their recognition), and uses of the essential oils classified according to their botanical sources.

Experiments on sunflower seed oil, H. E. FRENCH and H. O. HUMPHREY (*Missouri Univ. Engin. Expt. Sta. Bul. 25 (1926), pp. 27, figs. 6*).—The studies reported in this publication were undertaken to determine by comparison with other oils in general use the possible industrial uses of sunflower seed oil. The literature on the importation, domestic production, chemical composition, physical and chemical constants, and attempted uses of sunflower seed and oil is first reviewed. In the experimental work the oil used was pressed by two different companies from 11 samples of seed furnished by the Southeast Missouri Sunflower Growers Association. In attempts to remove the foots contained in the oil as it came from the mill, filtration through Filter-Cel or separation with a Sharples Super-Centrifuge proved most satisfactory. In tests with various bleaching agents, the best results were obtained with potassium hydroxide, followed by a mixture of fuller's earth and activated carbon.

The oil proved unsatisfactory as a frying oil on account of the low temperature at which it began to smoke and the characteristic disagreeable taste imparted to the product. Even steam distillation did not render the oil sufficiently tasteless to be acceptable as a salad oil. Partial hydrogenation of the purified and steam-distilled oil gave a product which proved satisfactory as a frying oil, but which was not satisfactory as a lard substitute.

The oil also proved unsatisfactory as a drying oil. It dried more slowly than linseed oil, and paints containing it possessed no superior weathering

qualities over linseed oil paints and darkened considerably on standing. A bibliography of 49 titles is appended.

On the chemical composition of poisonous beechnut cake, G. B. P. VAN KAMPEN (*Een Onderzoek naar de Chemische Samenstelling van Vergiftige Beukennotenkoek. Proefschr., Tech. Hoogesch., Delft; Wageningen: H. Veenman & Sons, [1925], pp. [7]+78, pls. 4, fig. 1; Eng. abs., pp. 75-78*).—As a wartime measure in the Netherlands, attempts were made to use beechnut seed oil for human consumption and the resulting beechnut cake for animal feeding. The latter had been considered harmless to cows, pigs, and sheep, but harmful to horses. Several cases of intoxication in cows fed the cake during 1919 were reported, as a result of which this investigation was undertaken to determine the nature of the poisonous constituents.

The trouble was found to lie not so much in the presence of poisonous nitrogenous compounds as in decomposition products of the residual oil of the cake. There were identified in the poisonous but not in the nonpoisonous cake azelaic acid, $\text{COOH}(\text{CH}_2)_7\text{COOH}$, and an unknown tribasic acid, $\text{C}_8\text{H}_7(\text{COOH})_3$. The possibility of rendering the cake harmless by complete extraction of the oil is suggested.

An improved method for the preparation of wheat gliadin, M. J. BLISH and R. M. SANDSTEDT (*Cereal Chem., 3 (1926), No. 3, pp. 144-149*).—The method described is based upon the observation that "when crude gluten which has been dried in vacuo at 65 to 70° C. is ground to a powder and treated with N/100 to N/10 acetic acid, only gliadin is dispersed. The extract may be filtered water-clear, and the gliadin recovered by the addition of salt, or by neutralization with alkali. This furnishes a basis for preparing gliadin in quantity and of a high degree of purity. It is superior to the established method from the standpoint of economy (in time, expense, and alcohol) and simplicity of operations."

The antirachitic value of irradiated cholesterol.—VI, A separation into an active and an inactive fraction, A. F. HESS, M. WEINSTOCK, and E. SHERMAN (*Jour. Biol. Chem., 70 (1926), No. 1, pp. 123-127*).—By certain modifications of the technique employed in the previous study (*E. S. R., 55, p. 594*) of the fractionation of irradiated cholesterol, antirachitic activity has been demonstrated in the filtrate from the digitonin precipitate. The modification consisted in carrying out the separation of the cholesterol digitonide in an atmosphere of nitrogen, separating the fraction as rapidly as possible, and using curative rather than preventive tests. The active fraction constituted only about 4 to 5 per cent of the original amount of cholesterol.

It is pointed out that these results are comparable with those previously reported by Dubin and Funk (*E. S. R., 53, p. 765*) for cod-liver oil, thus furnishing a proof that the active constituent in cod-liver oil is closely similar to, if not identical with, that of irradiated cholesterol. Another analogy between the two was furnished by the separation from irradiated cholesterol by extraction with liquid ammonia of an active residue comprising somewhat less than 4 per cent of the original material. The separation of a similar fraction from cod-liver oil has been reported briefly by Koch, Cahan, and Gustavson.

The anti-rachitic properties of irradiated sterols, O. ROSENHEIM and T. A. WEBSTER (*Biochem. Jour., 20 (1926), No. 3, pp. 537-544, pl. 1*).—Further attempts at the concentration and possible isolation of the active fraction of irradiated cholesterol (*E. S. R., 54, p. 195*) are reported, with results conforming in many respects to those of Hess, Weinstock, and Sherman noted above. It was found that the activity of irradiated cholesterol could be considerably

increased by conducting the irradiation in the absence of oxygen, i. e., in an atmosphere of nitrogen. In attempts to separate the active substance from the digitonin precipitate, negative results were obtained with air-irradiated cholesterol and positive with the samples irradiated in nitrogen.

Cholesterol was successfully irradiated by exposure in a thin layer on a glass plate, covered with a thin quartz disk, to daylight for an entire summer month in which there were many days of bright sunshine.

Attempts to activate various cholesterol derivatives gave negative results except in the case of ergosterol and cholesteryl acetate and palmitate. Irradiated ergosterol was highly protective even in doses of 1 mg. It is concluded that only members of the three groups of protoplasmic sterols (sterols occurring in animal or plant tissue) can be activated, and that both the secondary alcohol group and the unsaturated carbon linkage contained in the sterol molecule must be intact for successful irradiation.

In connection with the feeding experiments in which the Sherman-Pappenheimer low phosphorus diet 84 was used, the observation was made that patent flour occasionally carries enough of the antirachitic factor to invalidate the experiment, but that this source of error can be obviated by extracting the flour with ether.

Fractionation of irradiated cholesterol, I, II (*Jour. Biol. Chem.*, 71 (1926), No. 1, pp. 213-233).—Two papers are presented.

I. *Chemical observations*, M. J. Shear and B. Kramer (pp. 213-220).—On irradiating cholesterol, purified by repeated crystallization from hot acetone solution, in thin layers in air for 2 hours at a distance of 18 in. and recrystallizing the irradiated product, a small quantity of pale yellow oil was obtained which gave a marked positive reaction with aniline-hydrochloric acid. The process could be repeated a number of times. The yield of the oil, provisionally called U. V. oil of cholesterol, was about 5 per cent following irradiation for 1 hour at 18 in. and 10 per cent after 2 hours. About 40 per cent of the crude oil was not precipitable by digitonin. This fraction gave positive reactions with the aniline-hydrochloric acid, Liebermann-Burchard, and Salkowski tests and the Lifschütz reaction for oxysterol.

II. *Antirachitic potency of the fractions*, B. Kramer, M. J. Shear, and D. H. Shelling (pp. 221-233).—In this paper the antirachitic potency of the crude U. V. oil of cholesterol and the cholesterol-free oil obtained from it was tested by curative experiments with rats on the Steenbock rachitic diet 2965. With the authors' technique irradiated cholesterol, fed at a 0.01 per cent level, induced initial healing in 9 days in 3 out of 5 rats, showing that this amount was in the neighborhood of the minimum dose. As previously reported by Hess, Weinstock, and Sherman (see above), irradiated cholesterol lost its antirachitic potency following recrystallization. Crude U. V. oil of cholesterol when fed at a 0.1 per cent level brought about healing in only 2 cases out of 4, while at the same level cholesterol-free U. V. oil induced healing in all of the 6 cases tested. With 0.3 per cent of the U. V. oil, marked healing was obtained with both the crude and cholesterol-free oils. The cholesterol-free oil protected by cottonseed oil was found to retain its antirachitic potency after two months' storage.

Comparison between the pigeon and the rat methods of testing for anti-neuritic vitamin [trans. title], A. SEIDEL (*Bul. Soc. Chim. Biol.*, 8 (1926), No. 7, pp. 746-750, figs. 2).—This discussion of the choice of methods for determining vitamin B and the antineuritic vitamin is based upon a comparison of the effects obtained with rats as reported by Smith and Hendrick (*E. S. R.*, 55, p. 891) and with pigeons in testing the activity of the antineuritic vitamin con-

concentrate prepared as previously noted (E. S. R., 55, p. 609) with and without the addition of autoclaved yeast. In the rat experiments the basal diet was one supposedly adequate except for vitamin B, and in the pigeon experiments it was polished rice.

In both experiments the weight of the experimental animals was maintained after the addition of the yeast concentrate alone. In the rat experiments there was a growth response following the addition of autoclaved yeast, but in the pigeon experiments the autoclaved yeast was without effect. On the assumption that growth-promoting vitamin B is composed of the antineuritic vitamin and another constituent, in itself active or inactive as regards growth, the possibility is suggested that the rat needs both of these constituents and the pigeon only the antineuritic vitamin. If this is true, the pigeon, on account of its simpler needs, would seem to be the choice for determinations of the antineuritic vitamin, and the rat for vitamin B.

Note on colorimeter correction curves, S. L. WRIGHT, JR. (*Jour. Biol. Chem.*, 71 (1926), No. 1, pp. 209-212, figs. 2).—Marked variations in the colorimeter correction curves for sugar (Folin and Wu method) as reported by different workers are shown by curves calculated from the reported findings to give the correction in milligrams plotted against the apparent value as calculated by the ordinary method. These variations are thought to emphasize the necessity of individual calculation of a correction curve. Attention is also called to the high colorimetric correction required for creatinine determinations.

The influence of sodium chloride on the colorimetric determinations of pH, L. B. PARSONS and W. F. DOUGLAS (*Jour. Bact.*, 12 (1926), No. 4, pp. 263-265).—A study of the salt error of the sulfonphthalein series of indicators at 1, 2, and 3 M salt concentrations is reported. It is concluded that by subtracting 0.3 from the observed colorimetric pH value results may be obtained for solutions containing from 6 to 18 per cent salt which are in conformity with the electrometric data.

A rapid electrometric method for the measurement of hydrion concentration of flour-water suspensions, H. J. DENHAM and G. W. S. BLAIR (*Cereal Chem.*, 3 (1926), No. 3, pp. 158-162, figs. 2).—The quinhydrone electrode is used in the method described. Although it is said to be possible to conduct the determination directly on flour-water mixtures of convenient dilution, it has been found preferable to use an extract prepared by shaking a mixture of 20 gm. of flour with 200 cc. conductivity water in a special flask of borosilicate glass for 5 minutes in a mechanical shaker and then centrifuging for 5 minutes, after which the clear supernatant liquid is poured into the electrode vessel. The quinhydrone electrode has proved satisfactory over the entire range of pH occurring in flour extracts and has given results comparable with those obtained with the hydrogen electrode.

A rapid method for the colorimetric determination of hydrogen-ion concentration of crackers, R. T. BOHN and R. J. MARTZ (*Cereal Chem.*, 3 (1926), No. 3, pp. 183-187).—This adaptation of the colorimetric method of determining the H-ion concentration of crackers as recommended by Johnson and Bailey (E. S. R., 54, p. 108) consists essentially in distributing several drops of distilled water across the freshly broken surface of the cracker, placing on them drops of water or an alcohol solution of phenol red, and comparing the color with a standard set of color tubes for this indicator. If the pH is near the limit of range of the indicator the test should be repeated with the next indicator in the series. Overbaked crackers should not be used for the test as they tend to show a lower alkalinity.

Control of diastatic activity in wheat flour.—II, Experiments with flour milled on a commercial scale, R. C. SHERWOOD and C. H. BAILEY (*Cereal*

Chem., 3 (1926), No. 3, pp. 163-182, figs. 3).—This paper reports in detail experiments on a commercial scale confirming the conclusions drawn in the preliminary report (*E. S. R.*, 55, p. 611). The baking strength of flour milled from wheat low in diastatic activity was increased by the addition of 3 per cent of sprouted kernels to the wheat. The time for proofing was reduced, the color of the crumb was whiter, and the crust of the loaves browner and more pleasing in appearance when the flour contained germinated wheat. The protein quality was apparently unaffected by the addition, and the aging of the flour proceeded normally. Examination of the flour after 26 months of storage showed it to be as sound as flour milled at the same time from ungerminated wheat.

The gasoline color value of several classes of wheat, D. A. COLEMAN and A. CHRISTIE (*Cereal Chem.*, 3 (1926), No. 3, pp. 188-193, figs. 2).—The method previously described (*E. S. R.*, 55, p. 611) has been applied to several varieties of wheat and wheat flour.

The gasoline-soluble pigments varied greatly in amount with the different varieties. On the average the wheats of the hard red winter class contained the largest amount, followed by the common white class of wheat, and then by durum wheat. Certain varieties of durum wheat were consistently lower in gasoline-soluble pigments than others. No relationship was found between the protein and ash content of durum wheat flour and the gasoline-soluble pigments.

Miscibility tests in the detection of adulterated butter, H. J. ATKINSON (*Canad. Chem. and Metall.*, 10 (1926), No. 8, pp. 181-183).—Attention is called to sources of error in various miscibility tests for the detection of adulteration of butter with other fats, and a new test is described which is based upon the principle of dissolving the fat in a given solvent and adding from a burette a liquid in which the butterfat but not the adulterant is immiscible. Ethyl acetoacetate was finally selected as the precipitant and benzene and chloroform as the solvents, two determinations being required, one with chloroform and the other with benzene. This was found necessary because a mixture of 72 per cent lard and 28 per cent coconut oil gives the same turbidity number as butterfat when benzene is used as the solvent, and a mixture of 90 per cent lard and 10 per cent coconut oil the same number as butterfat when chloroform is the solvent. The technique with benzene is as follows:

Into a clean, dry 50-cc. beaker about 4.2 cm. in diameter, 3 cc. of benzene is run from a burette and to this is added 2 cc. of melted butterfat at 30° C. After the mixture has reached room temperature ethyl acetoacetate is added from a burette, 1 cc. at a time, until slight traces of precipitation are noticeable, and then 0.2 or 0.3 cc. at a time at 1-minute intervals until a decided turbidity is reached, the number of cubic centimeters required being taken as the turbidity number.

In the course of the experimental work leading to the development of the method, the miscibility tests reported by Bills (*E. S. R.*, 55, p. 610), were repeated with like results except in two instances. Pyridine was found to be immiscible with both butterfat and coconut oil and allyl alcohol immiscible with coconut oil.

Dehydration of fruits in California, A. W. CHRISTIE (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 6 (1927), No. 5, pp. 13-17, figs. 5).—This is a general discussion of the relative advantages of sun drying and dehydration for preserving various California fruits, with data on the production of dried fruits in California in 1925. The highest figures were for raisins, totaling 219,300 tons, followed by prunes 146,000, apricots 17,500, peaches 16,200, figs 9,600, apples 5,750, pears 3,500, and dates 300 tons.

Cultures and yeast foods tested for vinegar making (*Illinois Sta. Rpt. 1925, p. 149*).—In cider fermentations conducted by A. C. Vogele and F. W. Tanner simultaneously in 16-gal. kegs at 70° F., equally good results were obtained with uninoculated cider as with cider inoculated with pure cultures of yeast and acetic acid bacteria.

Low concentrations of ammonium acid phosphate and ammonium acetate (0.08 and 0.02 per cent respectively) added to the cider at the beginning of the experiment hastened the process, particularly the alcoholic fermentation, and did not detract from the clarity or fragrance of the product.

The use of water valves to exclude air from the fermenting liquid and thus prevent acetic acid formation until after the completion of the alcoholic fermentation was found to be of no advantage. The acetic acid fermentation was more rapid in kegs only one-half full than in those nearly full.

The effect of pickle scum on the pickle brine, M. A. JOSLYN (*Fruit Prod. Jour. and Amer. Vinegar Indus., 6 (1927), No. 5, pp. 22, 23, figs. 3*).—The film frequently occurring on pickle brine has been found to contain a species of *Mycoderma vini*, a naturally-occurring soil organism. This aerobic organism has a marked destructive effect upon the lactic acid formed by bacterial action during the storage of pickles in brine. It is suggested that open tanks of pickles in brine be sealed with a layer of neutral mineral oil to prevent the growth of this organism.

A causative factor of "floaters" during the curing of olives, R. S. ALVAREZ (*Jour. Bact., 12 (1926), No. 5, pp. 359-365*).—A bacteriological examination of olives which had developed blisters (becoming floaters) during curing, as described by Cruess and Guthier (*E. S. R., 50, p. 414*), has shown that a group of organisms rather than a single species is probably responsible for the trouble. These organisms are described as rather large, Gram-negative rods, showing great pleomorphism. They are highly fermentative but do not liquefy gelatin, peptonize milk, or attack cellulose. Although closely allied to the colon bacillus they are not identical with it, for true coli on inoculation into olives do not produce floaters.

One of the organisms isolated was found to resist a temperature of 80° C. for 45 minutes, showing heat sterilization to be impracticable for destroying the organisms. Concentrations of salt solution above 5 per cent inhibited the growth, but a concentration of 10 per cent was necessary to kill the organisms. Of other alkalies the concentrations found necessary to sterilize broth cultures were commercial lye 0.2 per cent (pH 12.5), sodium hydroxide 0.4 per cent (pH 12.21), and potassium hydroxide 0.5 per cent (pH 12.26). Frequent thorough sterilization of the vats and curing of the olives at low temperatures are suggested as the best means of preventing spoilage. A brine-holding solution of at least 5 per cent, if not injurious, would probably minimize the danger of spoilage.

Methods of preserving sardines, H. R. BEARD (*Canning Age, 7 (1926), No. 13, pp. 979-987, figs. 12*).—A description, with photographic illustrations, of the Maine, California, and foreign methods of canning sardines, together with a brief discussion of the research work of the U. S. Bureau of Fisheries on the advantages and disadvantages of the various methods now employed.

The principal tanning materials of Australia and their leather forming properties, M. B. WELCH and F. A. COOMBS (*[N. S. Wales] Technol. Mus. Bul. 10 (1926), pp. 20, pls. 7*).—A compilation, with references to the original literature, of information on the sources, availability, and tannin value of various Australian tanning materials. The most important of these is wattle bark. Other materials discussed include the bark of the mangrove and pine and the bark and gum of the eucalyptus.

METEOROLOGY

The high cost of weather, E. HUNTINGTON (*Amer. Rev. of Reviews*, 75 (1927), No. 1, pp. 38-42).—This article discusses briefly but broadly the effect of the weather of 1926 on crops, as illustrated particularly in wheat, cotton, apples, and corn. The loss of farm income due to unusual weather is estimated to have been \$1,000,000,000 and other losses due to the same cause to have been \$750,000,000. Weather conditions were favorable for large crops of cotton, winter wheat, and apples, but unfavorable for spring wheat and corn. There were unusually large crops, with low prices, of cotton and fruit.

The influence of weather factors on yield [trans. title], P. HOLDEFLEISS (*Kühn Arch.*, 9 (1925), pp. 53-78).—On the basis of observations on temperature and precipitation at the meteorological station of the Agricultural Institute of the University of Halle, extending over a considerable period of years and correlated with crop yields, it is concluded that the yield of peas is favored by warm and dry weather in March and April and by rainy and cool weather in May and June. The yield of potatoes is determined to a large extent by a warm October of the preceding year, especially by the mean minimum of that month. The growth of pine shoots depends especially upon the precipitation of the previous year; to a less extent upon the character of the preceding winter and on the average temperature of the period from April to June. The yield of winter wheat (squarehead) is largely determined by the temperature in March, while cool weather in May and June is favorable. The yield of oats is especially favored by relative dryness in the months of January to March, inclusive, and the same is true of winter rye. Warm weather in March is without influence on winter rye.

Climates of California, R. J. RUSSELL (*Calif. Univ. Pubs. Geogr.*, 2 (1926), No. 4, pp. 73-84, pl. 1).—This paper attempts to give "as full an areal analysis of California climates as present data warrant. . . . The classification followed, and to some extent adapted, is that of Wladimir Köppen." The climatic types are briefly described and regions are mapped.

Meteorological observations, [J. S. STEVENS] (*Maine Sta. Bul.* 328 (1925), pp. 260, 261).—Observations on temperature, precipitation, cloudiness, and wind at the University of Maine, Orono, during 1925 are summarized. The mean temperature for the year was 40.77° F., as compared with the 57-year mean of 42.775°. The precipitation was 47.31 in., as compared with the 57-year mean of 41.41 in. The number of clear days was 109.

Meteorological records, 1883-1925 (*New York State Sta. Rpt.* 1926, pp. 57-69).—Observations at the experiment station at Geneva, N. Y., on temperature, 1883-1925, and on precipitation, 1882-1925, are summarized in tables.

Climatology and meteorology of Pinheiro, State of Rio [trans. title], M. P. CAVALCANTI (*Rev. Zootech. e Vet. [Brazil]*, 12 (1926), No. 3, pp. 61-82, pls. 6).—This article briefly discusses the meteorology and climatology of this region with special reference to agriculture, as well as the application of the climograph in the study of the climate.

Report for 1924 of the German Phenological Service [trans. title], E. WERTH (*Mitt. Biol. Reichsanst. Land u. Forstw.* No. 28 (1926), pp. 338, figs. 3).—Phenological observations for the year are reported in detail, with brief descriptions of the climatic and vegetation districts of Germany.

Meteorological observations, 1924-25 (*Guam Sta. Rpt.* 1925, p. 20).—A condensed summary of observations at the station on temperature, precipitation, and direction of the wind is given. "The year was characterized by

heavy rainfall during the rainy season, followed by a serious drought, beginning in January and extending until June. The drought was one of the most severe and prolonged since the establishment of the station."

SOILS—FERTILIZERS

Properties of the colloidal soil material, M. S. ANDERSON and S. MATTSO (U. S. Dept. Agr. Bul. 1452 (1926), pp. 47, figs. 4).—The results of studies dealing with the properties of colloidal materials isolated from widely different soils are reported. Data are given on size of particles, specific gravity, adsorption of vapors, swelling, viscosity, volume of floc, adsorption of electrolytes, methylene blue required to render particles isoelectric, and H-ion concentration.

The different colloidal soil materials were found to vary considerably in all properties except specific gravity. A relationship between properties was indicated by the fact that variations of the colloids in one property usually paralleled variations in other properties. Variations in properties of the different colloids corresponded fairly closely to variations in the exchangeable bases and to variations in the $\frac{\text{SiO}_2}{\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3}$ ratio. The correlation between the properties and the silica ratio probably does not mean that all properties of the colloid are chiefly governed by the silica ratio directly. Certain properties are evidently governed more directly by the kind or quantity of exchangeable bases than by the silica ratio. However, the exchangeable bases and the silica ratio are usually correlated.

Soil colloids appeared to be more lyophobic than lyophilic in character, although they can not be looked upon as typical of either class. The importance of determining kind as well as quantity of colloid in a soil is pointed out. It is suggested that one or two properties, or the $\frac{\text{SiO}_2}{\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3}$ ratio, would characterize the kind of colloidal material fairly well.

A list of 57 references to work bearing on the subject is included.

Do colloids exist as a coating around the soil grains? G. J. BOUYOUKOS (*Soil Sci.*, 21 (1926), No. 6, pp. 481-487).—Studies conducted at the Michigan Experiment Station are reported which indicate that the colloids in the soil do not exist entirely as a coating around the soil grains but also as an independent component, either pure or containing different amounts of impurities and scattered irregularly throughout the soil mass. The experimental results and conclusions are strongly supported by a logical consideration of the form and amount of the colloids present in the soil. Optical examination of soils showed that they contain particles of sand and pebbles of various sizes which are not covered with colloidal gel. It was found that the material which passes through 200- and 325-mesh sieves is not clay. As a rule it contains less clay and colloids than the coarse material remaining behind.

The moisture equivalent of soils, M. D. THOMAS and K. HARRIS (*Soil Sci.*, 21 (1926), No. 6, pp. 411-424, figs. 3).—Studies conducted at the Utah Experiment Station of the moisture equivalent method as it is influenced by the amount of material centrifuged, by the texture and chemical treatment of the soil, and by the nature of the outside boundary are reported.

The results showed that increasing the size of sample reduces to a slight extent the amount of water retained in very coarse and very fine soils, whereas soils of intermediate texture show greater effects. The moisture gradient in the soil mass opposing the centrifugal force of the machine showed a similar maximum with intermediate textures. Very fine grained soils had a nearly

uniform moisture distribution at equilibrium. A period of many hours centrifuging was often required to establish capillary equilibrium in the case of heavy clays and very fine silts.

When samples of from 10 to 25 gm. were centrifuged, silt of about 10 μ average diameter retained more water than silt of 5 μ average diameter. This excess of water decreased with the increasing size of the sample. The very fine silts had a more apparent specific gravity than heavy clay, and also retained as much or more water. It is suggested that the capillaries in the silt which the centrifuge is unable to empty are filled entirely with water, whereas in the clay the corresponding interstices contain some colloidal material. As the capillaries of the outside boundary are reduced in size it was found that the adjacent soil becomes drier, and this reduction in the moisture content is reflected throughout the whole soil block. This effect conforms quantitatively to the thermodynamic theory of capillary equilibrium.

When the replaceable base of clay is entirely sodium the results indicate that the impermeability, and probably also the equilibrium moisture retaining power, are greater than when the replaceable base is potassium, ammonium, calcium, aluminum, or hydrogen. The colloidal swelling was found to be enhanced by the sodium in the complex.

Some soil and plant relationships, M. M. McCool and J. D. Romaine (*Soil Sci.*, 22 (1926), No. 1, pp. 31-34).—Studies conducted at the Michigan Experiment Station on the use of the heat of wetting method in studying the moisture relationships of soils and plants are briefly reported.

The nature of the plant materials seemed to affect the heat of wetting somewhat. The leaves of plants grown on unfertilized muck soil had a higher heat of wetting than those taken from differently fertilized soils, whereas plants grown on mineral soil gave similar but somewhat less striking results. Although fertilization did not affect the amount of heat evolved by alfalfa when moistened, it is considered apparent that the time of cutting and consequently the composition of the plant, does affect it.

Some effects of mulching paper on Hawaiian soils, G. R. Stewart, E. C. Thomas, and J. Horner (*Soil Sci.*, 22 (1926), No. 1, pp. 35-59, figs. 6).—Studies conducted at the experiment station of the Hawaiian Sugar Planters' Association are reported which showed that paper mulch exerts several effects upon Hawaiian soils planted to pineapples. Chief among these effects are a higher soil temperature, a higher content of soil moisture, and a more rapid elaboration of soil nutrients. The temperature effect of the paper mulch varied with the weather and with the season of the year, and it is thought probable that it will also vary with the degree of shading of the mulching paper by the pineapple plants.

The greatest increase in soil temperature due to mulching paper occurred in clear bright weather. Rain decreased the temperature differences between the mulched and the bare soil. In heavy rains the temperature differences disappeared, and for short periods the bare soil appeared to be slightly warmer. The maximum soil temperature occurred at from 2 to 4 p. m., about two hours after the maximum air temperature. The greatest differences between mulched and bare soils occurred during the warmest months of the year.

There was an appreciable effect of the paper mulch upon the retention of moisture in field soils, the mulched soils having a noticeably higher moisture content than the bare soils. A consistently higher nitrate content was found in paper mulched soils which had received no fertilizer, as well as in those receiving ammonium sulfate and a complete fertilizer mixture. This is taken to indicate that the paper mulch probably causes a more rapid elaboration of the principal soil nutrients.

Concentration of carbonates in two Minnesota soil types, P. R. McMILLER (*Soil Sci.*, 22 (1926), No. 1, pp. 75-82, figs. 2).—Studies conducted at the University of Minnesota are reported which showed that two important soil types in western Minnesota contain zones of pronounced carbonate accumulation at depths varying from 12 to 27 in., in which lime concretions are thickly distributed and in which the carbonate content ranges from 25.3 to 45.5 per cent. In the unaltered material below it varies from 7.7 to 22.7 per cent. No direct relation was found between the carbonate content and the fineness of texture of the subsoil. The color was distinctly grayer in the sections of carbonate concentration than in those above and below.

Contribution to the theory of the origin of alkali soils, A. A. J. DE'SIGMOND (*Soil Sci.*, 21 (1926), No. 6, pp. 455-479, figs. 3).—This is a translation by S. A. Waksman of the results of studies on the origin of alkali soils, made with particular reference to Hungarian conditions. A summary of these findings leads to the statement that alkali soils may originate under arid and semiarid conditions where in the past there is in the soil a temporary abundance of humidity intersected by dry periods.

The soils of the glacial region of northwestern Ohio, G. W. CONREY (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 233-244, figs. 7).—The results of a general survey of a region which includes a narrow belt bordering Lake Erie in northern and northeastern Ohio and a broad area in northwestern Ohio are briefly presented. The most striking topographic features of the region are the old beach ridges lying about the adjacent lake plain. These high-lying areas are well drained because of their gravelly nature. The level lake plain is practically flat, and was originally very poorly drained.

The soils of the region have resulted chiefly from the weathering of lake-laid and glacial deposits. The different soil series presented are briefly discussed.

The origin and nature of the soil organic matter or soil "humus."—I, Introductory and historical, S. A. WAKSMAN (*Soil Sci.*, 22 (1926), No. 2, pp. 123-162).—In a contribution from the New Jersey Experiment Stations a historical review of work on the subject is presented, together with a bibliography of 251 references.

The carbon-nitrogen ratio in soils and its relation to the decomposition of organic matter and nitrogen changes, S. WATERMAN (*Sci. Agr.*, 6 (1926), No. 10, pp. 357-359).—Studies conducted at the Ontario Agricultural College are briefly reported which showed that the carbon-nitrogen ratio in ten soil samples analyzed had much wider variations than has previously been stated. A bibliography is appended.

Sweet clover in relation to the accumulation, loss, and conservation of nitrates in soil, A. L. WHITING and T. E. RICHMOND (*Soil Sci.*, 22 (1926), No. 1, pp. 1-19).—Studies conducted by the Illinois Experiment Station are reported which showed that nitrification of both fall and spring plowed sweet clover proceeded rapidly, and to such an extent on one field as to furnish nitrate in excess of the requirements of a large corn crop. The spring plowed area was in better physical condition and required less labor in preparation than the fall plowed area. The rate of nitrification of sweet clover plowed in the spring at different dates prior to corn planting coincided closely with the date of plowing, that is, early plowing gave higher nitrate at an earlier date than later plowing. In two other fields all dates of plowing permitted a rapid nitrification and an accumulation sufficient to meet the needs of much larger crops than were produced.

Summer-plowed green sweet clover was found to nitrify rapidly, and large amounts of nitrates accumulated. Large losses resulted if no protective crop

was seeded. Oats and rye proved efficient in converting much nitrate into organic nitrogen and in reducing the amount formed, both of which reduced the losses. The oats was more valuable in reducing losses than the rye.

Studies on 13 Illinois experimental fields during a most disastrous season of rainfall are said to have demonstrated the importance of sweet clover in nitrogen economy.

Microorganisms concerned in the decomposition of celluloses in the soil, S. A. WAKSMAN and C. E. SKINNER (*Jour. Bact.*, 12 (1926), No. 1, pp. 57-84).—Studies conducted at the New Jersey Experiment Stations are reported which show that fungi, aerobic bacteria, and anaerobic bacteria are the most important agents concerned in the decomposition of celluloses in the soil. The amount of cellulose which is decomposed in soil under aerobic conditions was found to be dependent upon the amount of available nitrogen. Under anaerobic conditions a much smaller amount of nitrogen was required for the decomposition of the same amount of cellulose than under aerobic conditions. This is considered to be due to the much smaller amount of energy liberated and utilized by the organisms decomposing cellulose under anaerobic conditions. The optimum moisture concentration for the aerobic decomposition of cellulose was found to be two-thirds saturation to saturation.

Aerobic decomposition of cellulose began very early when available nitrogen was present. Anaerobic decomposition began late, after a continued lag period, indicating that in normal soils organisms capable of decomposing cellulose under anaerobic conditions are not found in great abundance.

The addition of cellulose to soils kept under aerobic conditions, especially in the presence of available nitrogen, caused a very large increase in the number and development of filamentous fungi.

There was a direct correlation between cellulose decomposition, development of fungi, and transformation of soluble nitrogen into microbial protoplasm. Most of the bacteria obtained from a soil in which cellulose decomposition took place were unable to decompose cellulose in pure culture. The elimination of fungi from the soil by treatment with volatile antiseptics was found to prevent cellulose decomposition in that soil under aerobic conditions. Reinoculation of the partially sterilized soil brought about an extensive development of fungi and a rapid cellulose decomposition.

It was found that under anaerobic conditions both in the soil, in the straw heap, and in the manure pile bacteria are entirely concerned in the decomposition of cellulose. Aerobic bacteria were capable of decomposing cellulose in the soil, and the opinion is expressed that they probably play an important part in this process in certain soils.

Some Actinomycetes were capable of decomposing celluloses, but they did not seem to play any direct part in this process in the soil itself. Their action was largely limited to the secondary products, either liberated or synthesized, and to some constituents of natural organic substances.

The fact that nitrogen becomes a limiting factor in the decomposition of cellulose in the soil is taken to indicate that nitrogen-fixing bacteria probably do not increase the store of soil nitrogen under aerobic conditions, especially in humid soils, when celluloses and straw are added as sources of energy. Nitrogen fixation takes place, however, when starches and lower carbohydrates, which are available sources, are also introduced.

The conclusion is drawn that under aerobic conditions in humid soils fungi are largely concerned in the decomposition of celluloses, and that in arid and alkaline soils bacteria apparently play an important part in the decomposition of celluloses.

Profiles of peat deposits in New England, A. P. DACHNOWSKI (*Ecology*, 7 (1926), No. 2, pp. 120-135, figs. 2).—In a contribution from the U. S. D. A. Bureau of Plant Industry 12 profiles of peat deposits from New England and 1 from New Brunswick, Canada, are described and arranged in 4 series, based on the composition and position of the layers. The profiles in each series showed good agreement considering the distance apart and differences in topography, soils, and drainage. The profile records from Connecticut and Massachusetts represent the oldest peat areas in New England, and show two distinct wet periods and intervening dry periods. The profiles from Cornwall, Vt., and from Crystal and Lewiston, Me., record only one high water stage, followed by a drier period during which the ground waters receded. The profiles from Maine and Canada correspond so closely that it seems likely they record the same glacial substage.

Factors and problems in the selection of peat lands for different uses, A. P. DACHNOWSKI (*U. S. Dept. Agr. Bul.* 1419 (1926), pp. 24, pls. 8, figs. 4).—The chief hazards in the agriculture and industry of peat lands are grouped as (1) differences between peat lands in their distinctive structural framework, (2) lack of a proper method of controlling the supply of soil moisture, and (3) the accumulation in the root zone of crops of excessive quantities of soluble salts from the mineral subsoil. It is stated that these three difficulties may occur together or that any one of them may cause disastrous results. An effort is made to formulate a basis for a more definite selection, and also for a safer and more economic procedure in the work of improving peat lands which have been abandoned in various sections of the country.

[**Soil studies at the Illinois Station**] (*Illinois Sta. Rpt.* 1925, pp. 6-31, figs. 5).—The progress results of a large number of soil and soil fertility studies at the station are briefly summarized, and include data on weights of soil strata, the effect of long continued cropping and fertilization on soil properties, limes and liming practices, nitrogen, potash, and phosphoric acid fertilization practices, the residual effect of fertilizers, the sulfur content of rainfall, the use of straw as a fertilizer, and the use of clover in soil improvement.

Effect of different methods of fertilizer application on seed and seedling, A. B. BEAUMONT (*Amer. Fert.*, 65 (1926), No. 3, pp. 25, 26).—Studies conducted at the Massachusetts Agricultural College are briefly reported which indicate that any method of application which allows the fertilizer to come into direct contact with the seed is detrimental to germination and stand.

Studies of certain physiological and chemical aspects of cereal straw (*New York State Sta. Rpt.* 1926, p. 17).—It is reported that a mixture of ammonium sulfate, acid phosphate, potassium chloride, and ground limestone was effective in rotting down straw in from three to four months. The process required frequent wetting and forking, and it is considered questionable if it is a practical one on any large scale.

Analyses of rainfall from a protected and an exposed gage for sulfur, nitrate nitrogen, and ammonia, E. M. JOHNSON, (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 10, pp. 589-591).—Studies conducted at the University of Kentucky are reported in which rainfall from a gauge protected from birds and from one not protected was analyzed for a period of 15 months for sulfur, nitrate, and ammonia. The total amount of sulfur in pounds per acre for the period was 56.07 in the rainfall from the protected gauge and 50.61 in that from the exposed gauge. The nitrate in the rainfall from the same period was 0.81 lb. per acre in the exposed gauge and 0.71 lb. in the protected gauge. There was a total of 17.44 lbs. per acre of ammonia in the water from the exposed gauge and 9.81 lbs. in that from the protected gauge.

The rate of absorption of nitrate of soda by oats and cotton when applied at different stages of plant growth, W. H. APPLETON and H. B. HELMS (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 10, pp. 596-605).—In studies conducted at the Alabama Experiment Station the results showed that when sodium nitrate was applied at the rate of 400 lbs. per acre to oats 14 days after planting, absorption of the nitrate was very slow for 3 weeks. After the third week the absorption increased, and all of the nitrate was absorbed by the close of the seventh week. When the nitrate was applied to oats at later stages of growth the rate of absorption was more rapid. Nitrate applied 42, 70, and 92 days after planting was completely absorbed in 20, 14, and 10 days, respectively. The nitrate of sodium nitrate applied at the rate of 600 lbs. per acre to cotton 14, 40, and 61 days after planting was completely absorbed in 36, 14, and 11 days, respectively. With both oats and cotton there was a close correlation between the rate of growth and the rate of nitrate absorption. The results of both experiments are taken to indicate that the loss of soluble nitrogenous fertilizers by leaching may be reduced by delaying the application until the crop will absorb it rapidly.

Potash: A review, estimate, and forecast, J. W. TURRENTINE (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, pp. IX+188, figs. 16*).—This is a review of work which has been done on the industrial development of potash, particularly in this country. Estimates are made of the possible production from the different sources discussed.

The availability of phosphates in calcareous or alkaline soils, J. F. BREAZEALE and P. S. BURGESS (*Arizona Sta. Tech. Bul. 10 (1926), pp. 205-237, figs. 3*).—Studies are reported which showed that calcareous or alkaline soils in semiarid regions do not respond to applications of insoluble phosphates, although they do respond to soluble acid phosphates. Soils containing black alkali were found to contain no free carbon dioxide, so that the solvent action of carbon dioxide upon insoluble phosphates in such soils was absent.

Floats was found to be practically insoluble in water containing no carbon dioxide and containing an excess of calcium carbonate. Floats was also practically insoluble in a saturated solution of carbon dioxide with calcium carbonate or calcium bicarbonate. It showed an appreciable solubility in a saturated solution of carbon dioxide with calcium sulfate, but slightly lower than in the absence of calcium sulfate.

Influence of lime and phosphatic fertilizers on the phosphorus content of the soil solution and of soil extracts, F. W. PARKER and J. W. TIDMORE (*Soil Sci.*, 21 (1926), No. 6, pp. 425-441).—Studies were conducted at the Alabama Experiment Station on soils from field experiments in Alabama, Illinois, Ohio, and Kentucky. The phosphatic fertilizers used included acid phosphate, rock phosphate, steamed bone meal, and basic slag.

Liming was found to increase the phosphorus content of the soil solution and of the extracts from soils receiving acid phosphate or basic slag. The influence of lime on the solubility of rock phosphate was not great, in some cases increasing and in others reducing it. Liming had a very decided depressing effect on the solubility of phosphorus in steamed bone meal.

The relation of the results obtained to the absorption of phosphorus by plants is discussed.

Influence of form, soil-zone, and fineness of lime and magnesia incorporations upon outgo of calcium and magnesium, W. H. MACINTIRE (*Soil Sci.*, 21 (1926), No. 5, pp. 377-391, figs. 3).—The results of a 4-year lysimeter study conducted at the Tennessee Experiment Station to determine the influence of form, soil zone, and fineness of lime and magnesia incorporations upon calcium and magnesium losses from soils are reported.

The maximum increase in calcium loss from surface soil incorporations during 4 years was only 6.8 per cent of the addition, and although some influence of form and fineness of lime was noted, the losses tended to be uniform from the untreated subsoil. Lower zone incorporations gave a maximum increased loss of 33 per cent of the addition. Although hydrated lime gave the greatest loss during the first year, its final loss was almost identical with those from two finer limestone separates.

The losses from the high calcium additions during the first year were uniformly maximum, with decided decreases for the next three years for both zones. The differences due to fineness, zone, and time were not so great for the dolomite additions.

There was very little difference between the magnesium losses from the controls and those from either limestone or dolomite additions to surface soils. The losses from subsurface soil incorporations were consistently greater than those from the surface soil incorporations. Both zones generally gave the maximum annual losses during the first year. The influence of fineness of dolomite separates was especially marked in the subsurface soil losses for both annual and 4-year periods.

In the case of completely disintegrated finer limestone separates in the subsurface soils there was no increased magnesium loss from the decomposition of the magnesium content of the limestone. Repressed magnesium solubility was indicated by the high calcium additions to the lower zone. The total calcium-magnesium leachings from the surface soil incorporations were small and related to the degree of fineness.

The total calcium-magnesium leachings from the subsurface soil incorporations were uniformly greater than those from the surface soil incorporations. Limestone separates gave total losses uniformly higher than those from the corresponding dolomite separates, the disparity decreasing with increasing fineness. The total loss from calcium hydroxide and that from 100-mesh limestone and dolomite were almost identical.

Influence of form, soil-zone, and fineness of lime and magnesia incorporations upon outgo of sulfates and nitrates, W. H. MACINTIRE (*Soil Sci.*, 22 (1926), No. 1, pp. 21-30).—Studies conducted at the Tennessee Experiment Station are reported which showed that the maximum increases in the average annual losses of sulfur and nitrogen by leaching from uncropped brown loam soil, treated with calcium and magnesium compounds and having a pH value of 6.38, were 5.8 and 18.8 lbs., respectively. Calcium hydroxide caused the greatest losses of sulfates from the surface soils. The finer separates of limestone and dolomite gave about the same results in this respect, and both caused greater losses than the coarser materials. The coarser separates had less effect than the finer on nitrate production, and these in turn caused greater nitrate losses than did calcium hydroxide. Each of the finer limestone separates was more active in this respect than the corresponding dolomite separate.

The influence of form and availability of treatment was not so consistent in increasing sulfate losses from the subsurface soils. Nine of the 10 limestone and dolomite separates caused greater nitrate losses than did calcium hydroxide from these soils. In this zone the influence of increase in surface of separates was not so marked, nor was the relationship between limestone and dolomite so well established.

As a whole, it appeared that neither degree of fineness of calcium hydroxide, limestone, and dolomite nor depth of incorporation consistently influenced the total losses of sulfates and nitrates during a 4-year period from this soil.

Fixation of calcium-magnesium from burnt limes, limestone, and dolomite incorporations in two soil zones, W. H. MACINTIRE and W. M. SHAW

(*Soil Sci.*, 22 (1926), No. 2, pp. 109–121, figs. 3).—Studies conducted at the Tennessee Experiment Station on the fate of equivalent additions of calcium hydroxide, calcium and magnesium oxide mixtures, limestone, and dolomite in the surface and subsoils of a loam soil after four years of outdoor exposure are reported.

After extraction of the soluble salts the subsoil of the untreated soil showed an acidity in excess of that of the surface soil as a result of four years of leaching without cultivation.

The calcium-magnesium fixation, leachings, and carbonate residues from additions of calcium hydroxide and calcium oxide-magnesium oxide mixtures to surface soils were similar. Their fixations and losses did not differ greatly from those from limestone and dolomite. Similar results were obtained with subsoils.

In general the limestone separates were more extensively fixed than the dolomites, especially in the coarser materials. The differences between limestone and dolomite fixations were in general not so great as those between leachings and carbonate residues.

The ratios of fixation to loss for the 13 additions used were 14.6:1 for the surface soils and 2.29:1 for the subsoils. The supplementary effect of the untreated subsoils served to increase greatly the amount of calcium and magnesium fixed from surface soil additions of all the calcium materials. The lesser fixation of calcium and magnesium in the subsoils was reflected in a correlative increase in losses. The limestone separates were more extensively disintegrated in the subsoils, but with one exception the fixation from subsoil additions was less than that from additions to the surface soils. In the dolomite group the combination of greater disintegration and increased loss resulted in greater fixation from subsoil additions of calcium oxide and magnesium oxide and for all separates except one.

The results are taken to indicate that the coarser the separate the deeper should be the incorporation to insure disintegration, and that dolomite should be ground finer than limestone.

Synthetic calcium silicates as a source of agricultural lime.—II, A comparison of their influence with that of other forms of lime upon certain microbiological activities in the soil, R. M. BARNETTE (*Soil Sci.*, 21 (1926), No. 6, pp. 443–453, figs. 2).—In a second contribution to the subject from the New Jersey Experiment Stations (E. S. R., 52, p. 818), studies are reported on the influence of several forms of lime, particularly calcium silicates, on the bacterial numbers, nitrate formation, and sulfate accumulation in several soils.

Chemically equivalent additions of ground limestone, of dicalcium silicate, and of calcium hydrate to soils deficient in basic materials increased the bacterial numbers in these soils in amounts varying with the forms and the soil. A rapid increase in the number of bacteria followed by a decrease to almost a constant number was observed after the addition of ground limestone, dicalcium silicate, and calcium hydrate.

Some correlation was obtained between the fertility of the soils under the various lime treatments and the number of bacteria. There was an increase in the formation of nitrates from ammonium sulfate with increasing applications of lime which could be correlated with increased crop yields. The final accumulations of unleached nitrates were the same regardless of the form of lime used and of the fact that different forms of lime had a varying influence on the rate of nitrate formation.

Two acid soils showed an increased sulfate formation with an increased application of lime, but a well limed soil showed very small increases of sulfate

with an increased lime addition. Chemically equivalent applications of four different kinds of lime affected the sulfate formation in the same manner in the three soils, producing substantially the same amount of sulfates.

The rapidity of the changes in the microbiological processes of the soil differed with the nature of the material, although the final effects of chemically equivalent quantities of the several liming materials were the same.

Relation of fineness of grinding to rate of sulfur oxidation in soils, R. E. STEPHENSON (*Soil Sci.*, 21 (1926), No. 6, pp. 489-494).—Studies conducted at the Oregon Experiment Station are reported which showed that the more finely sulfur is ground the more rapidly it is oxidized, and that sulfur ground to pass a 40-mesh sieve should contain enough fine material to satisfy the most urgent needs for soil use. The oxidation of sulfur was found to increase acidity or to neutralize alkalinity in alkaline soils. The acid produced from oxidized sulfur brought calcium into solution rather freely.

Rabbit's foot oil and organic ammoniate fertilizer, G. P. WALTON (*West. Rabbit Mag.*, 1 (1926), No. 8, pp. 5, 6, 9, 11-14, fig. 1).—A chemical study by the U. S. D. A. Bureau of Soils of the offal produced in the commercial slaughter of rabbits bred for meat in southern California is reported.

The offal, which amounted to about 44 per cent of the live weight, was found to include three dissimilar types of material. The heads and feet contain, on the original moist basis, 2.6 per cent of nitrogen, the alimentary tracts 1 per cent, and the enteric contents 0.7 per cent.

The data show the possibility of obtaining yields of 22.3 per cent of tankage containing 7 per cent of nitrogen and 5.5 per cent of phosphoric acid from a given weight of the total offal.

Analyses of commercial fertilizers, H. E. CURTIS, H. R. ALLEN, and L. GAULT (*Kentucky Sta. Bul.* 263 (1925), pp. 183-323).—Guaranties and actual analyses of samples of 782 brands of fertilizers and fertilizer materials collected for inspection in Kentucky during 1925 are presented.

Commercial fertilizers (Md. Univ. Quart. No. 118 (1926), pp. 32).—Guaranties and actual analyses of 725 samples of fertilizers and fertilizer materials collected for inspection in Maryland during the period from January 1 to August 1, 1926, together with a summary of the 1925 tonnage records, are presented.

Report of analyses of commercial fertilizers sold in New York State, July 1, 1924, to June 30, 1925 (N. Y. State Dept. Farms and Markets, Agr. Bul. 184 (1925), pp. 58).—Guaranties and actual analyses of 652 samples of fertilizers and fertilizer materials and agricultural lime materials collected for inspection in New York during the period are presented.

Commercial fertilizers in 1925-26 and their uses, G. S. FRAPS and S. E. ASBURY (*Texas Sta. Bul.* 346 (1926), pp. 3-58).—This bulletin contains statistics regarding fertilizers sold in Texas during 1925-26, information regarding the fertilizer law, and guaranties and actual analyses of 899 samples of fertilizers and fertilizer materials collected for inspection in the State during the year. Information is also given on the proper use of fertilizers.

AGRICULTURAL BOTANY

The plant cuticle.—I, Its structure, distribution, and function, B. LEE and J. H. PRIESTLEY (*Ann. Bot. [London]*, 38 (1924), No. 151, pp. 525-545, figs. 12).—The development, structure, and distribution of the cuticle have been studied with consideration of the fact that fats migrating from the protoplasts of both external and internal tissues may find their way to the walls during differentiation and along the walls to the surface, where they contribute to

the cuticle. The mobility of the fatty substances in the walls may be modified by external conditions which thus affect the thickness of the developing cuticle. This view is supported by an examination of cuticles on leafy shoots supplied with varying ratios of potassium to calcium. In submerged water plants a high potassium:calcium ratio produces a thin cuticle, supposedly because of leaching in the case of potassium soaps. Light and humidity affect cuticle thickness and consistency by the influence upon the oxidation and condensation of fatty acids. The cuticle influences evaporation rate and thereby the degree of condensation undergone by the cellulose wall. Cuticle resulting from chemical condensation in dry air is very resistant to stretching forces, as a result of which the condensation rate during cuticle development may affect the appearance of such epidermal outgrowths as hairs. It is suggested that the subsequent extension of parenchymatous tissues, such as the palisade parenchyma of the leaf mesophyll, may be affected in its direction by the resistance to stretching of the cuticular surface.

Experimental vegetation: The use of South African indigenous tree seedlings as phytometers, J. F. V. PHILLIPS (*So. African Jour. Sci.*, 22 (1925), pp. 197-214).—The present paper outlines preliminary investigations partly still in progress at the research station, Deepwalls, Knysna. An attempt was made to indicate the possibility of using certain South African native tree seedlings as phytometers, employing the growth response (height increment, fresh weight, dry weight, number of leaves, and leaf product increases) as measurements of either the whole environment or of certain of its factors, individually considered. Natural, free, and control phytometers are briefly defined, and examples are given of data yielded by experimental cultures of free, light-intensity control, and holarid-percentage control phytometers. It is considered as likely that native tree seedlings, as knowledge of their life histories and requirements increases, will prove to be of value as phytometers in practical forestry.

Duration of light and growth, J. ADAMS (*Ann. Bot.* [London], 38 (1924), No. 151, pp. 509-523).—In experimentation conducted with 16 species of plants, including wheat, rye, flax, hemp, soy bean, tomato, buckwheat, and sunflower, it was found that the rate of growth was more rapid at first in the plants receiving a diminished supply of light, but that those constantly exposed to daylight for a greater number of hours daily attained the greater height. It is deduced that the growth rate, whether in light or in darkness, depends on the amount of reserve material available for the formation of new tissue, and that, if two plants have the same supply of reserve material, the one grown in diminished light will make the more rapid growth while this reserve lasts. Plants grown under diminished light showed deficiency in mechanical tissue and a tendency to become decumbent, or, as in soy bean, to twine and to remain unbranched.

The effect of electrical illumination varied with cases. When the natural daylight period from December to March varied from 9 to 12 hours, the addition of an average nightly illumination of 9 hours with lamps varying from 100 to 300 watts showed a beneficial result in most cases, promoting growth rate and accelerating the time of blooming. As regards plants exposed to daylight for more than 12 hours daily from March to June, an average additional electrical illumination of from 5 to 6 hours nightly showed most effect in spring wheat, no acceleration of flowering time in buckwheat or tomato, and no flowering in soy bean. As compared with full daylight, electrical illumination of hemp retarded both height and weight. In tomato, soy bean, buckwheat, and hemp there appears to be an upper limit to the amount of light which a plant can utilize.

Respiration in plants [trans. title], M. POPOFF (*Biol. Gen.*, 1 (1925), No. 1, pp. 159-162).—Like the account previously noted (*E. S. R.*, 53, p. 520), this deals comparatively with respiration in plants and in animals.

The relation of temperature to growth and respiration in the potato plant, J. BUSHNELL (*Minnesota Sta. Tech. Bul.* 34 (1925), pp. 3-29, figs. 12).—A review of literature relating to potato yields is said to have shown that the optimum temperature for tuber yield is about 17° C. (62.6° F.), and that yields decrease rapidly with an increase of temperature.

The author investigated the effect of a range of temperatures above the optimum by growing potato plants in thermoregulated chambers set to operate at 20, 23, 26, and 29°. The plants showed conspicuous responses in the leaves and in the tubers, both decreasing in size with increase in temperature. At 29° no tubers formed. The maximum temperature for tuber growth under the conditions of the author's experiments was between 26 and 29°. Respiration during the night in the above-ground part of the plant increased with temperature. The carbohydrate content of leaves and stems, sampled at both sunset and sunrise, was not appreciably affected by this range of temperature. Reduction in the carbohydrate available for translocation, which resulted from the increased respiration at the higher temperatures, roughly corresponded to reduction in tuber growth. Thus the rate of tuber growth appeared to be a function of the available carbohydrate.

From the data of his experiments, as well as evidence from the literature, the author suggests that deficiency of carbohydrate arising from excessive respiration may be very generally the limiting factor in plant growth at temperatures above the optimum.

Absorption and exudation pressures of sap in plants, D. T. MACDOUGAL (*Amer. Phil. Soc. Proc.*, 64 (1925), No. 2, pp. 102-130, figs. 6).—"Previous studies [*E. S. R.*, 53, pp. 517, 624] have identified the reversible variations in diameter of tree trunks with changes in cohesion tension of the water column in the recently formed wood, and similar variations also take place in herbaceous stems. Daily changes of diameter of succulent plant bodies such as those of the cacti have been seen to follow a different program and to be due to variations in the water deficit in the succulent cortex, which may be many centimeters in thickness.

"The present paper [particular conclusions from which are detailed] presents some studies on nature of negative absorption pressures and of bleeding exudation pressures in plants based upon studies in hydration, water deficit, permeability, and colloidal reactions of cell masses in such succulent plants. Both absorption and exudation phenomena are demonstrated to be due to localized causes. Cell masses abutting on bore holes in stems have been induced to show absorption or exudation pressures at the will of the experimenter. The possibility of the participation of root action or 'root pressures' is not disproved, but on the other hand no positive evidence for such participation has been brought to light in these experiments. Intake of water by empty vessels or tracheids is registered as 'negative' pressures on manometers attached to stumps of stems, or in any manner which connects the instrument with spaces containing gases at less than atmospheric pressure. The capillary intake of water implied is not to be confused with the satisfaction of living cell masses by osmotic absorption or hydration of cell colloids. Both absorption and exudation pressures as measured by a manometer attached to bore holes filled with water in stems are traumatic phenomena. Their measurement, however, yields results of great value in determining osmotic values, water deficit, and permeability of the tissues."

The absorption of salts by storage tissues, W. STILES (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 617-633, figs. 4).—"These findings indicate that the absorption of salt by storage tissues can not be a simple process of diffusion of salt through a cell membrane. As this assumption underlies measurements of salt intake and of cell permeability made by the plasmolytic methods, conclusions with regard to these questions based on results obtained by plasmolytic methods should be confirmed by other methods or disregarded."

The absorption of ions by citrus and walnut seedlings, A. R. C. HAAS and H. S. REED (*Hilgardia [California Sta.]*, 2 (1926), No. 4, pp. 67-106, figs. 9).—A discussion is given of experiments on the exchange of ions between solutions and citrus and walnut seedlings as connected with certain problems of their nutrition.

Rough lemon and grapefruit seedlings are said to have removed relatively more potassium than calcium from solutions containing approximately equivalent amounts of these ions. When the potassium in the culture solution was low in amount, citrus seedlings absorbed more calcium, magnesium and phosphate from the solution than when potassium was abundant. An interchange of ions was observed between the solution and roots, which resulted in an increase in excretion of potassium in the solutions when the original concentration of potassium was low. Citrus seedlings absorbed more cation than anion from solutions of single calcium salts, causing an increase in the acidity of the solutions. Calcium ions were readily absorbed when sodium and potassium were absent or low in amount. The presence of chlorine ions reduced the absorption of nitrate ions by citrus seedlings. When various chlorides were added to culture solutions the greatest amount of chlorine was absorbed from those containing calcium chloride.

The changes in reaction of culture solutions in which citrus seedlings have been grown are attributed directly to differential absorption of ions, together with an excretion of certain ions. Acid culture solutions were not always found to change in the direction of neutrality, nor did neutral solutions always change in the direction of greater acidity. The authors claim that in complete nutrient solutions citrus seedlings may, in a comparatively short period, bring about so great a concentration of H ions as to be injurious to the roots. Bicarbonate ions were found in culture solutions from which citrus roots had removed nitrate ions. No stimulation of growth of citrus roots was found to occur in solutions of sodium carbonate. When calcium was completely absent from the solution a high initial alkalinity due to sodium carbonate proved very injurious to the roots of citrus seedlings. The complete absence of calcium from a culture solution containing favorable amounts of other essential ions was also injurious.

The authors believe that the nature of the growth obtained with citrus seedlings in water cultures at different pH values depends not only upon the maintained pH of the solution, but also upon the pH of the original solution as well as upon the nature of the acid or alkali used in maintaining the desired reaction.

Although the ash of walnut kernels was found to contain approximately 60 per cent of phosphate, the walnut seedlings rapidly absorbed all the phosphate from a complete nutrient solution. They removed less chlorine or sulfate than potassium from culture solutions containing an excess of potassium salt. When grown in solutions having equivalent concentrations of potassium chloride or potassium sulfate, walnut seedlings removed practically the same amount of calcium from both solutions. Although slightly more potassium was absorbed from the potassium sulfate culture, the absorption of sulfate exceeded that of

chlorine. Except in the case of potassium nitrate, the potassium absorbed by walnut seedlings from a nutrient solution to which different potassium salts were added always exceeded that of the anion added with it. The total amount of magnesium absorbed by walnut seedlings was found to be quite constant and was not affected appreciably by additions of potassium salts to the solution.

Walnut seedlings are said to have removed more cation than anion from solutions of single calcium salts, except in the case of the nitrate. The acidity of the residual solution was entirely dependent upon the absorption rate of the two ions employed. The addition of the chlorides or sulfates of sodium or potassium to calcium solutions brought a reduction in the absorption of calcium. The addition of potassium chloride or sulfate to calcium nitrate caused a final reaction more acid than the initial reaction, although when calcium nitrate alone was used walnut seedlings brought about a decrease in acidity. The presence of an excess of sodium chloride in a culture solution prevented walnut seedlings from absorbing large amounts of calcium. Increasing the concentration of the nutrient solution containing large amounts of sodium chloride caused no substantial differences in the amounts of sodium and chlorine ions absorbed by walnut seedlings. The apical portion of walnut roots grown in calcium-free solutions contained more calcium than the portions further removed from the apex, although the first evidences of injury were visible in this apical portion.

Testing corn stalks chemically to aid in determining their plant food needs, G. N. HOFFER (*Indiana Sta. Bul.* 298 (1926), pp. 31, pls. 2, figs. 15).—A description is given of a method for recognizing the deficiencies in the soil of nutrients essential for the proper growth of the corn plant. The method is based upon the color reaction of the cut surface of mature cornstalks to solutions of diphenylamine, potassium thiocyanate, and hydrochloric acid. A lack of nitrogen or potash in the soil is indicated by the tests. As a rule, plants of stunted growth not responding to tests for nitrogen or potash are said to be suffering from a lack of phosphorus. A key is given for the interpretation of the results of the test.

Some observations on the nitrate-reducing properties of plants, V. L. ANDERSON (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 699-706).—Nitrate occurs frequently in plants, the amount varying with growth conditions, but not constantly with species. A nitrate-reducing mechanism, termed atite, is claimed to have been found in 23 plants. The atite of potato is a thermolabile and oxidizable substance, which, under the conditions of the experiment, can convert only a limited amount of nitrate to nitrite. Acetaldehyde may affect the activity of the atite of different plants in different ways, possibly more than a single mechanism being involved. Nitrite was found in more than 20 per cent of the plants examined. The evidence does not indicate that atite is of much significance in the protein metabolism of the plant.

The formation of plant growth-promoting substances by micro-organisms, F. A. MOCKERIDGE (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 723-734).—The effect of varying quantities of nucleic acid derivatives on the growth of *Lemna minor* was investigated, and it was found that the effect obtained was approximately proportional to the quantity of material supplied. Examination was also made of the effect of varying proportions of a sterilized culture of *Azotobacter*, as a result of which it appears that the effect, though increasing with the quantity of the organism supplied, is not proportional. Both autolyzed and autoclaved yeast were examined and both were found to have a plant growth-promoting influence, more particularly the autoclaved material.

The growth-promoting effect of the bacteria used may be due to one or more of the nucleic acid radicals present or to some other substance, but all materials

so far found to have this effect on plant growth also contained these purine and pyrimidine bases.

The root-tubercles in *Arbutus unedo*, M. F. RIVETT (*Ann. Bot. [London]*, 38 (1924), No. 152, pp. 661-677, figs. 14).—The root tubercles of *A. unedo* are shown to be the arrested secondary and successive laterals of the season's growth. The arrest of growth is due to invasion by a fungus, first as a rampant ectotroph and subsequently as an endotroph in the peripheral cells. The invasion of the fungus is limited by the digestive action of the host cells of the tubercle, which may be regarded as phagocytes. Apparently the interchange of food materials between host and endophyte is very slight, affording no permanent mutual benefit. The relationship is regarded as one of balanced parasitism, the action of the tubercles being effective in conferring a degree of immunity on the root system as a whole.

The staling of fungal cultures.—I, General and chemical investigation of staling by *Fusarium*. II, The alkaline metabolic products and their effect on the growth of fungal spores, C. A. PRATT (*Ann. Bot. [London]*, 38 (1924), Nos. 151, pp. 563-595, fig. 1; 152, pp. 599-615, fig. 1).—Literature on the subject of the staling of fungi in culture is surveyed. *Fusarium* sp. was grown on Richards' solution and the staleness examined by the Botrytis germ-tube method. The results are detailed.

"The growth of Botrytis spores is affected by the addition to the fresh medium of various organic compounds which have been demonstrated in the stale medium. Alcohols and acetaldehyde are toxic only at high concentrations; they can play a very small part, if any, in 'staling.' Simple organic acids are toxic at sufficiently low concentrations to be responsible for the poor germinative capacity of the acidified stale medium. A graph is given in which the toxic effects of a number of organic acids are compared."

Organic acid radicals do not reduce the growth of Botrytis spores if the medium be made alkaline. They can not, therefore, act as staling agents in an alkaline stale medium. A study of the effect on the growth of fungal spores of the alkaline metabolic products has led to the conclusion that the small quantities of ammonia produced are probably ineffective, but that bicarbonates, potassium, and, in a lesser degree, ammonium are capable of inhibiting Botrytis growth when present in amounts even smaller than those found in the stale medium. It is suggested that staling is in general due to the formation of bicarbonate by the carbon dioxide of respiration whenever the medium is such that a basic radical is set free.

On the theory of "age and area," S. SCHONLAND (*Ann. Bot. [London]*, 38 (1924), No. 151, pp. 453-472).—A critical review is given of the age and area theory and related contributions.

GENETICS

The neurogenic theory of karyokinesis [trans. title], M. MÜHLMANN (*Ztschr. Wiss. Biol., Abt. B, Ztschr. Zellforsch. u. Mikros. Anat.*, 3 (1926), No. 2, pp. 377-382, fig. 1).—The author presents evidence in support of the theory that the centrosome acts as the central nervous control of the cell during division.

A cytological investigation of some species and species hybrids within the genus *Saccharum*, G. BREMER (*Genetica [The Hague]*, 5 (1923), Nos. 2, pp. 97-148, figs. 52; 3-4, pp. 273-326, figs. 40).—This is an English translation of the account previously noted from another source (*E. S. R.*, 49, p. 822).

The cytology of the sugarcane, G. BREMER (*Genetica [The Hague]*, 6 (1924) No. 6, pp. 497-525, figs. 20).—The fact, brought out in the first part of this inves-

tigation above noted, that the original forms of *Saccharum* have different chromosome numbers is considered to be a fact of importance in the division of that genus into species. This second part, considering the cytology of some cultivated varieties of sugar cane and presenting relevant facts in considerable detail, presents in conclusion the view that there exists in all probability in sugar cane a relation between regular or irregular reduction division and fertility. Both are supposedly influenced strongly by unfavorable growth conditions.

Hereditary doubling suggesting anomalous chromatin distribution in the mouse, C. H. DANFORTH (*Soc. Expt. Biol. and Med. Proc.*, 23 (1925), No. 2, pp. 145-147).—Anomalous individuals, ranging in degree from Y-shaped specimens with 4 hind legs and 2 tails to those with a slight degree of doubling in the external genitalia, have been produced in 2 strains of mice at Stanford University. One of the strains has produced as high as 12 per cent, and in certain selected matings 20 per cent of these individuals were produced. Only 1 mating between 2 abnormal individuals has been successful, but sibs and parents have been used for breeding. The peculiar condition appears to be hereditary, but can not be explained on the basis of 1 or 2 dominant, recessive, or cumulative genes.

Since a differential factor favoring the production and function of normal gametes in heterozygous individuals gives closer agreement with the observed data, it is suggested that the reduplication of a certain amount of chromatin material is involved.

A genetic and cytological study of dwarfing in wheat and oats, C. H. GOULDEN (*Minnesota Sta. Tech. Bul.* 33 (1926), pp. 3-37, pls. 3, figs. 4).—The segregation in F_2 and F_3 in a Kota-Marquis cross (E. S. R., 49, p. 841) and in a Chul-Marquis cross (made and studied first at the University of Saskatchewan by W. P. Thompson) indicated that two factors, a dominant dwarf *D* and an inhibitor *I* were involved. Back crosses of true breeding dwarfs gave proof of the presence of an inhibiting factor in the Kota and Chul parents which prevents the expression of a dwarf factor.

Cytological study led to conclusion that in the Kota-Marquis dwarfs chromosome number and behavior are as normal as in the parental material. In the Chul-Marquis dwarfs lagging chromosomes were present in most of the cells undergoing reduction division. It was suggested that the lagging chromosomes may have resulted from the presence in the heterotypic division of three homologous chromosomes which formed trivalents and allowed the remaining chromosome to lag behind. Such cells might arise through irregular pairing of the chromosomes in the mother cells of the F_1 plants and the recombination of the aberrant gametes so formed. Irregularities of this type affecting the chromosome pairs carrying the dwarf factor or factors and the inhibitor would result in the occurrence in F_3 of families showing a segregation varying from 3:1 of normals to dwarfs to practically all normals, which would easily account for ratios approximating 63:1.

Dwarf oats found in the progeny of plants heterozygous for the false wild character had about one-half the height of normal plants, were completely sterile, and always possessed the false wild character. The progeny of normal plants heterozygous for the false wild factor usually consist of a 1:2:1 ratio of false wild, intermediate, and cultivated individuals, but when dwarfs occur in families from such plants the cultivated class is practically eliminated and the remainder consists of false wild dwarfs and intermediate normals in a 1:1 ratio. Cytological study of the pollen mother cells of the oats dwarf showed reduction division to be extremely irregular. An almost complete lack of coordination among the chromosomes at the heterotype was apparent, and

the homotype probably did not take place. Very few normal appearing pollen grains were formed. In the case of the oats dwarf a close correlation evidently existed between dwarfing, the false wild character, cytological irregularities, and complete sterility. Chromosome counts gave 42 for *Avena sativa*, *A. fatua*, *A. sterilis*, and *A. nuda*, and 14 for *A. brevis*, *A. barbata*, and *A. strigosa*.

Quadruple allelomorphs affecting eye color in *Habrobracon*, A. R. WHITING and R. H. BURTON (*Amer. Nat.*, 60 (1926), No. 668, pp. 285-290).—In further studies of inheritance of orange-eyed character in the parasitic wasp (E. S. R., 46, p. 463) evidence is presented which indicates the existence of a series of quadruple allelomorphs, black (*O*), light (*o^l*), orange (*o*), and ivory (*oⁱ*), in decreasing order of dominance.

Two wing mutations in *Habrobracon* and their method of inheritance, P. W. WHITING (*Amer. Nat.*, 60 (1926), No. 670, pp. 443-454, fig. 1).—The origin and genetic relationships of two mutations, designated as wrinkled wings (*w*) and reduced wings (*r*), in the parasitic wasp (*H. juglandis*) are discussed. Both mutations are recessive or nearly so and are inherited independently, neither showing linkage with the orange eye factor or with the main factor causing the defect in the wing vein *r*.

The occurrence of pigmented facets in white eyes in *Drosophila melanogaster*, W. P. SPENCER (*Amer. Nat.*, 60 (1926), No. 668, pp. 282-285).—The occurrence of single pigmented facets in one or both eyes of white-eyed flies has been observed in as many as 53 per cent of the individuals in certain cultures. This condition appears to be inherited, but not as a simple recessive character unless environmental or genetic modifying factors mask the effect. Flies having several colored facets in both eyes did not produce a greater percentage of flies with colored facets than other matings of flies having smaller numbers of colored facets.

The marking of black-spotted Holstein cattle and its inheritance [trans. title], E. LAURECHT (*Ztschr. Induktive Abstam. u. Vererbungslehre*, 40 (1926), No. 3, pp. 139-196, figs. 24).—The author has studied the variations in color patterns in three old established herds of Holsteins, and by comparing the regions of black markings on the different individuals has concluded that there are six centers of black pigmentation, all of which may be separated or run in together, i. e., (1) eye and cheek, (2) ear and neck, (3) side of the neck, (4) upper arm or shoulder, (5) side of the body near the last rib, and (6) rump spots. In certain cases the individual spot may be broken up into several parts, this occurring most frequently in the center of the pigmentation on the side of the body. In the animals having smaller amounts of black the pigment first disappears from the shoulder, then from the side, and finally from the rump. The forelegs were colored more often than the hind legs, and a tabulation showed that the right legs were more often colored than the left. The total amount of area colored as estimated by cross section paper was independent of the sex, but in one herd there was more black on the females than on the males. Tabulations indicated that the total amount of color was correlated with the amount of pigmentation in the various centers for black on the different parts of the body.

In studying the variation and distribution of color, the animals were classified under five groups, but since few were allotted to the groups with the smaller amounts of black, three classes, designated as light, medium, and dark, were taken into account in studying the inheritance of color pattern. Crosses of the various types produced offspring classified in all three groups, which generally averaged intermediate between the two kinds. In light ×

light crosses or dark \times dark crosses, offspring of the opposite extreme were not obtained in either case.

A single pair of factors is suggested in explaining the inheritance of the amount of color. Homozygous individuals of the two sorts form the dark and light classes, respectively, and heterozygotes form the intermediate class, since much larger numbers were found in the latter group. Modifying factors are also operative, but very good agreement to the above hypothesis was obtained in the offspring in the three herds, and also when the records of other investigators on this subject were studied.

Inheritance of horns, wattles, and color in grade Toggenburg goats, J. L. LUSH (*Jour. Heredity*, 17 (1926), No. 3, pp. 73-91, figs. 4).—The results of studies of the inheritance of horns, wattles, and color in matings of Toggenburg bucks with does produced by grading up Mexican does with Toggenburg bucks at the Texas Experiment Station are reported.

The data on the inheritance of horns accumulated during three years agreed with the hypothesis that the polled condition is dominant, with the possible exception of one kid from horned parents which was recorded as probably not horned and which died young. The horns were better developed in males than in females, but the presence or absence of the condition was not sex linked or associated with sex.

The 3 years' matings dealing with the inheritance of wattles agreed with the hypothesis that wattles are due to a single dominant Mendelian factor except for 3 wattled kids which were produced by nonwattled parents. These cases, however, were otherwise explained. A study of the data indicates that the factor for wattles is not linked with sex or with the horned character. The simple explanation for wattles in goats did not appear to fit the inheritance of wattles in the station flock of Karakul sheep.

An analysis of the inheritance of black, white, and roan color, dorsal stripe, Toggenburg pattern, and spotting was attempted from the same matings by determining Yule's coefficient of association between the color of the dam and the color of the offspring. All of the correlations, except white spotting, indicated a strong tendency for kids to resemble their dams in color, but definite modes of inheritance were not determined. Solid white appeared to be epistatic to most of the other colors. Black and extensive white spotting also tended to be epistatic.

Genetic analysis of temperament of rats, M. P. SADOVNIKOVA-KOLTZOVA (*Jour. Expt. Zool.*, 45 (1926), No. 1, pp. 301-318, figs. 8).—The ability of 123 rats, all descendants of a cross of a wild gray rat and a white laboratory rat, to run a maze showed considerable variability, the curve having three chief peaks. It was further found that the time required by individuals in certain families differed significantly from the time required by individuals of other families, but it did not appear to be influenced by teaching the parents. It is suggested from the analysis that three genes are involved in the inheritance of this ability, one for general activity, one for emotion, and one for the seeking instinct.

These studies were conducted at the Institute of Experimental Biology at Moscow.

Abnormal sexuality in animals.—I, Genotypical, F. A. E. CREW (*Quart. Rev. Biol.*, 1 (1926), No. 3, pp. 315-359, figs. 14).—This is a discussion of the genetics of intersexuality and gynandromorphism in animals and insects, based mainly on the investigations of Morgan, Goldschmidt, and Crew.

Offspring from immature females hampered (*Illinois Sta. Rpt.* 1925, p. 88).—In studies with mice the offspring from immature females were found by G. A. Lindsey and E. Roberts to be significantly smaller at weaning than

the offspring of more mature females. This difference became less as the offspring became older, indicating that nourishment was probably the limiting factor.

Heredity involved in hairlessness of animals (*Illinois Sta. Rpt. 1925, p. 59*).—Studies by E. Roberts of the inheritance of hairlessness in rats have indicated that this condition is due to a single factor recessive to the normal.

Hyperglycaemia as a Mendelian recessive character in mice, P. J. CAMMIDGE and H. A. H. HOWARD (*Jour. Genetics, 16 (1926), No. 3, pp. 387-392*).—In studies of the sugar content of the blood of animals it has been found that after a 12- to 24-hour fast the sugars rarely varied more than 5 mg. from an average of 85 mg. per 100 cc. of blood, although certain individuals occasionally differed by as much as 25 mg.

By making suitable crosses with mice it was found that the tendency for a high blood sugar content was clearly and definitely inherited as a simple recessive Mendelian character. Two individuals having 116 and 120 mg., respectively, of sugar per 100 cc. of blood produced seven offspring with blood sugar varying from 114 to 124 mg. In three crosses of hyperglycemic individuals with normals the offspring all contained normal amounts of blood sugar. Three back-cross matings of heterozygotes with hyperglycemic individuals produced offspring which were practically equally divided between normals and hyperglycemics. The ratio was practically 3:1 in the offspring of three matings of heterozygotes \times heterozygotes.

Genetic studies on the nature of cancer, L. C. STRONG (*Amer. Nat., 60 (1926), No. 668, pp. 201-226*).—The author discusses the results of his studies previously noted (*E. S. R., 55, p. 731*), dealing with the inheritance of a susceptibility to cancer transplantation in mice, in connection with the results of other investigations from which fundamental conceptions of the nature of transplantable tumor tissue are brought out. The transplantable tumor appears to be controlled by the constitution of the cells and maintains a definite reactive capacity for a number of generations. Genetic changes in the constitution of the cells may occur sporadically at any time, changing to a greater or less degree the characteristics of the cells, as has occurred in the origin of the cancer.

A genetic study of the growth of a transplantable tumor (adenocarcinoma, dBrB), L. C. STRONG (*Jour. Expt. Zool., 45 (1926), No. 1, pp. 231-253, figs. 6*).—A more complete account of investigations noted above.

The question of xenia occurrence in horticultural plants [trans. title], G. HÖSTERMANN (*Angew. Bot., 6 (1924), No. 2, pp. 232-242, figs. 2*).—Phenomena connected with crossings of apple and of pear varieties are detailed.

An experimental study on xenia in the domestic fowl, S. KOPEĆ (*Jour. Genetics, 16 (1926), No. 3, pp. 269-286, figs. 3*).—Studies of the occurrence of xenia in hens' eggs are reported from the Government Institute for Agricultural Research, Puławy, Poland, based on color records classified according to 13 grades for 487 eggs laid by 5 Leghorn hens mated with an Orpington cock, 448 eggs laid by 4 Leghorn hens injected with testicles from Orpington roosters, 240 eggs laid by 2 unmated Leghorns, 308 laid by 2 Orpington hens mated with a Leghorn cock, 591 eggs laid by 5 Orpington hens injected with testicles from Leghorn roosters, 428 eggs laid by 2 unmated Orpington hens, 218 eggs from 8 F_1 hens (Orpington ♀ \times Leghorn ♂), and 857 eggs from 10 F_1 (Leghorn ♀ \times Orpington ♂).

The results showed that considerable seasonal variation occurred in the color of the eggs of either breed when unmated or when mated with cocks of the opposite breed. The average color intensities decreased from spring to

autumn and increased in the winter, but no significant differences were observed in the colors of the eggs laid by either breed when mated with roosters of the opposite breed or when unmated. It is noted that one very dark egg occurred among those laid by a Leghorn hen which had been injected with Orpington testicles, though others nearly as dark were laid by the controls. The color of the eggs of the F₁s was generally intermediate between the eggs of the two breeds.

Previous observations on the occurrence of xenia in fowls are discussed, from which it is concluded that the earlier work has not taken into account the normal seasonal variation in egg color.

An experimental study on the appearance of xenia in the domestic fowl [trans. title], S. KOPEĆ (*Pam. Państ. Inst. Nauk. Gosp. Wiejsk. Puławach* (*Mém. Inst. Natl. Polon. Écon. Rurale Puławy*, 6 (1925), A, pp. 23-59, figs. 2; *Eng. abs.*, pp. 54-59).—Essentially noted above.

The ovarian follicular hormone: A study of variation in pig, cow, and human ovaries, E. ALLEN (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 5, pp. 383-387).—This paper reports the results of a comparative study of the amount of follicular hormone present in the sow, cow, and human ovaries at various stages of the oestrous cycle. The measurements of the amounts of the hormone present were made in terms of rat units, i. e., the amount required to produce the changes in the vagina of a spayed female which are characteristic of the oestrous period.

Tests were made of the ovaries of two sows. One sow was killed just as the external signs of sexual activity were appearing, when 9 large follicles were found in one ovary and 8 in the other. The second sow was killed on the second day following the appearance of the external signs of heat, which was after ovulation had occurred. Eleven corpora lutea of the first to the second day in development had formed in one ovary, and one corpus luteum in the other. The results showed that the 2 ovaries of the first animal contained a total of 28 rat units of hormone, while the 2 ovaries of the other sow contained less than 2.1 units.

Available ovaries from cows were divided into 5 groups, corresponding to the different stages of follicular development, and were similarly tested. Twenty-six ovaries taken at oestrus contained an average of 4.6 rat units of the hormone per pair, which thus must represent the average amount of the hormone in 1 large follicle 1 to 2 days before ovulation. Extracts of the ovaries from several animals at all other stages of the cycle gave negative results, even though there were from 8 to 11 corpora lutea present in each of the groups.

The largest amount of the hormone recovered from human liquor folliculi has been 7 rat units per cubic centimeter and from a human corpus luteum 3.7 rat units per cubic centimeter of luteal tissue. The latter amount was recovered during the third week following the first day of menstruation.

It is pointed out that the cow and pig showed a wide variation in the amount of hormone present at different stages of the oestrous cycle, while in the human there is a considerable amount present in the corpus luteum as well as in the liquor folliculi. These differences are discussed in connection with the differences which have been observed between the menstrual cycle of primates and the oestrous cycle of the cow and sow.

Standardization of preparations of ovarian follicular hormone, E. P. BUGBEE and A. E. SIMOND (*Endocrinology*, 10 (1926), No. 2, pp. 191-200).—In working on the measurement of the strength of the follicular hormone it has been found that the dose should vary directly with the weight of the rat,

it not being necessary to have rats weighing approximately 140 gm., as the potency is computed by the rat units of Allen (see above) by multiplying the finding with larger rats by the weight of the rat divided by 140 gm. Rats of any age may be used, provided they have reached sexual maturity and have not passed the prime of life.

The time of ovulation in the menstrual cycle of the monkey, *Macacus rhesus*, E. ALLEN (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 5, pp. 381-383).—A tubal ovum has been recovered from two different monkeys in experiments at the University of Missouri. The one was recovered on the fourteenth day after menses, while the other was recovered on the tenth day of the cycle. These results, taken in conjunction with the one other known case of the recovery of a tubal ovum in the monkey, place the time of ovulation between the tenth and fourteenth days of the menstrual cycle.

Alcohol and the sex ratio in mice, C. H. DANFORTH (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 4, pp. 305-308).—In three experiments at Stanford University male mice were exposed twice daily to alcohol fumes for one hour, and the effects on the sex ratio of the young produced by these males when mated after one week's treatment were determined. The sex ratios among the offspring of the alcoholized males in the first, second, and third experiments were 178.9, 153.1, and 117.9 males, respectively, per 100 females. There were no controls in the first experiment, but in the second and third tests the sex ratios of the controls were 104.8, and 100.4 males per 100 females. It is pointed out that the difference is more than 3 times the probable error in the second experiment and 2.7 times in the third. The author concludes that all the available data dealing with the effect of alcoholization on sex ratio in mice point toward an increased percentage of males.

FIELD CROPS

Artificial plats for field experiments, T. L. LYON and E. W. LELAND (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 7, pp. 596-602, figs. 5).—The construction, uses, and advantages of artificial plats for field experiments adopted at the New York Cornell Experiment Station to avoid variations in soil productivity are described and illustrated.

A census of an acre of corn (by sampling), F. L. ENGLEADOW (*Jour. Agr. Sci. [England]*, 16 (1926), No. 2, pp. 166-195, figs. 3).—The nature and prevalence of gradations of interplant spacings in field crops and the relation between spacing and acre yield and plant development were investigated, employing Yeoman wheat on clay and Little Joss wheat on gravel soil. Systems of sampling an acre of grain are depicted and explained, with comments on the influence of seeding method, soil condition, seed quality, and damage agencies on plant development.

Plant development and yield per unit area showed well-defined relationships to spacing as represented by 5 aggregate grades of 1-8, 9-10, 11-12, 13-16, and 17-24 plants of Little Joss per foot. Comparison of the 1-spike, 2-spike, etc., plants showed that in tillering, from origin to spike formation and as affected by spacing, lay a prime determiner of cropping capacity. The yield from any unit length of drill is apparently affected by the populousness of adjoining and adjacent units.

Grazing periods and forage production on the national forests, A. W. SAMPSON and H. E. MALMSTEN (*U. S. Dept. Agr. Bul.* 1405 (1926), pp. 55, pls. 6, figs. 16).—Observations at the Great Basin Experiment Station and in other parts of the Wasatch Mountains of Utah were made to determine when the

range is ready for grazing, the intensity and frequency of grazing permitted, how to handle the stock, and the natural revegetation of the range.

The proper development of the later maturing herbaceous and browse species, and especially the important forage plants, seem to offer a safe index to range readiness. This stage may be identified by height, size, or flower stalk, or head production, depending on the species. The grasses, for instance, should in general be about 6 in. in height, and the earlier maturing ones should show flower stalks. The best grazing seasons in the central Wasatch region were found to be oak-brush zone (6,500- to 8,000-ft. elevation), May 20 to June 9 and October 1 to 15; aspen-fir (7,500 to 9,500 ft.), June 10 to July 9 and October 1 to 15; and spruce-fir (above 9,000 ft.), July 10 to September 30.

Frequent and close cropping seemed quite detrimental to both herbaceous and browse species and conducive to impoverishment of the soil and to increased run-off and erosion. It appeared of the greatest importance that the animals be excluded from the range until the forage is developed enough to be of good food value. Cropping resulting in reduced aerial growth is reflected in the root development, in the quantity of food stored in the underground parts, and in the production of a correspondingly small quantity of herbage the following season. The grasses are indicated as of primary value as forage plants since they withstand grazing better than most other vegetation. Artificial reseeding of the plains and the drier foothills to cultivated forage plants were without practical results, whereas the possibilities were considerably greater on mountain meadows and other favorable sites. Cropping a pasture each year to the maximum of its forage production sooner or later causes a sharp decline in its grazing capacity.

Improvement and maintenance of native pasture lands, the forage on which is largely bunch grasses, depends upon the periodical production of a fertile seed crop. To insure seed production of the more palatable forage plants requires prevention of too early grazing, avoidance of overgrazing, and effective control and distribution of stock. Deferred and rotation grazing, which imply withholding part of the range from grazing until after seed maturity each year, have given conspicuous results in range reseeding. Revegetation on the range was practically as rapid where deferred grazing was practiced as where the lands were protected yearlong from foraging animals.

[Agronomic experiments in Guam, 1925], J. GUERRERO (*Guam Sta. Rpt. 1925, pp. 9-15, figs. 6*).—In continued investigations (E. S. R., 55, p. 131), *Paspalum dilatatum* with roots spaced 6 by 6 in. covered the ground within 30 days and required a single cultivation, whereas 18 by 18 in. spacing required 90 days and three cultivations. The close planting is too costly except under intensive culture. Napier grass and Guatemala grass surpassed Merker grass, *Pennisetum setosum*, and Japanese cane in order in drought resistance. In fertilizer tests Guatemala grass made its best yields when limed only, while Napier grass and Japanese cane responded best to lime with manure. Molasses grass has suppressed Johnson grass and made good forage yields.

The behavior of varieties of alfalfa and kudzu and *Tephrosia* spp. and the relative efficiency of varieties of velvet beans, cowpeas, and mung beans, and Patani and Lima beans, pigeon peas, and *Tephrosia* spp. for cover crops are briefly described. The New Era pigeon pea required more care before it could suppress weed growth, but it occupied the land much longer than other legumes.

One-half lb. caustic soda and 1 lb. white arsenic were dissolved in boiling water; after adding 1 pint pine tar the solution was boiled slowly for about

15 minutes and diluted with 3 gal. water. A pint of the preparation poured into notches cut around the trunks of aroma (*Acacia farnesiana*) killed 50 per cent of the shrubs, and one-half pint applied to newly sprouted stumps killed 75 per cent of the plants so treated. A 4-oz. application of carbon disulfide poured into shallow holes in the ground immediately surrounding the trunks killed 25 per cent of the lot treated, but lighter applications or formalin, carbolic acid, and sulfuric acid similarly applied resulted negatively.

On newly broken grasslands, variously treated, barnyard manure gave the highest yield of both grain and forage, a limed plat followed, and a sulfur-treated plat ranked third in grain yield but fourth in forage. Although the green manure plat produced the least forage, it made more grain than the untreated check. Corn, cowpeas, and velvet beans each produced much more grain and forage in rotations than in continuous culture.

Nancy Hall and Pumpkin led the imported sweet potato varieties, which in general decidedly outyielded the native sorts. The greatest weight of roots of Porto Rico were produced where acid phosphate and manure in combination were applied. Varieties of yams, trellised, made increases ranging from 54 to 400 per cent in root yields per acre over untrellised yams.

[Field crops experiments in Illinois] (*Illinois Sta. Rpt. 1925, pp. 39-43, 48-55, figs. 4*).—After 28 years of selection, continued by C. M. Woodworth and F. L. Winter, the protein content of corn has attained 16.6 per cent in the high protein strain, or an increase of 5.68 per cent. The low protein strain has decreased from 10.92 to 8.38 per cent in protein. The original oil content, 4.7 per cent, rose to 9.86 per cent in the high oil strain and dropped to 1.51 per cent in the low oil strain. Ears on the original strain of Leaming corn were borne at a height of 49.6 in. but have been raised to 92.9 in. in the high strain and lowered to 11.7 in. in the low strain. The original percentage of 2-eared stalks, 6.7 per cent, has been increased to as high as 85 per cent, although results are variable.

Using Reid Yellow Dent as a standard, W. L. Burlison and G. H. Dungan found the 2-ear strain to have a percentage rating of 109.4 and the Leaming High Yield 108.3. The 2-ear strain probably will be found more useful for fodder or silage than for grain. The chinch bug resistant types of corn, Champion White Pearl, Democrat, Black Hawk, and Mohawk, ranked the highest on the Alhambra (Madison County) field.

Results to date indicated to Burlison, B. Koehler, and Dungan that corn selected after it is well dented is as good from the standpoint of productivity as seed corn selected when completely mature. Since corn left to mature on the stalk is often injured by freezing, harvesting of seed corn while in the dent stage seems a sound practice. Several types of cabinets and incubators on the market appeared promising to J. C. Hackleman for seed corn germination after certain alterations. Considering the limited capacity, the cost, and the danger of damaging a good egg incubator, it seems preferable to build a special cabinet.

Tests by R. W. Stark continued to demonstrate that hard red Crimean wheats, such as Turkey and Kanred, withstand the winters of central and northern Illinois better than soft wheats. Soft wheats, such as Fulcaster, Red Cross, Illini Chief, and Fultz, proved suitable to southern Illinois. Baking tests showed that Turkey Red and strains and hybrids of that variety produce the strongest flour, while flour from the soft wheats is more suitable for biscuits and pastry. Marquis and Illinois No. 1 spring wheats have made fair records in variety tests at Urbana and De Kalb and seem well adapted to central and northern Illinois. Wisconsin Pedigree and Oderbrucker have been the highest yielding barleys.

According to Burlison and Dungan, early oats are somewhat better adapted to Illinois conditions than late varieties. Iowa has the highest average yield during 4 years at De Kalb. Iowa 103 led in average yields during its 9 years at the station and also during 6 years at Alhambra.

In small grain breeding studies Woodworth and Winter found that winter rye plants vary in self-fertility or self-sterility, although rye has been considered practically self-sterile. Counts on wheat increase plats showed scab infection to range from 6 to 27 per cent. In studies of the resistance of different wheat varieties to Hessian fly, Red Russian showed 32.3 per cent infestation as compared to only 13.4 per cent for Dawson Golden Chaff.

Marked increases in the yield of potatoes were obtained by J. Pieper and W. P. Flint by using northern-grown seed of an adapted variety, and also by spraying the vines with an insecticide for chewing insects, together with a fungicide which repels some insects and also controls potato leaf diseases. Irish Cobbler and Early Ohio have been the highest yielding early varieties, while Rural New Yorker and Carmen No. 3 were the best late varieties.

Studies on the number of nodes of culms in barley, wheat, and rice plants [trans. title], M. YAMASAKI (*Nôgaku Kwaihô* (*Jour. Sci. Agr. Soc. [Japan]*), No. 278 (1926), pp. 1-35, pl. 1, figs. 4; *abs. in Japan. Jour. Bot.*, 3 (1926), No. 2, pp. (40), (41)).—In one of the two kinds of culms distinguished in barley and wheat, the insertion part of the spike constitutes a ridge which goes around the rachis (*N*-culm), while in the other the ridge goes only half way round (*T*-culm). On the basis of teratological as well as anatomical evidence, the author concludes that the *T*-culm is produced by the formation of an extra culm-internode of which the apex (where the spikelet is inserted) has the half-way ridge, and which is not developed in the *N*-culm. That the *T*-culm averages one more internode than the *N*-culm was confirmed by observations on 58 races of barley and 86 of wheat. The relative number of *T*- and *N*-culms in each race is naturally more or less variable, although in general the number of *T*-culms is smaller than that of *N*-culms. The better nutrition, greater moisture, and higher temperature appear to lead to the increase of *T*-culms. Similar phenomena were recognizable in the rice plant.

The preservation of the pollen of cereals [trans. title], T. SASAKI (*Nôgaku Kwaihô* (*Jour. Sci. Agr. Soc. [Japan]*), No. 275 (1925), pp. 259-287; *Eng. abs.*, pp. 10, 11).—Pollination experiments by the author during 6 years demonstrated that 40 per cent relative humidity is optimum for the preservation of barley pollen, 50 per cent for corn pollen, and 20 or 40 per cent for the pollen of peas. The duration of germinability of the pollen was not always the same as that of fertilizing power.

[Experiments with legumes in Illinois] (*Illinois Sta. Rpt. 1925*, pp. 31, 32, 37-39).—Kudzu, an acid-resistant legume, can not be used on sour soils of Illinois, according to W. L. Burlison and J. Pieper. Ladino clover, however, is very promising, and Cherokee clover, lespedeza, dalea, and velvet beans merit further tests. Wild white clover from England resembles the American common white clover but does not grow as well.

Burlison and G. H. Dungan found the variegated or Grimm types of alfalfa to excel in winter hardiness at the station and at De Kalb. South Dakota No. 12 alfalfa seemed to be about as winter resistant as the Grimm and Cos-sack varieties and the common Kansas grown alfalfa to be intermediate in winter resistance, whereas the Argentine variety has frozen out badly. Spring seeding continued to give best results under northern Illinois conditions.

Results obtained during 5 years by Burlison and Pieper with alsike clover at De Kalb showed that the average seed yield fluctuated from 3.3 to 1.21 bu. per acre, and the average yields of hay ranged from 2.57 to 1.76 tons per

acre. Phosphatic fertilizer increased the seed yield 13 per cent and the hay yield 6 per cent.

Burlison, Dungan, and W. P. Flint obtained the following average acre seed yield over 3 years from red clover: Clipped twice (spring) 0.41 bu., clipped once (spring) 0.45 bu., hay crop removed 1.59 bu., and first crop harvested for seed 0.73 bu. Hay yields obtained under the different systems of handling the crop were in line with those reported earlier. When the first crop was used for hay and the second for seed, acre hay yields averaged about 1.5 tons air-dry, and more than 3 tons when both crops were used for hay.

Alfalfa and red-clover seed tests (*U. S. Dept. Agr., Rpt. Sec. Agr. 1926, pp. 64, 65*).—Available results from trials in cooperation with State experiment stations have shown alfalfa seed from Turkestan to be of little value for most of the United States, particularly in those humid sections where alfalfa is important. South African seed produces plants not hardy enough for the Northern States, and in most tests plants from Argentina seed suffered seriously over the first and second winters.

Three general regions are distinguished in regard to the adaptability of red clover, i. e., (1) where severe winters prevail, (2) with milder winters and where anthracnose or other clover diseases are unimportant, and (3) with milder winters and where anthracnose or other clover diseases are of major importance. Clover from domestic seed, including that grown in Canada, resists severe winters better than any foreign clover so far tested, and in regions of severe winters only American-grown clover seed should be used. Seed of disease-resistant types of domestic clover should be used if possible where anthracnose or similar diseases prevail.

Alfalfa seed production in southern Idaho, A. E. McClymonds (*Idaho Sta. Bul. 143 (1926), pp. 3-20, figs. 7*).—Based on experiments at the Aberdeen Substation and experience in that region, information is given for the profitable production of alfalfa seed in southern Idaho. The discussion deals with varieties, preparation, cultural, irrigation, and harvesting practices, influence of the weather, and insect and weed pests and their control.

Effect of immaturity on shrinkage, shelling percentage, and germination of seed corn, H. W. ALBERTS (*Jour. Amer. Soc. Agron., 18 (1926), No. 7, pp. 603, 604*).—The effect of harvesting corn at five different stages of maturity on shrinkage, shelling percentage, and germination was studied at the Wisconsin Experiment Station, using Golden Glow in 1919, and Murdock in 1920. The percentage of shrinkage decreased progressively from the early milk to the full dent stage in both varieties, whereas the shelling and germination percentages rose up to the beginning-glaze stage. There was little difference between the beginning of the glaze stage and the full-dent stage in shelling percentage or in germination.

Summary of experiments on the manuring of mangels, 1892-1925, E. J. ROBERTS (*Univ. Col. No. Wales, Bangor, Dept. Agr. [Pub.], 1925, No. 1, pp. 11*).—Experiments by the University College of North Wales and the Counties of Anglesey, Carnarvonshire, Denbighshire, and Flintshire demonstrated farmyard manure to be essential to the production of a large crop of mangels. The average acre increase accruing from a dressing of 10 or 15 tons per acre at 41 centers was 9.28 tons. On land receiving only 10 tons of manure per acre an extra 10 tons produced an average increase of 3.7 tons over 35 centers but proved unprofitable in conjunction with a dressing of a complete fertilizer. An application of 128 lbs. of sodium nitrate, 349 lbs. of superphosphate, and 82 lbs. of potassium chloride used along with manure averaged as effective as a fertilizer application twice as large at 35 centers.

Considering the average of all the trials, potassium fertilizers showed only a moderate return, although in some cases a very decided and profitable response was had. Kainit was superior unit for unit to potassium sulfate and flue dust. Nitrogenous fertilizers showed a small return in tests from 1909 to 1913, inclusive, probably because most of the trials were conducted on soils already with large nitrogen reserves assembled by wild white clover of the previous meadow. Sodium nitrate proved superior to ammonium sulfate in trials at 35 centers, the average superiority being 1.4 tons per acre or 8 per cent. In a series from 1921 to 1925, no appreciable difference was seen between the effect of ammonium chloride and ammonium sulfate, while sodium nitrate surpassed both slightly. Common salt resulted in considerable and profitable crop increase when no potassium was used, but when added to a 448-lb. dressing of kainit its effect was small.

The influence of external conditions on the blooming of rice flowers [trans. title], Y. KOBAYASI (*Nôgaku Kwaihô (Jour. Sci. Agr. Soc. [Japan], No. 279 (1926), pp. 59-72, figs. 7; abs. in Japan. Jour. Bot., 3 (1926), No. 2, p. (31).*)—Studies of the effect of sunlight and darkness on the rice flowers gave indications that while blooming was noticeably retarded in darkness, the number of opening flowers was not reduced significantly. However, dehiscence of anthers, pollen shedding, and percentage of fertilization were not interfered with. The author observed that orange light, followed by yellow, accelerated blooming most, and that the process was also speeded by electrical illumination.

[Investigations with soy beans in Illinois] (*Illinois Sta. Rpt. 1925, pp. 32-37, fig. 1.*)—In the soy bean variety tests by J. C. Hackleman, Manchu led in seed yields and averaged 28.6 bu. of seed per acre for the period 1921-1924. Hong Kong led as a hay producing bean with a 5-year acre average of 2.62 tons. O. H. Sears found additional evidence that certain varieties of soy beans seem less susceptible to nodule bacterial infection than some other sorts. Soil acidity appeared to be an important factor controlling the longevity of the soy bean nodule bacteria even upon slightly acid soils. The effect of both limestone and inoculation on the growth and composition of soy beans was found to be similar in the field to those obtained in the greenhouse.

A study by Sears on the influence of soy beans upon other crops in the rotation indicates to date that a close relationship exists between the nitrogen cycle and this problem. In the 4-year rotation of corn, oats, red clover, wheat, and a catch crop of sweet clover, soy beans are substituted when the red clover fails. For a number of experiment fields on brown silt loam and black clay loam wheat yields after clover exceeded those after soy beans, the gain in favor of clover ranging from 2.9 bu. of wheat an acre without soil treatment up to 6.7 bu. when the land received residues, limestone, and phosphate. In the station rotation of corn, corn, corn, and soy beans, corn after soy beans has outyielded corn following corn, the increase in favor of soy beans ranging from 6.8 bu. when the land received manure and phosphate up to 11.7 bu. with manure alone.

In breeding the soy bean for oil content, C. M. Woodworth has found individual parent plants of any particular line to give progenies with the same mean oil content, even though the parents differ by as much as 4 per cent, making selection within such lines for high or low oil seem noneffective. Some lines isolated had an average oil content as low as 15 per cent. In a method devised, the extent of mottling of seeds on a given plant can be expressed by a single figure. Although the plants of a given progeny varied considerably, significant differences were found between progenies. The amount of mottling is apparently determined to some extent at least by the genetic constitution.

Influence of adjacent rows of soybeans on one another, R. J. GARBER and T. E. ODLAND (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 7, pp. 605-607).—At the West Virginia Experiment Station, each soy bean variety is grown in 18-ft. rows 30 in. apart in 4 or more systematically distributed 4-row plats and after discarding 1 ft. from the end of each of the 2 inner rows the remainder of one is used for obtaining seed yield and the remainder of the other for forage yield. Studies of the heights and yields of the ordinarily discarded border rows showed no appreciable effect of height or yield of one row upon the yield of an adjacent row. Under such conditions border rows seemed unnecessary. Since alternate rows are harvested for forage, the distance between rows harvested for seed is sufficient to minimize danger of mechanical mixtures.

Sugar cane experiments in the Lesser Antilles and British Guiana [trans. title], H. WILLIAMS (*Rev. Bot. Appl. et Agr. Colon.*, 6 (1926), No. 56, pp. 219-228; also *Sta. Agron. Guadeloupe, Bul. Tech.* 3 [1926], pp. 12).—A résumé of variety, fertilizer, cultural, and miscellaneous experiments with sugar cane reported on from the several islands of the Lesser Antilles and from British Guiana.

Investigations on high-nicotine tobacco (*New York State Sta. Rpt.* 1926, p. 18).—Variation between individual untopped plants of certain tobacco selections (E. S. R., 54, p. 534) was almost 1.5 per cent in the nicotine in the dry leaf. For plants grown from seed from earlier selections, the nicotine content has varied about 2 per cent for both untopped and topped plants. Topping has increased nicotine from 1.5 to 3.5 per cent in *Nicotiana rustica* and 1.5 to 2.5 per cent in *N. tabacum*. Fertilizing broadcast seeding of *N. rustica* increased nicotine slightly, especially when dried blood and urea in combination with potash were applied. Broadcast seeding has generally given much lower nicotine values than did cultivated plants.

Rate, date, and depth of seeding winter wheat, W. A. Moss (*Idaho Sta. Bul.* 145 (1926), pp. 3-11, fig. 1).—Experiments at the High Altitude Substation showed 65 lbs. per acre of treated seed to give best results for late plantings and 50 lbs. for early plantings, and depths of from 2 to 3 in. were indicated. September 1 appeared to be the best time to plant winter wheat on dry farm areas of eastern Idaho. Kharkof, Kanred, Triplet, and Turkey, in order, are currently the best yielding winter wheats. The best winter wheats have averaged 13.1 bu. more per acre than the four leading spring wheats.

The effects of different tillage methods on wheat yields are tabulated and recommendations given on cultural practices and on selection and treatment of seed.

A sow thistle survey of Ontario (*Farmers' Advocate and Home Mag.*, 61 (1926), No. 1772, pp. 1257, 1287, figs. 5).—Current results of a survey indicated that the Province of Ontario, Canada, is widely infested with perennial sow thistle, the heaviest infestation being possibly in Wellington and Perth Counties, followed by Simcoe, York, and Ontario Counties.

HORTICULTURE

[**Horticultural investigations at the Illinois Station**] (*Illinois Sta. Rpt.* 1925, pp. 144-147, 149, 150, 151, 152, 153-157, 159-167, 168-170, 172, 173, figs. 7).—Long-continued apple breeding experiments, conducted by C. S. Crandall, have resulted in many thousands of seedlings, among which 427 have been selected as of possible value to fruit growers. Peach breeding work, conducted by Crandall and G. E. Fager, has yielded 238 promising seedlings. Continued studies (E. S. R., 54, p. 334) by W. A. Ruth and V. W. Kelley upon

the summer pruning of young apple and peach trees showed that cutting back has very little influence in developing new side shoots. The first bud below the cut continued the vertical growth of the removed branch. With rare exception, the second bud below the cut produced the only strong lateral. In no case did the lateral branch compete with the leader either in rapidity or in direction of growth.

The results of variety tests with fruits, conducted by Ruth, F. E. Carver, and A. S. Colby, are briefly reported. Of many grapes tested by Colby for keeping qualities in cold storage, the Agawam, Barry, Delaware, Concord, Brighton, Herbert, Lindley, and Vergennes were especially satisfactory. With protection, certain vinifera varieties were fruited successfully outdoors. Preliminary observations on Moore Early and Concord vines indicated that training to either one- or two-cane trunks does not materially affect yields. Self-pollination of Quillen, Latham, Older, Plum Farmer, and Conrath raspberries yielded promising seedlings, as have also crosses between Royal and King and Plum Farmer and June. Observations by Colby on strawberry beds watered with overhead irrigation showed increases in yield approximating 200 to 300 per cent.

Vegetable fertilizer studies, conducted by J. W. Lloyd, showed the value of phosphorus for the tomato. Manurial substitutes were unsatisfactory for the muskmelon, and, although increasing yields, were unprofitable for sweet corn. Of three forms of phosphorus used on tomatoes, bone meal proved best, followed in order by acid phosphate and rock phosphate. Phosphorus gave the largest increases when used without manure, but the highest tomato yield was obtained where manure, limestone, bone meal, and potash were used in combination. Short season, early planted crops, such as spinach, lettuce, and beets, gave the greatest returns from fertilizers. Manure proved a better source of organic matter than did cover crops.

H. W. Anderson reports that the Conqueror watermelon is resistant to wilt and at the same time of good quality.

Sweet corn breeding studies, conducted by W. A. Huelsen and M. C. Gillis, have resulted in some promising strains. Homozygous corn strains are being developed for future cross-breeding purposes. Consistent increases in sweet corn yields were obtained by treating the soil with from 200 to 400 lbs. of acid phosphate per acre. Larger applications failed to give satisfactory returns. The use of muriate of potash at the rate of from 50 to 100 lbs. also increased yields, but the best results were obtained by combining potash and acid phosphate. Nitrogen alone or in combination with phosphorus and potash failed to increase yields. Huelsen found an apparent correlation between black discoloration in canned corn and the fertilizer treatment of the soil. Applications of acid phosphate in large amounts (800 lbs. per acre) apparently increased the black coloration. In some instances applications of potash in the form of muriate decreased this discoloration. There was evidently a close correlation between low yields and increased discoloration. Canned field corn with a known high protein content showed 6.5 times as much black color as field corn with a low protein content.

Comparisons by F. F. Weinard and H. B. Dorner of the yield and quality of roses grafted on *Odorata* and *Manetti* roots showed *Odorata* to be a satisfactory stock. Columbia roses grafted on *Manetti* and *Odorata* roots yielded an average of 23 and 22.2 flowers per plant, respectively. Weinard found that Laddie carnations yielded an average of 0.5 blossom more per plant on new than on used soil. Selection studies with roses and carnations indicated that commercial varieties are heterogeneous, and may be improved by plant

selection. Work with gladioli by Weinard and S. W. Decker indicated that corms must be allowed a definite rest period before forcing. Best results were obtained with plantings made in January or later. Corms stored at room temperature flowered on an average one week earlier than those stored at 38° F. A study by Weinard and J. Hutchinson of orchid seedlings resulting from crosses within the *Cattleya* group showed that blooms of these new varieties compared favorably with those of imported plants now forbidden introduction by quarantine.

[**Horticultural investigations at the New York State Station**] (*New York State Sta. Rpt. 1926, pp. 18, 19, 44-49*).—Fertilizer experiments in vineyards at Fredonia, Urbana, and Hudson again showed (E. S. R., 54, p. 537) that nitrogen alone is sufficiently beneficial to return a profit. No evidence was secured during the year to indicate any differences of any character between budded and grafted apple trees. French crabs proved superior to Northern Spy as root stocks for several standard apples. Slight but inconclusive evidence was obtained that Rome Beauty trees propagated from high-producing parents were yielding better than those from low-producing parents. Continued observations upon Baldwin trees obtained from widely scattered sources showed consistent uniformity irrespective of the point of origin. Observations upon cherries worked upon Mazzard and Mahaleb stocks showed the Mazzard to be distinctly superior for all sweet and for most of the sour cherries.

Nutrient studies with French crab seedlings showed that these trees will make good growth under a variety of proportions of the various nutrient salts provided that the solutions are very dilute and each ion is furnished in sufficient amount by frequent change of solutions. Dilute nutrient solutions gave somewhat better top growth and very much better root growth than did concentrated solutions. New roots developed only under conditions of very low total concentration of nutrient salts. Studies showed a very high variability in seedlings even under uniform conditions. In pure sand and with distilled water 1-year-old seedlings developed an unexpected amount of top and root growth, indicating the presence of a considerable reserve energy.

Sprays and spraying materials, T. J. TALBERT (*Amer. Soc. Hort. Sci. Proc., 22 (1925), pp. 44-53*).—In discussing various important spraying materials, their introduction, and development, the author reports that studies at the Missouri Experiment Station in 1924 and 1925 show that differences in the manner of preparing Bordeaux mixture had no material influence on its value in controlling fungi or its tendency to injure fruit and foliage. No greater injury resulted from using 40-hour-old Bordeaux mixture than from that used immediately after preparation. The author urges that the experiment stations take the leadership in the introduction of new sprays rather than simply follow the lead of commercial organizations.

Factors influencing the quality of fresh asparagus after it is harvested, C. S. BISSON, H. A. JONES, and W. W. ROBBINS (*California Sta. Bul. 410 (1926), pp. 3-28, figs. 13*).—Asparagus spears stored with their bases in water in chambers having temperatures of 33, 41, 56, 77, and 95° F. gained decidedly in length and weight. The gains were larger at the higher degrees, indicating that temperature is the chief factor determining the rate of growth in storage. In all lots the maximum rate of increase took place during the first day, followed by a slowing down. At 77 and 95° the development of molds decidedly shortened the period of storage. The increase in weight and length of spears was generally accompanied by a loss in reducing substances and in total sugars, the rate of which again was correlated with temperature. At 33° there was a very slight gain in these substances during the first 24 hours, and at 41 and 56° there was,

following an initial loss, a very slight gain in the second day, again followed by a decrease. This loss of sugars during storage is believed to be due to the transformation of sugars to lignin and other substances.

A microscopical study of the structure of spears showed a general increase in the amount of fiber at all temperatures utilized. This increase was substantiated by chemical determinations of crude fiber. The rate of increase of fiber was slowest at low temperatures.

As a practical deduction from the experiments, the authors point out that asparagus should be stored as quickly as possible after cutting in chambers maintained at slightly above 32°.

[Copra meal as a fertilizer], J. GUERRERO (*Guam Sta. Rpt. 1925, p. 16*).—Copra meal applied at the rate of 1,000 lbs. per acre proved a satisfactory fertilizer for Kentucky Wonder beans, increasing the yield to approximately twice that of the untreated plot.

Cantaloupe production in California, J. T. ROSA and E. L. GARTHWAITE (*California Sta. Circ. 308 (1926), pp. 48, figs. 29*).—This circular presents general suggestions upon the culture and handling of the cantaloupe under California conditions, discussing such points as seed selection, varieties, planting, irrigation, protection from insect and fungus pests, determination of picking maturity, packing, shipping, etc.

Ginger (*Jour. Jamaica Agr. Soc., 30 (1926), No. 8, pp. 326-334*).—A brief discussion of the culture and curing of ginger.

Breeding new varieties of canning peas, E. J. DELWICHE and E. J. RENARD (*Wisconsin Sta. Research Bul. 70 (1926), pp. 31, figs. 15*).—Individual plant selection has been a successful method of improving canning peas, resulting in productive strains possessing unusual uniformity in plant and pea characters and in the time of ripening. Mass selection, on the other hand, has yielded no such favorable results. Mutations were found at rare intervals, as shown in the discovery of aberrant forms totally unlike any peas ever grown by the station. Hybridization has also resulted in valuable new varieties—for example, Horal, a cross between the Horsford and Alaska varieties, which combines the desirable qualities of both parents and is unusually resistant to root rot. The authors discuss the methods employed in hybridization and the resulting segregation of characters, and describe the new strains and varieties which have resulted from these studies.

Has ringing any place in commercial orchard practice? F. S. HOWLETT (*Amer. Soc. Hort. Sci. Proc., 22 (1925), pp. 22-28*).—This is a report of studies at the Ohio Experiment Station upon the effect of removing 0.25-in. rings of bark from the base of one or two of the main scaffold limbs of young apple trees. Ringing decreased the number but had little effect upon the size of leaves. Measurements on nine trees showed only one case where the leaves of ringed limbs were significantly larger than those of untreated limbs. The foliage of ringed limbs of tilled trees or of those growing in sod with adequate fertilization was dark green and vigorous. The ringing on June 17 of limbs of 10-year-old Baldwin trees had a slight dwarfing effect on the terminal length growth as compared with that of unringed limbs. Despite a heavy frost, the ringed limbs produced a good crop of fruit the year following the treatment, while, at the same time, the unringed limbs on the same trees produced nothing. Ringing is suggested as a means of inducing filler trees to become fruitful.

The effect of ringing filler trees in an apple orchard and its commercial possibilities, F. N. FAGAN (*Amer. Soc. Hort. Sci. Proc., 22 (1925), pp. 20-22*).—The favorable results obtained from the June ringing of young Baldwin, Stay-

man Winesap, McIntosh, and Rome apple trees led the author to suggest the advisability of adopting this practice in a commercial way in closely planted orchards in which the danger of crowding is imminent. The only mortality resulting from ringing occurred in trees standing in thin soil underlaid with ledge.

Starting the apple orchard, C. L. BURKHOLDER (*Indiana Sta. Circ.* 133 (1926), pp. 27, figs. 9).—Touching briefly upon the economic status of apple growing in Indiana and upon the cost of establishing orchards, the author discusses the planting and general care of young orchards. Information upon soil management and fertilizers is contributed by F. P. Cullinan, and that upon insect and disease control by the departments of botany and entomology.

Experiments in cool storage of apples, D. B. ADAM and J. E. HARRISON (*Jour. Dept. Agr. Victoria*, 23 (1925), No. 4, pp. 226-234).—This is a further report (*E. S. R.*, 54, p. 643) upon the results of cold storage investigations with fruit in Victoria, Australia.

Records taken in 1923 on early picked, unwrapped Jonathan apples stored in direct expansion chambers at 32 and 37° F. showed much less scald development at the higher temperature, the percentages of sound fruits being 15+ and 77+ per cent, respectively. On the other hand, in the case of riper fruits practically no scald developed at either temperature, whether or not the apples were wrapped in oil paper. Similar investigations conducted in 1924 with Jonathan and Rome apples bore out the value of the higher temperatures in reducing scald in the Jonathan variety. Conflicting results obtained with oiled and plain paper wrappers prevented the drawing of definite conclusions, although in several instances the oiled wrappers were apparently the more effective. Jonathans picked April 7, 1924, and stored in direct expansion chambers at 32, 34, and 37° showed on June 25, 56, 55, and 97 per cent of sound fruits, respectively. On the other hand, in Rome apples, scald apparently developed more readily at 37 than at 32°, leading the authors to suggest that scald in the two varieties may be due to different causes. Observations on lots of Jonathan and Rome harvested at different stages gave further evidence that in these varieties mature fruits are the least susceptible to scald.

The growth of the fruit of the Elberta peach from blossom bud to maturity, M. A. BLAKE (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 29-39).—Measurements taken in 1925 at the New Jersey Experiment Stations upon the rate of growth of fruits of Elberta trees in their fifth season in the orchard showed two distinct periods of rapid accretion, namely, from June 2 to 8, 45 to 52 days after blooming, and again as the fruits attained full maturity in August. Observations on the opening of flower buds on twigs in the upper part and in the center of the tree showed that the latter were slower to open and in many cases failed to set and carry fruit through to maturity, suggesting that late blooming buds contribute but little to the crop. Observations on fruit development showed that those below a certain suture diameter on a given date failed to mature, indicating the advisability of adjusting the spray schedule to the larger-sized fruits. In presenting dimension ratios for the fruit of several varieties, the author points out that there may be considerable variability on a single tree due to the position on the tree, proximity to neighboring fruits, etc.

Fruiting habit of the grape, H. G. SWARTWOUT (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 70-74).—Data taken on 10 varieties of grapes pruned according to the four-arm Kniffin system showed that the shoots from canes on the upper wires are uniformly more productive than those originating from canes on the lower wires. Well-developed lateral canes were more productive than those

arising from wood 2 years of age or older. With the exception of Niagara, canes from wood 3 to 5 years old were more fruitful, both in respect to size and number of clusters per shoot, than were those from 2-year-old wood. Nodes producing laterals from 6 to 18 in. long were, with one exception (Elvira in 1923), more productive than those with none or very weak laterals. Records taken on canes 10 nodes in length showed the maximum production at the ninth and tenth nodes in Etta, Worden, and Catawba; at the seventh and eighth nodes in Concord, Wyoming, Missouri Riesling, Diamond, and Niagara; and at the fifth and sixth nodes in Moore and Elvira. In respect to ability to produce fruit from adventitious buds following the removal of the young canes, Missouri Riesling, Etta, Elvira, and Wyoming yielded nearly as much fruit as did normally pruned vines, while Diamond, Niagara, and Catawba were intermediate, and Concord, Moore, and Worden were comparatively unproductive.

Some effects of fruiting on the growth of grape vines, W. H. CHANDLER and A. J. HEINICKE (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 74-80).—Studies at Cornell University of the effect of removing the blossoms from unpruned Concord grapevines upon the weight increase of the roots and wood showed reductions in green weight of the tops and of the roots of fruiting plants of about 33 to 36 per cent and about 39 to 42 per cent, respectively. Records of leaf surface on fruiting and defoliated vines showed, with the exception of the pruned Delawares, a marked tendency for defoliation to increase leaf area. Determinations of the dry matter in roots and in tops showed, particularly in unpruned vines, that the total residue of dry matter from a given leaf area was much greater with fruiting vines than with defoliated vines, the differences being most evident in the roots. In explanation, the authors suggest the possibility that less material was used in respiration for a given dry weight of fruit than for the same dry weight of other tissues, or that the removal of material from the leaves to the fruits made possible a more rapid photosynthesis.

The influence of pruning on the germinability of pollen and the set of berries in *Vitis vinifera*, A. J. WINKLER (*Hilgardia [California Sta.]*, 2 (1926), No. 5, pp. 107-124, figs. 6).—Investigations conducted with several vinifera varieties of grapes pruned and defoliated in different degrees of severity ranging from nothing to the removal of all but the basal buds on spurs showed that pruning may exert a very definite influence upon pollen germination and upon the setting of fruits. Using as a standard normally pruned vines, increases in some instances in the germinability of pollen reached a maximum of 606 per cent. In 12 out of 17 cases severe pruning reduced the percentage of germination below that of normally pruned vines.

Especially in those varieties subject to the shelling of berries, moderate pruning greatly increased the set of normal berries per bunch as compared with that of the normally pruned vines. Furthermore the percentage of normal sized berries on the cluster was increased as the severity of the pruning was decreased. Both in number and in percentage of normal berries per cluster severely pruned vines were inferior in 6 out of 8 varieties tested to normally pruned vines.

The deleterious effect of severe pruning on both the pollen and the size and number of the berries per cluster is believed by the author to indicate that both the male and the female floral organs are affected by the degree of pruning. Data taken on the foliar development of treated vines are thought to indicate that the number of leaves, especially during the early part of the season, may be greatly concerned with the behavior of the pollen and the setting of the fruits.

Propagation of the date palm, with particular reference to the rooting of high offshoots, F. J. CRIDER (*Arizona Sta. Bul. 115 (1926)*, pp. 295-313, figs. 16).—Of several practices employed in the propagation of the date palm, alterations in the soil temperature of greenhouse beds in which offshoots were set gave no results in promoting rooting. No significant differences were found between sand, stable manure, and soil as rooting media. Comparing lath shelter and open nursery plantings, the percentage of rooting was slightly greater in the latter. The use of a canvas shelter proved altogether unsuccessful. Offshoots taken in late spring rooted much more successfully than those taken in early fall. Offshoots with roots formed prior to separation from the mother palm grew much more readily than those without roots. The mounding of earth about the base of attached offshoots induced rooting. In the case of high offshoots, the maintenance of a moist medium about the base of a shoot induced satisfactory rooting and apparently justified the construction of scaffolding to hold the boxes of soil. General instructions for the planting and care of offshoots are included.

FORESTRY

World forestry number (*World Agr., 6 (1926), No. 2*, pp. 433-444, figs. 10).—This number contains the following papers: The World Forestry Congress of 1926, by S. T. Dana; Past, Present, and Future of Forestry in Germany, by C. A. Schenck; Fifty Years of Forestry in the United States, by W. B. Greeley; Forest Development in the Philippine Islands, by G. P. Ahern; Forest Practices as Affected by Land Ownership, by R. S. Hosmer; Forest Work of the Tropical Plant Research Foundation, by D. M. Matthews; Public Policies Toward Private Forests, by W. N. Sparhawk; and Town Forests and Farming, by H. A. Reynolds.

The forest resources of Canada, R. D. CRAIG (*Econ. Geogr., 2 (1926), No. 3*, pp. 394-413, figs. 18).—A comprehensive article discussing various factors concerned in Canadian forestry, including climatic relations, species and their distribution, forest industries—their location and importance, and the general situation in regard to utilization and reforestation.

Danger of frosts studied at Wind River Nursery (*Jour. Forestry, 24 (1926), No. 7*, pp. 839, 840).—Studies by A. G. Simson show that under a cover of 10-oz. burlap 28° F. was not reached until the outside temperature dropped to 21°. At higher temperatures the insulating value of burlap was less, the differential being only 2° when the outside temperature was 42°. It is pointed out that the continued use in spring or fall of this heavy burlap covering tends to make the plants more susceptible to frost injury.

Theoretical considerations regarding factors which influence forest fires, L. F. HAWLEY (*Jour. Forestry, 24 (1926), No. 7*, pp. 756-763).—The mechanism of combustion is discussed in its relation to general forest conditions, including the effects of temperature, moisture content, air supply, ignition temperature, heat of combustion, and the state of aggregation or surface volume ratio of fuel. The state of aggregation is believed to outweigh all other variables affecting the ease of ignition, but from the standpoint of forecasting dangerous fire conditions moisture content, because of its tendency to large and rapid fluctuations, is deemed the most important factor.

Harvesting timber crops in the national forests of the East and South, R. M. EVANS (*U. S. Dept. Agr., Misc. Circ. 75 (1926), pp. II+13, figs. 9*).—A brief discussion upon the methods and procedure employed in the harvesting and sale of timber and other forest products in the national forests of the east-

ern United States, with comments upon the species of wood available and the uses to which they are adapted.

Predicting the second cut in national forest management plans, D. DUNNING (*Jour. Forestry*, 24 (1926), No. 7, pp. 785-790, fig. 1).—Accompanied by a general discussion, diameter growth prediction curves are presented based upon increment borings made upon 155 dominant and codominant white fir trees released by cuttings in 1882, the data being recorded approximately 40 years later.

Yield, stand, and volume tables for white fir in the California pine region, F. X. SCHUMACHER (*California Sta. Bul.* 407 (1926), pp. 3-26, figs. 3).—The tables presented in this paper are based upon measurements taken in 157 normally stocked, even aged sample plats of white fir, covering a range of age classes from 40 to 150 years and in various conditions of productivity. In general, white fir stands exhibited an exceptionally slow growth up to an age of about 30 years, followed by a marked acceleration to about the ninetieth year. On account of its abundant seeding ability and tolerance to shade the white fir is deemed well adapted to the shelterwood system of silviculture, in which the establishment of reproduction is provided for before all the overwood is removed. On account of the slow initial growth of white fir the preservation of advance reproduction is highly advisable.

Field manual of trees, J. H. SCHAFFNER (*Columbus, Ohio: R. G. Adams & Co.*, 1926, 3. ed., pp. 154).—A few minor changes and corrections have been made in this third edition of the work previously noted (E. S. R., 48, p. 238).

The commercial woods of the South (*South. Lumberman*, 125 (1926), No. 1629, pp. 163-179, figs. 25).—Information is offered in this general article upon the distribution, supply, production, properties, and uses of all the important lumber-producing species grown in the Southern States.

A universal index to wood, E. H. F. SWAIN (*Jour. Forestry*, 24 (1926), No. 7, pp. 735-755, figs. 2).—In this paper the author outlines a system of wood identification and classification based primarily upon structural characters, density, etc., rather than upon the usual botanical relationships.

DISEASES OF PLANTS

[**Plant disease investigations at the Illinois Station**] (*Illinois Sta. Rpt.* 1925, pp. 43-48, 150, 151, 152, 153, 158, 159, 170-172, figs. 7).—In continuation of studies previously reported by Holbert et al. (E. S. R., 53, p. 349) further data are given on the occurrence of root and stalk diseases of corn. It was found that scutellum rot reduced the yield 17.3 per cent during the 5 years 1920-1924; *Diplodia*, 34.2 per cent during the same period; *Gibberella*, 46.6 per cent during 1924; *Cephalosporium*, 6.2 per cent during the 3 years 1922-1924; and *Fusarium*, 8.6 per cent during the 3 years 1921-1923.

Experiments on time of planting, effect of applying limestone and fertilizer rotations, and breeding for resistance for the control of these diseases showed that nearly disease-free seed and seed infected with *Cephalosporium* and *Fusarium* made the best yields when planted at an early or intermediate date, May 1 to 15, while seed susceptible to scutellum rot gave the best yields when planted from May 10 to 21. Applying limestone gave little control. There was more lodging on soil cropped frequently in corn. Certain correlations of plant and ear characters with disease have been established by C. M. Woodworth and F. L. Winter, and through mass selection a strain of corn has been developed that shows an increased yield of 5.6 bu. per acre. Some indications were found by E. E. DeTurk et al. that phosphate utilization by strains of corn may have a bearing on disease.

Experiments by B. Koehler, G. H. Dugan, and J. R. Holbert showed encouraging results for the seed treatment of corn for the control of *Diplodia* and *Gibberella* when treated with some of the mercury phenolate compounds. No control of scutellum rot, however, was obtained by the treatments.

Investigations by H. W. Anderson have shown that none of the common spray materials controlled bacterial spot, or shot hole disease, of peaches, while sodium silicofluoride and combinations of this with sulfur gave excellent control and did not cause injury to the foliage.

Investigations on the effect of fertilizer and cultivation on the control of shot hole disease gave inconclusive results, but it was found that the amount of bacterial shot hole on nitrated plats was about the same as on those not nitrated. The trees on the untreated plats were defoliated much earlier in the season and were lacking in vigor throughout the summer.

In continuation of studies on the fire blight of pears and apples, Anderson reports that of 500 seedlings of *Pyrus callaryana* inoculated with pure cultures of the fire blight organism, none was resistant. Bartlett pears top-worked on *P. ussuriensis* seedlings also blighted. Fire blight is said to have been unusually destructive to apples throughout the State during the two years preceding the report. Cutting out of cankers as practiced by growers did not prove an unqualified success.

Investigations by A. S. Colby on the control of crown gall of raspberries have shown that germicides applied to the soil for the control of the disease must be thoroughly mixed with it.

In attempting to control raspberry anthracnose it was found that less than 10 per cent of the raspberry canes which were sprayed with a combination of lime sulfur and Kayso showed a heavy to medium infection, while the remaining canes showed only slight or no infection. Spraying canes with lime sulfur alone did not give as good results as those where a combination spray was employed.

Investigations on the control of aster wilt in gardens, by F. F. Weinard and S. W. Decker, indicate that plants which have not been transplanted show a greater resistance to wilt than those transferred from indoors. On the other hand, plants which had their growth checked by transplanting or drought were found to be probably more susceptible to wilt than those which had not been checked.

[Plant disease investigations at the New York State Station] (*New York State Sta. Rpt. 1926, pp. 26-31*).—A summary account is given of studies of raspberry mosaic, in which it is stated that the control of the disease through spraying and dusting for the elimination of the insect carriers did not give the results which were anticipated. It was found in the course of the investigations that only the youngest instars of the principal aphid carrier were effective in transmitting the disease. A new virus disease of black raspberries previously confused with streak and wilt was proved to originate in red raspberries and to be carried to the black raspberry by aphids. This disease is thought to be red raspberry mosaic as it affects black raspberries. It is said to be quite destructive to black raspberries and does not produce typical mosaic symptoms.

Attention was given to some of the diseases of canning crops, and *Ascochyta* blight of peas was found to cause more loss to the canning industry than any other disease. It is said to be seed borne, and progress is reported in locating sources of healthy seed.

The effect of time of planting Wells Red Kidney beans on the incidence of bean blight showed that early plantings were severely attacked by blight

of the foliage. Late plantings escaped foliage blight, but by reason of abundant rains there was much blight on the pods. Plantings made between June 15 and 20 at Geneva on clover sod turned under the previous fall are recommended for the control of this blight.

For the third successive season Phoma and bitter rot failed to appear in experiments carried on for their control, but data were secured showing the value of Bordeaux mixture and lime sulfur for the control of scab. Bordeaux mixture oil, lime-sulfur solution, dry mix sulfur lime, and a form of colloidal sulfur, all applied during the pink period, gave equally good control of scab. Russetting of the fruit was observed in one instance where Bordeaux mixture with 2 per cent engine oil emulsion had been used, and a similar amount of injury followed an application of lime-sulfur solution. Zinc sulfide applied at the rate of 5 lbs. to 100 gal. of water gave no indication of causing injury.

For the control of blackleg of cruciferous crops by seed treatments partial control was secured with dusts, but soaking the seed with organic mercury or corrosive sublimate solutions was not found dependable. Hot water treatments gave the best control. The hot water treatment of cauliflower seed gave good control of black rot, and about 1,500 lbs. of cauliflower, cabbage, and Brussels sprouts seed were treated in the spring of 1926 for farmers on Long Island. Some evidence of resistance to blight was found in tests of varieties of cauliflower from various sources. Inoculation experiments showed that mustard, rutabaga, flat turnip, and Chinese cabbage were all very susceptible to mosaic, but rape was somewhat resistant.

Preliminary experiments on the treatment of seed potatoes for the control of diseases are said to have given promising results where two organic mercury compounds were used.

Report on the occurrence of fungus, bacterial, and allied diseases of crops in England and Wales for the years 1922-1924, G. H. PETHYBRIDGE (*[Gt. Brit.] Min. Agr. and Fisheries, Misc. Pub. 52 (1926), pp. 97, fig. 1*).—The present report, dealing with the years 1922, 1923, and 1924, continues the series beginning with 1917, the most recent presentation of which, by Cotton, has been noted (*E. S. R.*, 49, p. 645). The information supplied by advisers is supplemented by that from regular reports containing data, and in some cases special memoranda, concerning plant diseases.

Plant diseases in relation to certification of seeds, H. T. Gussow (*Quebec Soc. Protect. Plants Ann. Rpt.*, 16 (1923-24), pp. 72-77).—It is insisted that study is urgently needed of the diseases conveyed by seeds, the mechanism by which seeds become carriers, and reliable information on the questions of rational and effective control of seed-borne diseases, together with precise information on their recognition in field or in the package.

A review of our knowledge concerning immunity and resistance in plants, J. E. HOWITT (*Quebec Soc. Protect. Plants Ann. Rpt.*, 16 (1923-24), pp. 9-24).—A review to date is given of the general subject of plant immunity and resistance, which is thought to promise a solution for some of the most outstanding and important pathological problems of the present time, such as the prevention of loss from grain rusts; the control of citrus canker in the South; the reestablishment of the American chestnut in the United States; the production of beans free from anthracnose, mosaic, and root rot; and the prevention of soil diseases, such as cabbage yellows, flax wilt, cotton wilt, tobacco root rot, and stem and root rot of canning peas. A review of the more important accomplishments in the production of resistant plants is concluded with the statements that substantial and permanent progress has been made in the production and selection of resistant varieties of plants; that

further and more extensive studies concerning the existence of biologic strains of different parasitic fungi are required; that knowledge concerning the biochemical causes of resistance is fragmentary and inadequate; and that future work on this subject lies largely in the field of biochemistry. The list of related literature comprises 213 titles.

Influence of time and temperature on the rate of growth of certain fungi, H. S. FAWCETT (*Abs. in Phytopathology*, 14 (1924), No. 2, pp. 119, 120).—Experiments with mycelia of *Pythiacystis citrophthora* and *Diplodia natalensis* when grown for long periods showed that they were not influenced by the time element in their response to temperature. During short periods of growth, especially at the higher temperatures, the time element was found to have an important influence on the rate of growth.

Recent advances in dusting methods, R. E. SMITH (*Abs. in Phytopathology*, 14 (1924), No. 2, pp. 121, 122).—Attention is called to some advantages of the selfmixer in the preparation of dust fungicides and insecticides.

Botrytis cinerea in Alaska, J. P. ANDERSON (*Phytopathology*, 14 (1924), No. 3, pp. 152-155, pl. 1).—It is claimed that more than three-fourths of the fungus injury to cultivated plants in southeast Alaska is caused by *Botrytis*. The author reports having collected the fungus on one or more species of 88 genera of seed plants, three of ferns, and on *Lunularia*. While *B. cinerea* is supposed to be the conidial stage of *Sclerotinia fuckeliana*, the author reports that he has never found the ascigerous stage of the fungus in Alaska, and that the sclerotial stage has been observed only a few times.

The growth of *Ophiobolus graminis* Sacc. in relation to hydrogen-ion concentration, R. W. WEBB and H. FELLOWS (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 9, pp. 845-872, figs. 8).—Kirby (E. S. R., 53, p. 348), Davis (E. S. R., 54, p. 649), and others having reported differently on the influence of soil reaction on the occurrence and severity of attacks of *O. graminis*, the authors studied the growth of the fungus under different H-ion concentrations in several types of liquid and solid media, and under different environmental conditions. A single spore strain of the fungus was used throughout the experiments.

In general, *O. graminis* grew well in pure culture on solid and liquid media over a wide range of active acidity and alkalinity. The pH range and the pH optimum for growth were variables, depending upon the physical and chemical nature of the medium and the environmental factors. Temperature influenced the optimum reaction for fungus growth in potato-dextrose decoction, but did not materially influence the pH range through which growth occurred. The optimum temperature was not altered by variations in the H-ion concentration. The length of the period of growth was found to influence the pH optimum for fungus growth in potato-dextrose decoction, but did not appreciably modify the pH growth range. Neither diffused light nor total darkness appreciably affected the pH optimum or the pH range for growth. While the H ion generally proved to be more toxic to the growth of the fungus than the OH ion, the toxicity of each was variable, depending upon the medium. The reaction of the substrate sufficient to cause death of the fungus was several tenths of a pH more acid or more alkaline than that sufficient to cause inhibition of growth. Progressive and reversible shifts in the reaction of the media were induced by the growth of the fungus. The direction and the magnitude of these shifts varied with the temperature, the duration of the growth interval, the initial reaction, and the chemical and physical natures of the media.

The production of substances toxic to plants by *Penicillium expansum*, C. C. BARNUM (*Phytopathology*, 14 (1924), No. 5, pp. 238-243, figs. 2).—As a result of his experiments the author claims that a toxic principle is produced

in the culture solution upon which *P. expansum* had been grown. This product of fungus growth is capable of causing wilting in certain herbaceous plants, whether absorbed through the cut ends of the stem or through the roots of the growing plants.

Spore germination of *Ustilago striaeformis*, W. H. DAVIS (*Phytopathology*, 14 (1924), No. 6, pp. 251-267, pls. 3, fig. 1).—An account is given of investigations undertaken to determine the natural conditions under which the spores of this fungus germinate, the nature of the germination, and the features of the fungus on each host investigated. This smut was found to parasitize timothy, redtop, June, and orchard grass. The smut spores are considered to be resting spores and, under natural conditions, must pass through a period of after-ripening before germinating. Under laboratory conditions an average rest period of 240 days was required for afterripening, and under field conditions about 265 days.

The cardinal temperatures for the germination of the smut spores from all four hosts were minimum 7°, optimum 22°, and maximum 35° C., with some variation in the minimum and maximum temperatures of spores from different hosts.

Reactions of selfed lines of maize to *Ustilago zaeae*, H. K. HAYES, E. C. STAKMAN, F. GRIFFEE, and J. J. CHRISTENSEN (*Phytopathology*, 14 (1924), No. 6, pp. 268-280).—In order to determine the possibility of developing varieties of corn resistant to smut a study was made in self-fertilized lines of several varieties and strains to ascertain their reaction to smut.

The results indicate that the development of resistant varieties is the most promising means for the control of corn smut. A normal variety of corn is said to be in a highly heterozygous condition, and selection in self-fertilized lines offers the most promising means of isolating smut resistant strains of corn. Ear infection is said to be more serious than infection of other parts of the plant, and flint varieties appear to be somewhat more susceptible, particularly to ear infection, than dent varieties.

The localization of smut on the plant is considered a strain characteristic. Some selfed strains were uniformly infected on one of the lower nodes of the stalk, others produced a high percentage of ear infection, and still others were infected chiefly in the tassel. F₁ crosses between resistant self-fertilized strains were more resistant than either parent, while F₁ crosses between resistant and susceptible strains produced an intermediate type of infection. Resistance and susceptibility are considered to be conditioned by genetic factors.

Notes on the climatic conditions influencing the 1923 epidemic of stem rust on wheat in Illinois, L. R. TEHON and P. A. YOUNG (*Phytopathology*, 14 (1924), No. 2, pp. 94-100, fig. 1).—Data are presented correlating precipitation and temperature with primary and secondary infections of stem rust in several localities in Illinois in 1923.

Anthracnose as a cause of red clover failure in the southern part of the Clover Belt, A. J. PIETERS and J. MONTEITH, JR. (*U. S. Dept. Agr., Farmers' Bul. 1510* (1926), pp. II+18, figs. 11).—A popular account is given of the anthracnose of red clover caused by *Colletotrichum trifolii*. This disease is said to be a limiting factor in clover culture in the South. The organism is widely distributed, and it is believed to exist to an unknown extent north of the Ohio River.

The authors state that the only way to avoid loss from the anthracnose is to use seed from a strain known to be resistant to the disease or seed produced from a stock propagated over a considerable period in the infected territory. Where seed of unknown origin must be used, it is recommended that seeding be made in late summer or early fall wherever experience has not shown this to

be impracticable. Late summer or early fall seeding is said to give the clover plants a chance to escape the early attack of the disease and produce a hay crop, even though there may be no second growth.

The rust of cowpeas, F. D. FROMME (*Phytopathology*, 14 (1924), No. 2, pp. 69-79, pl. 1, fig. 1).—In a previous paper (E. S. R., 45, p. 445) the difference in pathogenicity of a rust of cowpea from the bean rust (*Uromyces appendiculatus*) was pointed out. Additional study here reported has shown morphological differences between the rusts, and the author considers the fungus which attacks the cowpea to be *U. vignae*. In addition to occurring on four species of *Vigna*, this rust also attacks one species of *Dolichos* and one of *Phaseolus*. Infection studies with a strain of the rust obtained from the Blackeye cowpea showed it to be closely restricted in its host range. It has infected only a few varieties or strains of the Blackeye type.

Control of diseases of cucurbits, J. GUERRERO (*Guam Sta. Rpt. 1925*, p. 16).—Spraying with Bordeaux mixture before reaching the vining stage and once a week thereafter proved to be the most efficacious measure for the control of powdery and downy mildew. Muskmelon vines were killed by sulfur-dust applications, but neither cucumber nor squash vines were affected by the treatment.

Flax rust and its control, A. W. HENRY (*Minnesota Sta. Tech. Bul. 36* (1926), pp. 3-20, pls. 2).—The results are given of a study of flax rust caused by *Melampsora liniperda* or *M. lini*, as it is commonly known. In Minnesota and neighboring States, the disease is said to appear the latter part of June, but it does not assume epidemic form until late in July or early in August. The uredinial stage may persist until killing frosts occur, but apparently does not overwinter. The telial stage readily overwinters and starts the initial infections the following year. In an experiment on a peat bog, flax was sown in plats having water levels varying approximately from 1 to 5 ft. from the surface. The heaviest infections of rust occurred on the intermediate water levels, where the flax was the most vigorous.

Varietal resistance to the disease has been observed, and immune varieties of both blue- and white-blossomed seed flax have been found. Crosses were made between immune and susceptible varieties, and the F_1 plants of all crosses were immune. Segregation occurred in the F_2 generation, and the behavior of the segregates is said to indicate that it will be possible to combine immunity from rust with fiber characteristics or with other desired characters.

Certain strains of Argentine flax, in addition to being immune to rust, were fairly resistant to wilt. Wilt resistance and immunity to rust were not considered correlated but are apparently determined by different causes. Some evidence was obtained that indicates that the rust of cultivated flax may be specialized into physiologic forms. The use of immune varieties is considered the most promising method for control. While susceptible varieties are still in use home-grown seed should be used as far as possible, and it should be thoroughly cleaned to remove bits of straw; seeding should be done early; low-lying soils should be avoided; and on fields intended for flax, infected straw should be burned or removed before the new crop emerges.

Immunity to mildew (*Bremia lactucae*) and its inheritance in lettuce, I. C. JAGGER (*Abs. in Phytopathology*, 14 (1924), No. 2, p. 122).—Eight varieties of European lettuce immune to mildew in California and Florida were hybridized with the so-called Iceberg lettuce, a very susceptible variety. The F_1 plants proved to be immune to the disease, and this character was found to be inherited in a simple Mendelian ratio in the second generation.

Bacterial slime disease of lettuce, R. E. and E. H. SMITH (*Abs. in Phytopathology*, 14 (1924), No. 2, p. 122).—A bacterial disease of lettuce in the Imperial Valley and elsewhere in California is briefly noted.

Species of *Fusarium* isolated from onion roots, C. P. SIDERIS (*Phytopathology*, 14 (1924), No. 5, pp. 211-216, pls. 3).—In a study of the causal organism of the pink root of onions, the author isolated about 20 species and varieties of *Fusarium* from diseased and dead roots, some of which showed symptoms of the pink root disease while others did not. The following new species are reported and described: *F. cromyophthoron* n. sp. *F. rhizochromatistes* n. sp., *F. rhizochromatistes microsclerotium* n. v., *F. sclerostromaton* n. sp., *F. loncheceras* n. sp., and *F. loncheceras microsporon* n. v.

Mosaic and leaf roll of potatoes in Idaho, C. W. HUNGERFORD and J. M. RAEDEER (*Abs. in Phytopathology*, 14 (1924), No. 2, p. 123).—The authors claim that at least three distinct types of potato mosaic occur in Idaho. The green and pink rose aphid was found to transmit the russet dwarf type of mosaic. This type of disease may appear as a slight mottling late in the season, but progeny from such plants may develop the disease in a severe form. Leaf roll may also appear late in the season as a slight rolling of the upper leaflets, but progeny from such plants may show leaf roll in advanced stages.

***Alternaria solani* as a cause of tuber rot in potatoes, D. FOLSOM and R. BONDE** (*Phytopathology*, 15 (1925), No. 5, pp. 282-286, pls. 3; *abs. in Maine Sta. Bul.* 328 (1925), p. 257).—The authors report having isolated *A. solani* from lesions on potatoes in commercial storage, and with cultures from the lesions to have infected young tubers and foliage of greenhouse-grown plants. Immature tubers packed in diseased foliage became badly infected. Occasionally cultures did not react on media in the usual manner, and this is believed to indicate a saprophytic rather than a parasitic difference between biological strains.

Resistance of sorghum to loose and covered smuts, G. S. KULKARNI (*Phytopathology*, 14 (1924), No. 6, p. 288).—Dwarf, standard, and white milo and ferlita were found resistant to both *Sphacelotheca sorghi* and *S. cruenta*, while all varieties of kafir and shallu tested were susceptible to both species of fungi.

Studies of a new *Fusarium* wilt of spinach in Texas, J. J. TAUBENHAUS (*Texas Sta. Bul.* 343 (1926), pp. 3-23, figs. 6).—A detailed account is given of a disease of spinach, the occurrence of which in Texas was previously reported by the author (*E. S. R.*, 55, p. 849). This disease is said to be caused by the fungus *F. solani*, and although apparently similar in appearance to that of the spinach wilt described by Hungerford (*E. S. R.*, 54, p. 49), it was found to be distinct from the latter and prevalent in many parts of the State. The symptoms of the wilt are said to be typical of a *Fusarium* in which the causal organism is confined to the root. All attempts to isolate the causal organism from any other part of the plant have failed.

Soil temperature was found to be an important controlling factor in the spread of the spinach wilt in Texas. Under conditions in the central part of the State the disease did not spread under the average outdoor temperatures of 72° F., or of 70° in the soil at a depth of 2 in., or of 68° at a depth of 4 in. The disease is said to increase with the increase of soil temperature above those mentioned.

As the causal organism attacks potatoes, the author suggests that spinach should not be planted in soil recently occupied by that crop, and that plantings should not be made during the months of high soil temperatures.

In connection with the *Fusarium* wilt, a new *Rhizoctonia* root rot was found, which causes serious damage and also opens the way to infection by this wilt. *Rhizoctonia* on spinach is considered different from that which causes sore shin of cotton.

Curly leaf transmission experiments, H. H. P. SEVERIN (*Phytopathology*, 14 (1924), No. 2, pp. 80-93, fig. 1; abs., p. 123).—The results are given of numerous experiments on various phases of the transmission of curly leaf of sugar beets. The causative agent is said to be generally distributed in the foliage and beet root. Field and laboratory experiments have demonstrated that the disease is not transmitted through the soil or from beet to beet. Juice pressed from the leaves and roots of infected beets when inoculated into the crown of healthy ones caused typical curly leaf symptoms in some instances. The period of incubation in inoculation experiments varied from 12 to 39 days. When noninfective beet leafhoppers were allowed to feed on inoculated beets after curly leaf developed the disease was transmitted to healthy beets in from 2 to 13 days.

Infective beet leafhoppers are said to have retained their infectivity during all of the nymphal stages and during the entire adult life. Attempts to produce the disease by infecting the mouth parts of leafhoppers with *Bacillus morulans* failed to transmit the disease.

Progress report on curly-top of the sugar beet, E. CARNSNER and C. F. STAHL (*Abs. in Phytopathology*, 14 (1924), No. 2, pp. 122, 123).—Marked resistance to curly top in some strains of sugar beets is reported. Inoculation experiments are thought to give evidence that *Chenopodium murale* is more or less resistant to disease, and passing the virus of the disease through this resistant plant causes its attenuation. Successful production of curly top by artificial inoculation of beets is reported.

Effect of environmental conditions on western yellow blight of tomatoes, M. SHAPOVALOV (*Abs. in Phytopathology*, 14 (1924), No. 2, pp. 120, 121).—The author claims that the western yellow blight of tomatoes is of importance in seasons and regions with relatively high temperature, low humidity, and high evaporation. A progressive root decay was found in connection with the blight and species of *Fusarium* and *Rhizoctonia* were isolated from decaying roots, but their rôle in connection with the disease was not definitely determined.

The behavior of certain varieties of tomatoes towards Fusarium-wilt infection in California, M. SHAPOVALOV and J. W. LESLEY (*Phytopathology*, 14 (1924), No. 4, pp. 188-197, pls. 2; abs. in *Phytopathology*, 14 (1924), No. 2, p. 121).—The authors tested the reaction of a number of tomato varieties to the wilt fungus (*F. lycopersici*) by artificial inoculation and natural field infection. In the artificial inoculation experiments two distinct cultures of *Fusarium* were employed, both having been isolated from wilted plants in California. One of these cultures proved to be parasitic, causing the typical *Fusarium* wilt disease. The variety Norton proved resistant when tested in three widely separated localities in southern California, while Norduke, Marvel, and a California selection from Stone were resistant in two localities where tested. Most but not all of the varieties bred for wilt resistances at various experiment stations, as well as the variety Livingston Globe, proved resistant to wilt when planted in badly infected soil in California.

The relation of temperature and humidity to tomato leaf spot (*Septoria lycopersici*), F. J. PRITCHARD and W. S. PORTE (*Phytopathology*, 14 (1924), No. 3, pp. 156-169, pl. 1, figs. 9).—A study was made of the distribution of tomato leaf spot in the United States. The heaviest losses caused by this disease were found to occur in the Middle Atlantic and Middle Western States, the disease being considered of little importance in the Northern and Southern States and apparently absent in the Pacific coast region. A rather definite correlation between relative humidity and temperature is believed necessary for the development of the fungus.

The stripe or streak disease of tomatoes in Quebec, T. C. VANTERPOOL (*Quebec Soc. Protect. Plants Ann. Rpt.*, 16 (1923-24), pp. 116-123, pls. 2).—In 1923 tomatoes at Macdonald College showed a disease characterized by a long spindling growth of the upper part of the plants, a spotting, curling, and shriveling of the leaves, small irregular brown spots on the fruit, and brown, oblong, sunken markings on the stem and petioles. This disease resembles somewhat one which has been reported under a variety of names since about 1892. The author began a study of this disease in 1924, and the present is a progress report of that work, noting symptoms, distribution, and experimentation.

Host plants of *Bacterium tabacum*, J. JOHNSON, C. M. SLAGG, and H. F. MURWIN (*Phytopathology*, 14 (1924), No. 4, pp. 175-180, pls. 2).—Inoculation experiments conducted primarily to study winter hosts of *B. tabacum* gave infections upon 12 species of *Nicotiana* and 7 other members of the Solanaceae, 4 species of Cucurbitaceae, 13 of Leguminosae, 11 of Gramineae, 7 of Cruciferae, 6 of Compositae, 5 of Polygonaceae, 3 of Chenopodiaceae, 3 of Labiatae, 2 of Malvaceae, 2 of Umbelliferae, and single species of 13 other families of plants. The large majority of the plants inoculated were infected, and it is believed that the host range of *B. tabacum* is much larger than indicated by the results of the authors' experiments.

Overwintering of tobacco wildfire bacteria in New England, P. J. ANDERSON (*Phytopathology*, 14 (1924), No. 3, pp. 132-139).—As a result of three years' experiments and observations on the conditions under which wildfire bacteria pass the winter, the author concludes that organisms pass the winter most successfully in situations where they are not subjected to keen competition from the growth of other organisms, principally in fairly dry situations, as in cured leaves in the barn, leaves on plants standing in the field or thrown on the ground too late to rot, on boards and sash of seed beds, and dry fragments of pods.

Tobacco wildfire and tobacco seed treatment, H. E. THOMAS (*Phytopathology*, 14 (1924), No. 4, pp. 181-187, fig. 1).—Experiments of the author appear to indicate that there is little probability of carrying over *Bacterium tabacum* in refuse in fields, only slight infection having been secured in plats where refuse was buried under the plants.

For the control of the disease the author found that tobacco seed treated with mercuric chloride 1-1,000 germinated nearly or quite as well on soil and in thin sowings in moist chambers as did untreated seed. When seed from the same treated lots was held in bulk in muslin or in cheesecloth bags no germination was obtained at 26° or at 33° C. (78.8 and 91.4° F.). Seed treated with copper sulfate, potassium permanganate, potassium dichromate, and sulfuric acid showed no appreciable injury in the concentrations tested. The drying of wetted seed rapidly in direct sunlight or slowly in the laboratory did not impair germination.

A chemical and pathological study of decay of the xylem of the apple caused by *Polystictus versicolor*, R. G. SMITH (*Phytopathology*, 14 (1924), No. 2, pp. 114-118).—The results are given of chemical analysis of sound apple wood and apple wood attacked by *P. versicolor*.

Due to fungus attack a decrease was found in all constituents except benzene extract, lignin, and the undetermined constituents. Lignin showed a marked increase, and, since no new lignin could have been formed, the author believes that the increase is due to a concentration by removal of other constituents.

The study of resistance to crown-gall in *Prunus*, C. O. SMITH (*Abds. in Phytopathology*, 14 (1924), No. 2, p. 120).—A preliminary note is given of studies

on resistance to crown gall, a detailed account of the investigations having been noted (E. S. R., 54, p. 750).

Biological and cultural studies of *Exoascus deformans*, A. J. Mix (*Phytopathology*, 14 (1924), No. 5, pp. 217-233, figs. 2).—The author claims that *E. deformans* can be readily isolated from ascospore-bearing leaves and grown in a variety of common culture media. The minimum temperature for growth of the organism in culture is below 10° C. (50° F.), the maximum between 26 and 30°, and the optimum 20° or lower. The thermal death point of the fungus in culture was found to be 46°. Cultures were completely devitalized when kept for a few days at 30°. The organism is said to withstand drying on cover slips for 315 days. It has a wide toleration of acidity and alkalinity in culture media, growth occurring at H-ion concentrations below pH 3.3 and above pH 9.75.

Attempts to isolate the fungus from the surface of healthy peach twigs and buds and from the soil beneath infested trees were unsuccessful. A few successful isolations were made from the interior of diseased leaves and stems. Peach trees were successfully inoculated with conidia of the fungus from culture, and typical leaf curl resulted. The virulence of the fungus was not impaired by being kept in pure culture for 22 months. Attempts to inoculate very young seedlings grown from peach pits were very unsuccessful.

Notes on cranberry fungi in Massachusetts, N. E. STEVENS (*Phytopathology*, 14 (1924), No. 2, pp. 101-107).—A summarized account is given of an intensive study of the fungi associated with the decay of cranberries in Massachusetts. Fungi belonging to at least 25 genera have been isolated from decayed or sound cranberries, some of them only a few times, but more than one-third of the author's cultures yielded *Fusicoccum putrefaciens*. Other fungi which were also found 10 or more times in cultures were *Glomerella cingulata vaccinii*, *Phomopsis* sp., *Sporonema oxycocci*, *Guignardia vaccinii*, *Penicillium* spp., *Dematium* sp., *Pestalozzia guepini vaccinii*, *Acanthorhynchus vaccinii*, and *Alternaria* sp.

The effect of storage temperature, time required for development of disease in storage, distribution of infection by flood water, etc., are discussed.

Mosaic disease of loganberry, S. M. ZELLER (*Abs. in Phytopathology*, 14 (1924), No. 2, p. 119).—A destructive mosaic of loganberry is reported as occurring from Sonoma County, Calif., to Snohomish County, Wash. Nearly all the younger plantings are affected, and the plants are said to die in from three to four years after the first symptoms appear.

Grape rust in Florida, C. L. SHEAR (*Phytopathology*, 14 (1924), No. 3, pp. 170-171).—The occurrence of *Physoopella vitis* on grapevines at Orlando, Fla., is reported, most of the varieties of grapes being practically defoliated.

Alternaria rot of lemons, E. T. BARTHOLOMEW, (*California Sta. Bul.* 408 (1926), pp. 3-32, pls. 3, fig. 1).—A description is given of the *Alternaria* rot of lemons, the disease being compared with endoxerosis, or internal drying, with which it has been confused. The latter disease is said to be due to physiological causes.

Alternaria rot is reported to occur in all the lemon districts of California, and it probably causes more decay of lemon fruits than any other fungus with the possible exception of *Penicillium*. The author's investigations show that infection of the fruit may occur through the buttons or by spores or mycelium between the button and the fruit, and that infection occurs very early in the development of the fruit, but that decay does not begin until after the fruit is placed in storage.

Present methods of orchard spraying are said to be ineffective for the control of *Alternaria* rot, and the removal of the buttons and efforts at sterilization with fungicides were found to be inefficient and impracticable.

Picking the fruit before it is ripe and while it still retains a high degree of vitality, washing and thorough drying, and storage at a temperature of 55° F. or below are recommended as means for the control of this trouble.

Notes on the life history of the snapdragon rust, *Puccinia antirrhini*, E. B. MAINS (*Phytopathology*, 14 (1924), No. 6, pp. 281-287).—The author reports having obtained germination of the teliospores of *P. antirrhini* from five out of seven collections studied. Sowings of the germinating teliospores on young, rust-free snapdragons did not give infection in any case, and this is considered to indicate that the rust is heteroecious and has pycnia and aecia on an alternate host. It is considered that the most likely method of discovering this host is by observations in California on native species of *Antirrhinum* in localities where they are infected with the rust.

Herpetomonad flagellates in the latex of milkweed in Maryland, F. O. HOLMES (*Phytopathology*, 14 (1924), No. 3, pp. 146-151, figs. 10).—The author reports a flagellate infection of milkweed, probably *Asclepias syriaca*, discovered during the autumn of 1923 near Baltimore, Md. The flagellates are said to correspond fairly closely to those known as *Herpetomonas elmassiani*. So far as is known this is the first report of such organisms in the United States.

A red and black hemipterous insect (*Oncopeltus fasciatus*) is suspected of carrying the flagellates from plant to plant.

Decay of Douglas fir due to *Poria incrassata*, S. M. ZELLER (*Abs. in Phytopathology*, 14 (1924), No. 2, p. 119).—This fungus is reported to cause rapid and extreme damage to Douglas fir structural timber and flooring when there is contact with soil as a source of moisture.

Hypoxylon poplar canker, A. ПОВАН (*Phytopathology*, 14 (1924), No. 3, pp. 140-145, fig. 1).—A description is given of a canker of poplar trees discovered in Essex County, N. Y., and studied in 1920. A survey is said to have shown that more than 36 per cent of the quaking aspen trees were affected and 26 per cent of them killed by the disease.

Later the disease was found to occur in Maine and in Michigan. It is caused by *H. pruinatum*, which produces trunk cankers and finally kills the trees by girdling them. Young trees are said to be more susceptible than older ones, no infections having been found on trees more than 6 in. in diameter.

ECONOMIC ZOOLOGY—ENTOMOLOGY

Animal ecology, with especial reference to insects, R. N. CHAPMAN (*Minneapolis, Minn.: Burgess-Brooke, 1925, pp. IX+187+183, figs. 125*).—The author here presents a mimeographed outline of a course in animal ecology, mainly for use of advanced students and investigators, based upon work offered at the University of Minnesota. Copious lists of references are included.

The value of life history studies from the viewpoint of systematic entomology, E. C. VAN DYKE (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 703-707*).—This is a discussion presented at a joint meeting of the Pacific Slope Branch of the American Association of Economic Entomologists and the Pacific Coast Entomological Society.

The fundamental importance of life-history data in biological control work, H. S. SMITH (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 708-714*).—The author discusses the ways in which a knowledge of the different phases of the life history of entomophagous insects is essential in biological control work.

The natural "cleaning up" habit of insects, D. C. MOTE, J. WILCOX, and E. G. DAVIS (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 745-748).—In this contribution from the Oregon Experiment Station, the authors call attention to the habit of certain insects of passing their legs and antennae between their mouth parts and removing powdered materials in this manner. In an attempt to distinguish cleanliness from irritation as the incitant of this action, the western spotted cucumber beetle, German cockroach, European earwig, *Syneta albida* Lec., and the asparagus beetle were stimulated with sodium fluoride, calcium arsenate, lead arsenate, sodium fluosilicate, wheat flour, and powdered milk sugar.

Hippelates flies and certain other pests of the Coachella Valley, California, W. B. HERMS (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 692-695).—It is pointed out that during the past 10 years *H. flavipes* Loew has become increasingly numerous in the Coachella Valley, which borders upon the Salton Sea and lies on an average of about 125 ft. below sea level. This fly is now a veritable pest and is believed to play a part in the transmission of the so-called pink eye affecting many of the inhabitants. The black widow spider (*Latrodectes mactans* Fab.) is said to occur in the valley in considerable numbers and to have been responsible for several serious cases of spider bite, one of which was fatal. The German cockroach is also increasing so rapidly that it is becoming a real pest.

[Entomological work at the Guam Station], S. R. VANDENBERG (*Guam Sta. Rpt.* 1925, pp. 17-19).—The coconut scale (*Aspidiotus destructor*) has apparently existed in Guam since 1911, or even earlier, but has been held in check by natural enemies introduced with it. The present outbreak appears to have been due to the fact that the natural enemies were greatly reduced in numbers during the last two years, or that conditions arose greatly favoring the rapid multiplication of the scale. The pest was first discovered in the northwestern part of the island, whence it spread south and then east, where infestation was slight. In addition to the coconut it attacked breadfruit, papaya, banana, avocado, mango, guava, royal palm, lemon, orange, cassava, coffee, tomato, eggplant, taro, and many weed and brush plants. A brief account is given of its life history, followed by a discussion of control work. Four or five individuals of the ladybeetle *Lindorus lophanthæ* were introduced in March, 1925, but were attacked by red ants and failed to become established. Three important natural enemies have been found in the island, including the small ladybeetle *Crytogonus orbiculus nigripennis*, the golden chalcid *Aphelinus diaspidis*, and a smaller and less numerous parasite attacking the male scale only, thought to be a form of *Aspidiotiphagus citrinus*. This ladybeetle is said to be widely distributed and, with the aid of control measures, has seemed to bring the scale under control in certain districts in the northern part of the island.

Other important insect pests briefly mentioned include the European corn borer, which has taken as high as 50 per cent of the corn crop, the sugar cane borer *Rhabdocnemis obscurus*, which also attacks the coconut palm, the rice bug of India *Leptocorisa varicornis*, and five or more species of mealybugs, which cause considerable damage.

[Report of the New York State Station division of entomology] (*New York State Sta. Rpt.* 1926, pp. 36-44).—In reporting upon studies of apple insects, it is stated that the major part of the work consisted in determining the susceptibility of the eggs and caterpillars of the fruit tree leaf roller to various insecticides, special consideration being given to field tests to ascertain the toxicity of oil sprays to the eggs. The results obtained indicate that the

homemade lubricating oil emulsion containing 8 per cent oil is an efficient ovicide, and that, if used as buds are swelling or not later than when green tissues show at the tips, a single application in occasional years produces apparently no permanent ill effects to the health of the trees. The oil treatment is thought to be warranted as an emergency measure in orchards where the crop at the time of picking shows from 15 to 20 per cent or more apples injured by the leaf roller.

Tests of commercial or proprietary miscible oils have indicated considerable variation in their killing properties, some having been much more effective than others. The results of experiments with arsenicals indicate that the leaf roller can be controlled with thorough and timely applications of such sprays, but one or two applications in addition to those provided in the standard spray schedule are necessary during the period when the eggs begin to hatch. Natural enemies, particularly an active hymenopterous parasite, *Trichogrammatomyia tortricis* Gir., are said to have destroyed many of the leaf rollers during the spring.

The studies of the life history of the codling moth showed that during a normal season there is one complete brood and a partial second brood of caterpillars that attack apple fruits. Along Lake Ontario the period of hatching of the first brood extends over a period of 7 weeks, and stings on the surfaces of apples can best be prevented by two cover sprays, one about 2.5 weeks and the other 5 weeks after the calyx period. The treatment for the second brood is advised for about the second week in August. At Geneva the codling moth appears earlier in the season, the hatching period generally being shorter than in the foregoing area, while the second brood is usually larger.

Lubricating oil emulsions containing no more than 2 per cent oil proved inefficient as ovicides, and, while heavy applications materially reduced the number of the nymphs, the oil sprays were not on the whole as effective as lime sulfur containing nicotine sulfate. Moreover, there are indications that oil emulsions regularly applied as a delayed dormant treatment may injure the trees. Reference is made to control work with the pear psylla which has been reported in detail in bulletins previously noted (E. S. R., 54, pp. 455, 456).

In discussing the control of sucking insects with dust mixtures, it is stated that the data indicate unmistakably that the San Jose scale, in the case of severely infested orchards, is not satisfactorily combated with sulfide dusts, which at first appeared to be the most promising material for a pest of this character. Calcium and sodium fluosilicates are mentioned as promising insecticides for use in dusting operations, and are being tested for the cucumber beetle and the codling moth. Finely ground tobacco is said to display very promising qualities as an aphicide and seems destined to prove valuable in combating several species. Cherry fruit flies (*Rhagoletis* spp.) proved susceptible to dust mixtures containing nicotine as well as to applications of finely ground calcium cyanide, which opens up a new field of inquiry.

Reporting upon studies with grape insects, it is stated that the grape berry moth was so scarce in Chautauqua County that no field experiments could be conducted. Ecological investigations of this insect have shown that the foci of infestation in practically every instance where the pest was found were coincident with an area in which the snow cover during the previous winter had been practically continuous due to the drifting of snow, which indicates that a considerable degree of immunity to the pest can be secured by the avoidance of trees and other high objects adjacent to vineyards. During the summers of 1925 and 1926 considerable injury to grapes was caused by the climbing cutworms.

The most practical method of killing cucumber beetles thus far evolved has been to drive, by dusting, the pests from the main crop to the untreated squash seedlings. On the day following treatment the beetles may be killed on the traps by means of box fumigators, using a dust of 4 or 5 per cent nicotine content and an exposure of from 3 to 5 minutes.

In control work with aphids that injure cauliflower seed beds, laboratory tests of tobacco dusts of approximately 1, 2.5, and 5.5 per cent nicotine content showed that, under uniform conditions, the greater the nicotine content the more highly toxic the dust mixture, although the factor of time exposure had an important influence in determining the relative merits of tobacco with low nicotine content. The longer the exposure the more effective became such dust mixtures. *Macrosiphum solanifolii* Ashm. and the green peach aphid were numerous on potatoes for a short period during early July, but the unseasonably cool weather during the remainder of the month rapidly reduced their numbers to insignificant proportions. An application of nicotine spray at the strength of 1 pint of nicotine sulfate (40 per cent nicotine) to 100 gal. of water and of nicotine dust at the strength of 2 pints of nicotine sulfate (40 per cent nicotine) to 50 lbs. of hydrated lime, made when aphids were most abundant on the terminal shoots and leaves, resulted, under favorable circumstances, in a high rate of reduction provided the spray hit and the dust was placed within lethal range of the aphids. It appears that the satisfactory solution of the aphid problem is largely one of machinery and mechanics rather than of the comparative values of wet or dry forms of nicotine preparations. See also Technical Bulletin 121, noted below.

[**Economic insects in Pennsylvania**] (*Penn. State Hort. Assoc. Proc.*, 67 (1926), pp. 21-28, 37-39, 50-56).—Papers presented at the annual meeting of the Pennsylvania State Horticultural Association held at Harrisburg in January, 1926, which relate to economic insects and their control, include the following: The Value of Oil Emulsion Sprays for Red Spider and the Rosy Apple Aphis, by H. E. Hodgkiss (pp. 21-28); The Oriental Fruit Moth, by S. W. Frost (pp. 37, 38); The Oriental Moth in Franklin County, by J. R. Stear (pp. 38, 39); Recommendations on Spraying Program for the Oriental Moth, by H. E. Hodgkiss (p. 39); and Should We Lift the Japanese Beetle Quarantine? by C. H. Hadley (pp. 50-56).

[**Reports of the economic biologist of British Guiana**], L. D. CLEARE, JR. (*Brit. Guiana Dept. Sci. and Agr. Rpts.* 1923, pp. 47-51; 1924, pp. 65-68).—These reports deal with the occurrence of the more important insects and control work conducted.

Recent introductions of beneficial insects in Hawaii, O. H. SWEZEY (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 714-720).—This is a contribution from the Hawaiian Sugar Planters' Experiment Station, in which an account is given of the introduction of beneficial insects during the period 1920-1925.

Further studies concerning the aphiscidal properties of tobacco dust, H. C. HUCKETT (*New York State Sta. Tech. Bul.* 121 (1926), pp. 3-29, figs. 4).—This is an extended account of studies conducted from 1923 to 1925, in continuation of work previously noted (*E. S. R.*, 49, p. 552).

In a comparative study under laboratory conditions, it was found that the higher the percentage of nicotine in tobacco dusts of fine quality, the greater the toxicity within limited periods of time throughout an experimental period of 1 to 7 days. Pure tobacco dust, or tobacco-hydrated-lime-dust mixtures, the tobacco of which contained approximately 1 per cent nicotine, under favorable conditions, varied in degree of toxicity according to the length of aphid exposure, 30-minute exposures being ineffective, while 3-hour exposures were attended with marked increase in the killing efficiency of such dusts. The

addition of hydrated lime to tobacco dusts of low or high nicotine content in a 50 to 50 proportion improved the physical properties of the dusts and rendered them more actively toxic. The dusts of low nicotine content showed the greater improvement by such additions, but hydrated lime in amounts greater than equal parts of each by weight proved detrimental. The addition of water to pure tobacco dusts had very little effect, if any, in improving the toxic properties of the dusts. The addition of water to dust mixtures of tobacco and hydrated lime had in all cases a marked effect in heightening the toxic value of such mixtures in the dry forms, whether determined immediately following such addition or after a period of 4 to 7 days' exposure. The amounts of water, whether 5, 10, 15, or 20 per cent, appeared to make relatively little difference, all cases being equally effective.

*Under field conditions, tests were carried on with tobacco dust of approximately 1 per cent nicotine content upon aphids infesting cauliflower seedlings in the seed bed, earlier reports upon which have been noted (E. S. R., 53, p. 359; 54, p. 552). Tobacco-dust treatment gave superior results over other forms of nicotine treatment, due, it is thought, to the slower liberation of nicotine fumes in lethal quantities over an extended period of time, thus protecting the plants from daily reinfestation, and, also, to its fertilizer effect on plant growth. Tobacco dust diluted with hydrated lime in proportions equivalent to equal parts by weight affected the growth of the plants as favorably and controlled the aphids as effectively as pure tobacco dust.

Airplane dusting for the control of vegetable pests on the Mexican west coast, A. W. MORRILL (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 695-699).—This is an abstract of an address by the author, an account of which has been noted from another source (E. S. R., 56, p. 57).

Technical aspects of petroleum oils and oil sprays, E. R. DE ONG (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 733-745).—A discussion of the tests by which the character of petroleum oil may be designated, with special reference to volatility and sulfonation in evaluating oils to be used for sprays.

The use of oil spray on citrus trees, R. S. WOGLUM (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 732, 733).—This is an abstract of the author's paper presented at the annual meeting of the Pacific Slope Branch of the American Association of Economic Entomologists.

Fumigation with hydrocyanic acid gas: Concentration and distribution as influenced by fumigation procedure, B. J. SMIT and T. J. NAUDE (*Union So. Africa Dept. Agr. Sci. Bul.* 48 (1926), pp. 23, figs. 10).—The authors' experiments show that in the pot method the generated gas rises rapidly to the highest part of the chamber and descends along the sides of the chamber to the floor.

"In the course of this movement every part of the chamber sampled receives a wave of gas stronger than that of the theoretical concentration. These strong concentrations, however, do not persist long, as in about 10 minutes after charging the distribution has become uniform all over the chamber. This rapid movement of the gas is caused by the heat of the reaction between the hot sulfuric acid and sodium cyanide, and by the steam rising from the generator.

"When in fumigations with liquid hydrocyanic acid the liquid is allowed to evaporate without heating or other aids to evaporation, the nature and area of the surface on which the liquid is poured has an important effect on the spread of gas. An unlimited smooth surface (cement) gives much more satisfactory results than a limited smooth surface (porcelain). An unlimited porous surface (air-dry soil) gives results much inferior to either of the preceding.

"When the evaporation of hydrocyanic acid is aided by application of a moderate amount of heat the results obtained are practically the same as in the pot method."

Paradichlorobenzene as a soil fumigant, E. O. Essig (*California Sta. Bul.* 411 (1926), pp. 3-20, figs. 10).—Following a brief review of the literature, the author reports upon experiments with paradichlorobenzene (PDB) for the control of the western peach borer and other pests, started in 1921 and continued up to the time of writing. It is pointed out that in California the western peach borer attacks a variety of trees on different rootstocks, and that the problem is much more varied than in the eastern part of the United States, where only the peach budded on peach roots is affected. Its California hosts include the peach, cherry, prune, and apricot. Preliminary tests demonstrated the effectiveness of the treatment.

With prunes, the age of which trees varied from 4 to 25 years, the control of the borers averaged from 80 per cent to 95 per cent in most cases and in a few instances approached extermination for the season. During the past four years thousands of acres have been treated without the loss of a single tree or evident injury to any. With apricots, of which the majority of the older trees are on Myrobalan rootstocks and very susceptible to borer attack, all ages of trees from those just set out to those 25 or 30 years old were treated. The only injury noted was to large roots which were close to the surface, some of which were either injured or killed by the gas and the trees greatly weakened. The dosage of PDB for control of the western peach borer is 1 oz. for an average tree. On very large trees it may be increased to 1.5 or 2 oz. Nursery stock treated by the furrow system should receive about 1 oz. to a linear yard of furrow. The material may be applied with fair success from May to November, but the best results have been secured from applications made in September and October.

Two years of experimental work with PDB on the pear root aphid (*Eriosoma lanuginosa* Hartig), conducted in Contra Costa County, proved the treatment to be efficacious on all ages of pear trees grafted to both French and Japanese rootstocks. Irrigation immediately after the application of PDB has not injured any of the thousands of trees treated. The dosage for control of this pest is from 1 to 1.5 oz. to a tree.

Experiments and demonstrations with PDB used at the rate of 1 to 1.5 oz. per tree for the control of the woolly apple aphid were conducted in Alameda, Sonoma, and Santa Cruz Counties, and the only injury thus far noted has been to trees having one or more rootstocks near the surface of the soil. The injury to apple trees reported from the East is not apparent in the work done to date in California.

More than a hundred separate patches of raspberry and blackberry plantings on light and heavy soils in the San Fernando Valley were treated for the control of *Bembecia marginata* Harris between June 7 and July 17 at the rate of 0.5 oz. for the smaller plants and 0.75 oz. for the larger ones. The gas treatment did not injure the bushes, as has been reported to be the case in New Jersey.

This insecticide was used against the grape phylloxera at the rate of 8 to 16 oz. to a vine, applied in furrows radiating from the vines. Some of the vines showed injury soon after the treatment, but subsequent examination of the roots of the treated vines showed no evidences of phylloxera while roots from the check vines showed great numbers present. The following spring the phylloxera were found on the roots of the treated vines in limited numbers, but the injured vines made a noticeable advance in growth over the infested

untreated vines in the same vineyard. In an experiment conducted in July in which 0.5 oz. of PDB was used to a vine, examination in November showed practically no control on the light soil while no insects could be found on the vines in the heavier soil.

In control work with wireworms in dahlia roots, the results of preliminary work with PDB were so promising that an entire patch was treated. The retarded plants at once took on new life, and an excellent crop of flowers was produced in the face of what seemed sure ruin. The dosage used was about 1 teaspoonful placed about 2 in. above the planted tuber. Since only a few dead wireworms could be found in the soil, it was concluded that the chemical acted chiefly as a repellent, but it was so effective that not a single living wireworm was found in any of the several hundred tubers treated.

In control work with the garden centipede *Scutigera immaculata* Newport on asparagus unsatisfactory results were obtained, due apparently to the rapid escape of the vapor because of the porous condition of the peaty soils where the tests were made.

Naphthalene fumigation of greenhouses, A. HARTZELL (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 780-786, fig. 1).—Fumigation with commercial flake or ground naphthalene at a concentration of 1.5 oz. per 1,000 cu. ft. of air space with exposures lasting overnight proved to be an effective and practical method for controlling red spider (*Tetranychus telarius*), *Heliothrips femoralis*, and the onion thrips in greenhouses. It is pointed out that observations covering a period of two years in which the tolerance of 40 species of plants was repeatedly tested indicate that this fumigant is adaptable to general greenhouse use.

The control of grasshoppers by airplane dusting, A. A. GRANOVSKY (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 791-795).—This is a brief review of some Russian literature with reference to the control of the migratory grasshoppers, *Locusta migratoria* L. and *Calliptamus italicus* L., by airplane dusting. It is pointed out that several arsenical dusts have been tried experimentally with varied results. Disodium acid arsenite and disodium acid arsenate dusts were used with striking success against hoppers when they were on the wing, indicating that certain arsenicals can probably be used as contact insecticides.

Control experiments on the Surinam cockroach (*Pycnoscelus surinamensis* L.), C. F. DOUCETTE and F. F. SMITH (*Jour. Econ. Ent.*, 19 (1926), No. 4, pp. 650-656).—The authors report upon a study made of the habits of this tropical cockroach, which has been found doing injury in several greenhouses in the eastern part of the United States. Experiments conducted to determine practical control measures adaptable in commercial greenhouses are reported upon. The work with poison baits indicates that their use over large areas would be impractical. Sodium cyanide in solution applied to the soil was the most promising control material used.

Notes on the recent outbreak of Toxoptera graminum, C. N. AINSLIE (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 800, 801).—In the course of this discussion it is pointed out that portions of the State of Minnesota, a region heretofore supposed to lie too far north for any general increase of the green bug, were the scene of unusual damage by it during the spring and summer of 1926.

Crepe myrtle plant louse, H. L. DOZIER (*Jour. Econ. Ent.*, 19 (1926), No. 5, p. 800).—The author considers the plant-louse enemy of the crepe myrtle, perhaps the most widely used ornamental shrub throughout the Gulf States, to be no other than *Myzocallis kahawaluakalani*, described by Kirkaldy from Honolulu. It is pointed out that at times this aphid renders the foliage of the crepe myrtle unsightly by the black sooty mold that grows in its "honeydew"

excretion. The ladybeetle *Olla abdominalis sobrina* Casey and a species of *Chrysopa* are important enemies of the pest in the Gulf Coast section.

The pea aphid as an alfalfa pest in California, C. M. PACKARD and R. E. CAMPBELL (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 752-761).—The data here presented have been noted from another source (E. S. R., 55, p. 153).

The peach cottony scale, P. J. PARROTT and S. W. HARMAN (*New York State Sta. Circ.* 89 (1926), pp. 8, pls. 2).—This is a practical summary of information upon the peach cottony scale (*Pulvinaria amygdali* Ckll.), a comparatively unknown pest which during the past two years has become very destructive to peach orchards in western New York, being most conspicuous in plantings in Wayne, Monroe, Orleans, and Niagara Counties that are within a range of from 5 to 7 miles of the shore of Lake Ontario. The circular presents a description of the insect, an account of its life history and habits, and information on the nature of its injury to peach trees, control measures, lubricating oil emulsions, factory-made lubricating oil emulsion, commercial miscible oils, combinations of fungicides with lubricating oil emulsion, timing of the application, and precautions for prevention of oil injury.

In 1925 the hatching of the eggs, the number of which ranges from 800 to as high as 3,000 and upwards per insect, was well under way by June 11 and apparently completed by July 1, but in 1926, due to weather conditions, hatching was not completed until July 27. Upon hatching out the young scales swarm over the trees, establishing themselves on the tender bark near the tips of the succulent shoots, or preferably along the midribs and veins of the leaves. In the fall migration from the leaves to the twigs takes place. Its injury is caused by the abstraction of sap and the smutting of the fruit and leaves.

In control work oil mixtures have proved most effective. The homemade lubricating oil emulsion devised by the U. S. D. A. Bureau of Entomology, consisting of red engine oil 2 gal., water 1 gal., and potash fish oil soap 2 lbs., is considered from the standpoint of economy to be about the cheapest oil spray available. The boiled homemade oil emulsions are preferred by the author to the cold-mixed homemade emulsions, since they are, on the whole, more stable. Attention is called to the fact that factory-made lubricating oil emulsions which have great stability and uniform strength are now on the market. During the spring, lubricating oil emulsion applied in combination with Bordeaux mixture for the control of leaf curl effectively controlled the scale.

Notes on some Lepidoptera from eastern Texas, L. J. BOTTIMER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 9, pp. 797-819, figs. 3).—This account is based upon collections, observations, and rearings of Lepidoptera from eastern Texas made by the Federal Horticultural Board in the latter part of 1922 and again in 1923, in connection with the eradication work with the pink boll worm. The work was conducted with a view to discovering host plants of the pink boll worm other than cotton and to enlarging the list of Lepidoptera likely to be mistaken for this comparatively new cotton pest. Of the 40 species of Lepidoptera listed, *Chaetocampa crotonella*, *Isophrictis rudbeckiella*, *Recurvaria eryngiella*, and *Gelechia monotaeniella* are described as new, and 2 already described are here recorded for the first time from the United States. The variety *I. similiella denotata* is also described as new, and the genus *Chaetocampa* has been erected by Busck. The paper has been confined largely to new species and to previously unrecorded data regarding the habits and distribution of other forms. The paper supplements an account by Heinrich, previously noted (E. S. R., 45, p. 156).

The biology of the Lepidoptera, M. HERING (*Biologie der Schmetterlinge*. Berlin: Julius Springer, 1926, pp. VI+480, pls. 13, figs. 82; rev. in *Ent. News*, 37 (1926), No. 9, pp. 309-312).—This work deals at length with the various phases of the life history and habits of the Lepidoptera. The first part takes up the ontogenesis (pp. 44-116); the second part deals with the adults, their nutrition, reproduction, senses, and flight (pp. 117-222); and the third part deals with general problems (pp. 223-468). A list of 48 references to the literature and indexes to the genera and subject matter are included. The review is by W. T. M. Forbes.

The peach and prune root-borer injurious to cherries, B. G. THOMPSON (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 779, 780).—Notes are presented on the injury, life history, and parasites of *Synanthedon opalescens* (H. Edw.), which was found only in the roots and crown below the union of the bud and root in cherries budded to *Prunus mahaleb* rootstock.

Some possibilities in codling moth control, G. M. LIST (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 748-752).—Attention is called to the fact that under some conditions spraying alone is not proving satisfactory, and that the use of bands, orchard sanitation, and the picking of wormy fruit should be practiced. Ovicides are said to show possibilities as a means of reducing the number of stings, oils having proved the most efficient. It is possible to trap large numbers of adult codling moth, and a fermenting sweetened apple juice is proving a valuable attractant. The traps can be used as a means of determining the insect development in an orchard for the establishment of spray dates.

Codling moth attacks cherries, D. C. MORE (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 777, 778).—In this contribution from the Oregon Experiment Station, the author records the rearing of codling moth from larvae feeding on cherries from three different counties of the State.

The oriental peach moth, A. PETERSON and G. J. HAEUSSLER (*U. S. Dept. Agr., Dept. Circ. 395* (1926), pp. 28, figs. 17).—This is a summary of information on the status of knowledge of the pest, including control measures. A table showing the number of broods of moths of the oriental peach moth and dates of emergence of the first and last adults of each brood for several localities, including Fort Valley, Ga., Leesburg, Va., Riverton and New Brunswick, N. J., Chambersburg, Arendtsville, and Harrisburg, Pa., and New Haven, Conn., is contained in the account.

Observations on the characteristic injury caused by the Lima bean pod borer, Etiella zinckenella Treit., and other insects with which its injury is confused in California, A. O. LARSON (*Jour. Econ. Ent.*, 19 (1926), No. 5, pp. 699-702).—This is an account of the characteristic appearance, before and after harvest, of beans cut by *E. zinckenella*, as well as that of beans injured by other caterpillars and bean weevils.

Tobacco cutworms and their control, S. E. CRUMB (*U. S. Dept. Agr., Farmers' Bul. 1494* (1926), pp. II+14, figs. 11).—This is a practical summary of information on the subject.

The use of powdered larvicides in combating mosquitoes [trans. title], E. ROUBAUD (*Bul. Soc. Path. Exot.*, 19 (1926), No. 4, pp. 287-302, figs. 3; abs. in *Rev. Appl. Ent.*, 14 (1926), Ser. B, No. 7, pp. 121, 122).—Tests made of trioxymethylene, arsenical powders, and a proprietary preparation are reported upon. Applied in equal volume in the proportion of 5 per cent in an inert powder, calcium arsenite appeared to be the most active, followed by acetoarsenite of copper. The proprietary preparation Stoxal is most highly recommended for use on a large scale, due to its rapidity of action and harmlessness for other forms of life. Its effectiveness is more lasting than the others (as

long as 20 hours after contact with the water), and its action is quicker than that of the arsenicals.

The horse bots and their control, F. C. BISHOPP and W. E. DOVE (*U. S. Dept. Agr., Farmers' Bul. 1503 (1926), pp. II+14, figs. 8*).—This is a practical summary of information on the subject.

The lesser bulb fly, *Eumerus strigatus* Fallen, in Oregon, J. WILCOX (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 762-772, pl. 1, figs. 3*).—In this contribution from the Oregon Experiment Station the author reports that the lesser bulb fly, which was first reported from Oregon in 1918, is now established in the commercial onion and narcissus producing sections of the State.

The cherry fruit fly, H. GLASGOW and F. L. GAMBRELL (*New York State Sta. Circ. 87 (1926), pp. 10, figs. 3*).—This practical account, mentioned in the report noted on page 251, deals with the life history, control, and supplementary control measures. A chart showing the life history of the pest in relation to the development of the cherry crop and a cherry spray schedule in tabular form are included.

Water and water solutions of organic compounds as dips for the soil of potted plants infested with the Japanese beetle, W. E. FLEMING (*Jour. Agr. Research [U. S.], 33 (1926), No. 9, pp. 821-828*).—This is a report of investigations conducted at the Japanese Beetle Laboratory at Riverton, N. J., in which experiments were made to determine whether an established infestation of the Japanese beetle in the soil of small potted plants could be destroyed by submersion for a definite period in water or water solutions (emulsions) of *o*-cresol, phenol, benzyl chloride, carbon disulfide, nitrobenzene, and sodium cyanide.

"The larvae resisted asphyxiation in water for 15 days. No correlation was found between the rate of larval mortality and the concentration of the dissolved oxygen of the water. Carbon disulfide emulsion was the most effective of the solutions in killing the larvae in the submerged soil. The insecticidal concentrations, however, usually injured plants. It was apparent in these experiments that the effective action of any dipping solution is so dependent upon soil imbibition, soil adsorption, and soil absorption as to limit the application of even an effective insecticide to conditions where these factors are favorable."

A list is given of 20 references to the literature.

A contact spray for the control of the Japanese beetle (*Popillia japonica* Newm.), E. R. VAN LEEUWEN (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 786-790*).—This contribution from the Japanese Beetle Laboratory at Riverton, N. J., deals with an emulsion of oleoresin of pyrethrum flowers and sodium oleate as a contact spray for the control of the Japanese beetle. The experiments include laboratory and field tests on various types of plants for injury and toxicity tests on the beetle.

The cadelle, E. A. BACK and R. T. COTTON (*U. S. Dept. Agr. Bul. 1428 (1926), pp. 42, figs. 15*).—This is a summary of information on the status of knowledge of this pest, based on a review of the literature, in connection with a list of 35 references, and investigations conducted. Much of the data on the biology of the species is presented in tabular form.

The Arizona cotton boll weevil problem, T. P. CASSIDY (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 772-777*).—This is a brief discussion of the boll weevil on *Thurberia* or wild cotton and its relation to the cultivated crop by an agent of the U. S. D. A. Bureau of Entomology.

The problem of insects injurious to alfalfa, S. B. DOTEN (*Nevada Sta. Rpt. 1925, pp. 16, 17, fig. 1*).—Tests showed spraying and dusting with arseni-

cals to be highly effective against the alfalfa weevil. The application of arsenicals by dusting was much more feasible than as sprays. Good results were obtained with both methods, although spraying seemed to be somewhat more effective. The tests of the year showed clearly that horse-drawn sprayers are effective and useful in this type of spraying, more so than the gasoline-power sprayer that was tested. A bulletin by Snow covering the spraying tests of the years 1923 and 1924 has been noted (E. S. R., 53, p. 454).

The collection and utilization of pollen by the honeybee, R. L. PARKER (*New York Cornell Sta. Mem. 98 (1926), pp. 3-55, figs. 16*).—The first part of this account deals with the collection of pollen (pp. 6-30), and is followed by an account of the utilization of pollen (pp. 30-49). Both are preceded by a review of the literature on the subject in connection with a bibliography of six pages.

The author finds that pollen alone is collected from relatively few plants, the majority of species visited yielding both nectar and pollen. Of all the bees observed 25 per cent collected pollen only, 17 per cent gathered both pollen and nectar on the same trip, and 58 per cent collected nectar alone. It was found that bees gathering nectar utilize pollen from the same species of plant from which they are gathering nectar. The average pollen load is nearly 20 per cent of the weight of the carrying bee, or 0.0150 gm., while the large loads weigh 0.0197 gm. The availability of pollen is influenced by relative humidity and temperature. With some plants the period is limited to the early morning while other plants yield more or less pollen all day. Pollen is gathered at all times when it is available whether or not it is needed immediately.

Pollen was found to be the chief source of protein in the food of bees, a lack of it causing a cessation or a slackening of brood rearing, while pollen coming to the hive acted as a stimulus to brood rearing. When there was a plentiful supply of pollen in the hive and other conditions were favorable brood rearing progressed rapidly. During the period of mass feeding royal jelly is supplied abundantly, and during the period of progressive feeding undigested pollen is mixed with the food derived from a secretion. Pollen tubes, such as appear in germinating pollen, have not been seen in pollen within the digestive organs of the bee, but grains which were cracked or have a part of the wall missing were often found. Substitutes for pollen, such as rye, wheat, oats, pea meal, corn, buckwheat ground fine, and Mellin's Food, were not found to be beneficial. Larvae fed these foods die just after the period of mass feeding.

The reappearance of *Harmolita grandis* and *Harmolita vaginicola* in Utah, R. W. DOANE (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 730-732*).—The author reports that the wheat-straw worm and the wheat-sheath worm (*H. vaginicola* Doa.), both of which were destructively abundant in Utah in 1914 and 1915, have been much less abundant during the past 10 years, but in 1926 they again appeared in sufficient numbers to destroy some fields and affect others seriously.

***Habrobracon brevicornis* Wesm., P. GENIEYS, trans. by L. O. HOWARD** (*Ann. Ent. Soc. Amer., 18 (1925), No. 2, pp. 143-202, figs. 35*).—This deals with the effect of environment and the variations which it produces, and with the biology and the morphology of the insect.

A study of some hymenopterous parasites of aphidophagous Syrphidae, M. KAMAL (*Jour. Econ. Ent., 19 (1926), No. 5, pp. 721-730*).—This paper summarizes the results of investigations by the author during the past two years on the parasites of the aphid-feeding Syrphidae of southern California.

Hereditary transmission of tularaemia infection by the wood tick, *Dermacentor andersoni* Stiles, R. R. PARKER (*Pub. Health Rpts. [U. S.]*, 41 (1926), No. 28, pp. 1403-1407).—Experiments are recorded which demonstrate the hereditary transmission of *Bacterium tularense* in the intermediate tick host *D. andersoni* (= *D. venustus*). Eight of 15 females engorged on infected hosts transmitted infection to their progeny.

ANIMAL PRODUCTION

The digestibility of certain fruit by-products as determined for ruminant.—I, Dried orange pulp and raisin pulp, S. W. MEAD and H. R. GUILBERT (*California Sta. Bul.* 409 (1926), pp. 3-11, figs. 3).—The average digestibility of dried orange pulp and raisin pulp when fed with alfalfa hay as determined with 5 wethers according to usual methods is reported in the following table:

Coefficients of digestibility of dried orange and raisin pulp

Kind of feed	Dry matter	Crude protein	Ether extract	Crude fiber	Nitrogen-free extract
	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>	<i>Per cent</i>
Dried orange pulp.....	89.33±0.31	78.54±0.35	48.89±1.44	83.73±1.61	95.40±0.17
Raisin pulp.....	44.78±.64	24.13±.40	90.16±.24	18.54±.55	52.01±1.10

Estimates of the feeding value, based on the digestibility studies, indicated that dried orange pulp was comparable to barley, dried beet pulp, and other feeds of a similar nature, while raisin pulp had approximately two-thirds of the feeding value of these feeds.

Commercial feeding stuffs in Kentucky in 1925, J. D. TURNER, H. D. SPEARS, W. G. TERRELL, and P. H. SENN (*Kentucky Sta. Bul.* 268 (1926), pp. 97-137).—A summary of the official analyses of feeding stuffs, giving the manufacturer's name, kind of feed, and number of samples equal to or below their guaranty (*E. S. R.*, 53, p. 269.)

The effect of feeding cellulose on the pulse rate of steers, H. W. TITUS (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 9, pp. 887-891).—The pulse rate taken just before watering at 10 a. m. and 3 p. m. of the steers used in the study of the effect of fiber on digestibility at the New Mexico Experiment Station (*E. S. R.*, 56, p. 159) showed that as the content of paper pulp in the alfalfa hay ration was increased there was a marked tendency for the pulse rate to increase. This increase was found to be proportional to the increased apparent digestibility of the paper pulp as compared with alfalfa.

It is suggested that a refined method for determining pulse rate over a long interval might be a rather accurate index of metabolic activity.

Fattening steer calves: Corn and oilmeal in dry-lot rations, previous to feeding on grass, G. BOHSTEDT (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 217-224, figs. 3).—Four lots of ten steer calves were used for comparing the rations fed to heifer calves in the previous trial (*E. S. R.*, 54, p. 361). During the 161-day dry lot feeding period those receiving the basal ration of alfalfa hay and corn silage made an average daily gain of 1.37 lbs. With the supplement of 2 lbs. of oil meal per head daily to this ration the average daily gain was increased to 1.87 lbs. When the basal ration was supplemented with both corn and linseed oil meal the average daily gain was 2.12 lbs., and when the corn was fed only during the last 13 weeks of the feeding period the average

daily gain was 2.07 lbs. From the results of the dry lot feeding it appeared that, as in previous experiments, the more corn that was fed in the ration the greater were the calculated returns over feed costs.

At the conclusion of the dry lot feeding period all lots were fed on corn and oil meal with blue grass pasture. When first turned on pasture all lost in weight, but the corn-fed calves lost much more and required a longer time to regain the lost weight. It is pointed out that it would have been more economical to have sold the corn-fed cattle directly after the dry lot winter feeding period.

The average daily gains made during the pasturing period of 84 days for those which in dry lot had received the basal ration, the basal ration plus oil meal, the basal ration plus corn and oil meal, and the basal ration plus oil meal with corn during the last 13 weeks were 1.60, 1.16, 0.91, and 0.97 lbs., respectively.

After finishing, the cattle were slaughtered. The carcasses were all considered as very desirable for the butcher's trade because of the small amount of waste.

Stanchion-feeding compared with group-feeding of baby beeves, G. BOSTEDT (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 225-229, figs. 3).—Two lots of baby beef calves were full-fed for 203 days on a ration of corn and linseed oil meal 9:1 with alfalfa hay and corn silage. During the first 98 days one of the lots was fed as a group, while the calves of the other lot were individually fed in stanchions. The method of feeding the two lots was reversed during the last 105 days of feeding.

In the first period the calves fed in stanchions made an average daily gain of 2.38 lbs. per head as compared with 2.66 lbs. for the group-fed calves. During the second feeding period the group-fed calves made an average daily gain of 1.85 lbs. as compared with 1.27 lbs. for those fed in stanchions. The explanation of the greater gains of the group-fed calves was that during the first 98 days the group-fed calves ate an average of 0.41 lb. more grain, 0.95 lb. more hay, and 2.18 lbs. more silage per head daily than the stanchion-fed calves, with somewhat greater differences in the second period.

From these results it is concluded that feeding as a group tends to stimulate the feed consumption and increase the rate of gain and the margin over feed cost.

[Experiments with beef cattle at the Illinois Station] (*Illinois Sta. Rpt.* 1925, pp. 68-71, fig. 1).—The results of the following experiments are briefly reported:

Corn Belt rotation will maintain beef herd.—Five years' results on this project by H. P. Rusk (*E. S. R.*, 54, p. 359) have shown that a good stand of sweet clover will furnish approximately 170 days of pasture per acre when grown in the rotation of corn, corn, oats, and sweet clover, while good blue grass pasture yielded only 101 days' pasturage per acre.

Soft corn found valuable for fattening steers.—In an experiment conducted by Rusk, R. R. Snapp, and J. H. Knox, 6 lots of 10 2-year-old steers fed soft corn by different methods in conjunction with oil meal and alfalfa hay for 90 days made average daily gains as follows: Shock corn 3.05 lbs., ear corn silage 3.35 lbs., broken ears from the field as needed 3.12 lbs., corn pastured in the field 3.29 lbs., ear corn silage plus oats 3.42 lbs., and hard ear corn from the previous year 3.55 lbs. The steers fed broken ear corn from the field dressed 61.6 per cent, while the steers in the other lots dressed 62.2 per cent.

Studies by S. Bull and J. H. Longwell of the carcasses of the steers inspected by several packing house men and retail meat dealers indicated that all pre-

ferred those from the cattle receiving sound corn. The marbling and coloring of the beef was much better than from those fed on soft corn, and in addition the meat was firmer. Chemical analyses of the ribs, however, showed no differences in the water and fat contents or in the palatability of the beef produced on soft and hard corn.

Feeding bone meal to range cattle on the Coastal Plains of Texas, H. SCHMIDT (*Texas Sta. Bul. 344 (1926), pp. 3-37, figs. 5*).—Following a general summary of animal requirements for minerals the results of feeding mineral supplements to range cattle are reported. By making regular tests of the desire of cattle to chew bones it was found that this habit could be broken by allowing cattle on pasture access to a mineral mixture of 2 parts of bone meal and 1 part of salt. Considerable time was required to overcome the habit, especially in certain individuals, and two cows which would not eat the minerals could not be broken of the habit of bone chewing. The loss of animals and the necessity of furnishing supplemental feed was considerably greater in cattle not receiving the mineral supplement. The gains of the cattle, the numbers of calves reared, and their weights at weaning were considerably better for lots receiving the mineral mixture, and practically no cases of creeps developed, though this condition was common in the control lots.

Efforts to use ground rock phosphate alone or in mixture with salt and bone meal were entirely unsuccessful. Bone meal alone was also refused by the animals.

[Nutrition studies with sheep at the Illinois Station] (*Illinois Sta. Rpt. 1925, pp. 73-75*).—Brief results of the following feeding and nutrition experiments are reported:

Check made on energy values of sheep feeds.—In continuing the study of the energy value of roughages by W. G. Kammlade, H. H. Mitchell, and T. S. Hamilton (*E. S. R., 54, p. 361*), 4 lots of 5 sheep each were used for determining the amount of timothy, clover, or alfalfa hay or oat straw required to maintain body weight when fed with minerals and 0.14 lb. of linseed oil meal daily per 100 lbs. of live weight. There were required 1.896 lbs. of alfalfa, 1.781 lbs. of clover, and 1.517 lbs. of timothy hay per 100 lbs. of live weight for maintenance in these experiments. The high value, 1.488 lbs., for oat straw was attributed to the fact that some of the sheep would not eat sufficient straw to maintain body weight. The relative nutritive values of these feeds were found to agree more closely with Armsby's net energy values than with Henry and Morrison's values for total digestible nutrients.

No losses caused by soy bean hay fed to ewes.—In a comparison by Kammlade of alfalfa and soy-bean hay for pregnant ewes, one lot received 3.12 lbs. of alfalfa hay per head per day until lambing time, while the other lot received 3.77 lbs. of soy-bean hay. The amounts of the respective hays refused averaged 1.7 and 15.2 per cent. The same kind of hay supplemented with grain was fed after lambing to both ewes and lambs.

There was no apparent injurious effect resulting from the feeding of the soy-bean hay to pregnant ewes or lambs, and the gains made by the lambs were comparable with those produced in the alfalfa-hay lot, though somewhat more hay was consumed in the soy-bean lot.

[Experiments with sheep at the Nevada Station] C. E. FLEMING (*Nevada Sta. Rpt. 1925 pp. 18, 19*).—The results of experiments in continuation of those previously noted (*E. S. R., 53, p. 467*) are briefly reported.

The problem of producing more and better lambs in Nevada range flocks.—Several years' repetitions of this test have indicated that it is possible to increase materially the yield of wool and the weight and uniformity of the

lamb crop by progressive improvement in the type of bucks used in range flocks.

The problem of producing pasturage for sheep under western Nevada conditions.—By dividing the pasture into paddocks which were grazed successively 96 ewes and 120 lambs were pastured for 119 days on 9.9 acres of blue grass and common white clover. When the soil was soaked with irrigation water the sheep were removed. It is pointed out that the carrying capacity of grazing pastures depends directly upon the way in which they are managed.

Progress of reindeer grazing investigations in Alaska, L. J. PALMER (*U. S. Dept. Agr. Bul. 1423 (1926), pp. 37, pls. 18, figs. 3*).—This bulletin reports the progress in reindeer investigations in Alaska which has been made since the publication of Department Bulletin 1089 (*E. S. R., 48, p. 70*). The different types of animals and the methods of handling and training sled reindeer have been studied.

In tests with cultivated grains and grasses such feeds have proven as satisfactory as the native lichen forage. Studies of the forage cover have shown that lichens are seldom present in pure stand, though they are the main forage for winter grazing. A rapid change in the flora has been found to follow close grazing of the lichens. One denuded area regained 50 per cent of its former stand in 4 years, and the time required for a normal stand appears to range from 7 to 30 years, depending upon the area. The studies so far have indicated that winter grazing requires 30 to 45 acres per head, while summer grazing requires 10 to 15, or a total of 40 to 60 acres are required for grazing purposes for an animal per year.

Better methods of herd management and provisions for transportation and marketing of the meat appear to be the lines of attack for most encouraging progress in the reindeer industry in the future.

[Experiments with swine at the Illinois Station] (*Illinois Sta. Rpt. 1925, pp. 55-57, 59, 60*).—The results of the following experiments are briefly reported:

Intermediate pigs still superior in type test.—Continued studies of swine type by R. J. Laible, R. A. Smith, S. Bull, and J. H. Longwell (*E. S. R., 54, p. 363*) have generally agreed with earlier results. Two lots each of the intermediate and rangy types were used in the experiment, one lot of each type being individually hand-fed corn, middlings, tankage, and alfalfa meal, while the other two lots were self-fed a mixture of corn, middlings, and tankage with alfalfa pasture. The differences in the rate and economy of gains made by the two types under both methods of feeding were not significant, but there was a slight advantage for the intermediate type in the age and weight at which marketable finish was attained. Studies of the finished carcasses showed that when 37 per cent or more fat can be separated with the knife the carcass is finished. A larger percentage of the intermediate pigs were finished according to this test at 225 lbs. live weight. Cutting tests showed that there was a slightly larger percentage of fat cuts from the intermediate type carcasses than from those of the rangy pigs. The percentage of fat in the self-fed pigs of both types was approximately 6 per cent greater than in similar hand-fed animals. The 3 years' results indicated the superiority of the intermediate-type animals over those of the rangy type from the butcher's standpoint, but the difference was less when the animals were finished by self-feeding.

Fattening pigs do well when fed soft corn.—In a 33-day test conducted by Laible and Smith three lots of pigs were fed on a mixture of 50 per cent of tankage, 25 per cent of linseed oil meal, and 25 per cent of alfalfa meal with ear corn silage, soft ear corn, and sound ear corn in the different lots. There

was practically no difference in the average daily gains, 0.54 and 0.52 lb., in the lots receiving soft ear corn and sound ear corn, respectively, and similar results were obtained in regard to the feed required per 100 lbs. of gain calculated to a uniform basis of 14 per cent of moisture. The ear corn silage, however, proved unsatisfactory, as a gain of only 0.27 lb. per day was made and the amount of feed required per unit of gain was very high.

Crossbreeds versus purebreds in producing market hogs, P. S. SHEARER, J. M. EVVARD, C. C. CULBERTSON, ET AL. (*Iowa Sta. Leaflet 20 (1926), pp. 11*).—The data are presented on 5 litters of pigs from birth to 225 lbs. live weight produced by double matings of purebred Poland China sows with Duroc Jersey and Poland China boars. Among these pigs there were 31 crossbreeds and 21 purebreds. At birth the purebreds were slightly heavier, averaging 2.89 lbs., as compared with 2.66 lbs. for the crossbreeds, but 67 per cent of the purebreds were classified as very strong, while 71 per cent of the crossbreeds were so classified. Of those born dead, 9.5 per cent were purebreds, while only 3.2 per cent were crossbreeds, though in the latter group there were 10 per cent weak pigs, while none of the purebreds were classified as weak.

Both purebreds and crossbreeds were allowed to run together in the litters with their dams until weaning, during which time the crossbreeds made an average daily gain of 0.599 lb. as compared with 0.555 lb. for the purebreds. The same percentage of pigs were saved to weaning in both types, but in body measurements the crossbreeds made somewhat better gains.

After weaning, the crossbreeds and purebreds were separated and self-fed on shelled corn plus a supplemental protein mixture of tankage, corn oil cake meal, and alfalfa meal 2:1:1 with minerals. During this feeding period the crossbreeds generally excelled the purebreds in rate of gain, capacity for feed consumption, economy of utilization of feed, calculated profits over feed costs, and in body growth as determined by various measurements.

[**Swine feeding experiments at the Guam Station**], C. W. EDWARDS (*Guam Sta. Rpt. 1925, pp. 4-8, figs. 3*).—In a 45-day test nine 80 to 85-day-old pigs were self-fed free choice on coconut meal, cracked corn, and tankage supplemented with minerals. A total of 258 lbs. of feed was required per 100 lbs. of gain, the average daily gain per pig being 0.933 lb. The ration as consumed consisted of 12.25 per cent of tankage, 50.77 per cent of corn, and 36.98 per cent of coconut meal.

In another test, lasting 80 days, five boars averaging 84 lbs. in weight were placed on Para grass with access to a self-feeder containing coconut meal and minerals. An average daily gain of 1.12 lbs. was made, and 343 lbs. of feed were required to produce 100 lbs. of gain.

In another experiment, lasting 80 days, six 29-lb. pigs were given free access to a self-feeder containing cracked corn and coconut meal with minerals. An average daily gain of 0.579 lb. per head was made on this ration with a feed consumption of 297 lbs. per 100 lbs. of gain.

In a fourth experiment 9 grade sows averaging 125 to 130 days of age were self-fed during a 60-day period on a ration consisting of coconut meal and cracked corn with Para grass pasture. An average daily gain of 1.08 lbs. per head was made on this ration with a feed consumption of 362 lbs. per 100 lbs. of gain.

General results of these experiments have demonstrated the value of tankage as a feed for pigs during at least a period following weaning. The results have also shown that no harm was associated with the feeding of coconut meal as the entire concentrate ration. Larger amounts of coconut meal were consumed in connection with a ration of corn in self-feeders than are generally recommended.

Corn Belt rations for fattening spring pigs on pasture and in dry lot, J. M. EVVARD, C. C. CULBERTSON, W. E. HAMMOND, and C. F. BASSETT (*Iowa Sta. Leaflet 19 (1926), pp. 16*).—In making a study of various rations for pasture and dry lot feeding 12 lots of pigs, averaging approximately 43 lbs. in live weight, were fed for 110 days on rape pasture with various grain rations, while another lot was fed on alfalfa pasture, and four other lots were fed in dry lot.

Two of the lots fed on rape pasture received shelled corn self-fed and one lot received tankage also self-fed, while the other lot received 0.25 lb. of tankage hand-fed per pig daily. Both lots received a mineral mixture of salt, limestone, boneblack, and potassium iodide. The results showed that the pigs receiving the limited feeding of tankage made an average daily gain of 1.5 lbs., and required 340 lbs. of feed per 100 lbs. of gain, while those receiving tankage self-fed made an average daily gain of 1.68 lbs., and required 329 lbs. of feed per 100 lbs. of gain. When ground oats, whole oats, or dehulled oats were self-fed in addition to the corn the pigs made average daily gains of 1.60, 1.50, and 1.71 lbs., respectively, and required a total of 345, 346, and 346 lbs. of feed per 100 lbs. of gain. When dry ground oats, dry whole oats, soaked ground oats, or soaked whole oats were fed with tankage during the first 92 days of the experiment, after which corn was added to the ration, the pigs made average daily gains of 1.19, 1.30, 1.38, and 1.19 lbs., respectively, consuming 384, 384, 409, and 416 lbs. of feed per 100 lbs. of gain. When dehulled oats or oat residues were similarly fed the average daily gains were 1.62 and 1.04 lbs., and the feed consumption per 100 lbs. of gain was 364 and 495 lbs., respectively. When table scrap meal was self-fed for the first 60 days, followed by tankage for the rest of the experiment, corn being fed throughout, an average daily gain of 1.48 lbs. was made, and the total feed consumption per 100 lbs. gain was 328 lbs.

When corn and tankage were both self-fed with alfalfa pasture the pigs made an average daily gain of 1.73 lbs., and consumed a total of 329 lbs. of feed per 100 lbs. of gain.

Similar feeding of corn and tankage in dry lot produced an average daily gain of 1.57 lbs., and required 365 lbs. of feed per 100 lbs. of gain. Substituting the so-called Trinity mixture, tankage, linseed oil meal, and alfalfa meal 2:1:1 for the tankage used in the above lot or modified Trinity mixtures consisting of tankage, linseed oil meal, and alfalfa meal 6:3:1, and a one-third mixture, in which alfalfa leaf flour replaced the 10 parts of alfalfa meal, average daily gains of 1.71, 1.71, and 1.64 lbs. per head daily were made, the feed requirements per 100 lbs. of gain being 348, 358, and 345 lbs.

From these results it is concluded that the addition of oats, either ground or whole, at current prices increased the calculated profits when added to the full-fed ration of corn with limited amounts of tankage on rape pasture. Dehulled oats also increased the rate of gain but lowered the margin because of the enhanced cost. The oat residues, which were the by-products of dehulling, proved to be an inefficient feed. The feeding of the oats whole and dry appeared to be more economical than grinding or soaking. Alfalfa proved slightly superior to rape pasture for growing and fattening pigs, but the four lots fed in dry lot also did well and made creditable gains with satisfactory profits over feed costs. The mixture of tankage, linseed oil meal, and alfalfa meal proved slightly superior to tankage as the supplement to corn when fed in dry lot, but alfalfa leaf flour was apparently not much superior to straight alfalfa meal.

Corn gluten feed, enzymes, oat feed, minerals, and water supply for fattening spring pigs, C. C. CULBERTSON, J. M. EVVARD, W. E. HAMMOND, and

C. F. BASSETT (*Iowa Sta. Leaflet 18 (1926)*, pp. 10).—In these experiments 9 lots of 5 pigs each, averaging approximately 50 lbs. in live weight, were self-fed in dry lot during the summer to a weight of 225 lbs. Two check lots received shelled corn self-fed plus a supplemental protein mixture of tankage, linseed oil meal, and alfalfa meal 70:25:5, which was fed with a mineral mixture consisting of salt, limestone, boneblack, and potassium iodide. These 2 lots made average daily gains during the experiment of 1.61 and 1.68 lbs., respectively, requiring a total of 346 and 344 lbs. of feed per 100 lbs. of gain. Another lot was similarly fed, but instead of being watered in open troughs 2 or 3 times daily, the pigs in this lot had access to an automatic waterer. An average daily gain of 1.60 lbs. was made, and the feed requirement per 100 lbs. of gain was 356 lbs.

In other lots equal portions of the protein supplement were replaced by the following amounts of other supplements: 4 per cent of Protozyme, 12 per cent of Protozyme, 50 per cent of corn gluten feed, 25 per cent of ground oat feed, and 50 per cent of ground oat feed. The results showed that these lots made average daily gains of 1.71, 1.47, 1.63, 1.62, and 1.52 lbs., respectively, and required as feed per 100 lbs. of gain 338, 362, 355, 354, and 369 lbs. The mineral supplement of another lot was modified by the addition of 10 per cent of sodium bicarbonate, 4 per cent of venetian red, and 1 per cent of manganese sulfate. This lot made an average daily gain of 1.67 lbs. and required 359 lbs. of feed per pound of gain.

The comparative results in connection with the Protozyme showed that the addition of 4 per cent in the supplemental protein mixture apparently increased the gains slightly and decreased the feed required per unit of gain, but increased the cost of feed, consequently lowering the profit. When 12 per cent of this substance was included in the supplemental protein mixture the gains and feed consumption were reduced, and larger amounts of feed were required per unit of gain. The substitution of corn gluten for a portion of the supplemental protein mixture did not prove profitable. The addition of 25 per cent of oat feed in the supplemental protein mixture produced practically the same gains and showed practically the same margin over feed costs as the check lot. When 50 per cent of the oat feed was added, however, the gains were appreciably reduced, but the cost of gain was not materially affected. The additions to the mineral mixture proved beneficial, as the pigs made more rapid gains, but more feed was required per unit of gain and the cost was slightly increased. No advantage was evident from the use of the automatic waterer.

Protein supplements, mineral mixtures, outdoor sunshine, and water supply for fall pigs, J. M. EVVARD, C. C. CULBERTSON, and W. E. HAMMOND (*Iowa Sta. Leaflet 17 (1926)*, pp. 19).—The results of experiments dealing with the effect of adding various supplements to rations of corn and tankage self-fed are reported. Three lots of pigs averaging approximately 56 lbs. per head were used, the data being calculated for a 120-day feeding period or until a weight of 225 lbs. was attained. All lots except one had the self-feeders placed in the houses.

Two of the lots were fed a basal ration, plus a mineral mixture of salt, ground limestone, boneblack, and potassium iodide and were considered as controls. These lots made average daily gains of 1.57 and 1.51 lbs., respectively, in the entire feeding period and required 110.5 and 109 days, respectively, to reach 225 lbs. live weight. They consumed a total of 433 and 427 lbs. of feed per 100 lbs. of gain. A third lot receiving the same feed except that the self-feeders were placed out-of-doors in the sunshine made an average daily gain of 1.54 lbs. and consumed 394 lbs. of feed per 100 lbs. of gain. A fourth lot receiving

the same feeds as the check lot except that water was supplied in an automatic water heater made an average daily gain of 1.63 lbs., and consumed 388 lbs. of feed per 100 lbs. of gain. Additions of 0.5 and 5 per cent of radioactive mantle ash and tankage increased the rate of gain to 1.66 and 1.69 lbs. daily and reduced the amounts of feed required per 100 lbs. of gain to 413 and 384 lbs., respectively, but because of the high price mantle ash was not an efficient supplement. The so-called Trinity mixture, consisting of tankage, linseed oil, and alfalfa meal 2:1:1 produced an average daily gain of 1.56 lbs. and required 408 lbs. of feed per 100 lbs. gain, while modifications in the Trinity mixture during the progress of the experiment by decreasing the alfalfa meal from 25 per cent to 5 per cent with a corresponding increase in the amount of tankage, produced an average daily gain of 1.70 lbs., and required 390 lbs. of feed per 100 lbs. of gain.

It is pointed out that alfalfa meal and linseed meal when combined with tankage make a more efficient protein mixture than tankage alone. The modification in the Trinity mixture also proved slightly more efficient than the regular Trinity mixture and is suggested when the pigs are in good shape, but when the pigs are not doing nicely it is not advisable to reduce the amount of alfalfa meal.

The feeding of two types of table scrap meal in connection with the shelled corn and mineral rations produced an average daily gain of 1.54 lbs. each. The amounts of feed required per 100 lbs. of gain were 409 and 418 lbs., respectively. They thus increased the rate of gain over the check lot and lessened the feed requirement. In three of the lots the mineral mixture was modified, in one case by the addition of 2 per cent manganese sulfate, in another by the addition of 10 per cent of sodium bicarbonate, and in a third by 5 per cent of venetian red. As compared with the check lots in the rate of gain and the feed required per unit of gain these additions proved beneficial. The calculated profits over feed costs were also relatively high in the three lots.

Protein supplements to corn in dry lot for fattening pigs, E. G. GODBEY and A. L. DURANT (*South Carolina Sta. Bul. 234* (1926), pp. 3-14, fig. 1).—This bulletin reports the results of three experiments in which the efficiency of various protein supplements to corn was compared. All three experiments were similarly conducted with 6 lots of approximately 10 pigs, ranging in average weight from 62 to 75 lbs. per head. The supplements compared were tankage, fish meal, soy bean oil meal, peanut oil feed, soy bean oil meal and fish meal, and peanut oil feed and fish meal. The proportionate amount of supplement and corn fed was varied with the age of the pigs, but was similar in all three experiments.

The combined results showed that the pigs on corn and tankage made an average daily gain of 1.61 lbs. per head and required 369 lbs. of corn and 38 lbs. of tankage per 100 lbs. of gain to reach an approximate market weight of 200 lbs. With the supplement of fish meal the pigs made an average daily gain of 1.87 lbs. and required 323 lbs. of corn and 50 lbs. of fish meal per 100 lbs. of gain, reaching the required weight in 72 days. Gains of 1.46 lbs. per head daily were made by those pigs receiving soy bean oil meal, and the feed consumption per 100 lbs. of gain was 350 lbs. of corn, 59 lbs. of soy bean oil meal, and 91 days were required to attain market weight. With the peanut oil feed the average daily gain was 1.28 lbs., and 359 lbs. of corn and 103 lbs. of peanut oil feed were required per 100 lbs. of gain. With the combination of soy bean oil meal and fish meal the required weight was reached in 72 days, the pigs making an average daily gain of 1.88 lbs., and requiring 309 lbs. of corn and 24 lbs. each of soy bean oil meal and fish meal per 100 lbs. of

gain. The required market weight of 200 lbs. was also reached in 72 days by the pigs receiving the supplement of peanut oil feed and fish meal. The average daily gains made by the pigs on peanut oil feed and fish meal were 1.84 lbs. per pig, and the feed requirement was 314 lbs. of corn and 30 lbs. each of peanut oil feed and fish meal.

From these experiments it is concluded that fish meal is superior to tankage as a supplement to shelled corn for pigs fed in dry lot, but that vegetable protein alone is not as efficient as protein from animal sources. Soy bean oil meal produced more rapid and more economical gains than peanut oil feed (with hulls) as a supplement to corn. The combination of plant and animal proteins as supplements to corn proved more efficient than the animal proteins fed alone. Cases of stiffness and lameness were observed in the pigs receiving the corn and soy bean oil meal ration.

Wyoming corn for pork, W. L. QUAYLE (*Wyoming Sta. Bul.* 148 (1926), pp. 16, figs. 4).—This bulletin reports the results of three comparative feeding trials with Wyoming irrigated corn, Wyoming dry-land corn, and eastern Nebraska corn. In the first trial, which lasted 70 days, pigs averaging approximately 142 lbs. made average daily gains of 1.73, 1.70, and 2.00 lbs. on the respective types when self-fed with tankage and alfalfa. In the second trial 53-lb. pigs were fed for 100 days and made average daily gains of 1.53, 1.44, and 1.31 lbs., respectively, on the different types of corn. In the third trial 107-lb. pigs were fed for 84 days, making average daily gains of 2.01, 1.93, and 1.89 lbs., respectively.

In two of the three trials it required from 3 to 7 per cent more eastern Nebraska corn than Wyoming corn to produce 100 lbs. of gain. Due to the higher price of the eastern Nebraska corn gains were made at a relatively cheaper rate on the Wyoming corn. It is concluded from these hog-feeding trials that Wyoming corn is at least fully as efficient for pork production as corn from eastern Nebraska.

Chemical analyses of the three types showed that the differences in the moisture content of Wyoming corn and eastern Nebraska corn were practically negligible, notwithstanding the common belief which exists that Wyoming corn usually contains more moisture.

Fattening pigs with rye, G. W. MORGAN and C. N. ARNETT (*Montana Sta. Bul.* 192 (1926), pp. 19, figs. 7).—The results of 4 tests of winter fattening fall pigs and 3 tests of fall fattening spring pigs by self-feeding grain rations of barley or rye alone, or mixtures of these 2 grains in equal parts, or 3:1, or 1:3 are reported. Second or third cutting alfalfa hay was fed as a supplement in all the experiments, except that during the last 40 days of the first winter feeding trial the pigs received tankage. The fall pigs varied from 35 to nearly 60 lbs. in weight at the beginning of the different experiments. The average initial weights per pig in the 3 experiments with spring pigs were 122, 67.5, and 77 lbs. The feeding period was continued in all the experiments until the pigs averaged approximately 200 lbs. in live weight.

The combined results showed that the highest daily gains were made by fall pigs on the ration of 25 per cent of barley and 75 per cent of rye, and the smallest daily gains were made when barley or rye were fed alone. The spring pigs made the largest average daily gains on the mixture of equal parts of barley and rye. With one exception the feed required per unit of gain by both fall and spring pigs decreased as the proportion of rye in the grain mixture was increased.

It is pointed out that the pigs finished on the rations containing barley were in better condition and carried more fat than those finished on rye, but local butchers preferred the rye-finished animals because of the greater proportion of lean to fat in the carcass.

Fillies made good growth on soybean ration (*Illinois Sta. Rpt. 1925, p. 72, fig. 1*).—Draft fillies fed approximately 1 lb. of soy-bean hay, 1 lb. of sheaf oats, and 0.25 lb. of grain per 100 lbs. daily for 140 days gained at the rate of 1.45 lbs. per day in an experiment conducted by J. L. Edmonds and C. W. Crawford.

[Feeding and nutrition experiments with poultry at the Illinois Station] (*Illinois Sta. Rpt. 1925, pp. 77-83, figs. 3*).—The results of the following experiments are briefly reported:

Study composition of gains made by chickens.—In continuing the study by H. H. Mitchell, T. S. Hamilton, and L. E. Card of the changes in the composition of White Plymouth Rocks during growth (*E. S. R., 55, p. 669*), 10 fertile eggs were dissected and analyzed on each day of incubation from the fourth to the twenty-first days as well as fresh eggs and chicks of from 1 to 3 days of age. The results showed that the dried weight of the embryo increased rapidly at about the twelfth day of incubation, reaching a maximum on the sixteenth day, and was followed by a retardation in the rate of growth on the seventeenth day. During incubation the weight of the eggs decreased 11 gm., the weight of the dry substance about 3.5 gm., and the energy value about 28 calories. A distinct transfer of calcium from the shell to the embryo was indicated.

Study vitamin deficiencies in poultry rations.—In vitamin studies by Mitchell and Card, 12 lots of 15 chickens each were fed on a basal ration of white corn, tankage, yeast, cottonseed oil, and salt, which was presumably low in the fat-soluble vitamins. Three of the lots received no other supplements, three received heated and aerated cod-liver oil in place of the cottonseed oil (supplying D but not A), three received 5 per cent of spinach (supplying A but little D), and three lots received untreated cod-liver oil (supplying A and D). Four of the lots, one receiving each type of ration, were kept in a darkened room. Four similar lots were also kept in a darkened room but received 15 minutes' exposure to ultra-violet light, and the other four lots were kept at the poultry plant and allowed direct exposure to the sunlight. Those birds receiving the rations deficient in vitamin A or vitamins A and D died off rapidly, but those having access to sunlight lived longer and reached heavier weights. Mortality was low in the other six lots, but the birds having access to direct sunlight were in better condition at the conclusion of the experiment, as many from the other lots had deformed legs and feet, weak legs, and rough feathers.

It is concluded that the limiting deficiency in the basal ration was a lack of vitamin A, and that the environment of the chickens kept at the poultry plant was more favorable for normal growth and development than were the conditions of the other lots kept at the laboratory. Deaths from the vitamin A deficiency resulted in most cases before ophthalmia developed.

Energy values of farm chicken feeds studied.—In the course of the determination of the net energy values of common farm feeds for chickens it was found by Mitchell that from 82 to 85 per cent of the gross energy of corn and wheat was metabolizable, though the heating effect of these foods on chickens seemed to be extremely variable and efforts were made to find the conditions responsible for the wide degree of variation.

Heat produced in fasting chickens was found to increase for all temperatures lower than 55 to 70° F., different chickens showing different temperatures at which heat production was increased.

Annual persistency in relation to winter and annual egg production, F. A. HAYS and R. SANBORN (*Massachusetts Sta. Tech. Bul. 9 (1926), pp. 189-203, fig. 1*).—In continuing this series (*E. S. R., 55, p. 672*), the correlation

between the number of days that the birds in the Rhode Island Red flock laid before the complete onset of molt and the following conditions related to production were as follows: The date that hatching commenced, -0.2208 ± 0.0137 ; age at first egg, -0.6146 ± 0.0090 ; weight at first egg, -0.3225 ± 0.0131 ; net winter rate, $+0.1835 \pm 0.0141$; length of winter pause, $+0.1017 \pm 0.0182$; total days broody, $+0.0532 \pm 0.0209$; winter production, $+0.4551 \pm 0.0115$; and annual production, $+0.7082 \pm 0.0072$. The variability of the birds for the various characters used is indicated in each case as well as the regression coefficients, and the correlation coefficients are further calculated for each on the basis of the proportion of the population above or below the mean for each character.

From the analysis of the data it is concluded that persistency is positively correlated to a greater or a less extent with early hatching, winter rate of laying, length of winter pause, winter production, and annual production, and is negatively correlated with the age at first egg, weight at first egg, and presence of broodiness.

The litter problem, D. C. KENNARD and L. B. NETTLETON (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 229-231).—Essentially a discussion of the use of straw, shavings, peat, and slag as litter for poultry houses, based on the results of tests at the station.

Poultry keeping in back yards, M. A. JULL and A. R. LEE (*U. S. Dept. Agr., Farmers' Bul.* 1508 (1926), pp. II+29, figs. 26).—A revision of Farmers' Bulletin 1331 (E. S. R., 49, p. 777).

DAIRY FARMING—DAIRYING

[Feeding experiments with dairy cattle at the Illinois Station] (*Illinois Sta. Rpt.* 1925, pp. 90-92, figs. 2).—The results of three experiments conducted by W. B. Nevens are briefly reported.

Thickly planted soy beans make best quality hay.—Hay from soy beans planted thickly was found to have less coarse stems, and smaller amounts of hay were refused than when the soy beans were not so thickly planted.

Legume hays fill lime needs of dairy cows.—Mineral supplements to rations including legume hays at the rate of 3 to 4 per cent of the concentrate mixture were found to be too laxative, and 1 to 2 per cent of mineral supplements appeared to be adequate. Mineral supplements to rations containing timothy hay and corn silage were ineffective in preventing a more rapid decline in milk production than occurred when alfalfa hay was fed. There appears to be no craving for lime by dairy cattle when receiving rations of legume hays and corn silage as roughage.

Silages from immature corn had low feeding value.—The large southern varieties of late maturing corn, containing about 22 per cent of dry matter, produced silage of good keeping qualities but of low feeding value and palatability. An early maturing prolific type of corn gave as large yields in dry matter as the southern varieties. Acid determinations showed small differences in the silage from early and late maturing types, though an immature southern corn produced silage of very low palatability for sheep. This silage had a sharp and slightly bitter taste.

Feeding dairy animals, L. S. CORBETT (*Maine Agr. Col. Ext. Bul.* 164 (1926), pp. 43).—The principles of feeding are briefly presented with special reference to dairy animals, together with the chief requirements of the feeding stuffs law, definitions of feeds, and other related information.

Liberality and economy in feeding dairy cows, A. E. PERKINS (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 210-216, figs. 4).—A discussion of the economy

of liberal feeding for milk production based on data previously noted in Bulletin 334 (E. S. R., 41, p. 274). It is pointed out that high-producing cows should be fed liberally, but not all cows have sufficient capacity to utilize large amounts of feed economically.

Experimental disturbances in the milk secretion of the cow, F. A. DAVIDSON (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 9, pp. 873-885, figs. 5).—As was reported in a previous paper (E. S. R., 52, p. 175), returning 300 cc. of milk into one quarter of a cow's udder after milking dry at the Illinois Experiment Station markedly decreased the lactose content and amount of the milk produced and increased the fat, protein, and ash contents of the milk from that quarter in the first 2 or 3 subsequent milkings.

Injections of 300 cc. of an isotonic salt solution of sodium and potassium chlorides and sodium and potassium citrates or an isotonic lactose solution had similar effects, but injections of 300 cc. of distilled water showed no regular effects. Leaving one-half of the milk in the udder appeared to affect only the fat content, thus differing from the influence of the injections of the milk or of the salt or lactose solutions.

In discussing the results it is suggested, with reference to milk secretion, that during milking the secretory cells are gradually giving off their products which are drawn away. This process lowers the concentration within the secretory cells to a point below that of the milk itself, so that when milk is injected there tends to be an absorption of the soluble materials by the cells which would affect the composition of the milk subsequently secreted. With milk left in the udder the concentration of solvents was not reduced within the secretory cells, absorption was limited, and the composition of the subsequent milk was not so greatly changed.

Official records as material for studying inheritance of milk and butterfat production, M. H. FOHRMAN (*Jour. Dairy Sci.*, 9 (1926), No. 3, pp. 286-292).—The coefficients of correlation between the initial and reentry butterfat records of 19 age groups of Guernsey cows and 33 age groups of Jersey cows and the initial and reentry milk records of 16 age groups of Ayrshire cows are given as determined from studies in the U. S. D. A. Bureau of Dairying.

The correlation coefficients for the Guernseys varied from 0.8591 to 0.3290 and averaged 0.6605, for the Jerseys from 0.8116 to 0.3391, averaging 0.6071, and for the Ayrshires from 0.6445 to 0.0826, averaging 0.5021. The mean standard deviation and the coefficient of variation are given for each age group. There was found to be a greater variability among the reentry records than in the initial records. With increases in the length of time between the initial and reentry records there was some tendency for the correlations to be lowered.

Environmental influences are assumed to be the cause for the correlation coefficients not being 1 in the different groups.

Good bulls and good foundation cows the source of better dairy cattle, L. H. FAIRCHILD (*Indiana Sta. Bul.* 299 (1926), pp. 20, figs. 12).—data are presented showing the influence which the Jersey and Holstein bulls in the station herd have had in improving the average production of their daughters as compared with the daughters' dams. The average milk and fat production of the several generations which have descended from the foundation cows of each of these herds are also given.

[Experiments in dairying at the Illinois Station] (*Illinois Sta. Rpt.* 1925, pp. 97-102).—The results of the following experiments are briefly reported:

Some causes found for poor pasteurization.—A continuation of the study of pasteurization by M. J. Prucha (E. S. R., 54, p. 374) has shown that the reasons for inefficient pasteurization under commercial conditions as compared with

laboratory conditions include the difficulty of heating every drop of milk to the proper temperature and for the full length of time. Leaky valves of the pasteurizing vat, foam on the milk, recording thermometers not registering correctly, and valves in the outlet pipe not set sufficiently close to the vat were found to be some of the reasons for this condition.

Limes seem best neutralizers of cream acidity.—In studies by B. A. Stiritz and H. A. Ruehe of various neutralizers for acidity of cream used for the manufacture of butter it was found that a better quality of fresh butter and a more thorough churning were secured with a 5 per cent solution of soda ash or sodium bicarbonate and a 10 per cent solution of lime than with a stronger solution of these neutralizers. Soluble neutralizers reacted completely in 2 minutes, while the calcium limes required 5 minutes, and the magnesium limes 10 to 15 minutes. The amount of reduction of the acidity during pasteurization seemed to depend upon the solubility of the neutralizer and upon the formation of carbon dioxide gas which was driven off by heat. Soda ash increased the amount of the fat lost in the buttermilk, while sodium bicarbonate and the limes gave a more exhaustive churning. None of the neutralizers used improved the quality of the fresh butter, but when used separately they gave higher scores than when two were used together. When soda ash was used in the neutralizer, either by itself or with lime, the butter was of a higher quality at the start, but did not hold up as well in storage as butter in which sodium bicarbonate was used as a neutralizer, and rancidity frequently developed in storage from butter in which soda ash had been used for neutralizing the cream.

Butterfat loss from incomplete churning reduced.—Studies of the possibilities of reducing the amount of fat lost in the buttermilk by Ruehe and Stiritz showed that the addition of 1 per cent of salt to the cream before churning was effective, a small amount, 0.2 to 0.3 per cent, of which was incorporated in the butter. The addition of hydrochloric acid to the cream before churning was more effective than sodium chloride and did not appear to increase the total acidity of the butter. A combination of the two products was more effective than when either was used alone. It was not possible to reduce the fat content of buttermilk from neutralized cream below an average of approximately 0.5 per cent. The use of disodium phosphate, sodium citrate, or thorium nitrate proved ineffective in decreasing the fat content of buttermilk, and oleic acid, because of its deteriorating effect on the quality of the butter, was unsatisfactory.

Butter quality depends upon that of cream.—These investigations conducted by Prucha and J. M. Brannon have indicated that the keeping quality of butter is largely dependent upon the quality of the cream from which the butter is made, due to the relation of bacteria to the development of flavors in butter.

Previous tests on ice cream quality confirmed.—In studies by A. S. Ambrose and P. H. Tracy of the effect of various ingredients on the quality of the ice cream produced, it was found that those ice creams having a low acid content had a smoother texture and a greater resistance than those with a high acid content. The best flavor was obtained when the acidity ranged from 0.1 to 0.2 per cent. The addition of dehydrated egg yolks produced a smoother texture and greater resistance, but the flavor was objectionable to many, and a similar texture and resistance could be obtained by the addition of milk solids. The source of milk solids was proven of considerable importance. Homogenization of the ice cream mix produced a more desirable product, having somewhat the same effect as the use of additional milk solids. A low overrun usually gave a smoother texture and increased resistance. When the ice cream was drawn

from the freezer in a very soft condition it tended to become coarse in texture on thickening.

Best methods determined for counting bacteria.—Studies by Prucha of the methods of making determinations of the bacterial content of milk for different purposes indicated that the reductase test was probably best suited for grading raw milk as received at the milk plant from farmers. The direct-count method may also be used for this purpose, but for commercial plant control and for the examination of milk as delivered to the consumer the plate method appeared to be best suited.

[*The preparation of Lactobacillus acidophilus milk*].—In attempts by Prucha to prepare acidophilus milk under commercial conditions the best results were obtained by inoculating the milk with a pure culture of *L. acidophilus* in from 3 to 6 per cent concentration, incubating at 100° F. until the acidity reached from 0.6 to 0.7 per cent acid, cooling to 40 or 50° to arrest bacterial growth, and shaking with 1 per cent of fat. It is stated that the milk when thus prepared and stored at a temperature of 40° or lower can be kept 2 or 3 days without wheying off or deteriorating in flavor.

The number of cells in cream, skim milk, and separator and centrifuge slimes, R. S. BREED (*New York State Sta. Circ. 88 (1926), pp. 7*).—Determinations of the cell contents of cream and of different portions of the milk when separated by gravity, by separators, and by centrifuging showed that gravity-raised cream contained large numbers of cells. Cream caused to rise by slow speed centrifuging contained somewhat smaller numbers of the cells in the milk, but cream obtained by separators was practically free from cells. The skim milk produced by any of the methods contained few cells, as they either rose with the cream or were precipitated in the separator slimes.

The centrifuge slimes obtained in Stewart-Slack tubes were variable as to the relative amounts of the total cells in the milk which they contained. Trommsdorff tubes were efficient for measuring the amount of slime, but as no definite relation between the cell content and the amount of slime was established they were inefficient for determining the numbers of cells present.

Cream separators operated under normal conditions precipitated practically all of the cells present in the milk.

Produce clean milk, C. N. SHEPARDSON (*Colo. Agr. Col. Ext. [Bul.] 245-A (1925), pp. 12, figs. 9*).—A brief popular account of the more important factors influencing the production of clean milk.

Practical dairy tests, A. D. BURKE (*Milwaukee: Olsen Pub. Co., 1926, pp. 219+[3], fig. 1*).—This book gives outlines for conducting various chemical tests of milk and dairy products.

Some factors influencing the keeping quality of butter, D. J. RETIEF (*Union So. Africa Dept. Agr., Sci. Bul. 43 (1926), pp. 22, figs. 3*).—This deals with the effect of bacterial contamination, acidity, and other factors on the keeping quality of butter, including data from various experiments related to the improvement of the quality of butter through pasteurization and neutralization of the cream.

Peroxidase as a factor in butter deterioration, L. S. PALMER and M. M. MILLER (*Jour. Dairy Sci., 9 (1926), No. 3, pp. 272-275*).—The results of an experiment at the Minnesota Experiment Station are presented in which a peroxidase solution concentrated from horse-radish roots was added to both sweet and ripened pasteurized cream. The butter made from the samples containing peroxidase showed no differences in composition as compared with check samples even after storage for 11 months at room temperature or at 0° C. Tests for peroxidase throughout the storage period were positive for the samples

to which this substance had been added. These results indicated that peroxidase is not a direct cause of butter deterioration. Pasteurization enhances the keeping quality of butter by the elimination of agents causing deterioration other than peroxidase.

Microscopy of cheese [trans. title], O. LAXA (*Sborn. Českoslov. Akad. Zeměděl. (Ann. Czechoslovak Acad. Agr.)*, 1 (1926), No. 1, pp. 47-65, figs. 32; *Fr. abs.*, p. 65).—The microscopic appearance of various types of cheese is described and illustrated. It was found that the structure of cheese depends upon the quality of the milk used, the kind of coagulation, and the method of manufacturing and ripening.

Cottage cheese, P. S. LUCAS (*Michigan Sta. Circ.* 97 (1926), pp. 10, figs. 3).—General directions for the manufacture of cottage cheese and various modified types are given.

VETERINARY MEDICINE

A text-book of pathology, F. DELAFIELD and T. M. PRUDDEN, rev. by F. C. WOOD (*New York: William Wood & Co., 1925, 13. ed., rev., pp. VI+1354, pls. 18, figs. 810*).—This is another revised edition of the work previously noted (E. S. R., 50, p. 180).

Chemical pathology, H. G. WELLS (*Philadelphia and London: W. B. Saunders Co., 1925, 5. ed., rev., pp. 790*).—This is a revised and reset edition of the work previously noted (E. S. R., 45, p. 381).

The National Formulary ([*Baltimore*]: *Amer. Pharm. Assoc., 1926, 5. ed., pp. XLI+545*).—This fifth edition (E. S. R., 36, p. 378), prepared by the Committee on National Formulary of the American Pharmaceutical Association, is official from July 1, 1926.

The dispensary of the United States of America, H. C. WOOD, C. H. LAWALL, H. W. YOUNGKEN, J. F. ANDERSON, and I. GRIFFITH (*Philadelphia and London: J. B. Lippincott Co., 1926, 21. ed., rev., pp. XXX+1792*).—This thoroughly revised and partly rewritten edition (E. S. R., 39, p. 884) is based upon the tenth revision of the United States Pharmacopoeia (E. S. R., 55, p. 473), the National Formulary above noted, and the British Pharmacopoeia. Following an explanatory introduction, a list of abbreviations, and the texts of the Food and Drugs Act and the Harrison Narcotic Act, the three parts of this work deal with (1) drugs recognized by the United States Pharmacopoeia, the Pharmacopoeia of Great Britain, or the National Formulary (pp. 1-1179), (2) unofficial drugs (pp. 1181-1531), and (3) matters included in the General Tests, Processes, and Apparatus of the U. S. Pharmacopoeia and the Appendix of the British Pharmacopoeia which are not given elsewhere in the volume, together with a collection of formulas for reagents used in the examination of urine, blood, etc., which is an amplification of the Diagnostical Agents and Clinical Tests of the U. S. IX (pp. 1533-1649), and preparations of the National Formulary (pp. 1650-1689).

[**Livestock disease investigations**] (*Illinois Sta. Rpt. 1925, pp. 61-68, 76, 77, 84-88, figs. 5*).—In studies by R. Graham, E. A. Tunnicliff, and E. R. Frank of avian tuberculosis in market pigs, the glands of 163 tuberculous swine originating in 27 counties, detected among 6,041 hogs in 85 carloads, were investigated. Of the 62 animals the glands of which were typed in guinea pigs and chickens, 82.2 per cent were avian, 11.2 per cent avian and mammalian, and 6.4 per cent mammalian. The accuracy of the laboratory tests, checked by inspection of the farms from which the tuberculous hogs had been shipped, suggest the probability that avian tuberculosis in swine is being perpetuated in these animals independently of continuous direct exposure to infected fowls, and

further that the avian infection may be found to be transmitted from pig to pig.

A brief reference is made to further studies of inheritance of resistance in the offspring of hogs naturally resistant to hog cholera (E. S. R., 54, p. 377). The progress of immunization work with suckling pigs, conducted under practical farm conditions by Graham and Tunncliff, is summarized. Only a small percentage of pigs given serum and virus while sucking succumbed to cholera several months later when they were exposed to the disease, but definite conclusions regarding the practicability of immunizing suckling pigs can not be drawn until further work has been carried out. Experiments started during the year by Graham and Tunncliff in cooperation with W. E. Carroll show that pigs in lots free from roundworm infestation gained faster and appeared thriftier than hogs on infested lots. A comparison is being made of pigs kept on clean pastures with others raised on pastures infested with swine parasites.

Bacteriological examinations made of the nongravid uteri and ovaries of sows infected with *Bacterium abortum* (Bang) by Graham and Tunncliff suggest that naturally infected females may harbor the virus of the disease in the reproductive organs for an indefinite period, thus differing from cattle, in which the virus is eliminated from the uterus of the aborting cow in from 6 to 8 weeks following abortion. Pigs fed virulent cultures of *B. abortum* were found to be harboring the organism in the testicles several weeks later at the time of castration. It is pointed out that febrile diseases appear to be responsible for some cases of abortion in swine.

In immunity studies of hemorrhagic septicemia by Graham, Tunncliff, and Frank, it was found that rabbits and guinea pigs injected with the artificial aggressin resist artificial infection more consistently than following bacterin injection. The resistance produced by artificial aggressin, however, is neither dependable nor consistent measured by laboratory methods. Attempts by these authors to develop an experimental antitoxin for the prevention and treatment of *Clostridium botulinum* type C food poisoning were commenced.

A comparison made by Frank, W. G. Kammlade, and A. K. Mackey of carbon tetrachloride with copper sulfate treatment in removing stomach worms from sheep showed the former to be the more efficient. The dose consisted of a No. 11 capsule containing 5 cc. of the carbon tetrachloride and as much dry magnesium sulfate as it would hold.

In work by Graham, Tunncliff, and Frank (E. S. R., 54, p. 380) during the year 54,519 fowls in 407 flocks from 64 counties were given the agglutination test and 11.71 per cent found infected with bacillary white diarrhea. In connection with the routine application of the agglutination test, a comparison was made of the accuracy of 1 to 10, 1 to 50, and 1 to 100 dilutions, and the results indicate that the 1 to 10 detects the highest percentage of reactors, or 4 per cent more than the 1 to 50 dilution and approximately 9 per cent more than the 1 to 100 dilution. This comparison of the different dilutions led to the adoption by the station of a 1-tube test using the 1 to 10 dilution. A comparison was made during the past two years of the agglutination test with the intradermic test with more than 5,000 blood samples. Pullorin was injected intradermally into the wattles of fowls tested, and, while definite information was not obtained, the results have not eliminated pullorin as a diagnostic agent for the disease.

A brief reference is made to further work by Roberts and Card on the breeding of chickens in an effort to establish strains resistant to bacillary white diarrhea (E. S. R., 54, p. 380). Though definite conclusions can not yet be drawn, 53 out of 335 day-old chicks were found resistant to the disease.

Studies by Roberts and G. A. Lindsey of the effect of Fowler's solution upon animals indicate that those receiving the solution are more susceptible to disease than untreated animals.

[Work of the veterinary division], W. G. FREEMAN (*Trinidad and Tobago Dept. Agr. Rpt. 1925, pp. 27-30*).—An account of the occurrence of and control work with infectious diseases of livestock.

Report of proceedings in Northern Ireland under the Diseases of Animals Acts with returns of the exports and imports of animals for the year 1924, F. W. EMERY (*North. Ireland Home Off., Rpt. Proc. Diseases Anim. Acts [etc.], 1924, pp. 24*).—This is a report of the chief veterinary officer for the year 1924, with appendixes including statistical data on diseases among animals in Northern Ireland, exports and imports of animals, etc.

Report of the veterinary officer for the year 1924, C. R. TURBET (*Fiji Dept. Agr. Ann. Rpt. 1924, pp. 8-12*).—This report includes a discussion of the diseases of livestock in Fiji and control work conducted.

Animal diseases regulations with notes on diagnoses, F. E. LIONNET (*Mauritius Dept. Agr., Gen. Ser. Bul. 34 (1926), Eng. ed., pp. 24*).—This bulletin, which replaces one previously noted (*E. S. R., 37, p. 780*), presents the text of the revised ordinance and of the new rules made thereunder.

Does the flesh of animals suspected to be infected by foot-and-mouth disease form a source of danger for the spreading of virus? L. F. D. E. LOURENS (*Vet. Rec., 6 (1926), No. 45, pp. 995-998*).—The experiments here reported by the director of the Netherlands State Serum Institute at Rotterdam, three of which are described in detail, show that the virus of foot-and-mouth disease is particularly sensitive to the acids formed during the process of the ripening of the flesh. The work is considered by the author to indicate that there is no danger of the spread of foot-and-mouth disease in the flesh of animals slaughtered in the incubation period of the disease, nor even in that of animals killed in the eruptive stage of the disease. It was not possible to infect other animals with the flesh of sick animals 48 hours after the latter had been killed. The virus of foot-and-mouth disease died within 24 hours in vitro when mixed with meat juice.

Reference is made to investigations made by Schlögel in the State laboratory at Rheims concerning the prevalence, the resistance, and the destruction of the virus of foot-and-mouth disease in the skeletal muscles of diseased guinea pigs. In these experiments Schlögel used the flesh of 9 diseased guinea pigs, which were infected by virus from the seven-hundredth guinea pig generation. All check guinea pigs injected with the serum of the killed animals got the disease after 24 hours. The experiments are considered to prove that the virus can be present in flesh from diseased guinea pigs, but, by formation of acid, the virus is killed in every case within 18 hours. An editorial discussion of this work follows (p. 999).

A case of typhus-like fever following tick bite, R. R. SPENCER (*Pub. Health Rpts. [U. S.], 41 (1926), No. 45, pp. 2523, 2524*).—The author reports upon a case at Norfolk, Va., of typhus-like fever following a tick bite, the clinical aspects of which, in nearly every detail, suggested typhus fever, although it was not supported by the laboratory findings. Failure of the serum to agglutinate *Bacillus proteus* X₁₀ and the negative results of animal inoculation do not, however, exclude typhus fever. The patient had been bitten in several places by a tick which came from a calf hide shipped from North Carolina or Virginia, and similar ticks were secured and proved to be *Amblyomma americanum*.

On the toxic action of sarcosporidiotoxin and its serological study [trans. title], S. SATO (*Jour. Japan. Soc. Vet. Sci., 5 (1926), No. 1, pp. 25-37*;

Eng. abs., pp. 32-37).—This contribution from the department of pathology and bacteriology of the Keio Medical College deals with the materials and method of extraction of the toxin, the properties of the sarcosporidiotoxin, toxic action of the toxic principle, and an immunological study with the toxin. It was found that rabbits may be highly immunized by repeated injections of the toxin.

Tumors of domestic animals, R. J. FORMAD (*U. S. Dept. Agr. Bul.* 1449 (1926), pp. 40).—In this account the author deals first with the etiology of tumors, including the constitutional dyscrasia or diathesis theory, the mechanical or irritation theory, the "embryonal rests" or preformation theory, the theory of nervous influence, and the parasitic theory. This is followed by a discussion of the classification of neoplasms (1) by nature, (2) by structure, and (3) by shape. Nomenclature is next briefly considered, followed by an extended discussion of the various tumors.

A promising treatment for infectious abortion, F. R. EDWARDS and J. H. COFFMAN (*Georgia Sta. Press Bul.* 252 (1926), pp. 2; also in *Jersey Bul. and Dairy World*, 45 (1926), No. 46, pp. 1971, 2002; *North Amer. Vet.*, 7 (1926), No. 12, pp. 31, 32).—This is a progress report on work at the Georgia Experiment Station with acriflavine (diamino-methyl-acridinium chloride hydrochloride). The cows used in the experiment had all aborted on one or more occasions and had all given positive reactions to the agglutination test in dilutions ranging from 1 to 50 to 1 to 500 and higher. Three successive intravenous injections of the acriflavine in physiological saline solution, in dilutions of 1 to 500, 1 to 350, and 1 to 200, respectively, were given one week apart. The cows were divided into three groups of two each, and those in the first group received 100 cc., the second 150 cc., and the third 200 cc. of the solution at each injection. Three tests of the presence of the disease in the experimental cows were employed, (1) the agglutination test of the blood sera of the cows, (2) the intraperitoneal injection of milk from the cows into guinea pigs, and (3) the calving records of the cows. It was found that within one year after the work was started the reaction of the blood from one of the cows gradually became less markedly positive, and in 14 months it was negative to the test. The blood from all other cows was gradually losing its power to agglutinate the organism.

"The calving record is perhaps the most important of all from a practical standpoint. All cows receiving the two larger doses have bred and produced normal calves following a normal gestation period. Two of these cows had previously become nonbreeders from the disease. The two cows in the group receiving 100 cc. of the solution were nonbreeders and did not breed following the treatment. This would seem to indicate that large doses of the chemical are necessary. The use of acriflavine had no apparent bad effect on the cows except to reduce the flow of milk for a few days. Swellings were produced along the jugular groove and persisted for some time. This swelling was probably due to a needle of too large caliber being used for the first injection, allowing a slight leakage at the point of puncture in the vein. These swellings appeared within a few hours after the injection of the acriflavine, and, while they remained for some time, they did not seem to cause any physical reaction of the animal."

The problem of an obscure hemorrhagic disease in cattle, E. RECORDS and L. R. VAWTER (*Nevada Sta. Rpt.* 1925, pp. 19, 20).—This is a brief account of the work which led to the discovery that a new organism, described as *Clostridium hemolyticus bovis*, is the cause of this disease of cattle in Nevada. It has also been found possible to isolate the causative organism from the blood stream of clinical cases of the disease during life in some instances. During

the year the preparation and use of a lesion fluid substance similar to black-leg aggrassin as an immunizing agent was thoroughly tried out but was found to be of no value. Preliminary tests of culture filtrates for the same purpose, however, yielded very promising results, and it is thought that a reliable immunizing agent will be available for field use within a year. It is stated that the serum for the treatment of natural cases of the disease has now reached a high state of efficiency, recovery running about 75 per cent as against about 100 per cent of deaths in cases not receiving the serum. An account of the work, by Vawter and Records, has been noted (E. S. R., 54, p. 677).

The etiology of tuberculosis in relation to satisfactory immunization in cattle, J. J. THOMSON (*Ann. Pickett-Thomson Research Lab.*, 2 (1926), No. 3, pp. 31-49).—The author finds that if treatment is given over two generations immunization is possible in all cases, with the exception of offspring of cows in ill health. His work indicates a partial immunization of the dam and an immunization of the sire so that he will pass all tests for a long period. He considers immunization quite feasible in one generation, but less successful practically because calves from stock which is not immunized require far more feeding and care than those bred from cows and bulls rendered resistant to the disease.

The chemotherapy of surra of horses and cattle in India, J. T. EDWARDS (*Jour. Compar. Path. and Ther.*, 39 (1926), Nos. 2, pp. 83-112, figs. 2; 3, pp. 169-201, fig. 1).—In this progress report it was found that outbreaks of surra, which occasionally occur in India, with high mortality, particularly among buffaloes, are easily checked by intravenous injections of relatively simple trypanocidal agents, such as tartar emetic or bismuth phosphate. Single injections usually suffice. A suitable therapeutic dose of tartar emetic is 5 cc. of an m/10 3.2 per cent solution per 100 lbs. body weight. The treatment does not destroy the whole of the trypanosomes in the animal's system, some persisting thereafter in a latent state of activity, apparently indefinitely. The results obtained after treatment with tryparsamide do not appear to be appreciably superior.

In equines it was found that the results obtained by the application of Bayer 205 surpass those obtainable by other medicaments. A suitable therapeutic dose for intravenous administration is 5 gm. in 10 per cent aqueous solution per 1,000 lbs. body weight. Tartar emetic comes next in value to, though far behind, Bayer 205. Bismuth compounds would appear to have much the same (though somewhat less intense and much less efficacious) action as the chemically related antimony preparations, studied in the form of tartar emetic. Tryparsamide proved disappointing in the results obtained.

A list is given of references to the general literature on Bayer 205, tartar emetic, tryparsamide, and bismuth compounds.

Training the dog, A. G. BLAIR (*Danville, Ind.: Danville Pub. Co.*, 1926, pp. 118, pls. 12).—This is a practical account.

Experimental researches on the variolous, diphtheric affection of fowls, J. VERGE (*Recherches Experimentales sur l'Affection Diphtero-Variolique des Oiseaux*. Toulouse: J. Bonnet, 1926, pp. 230; rev. in *North Amer. Vet.*, 7 (1926), No. 8, p. 64).—This monographic account includes a complete chronological review of investigations of the disease since 1868.

Studies of fowl pest, I [trans. title], W. PFENNINGER and E. METZGER (*Schweiz. Arch. Tierheilk.*, 68 (1926), No. 1, pp. 2-21).—This first contribution deals with the natural and the experimental infection.

Studies of fowl pest, II [trans. title], W. PFENNINGER and Z. FINIK (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 99 (1926), No. 1-3, pp. 145-153, figs. 2).—This second paper on the subject above noted is a contribution to the knowledge of the

histological changes in the central nervous system, based upon studies of the brain of 8 spontaneous and 17 experimentally infected fowls.

A coryne-bacillus as a cause of abscess in the feet of hens, Y. KAWAMURA (*Jour. Japan. Soc. Vet. Sci.*, 5 (1926), No. 1, pp. 21-24; *Jap. abs.*, pp. 23, 24).—Cases of this affection of fowls, due to *Staphylococcus pyogenes aureus*, were first reported by Kaupp in 1921 (*E. S. R.*, 45, p. 888). Investigations at the veterinary laboratory of the Ministry of Agriculture and Forestry at Nishigahara, Tokyo, led to the isolation of a coryne bacillus and the production of necrosis by inoculation of pure cultures into the soft structure of chicken soles.

AGRICULTURAL ENGINEERING

[Agricultural engineering studies at the Illinois Station] (*Illinois Sta. Rpt. 1925*, pp. 129-143, figs. 2).—The progress results of a number of studies on different features of agricultural engineering are briefly summarized.

In work on tandem hitches, A. L. Young has found that short levers should be avoided, especially when used to distribute the pull between the front and rear horses, and that in working out 4-3 and 4-4 teams on 3-bottom plows such side draft as must be taken by the team should, for the most part, be placed on the lead horses. Supporting the front evener and the lead rod when turning at the end has not been found so important a factor as it might appear. It is considered doubtful that on the average farm a team should be strung out more than the length of two horses. The pulley has been found to have some advantages as an evener between the front and rear horses.

The work on the drying of soft corn by W. L. Burlison, E. W. Lehmann, and R. C. Kelleher has indicated that in general drying with forced unheated air is a slow and costly process when the temperature is low and the humidity is high.

Data are also reported on the use of electricity in agriculture, the development of electric water systems, 2-chamber septic tanks, plow draft under different conditions, the development of terracing practices, machines used in soy bean growing, and thresher adjustments.

Effect of the size of soil columns on the capillary rise of water, H. A. WADSWORTH (*Agr. Engin.*, 7 (1926), No. 6, p. 209, fig. 1).—Studies conducted at the California Experiment Station upon the rate of capillary rise of water through soil masses of varying cross section are briefly reported.

The results indicate that within certain limits the capillary rise which may be expected through soil masses becomes greater as the cross section becomes greater. This was true for sizes up to 25 sq. in. in cross section. Beyond this limiting size, an increase in area did not result in a significant increase in rate of rise.

Intensive soil samples taken from carefully selected points within the soil mass indicated that points in the same horizontal plane carry about the same moisture content. There was no indication of a concentration of moisture within the center of the cross section nor in the zone lying in immediate contact with the walls of the column.

Centrifugal pump tests, H. E. MURDOCK (*Montana Sta. Bul. 190* (1926), pp. 22, figs. 15).—Data from tests of a number of horizontal and vertical centrifugal pumps are reported and discussed and the test methods described.

Water works practice (*Baltimore: Williams & Wilkins Co.*, 1925, pp. XX+790, figs. 50).—This is a manual of information on water works practice, issued by the American Water Works Association. It contains sections on collection of water, quality of water supply, treatment of water, distribution of water,

financing and management, and fire protection, together with an introduction and appendix.

Action of sodium and magnesium sulfates on Portland cement, G. R. SHELTON (*Indus. and Engin. Chem.*, 18 (1926), No. 8, pp. 854-856, figs. 2).—Studies conducted at the University of Saskatchewan on the effect of sodium and magnesium sulfate solutions on commercial and white Portland cements to determine the action on Portland cement clinker and on its compounds taken separately are reported.

The white Portland cement was made by heating to a high temperature an intimate mixture of powdered marble, alumina, and flint in the proper proportions contained tricalcium aluminate, tricalcium silicate, and β -dicalcium silicate. Its reactions differed from those of commercial cement when both were similarly treated with solutions of sodium and magnesium sulfates, one difference being in the appearance of gypsum in the tests with crystalline commercial cement. The reaction products of white cement with sulfates were more like those of the pure cement constituents than were the products formed in the case of commercial cement.

The difference in character of the hydrated cements was very apparent, fine sulfoaluminate needles being abundant in the hydrated commercial cement, while none were found in the white cement. The crystalline grains, as centers of gelatinous particles, lasted for a much longer time in the latter. The presence of silicates seemed to have influenced the speed of disintegration of hydrated tricalcium aluminate crystals, since in the tests with the two varieties of cement and solutions of sodium sulfate these crystals lasted for a much shorter time than they did in the tests with pure hydrated tricalcium aluminate. Solutions of magnesium sulfate were especially destructive in their action on crystals of hydrated tricalcium aluminate, regardless of the presence or absence of calcium silicate.

The characters of the layers surrounding crystals of hydrated lime varied with the sulfate solutions used. In sodium sulfate the layers were apparent only on the edges of the lime crystals and were made up of granular masses. In magnesium sulfate solutions the lime crystals were heavily enveloped, the coating frequently consisting of a transparent homogeneous layer as well as granular masses.

The weight and lateral pressure of sunflower silage, H. E. MURDOCK (*Montana Sta. Bul.* 191 (1926), pp. 19, figs. 5).—Tests of the weight of sunflower silage and the pressure it exerts on the walls of silos are reported.

The results showed that, when thoroughly compacted, sunflower silage weighs from one and one-half to three times as much as corn silage. The lateral pressure on the walls of silos holding sunflower silage was found to be much greater than it has been assumed to be for corn silage, and for tall silos it is more than twice as great. The deductions from these two findings are that a silo of any given dimensions will hold in the neighborhood of from one and one-half to three times as much sunflower silage by weight as it will of corn silage. The hoops or the reinforcing used in building a silo for sunflower silage should be nearly double those used in building a corn silage silo.

Tables and formulas are presented giving the sunflower silage capacities of various sizes of silos and the methods of calculating the amounts of hoops or reinforcing needed in constructing such silos.

Turn the switch—let electricity do the work, T. E. HENTON and K. McMAHON (*Indiana Sta. Circ.* 134 (1926), pp. [1]+16+[1], figs. 24).—Popular information on the use of electricity in household and barnyard belt work is presented.

Tractor lug studies on sandy soil, J. W. RANDOLPH (*Agr. Engin.*, 7 (1926), No. 5, pp. 178-184, figs. 8).—Studies conducted at the Alabama Experiment Station are reported, the purpose of which was to determine the laws governing the traction of wheeled tractors.

The data presented cover a study of angle lugs with a sandy soil under laboratory conditions and include only the reaction on the machine above the soil. They show that the greatest factor in the transmission of force from any lug is the complete utilization of the arch action of the soil by the tractor. The resistance to shear was found to determine the tractive value of the soil. If the soil is confined by a rim causing arch action, the shear area is increased by bringing the line of shear more nearly parallel to the surface of the ground, the shear angle of unconfined soil being 45°. The compressing action of the rim not only increases the arch action but also the shear value per square inch.

The characteristics of a tractor taken in the order of their importance with reference to tractive value were found to be (1) the distribution of the weight on the driving wheels, (2) the depth of lugs, (3) the width of lugs, solid or broken, and (4) the angle of the lugs across the rim. With a given width of rim the output was found to increase up to a maximum as the weight carried by the wheel was increased up to a certain point. Beyond this point the output decreased. With a given weight carried by a wheel the output was found to increase with the rim width when the weight was sufficient to force the lugs into the soil. Other factors remaining constant, output was found to be proportional to the depth of lug within the range of lugs studied and varied but slightly with the width of lug.

Different types of lug were found to have advantages under different soil conditions. A solid angle iron lug was best in loose soils having slight arch action. Where there was appreciable arch action sharp spade lugs showed an advantage, since they had less resistance in entering and, due to the arch action, were able to produce the same output as, or a greater output than, a solid lug. The spacing of spade lugs was found to depend upon the arch action of the soil, which in turn was governed by the confining and compressing action of the rim. The angle of the lugs across the rim had little effect upon output. The highest tractive efficiency was produced by a weight carried by the wheel just sufficient to force the lug into the soil.

Plows and plowing, J. M. SMITH (*Alberta Univ., Col. Agr. Bul.* 6, 2. ed., rev. (1926), pp. 32, pls. 3, figs. 25).—This is the second revised edition of this bulletin (E. S. R., 44, p. 587).

Summer tillage implements, A. J. OGAARD (*Mont. Agr. Col. Ext. [Circ.]* 79 (1926), pp. 43, figs. 61).—Information relating to various types of implements used for summer tillage by many dry land farmers throughout the Northwest is presented.

Some results of tests of the operation of combines in Illinois, I. P. BLAUSER (*Agr. Engin.*, 7 (1926), No. 6, pp. 205-207, figs. 3).—Studies conducted at the Illinois Experiment Station are reported which dealt primarily with the total losses in harvesting with the combine in both wheat and soy beans. The equipment consisted of a 16-in double cylinder thresher which was used to rethresh the straw collected from the threshing machine and combine. The threshed grain and the straw were collected at the same time to determine the percentage of loss. In the case of the combine a count was made directly back of the cutter bar at the same place the test was made to determine the amount left on the ground.

The losses behind the cutter bar of the binder and the combine were about the same, averaging about 0.75 bu. per acre for wheat. The loss around the

shocks averaged about 1 bu. per acre. From 0.75 to 1 bu. per acre was recovered by raking the shock rows. The loss around the shock was found to be eliminated entirely by the combine, as the material never touches the ground. The average loss for 53 threshing machines tested was 1.36 per cent, bringing the total loss by the ordinary method of harvesting and threshing to a little over 8 per cent. The average total loss from 14 tests made with the combine in wheat was a little under 6 per cent.

The saving in threshing of soy beans with the combine was much greater than by any other method of harvesting and threshing, even though the total loss was considerably higher than that in harvesting wheat. The same combine that had been used to harvest wheat, oats, sweet clover, red clover, and timothy gave an average total loss of 10.62 per cent in 14 tests in harvesting soy beans. For harvesting soy beans the cylinder speed was reduced, special shoes were put on the cutter bar, permitting the machine to cut lower, and the small grain riddles were replaced with soy bean riddles. With this combine, where the beans were standing in good shape, the loss was under 6 per cent and in no test did it go over 17.9 per cent.

Counts made during the past season back of the cutter bar of a mower, self-rake reaper, and binder in soy beans, where the yield was 36.8 bu. per acre, showed losses of 18.2, 14.6, and 25.2 per cent, respectively. Considering losses occurring between the machine used in cutting and the threshing machine and the threshing machine losses, the total losses in this series of tests were approximately 34, 30, and 41 per cent for the mower, self-rake reaper, and binder, respectively. With the special shoes and floating cutter bar the combine was found to give a lower loss behind the cutter bar than the binder. The lower cutting of mower and self-rake reaper was offset by the scattered stalks and shattered beans back of the cutter bar.

These results were taken to indicate that the combine reduces the losses considerably in harvesting and threshing.

Stationary spray plants in California, B. D. MOSES and W. P. DUBUZ (*California Sta. Bul. 406 (1926), pp. 29, figs. 13*).—This bulletin is a contribution from the divisions of agricultural engineering and pomology of the station and the stationary spraying subcommittee of the California Committee on the Relation of Electricity to Agriculture. It is the first of a series planned to report the results of investigations conducted jointly by the station and the committee.

A stationary spray system consists of a central pumping station and pipe lines laid systematically throughout the orchard with outlets at regular intervals to which hose are attached for spraying the trees. The principal advantages of stationary spray plants were found to be that spraying may be done when necessary in spite of adverse soil or weather conditions, and that pests requiring quick action may be speedily controlled.

There was found to be a possibility of combining the advantages of the portable sprayer and the stationary spray plant by piping sections of the orchard that would be benefited and using the portable sprayer for supply and power. In this arrangement the portable rig becomes the pumping station for the permanent piping system, and at other times is available for spraying parts of the orchard where there is no pipe line.

A bibliography is included.

The farmer's shop book, L. M. ROEHL (*Milwaukee: Bruce Pub. Co., 1924, pp. 432, figs. 131*).—This is a handbook of information relating to construction and repair jobs on the farm.

A method of studying farm fires, E. G. LANTZ (*Agr. Engin., 7 (1926), No. 6, pp. 213, 214*).—In a contribution from the Pennsylvania Experiment Station the

methods followed in a study of farm fires and their prevention are briefly outlined and a few of the results presented.

In hay barns the seat of the heating and the subsequent ignition was found to be under or nearly under the point where the hay fork dropped the hay. As the hay was removed a cone of compressed hay was found which had formed a heat chamber. An almost universal tendency was also found to roll the large bunches of matted hay which dropped from the hay fork to one side instead of tearing them apart and leveling the mow. Temperature measurements indicated that these balls of hay were in themselves small heat chambers. It was necessary to eliminate the matted condition before a loose and well-ventilated mow was possible.

Temperature measurements at different points and depths in a mow as it was being filled showed that the heat rose through the cone of compacted hay. If the temperature was taken 3 or 4 ft. below the surface of the mow and directly at the point where the fork dropped the hay, it was rarely ever more than 5° below the highest temperature registered.

RURAL ECONOMICS AND SOCIOLOGY

[Investigations in agricultural economics at the Illinois Station, 1925] (*Illinois Sta. Rpt. 1925, pp. 102-129*).—The results obtained during the year in investigations in progress are summarized.

In studies of farm earnings by H. C. M. Case, M. L. Mosher, and K. H. Myers, a table is given summarizing by 14 areas of one or more counties the business records of 606 farms for 1924. The rate earned on investment in the several areas varied from 3.75 to 8.22 per cent, averaging 6.25 per cent, which for the average operator amounted to \$1,212.70 as payment for his labor and management after all expenses had been paid and 5 per cent allowed on capital invested. The relatively high level of grain prices as compared with the prices of livestock in 1924, together with climatic conditions, gave the grain-selling sections an unusual advantage over the heavier livestock-producing sections during 1924.

Detailed cost-accounting investigations were continued by Case, C. A. Bonnen, and H. A. Berg in 1924 for the twelfth year. Data are summarized for 1923 and 1924 for Knox and Warren Counties, and for 1920-1924 for Champaign and Piatt Counties.

A study by H. P. Rusk, Case, and R. H. Wilcox on 25 farms in McLean and Woodford Counties showed that feed constituted 84.4 per cent of the total cost of carrying the breeding herd and growing and fattening the 1924 spring pigs. An average of 433 lbs. of concentrates were fed for each 100 lbs. of gain. The loss of pigs before weaning averaged 38.5 per cent and had a marked influence on the cost of production. The profit per 100 lbs. of gain averaged \$1.62, decreasing from \$2.50 profit to \$3.17 loss as the cost of production increased from \$7 to \$8 to over \$12 per 100 lbs.

The average cost in 1924 of producing 100 lbs. of milk on 11 farms in DuPage, Lake, and Stephenson Counties with herds averaging 17 cows was found by Case, Bonnen, and K. T. Wright to be \$3.07, and the average production per cow was 6,468 lbs. of milk. The cost and average production per cow varied on individual farms from \$1.89 and 8,496 lbs. to \$5.26 and 4,890 lbs. On 12 farms in Washington, Clinton, and Madison Counties with herds averaging 12 cows the average cost per 100 lbs. of milk was \$1.84 and the average production per cow 6,158 lbs. The cost and average production per cow varied from \$1.28 and 7,586 lbs. to \$4.54 and 3,492 lbs. Feed costs per 100 lbs. of milk

produced varied from \$1.35 to \$3.59 on the farms in the first section and from \$1.14 to \$3.52 in the second section.

Survey records in 1924 on 25 tractor farms in Champaign County by R. C. Ross and R. I. Shawl showed the average yearly use of tractors to be 256.5 hours and the average hourly cost to be \$1.13. Records from 18 other farms showed 298 hours of use at a cost of \$1.05 per hour. Horse labor costs in 1924 averaged 14 cts. per hour for an average of 791 hours of use on 14 Champaign and Piatt County farms, and 16.4 cts. per hour for an average of 732.5 hours of work on 18 Knox and Warren County farms.

Case, R. R. Snapp, and Wilcox found the average net costs per pound of gain of feeding cattle in De Kalb County for the 5 winters 1918-19 to 1922-23 were 28 cts., 33.2, 18.1, 12.6, and 15.8 cts., respectively. The prices received per bushel of corn fed were \$1.12, 30 cts., 32, 63, and 62 cts., respectively. In 1922-23 the cost of feed comprised from 76 to 79 per cent of the total cost of feeding cattle of different classes, and from 350 lbs. of corn for calves to 840 lbs. for heavy cattle was fed for each 100 lbs. of gain.

C. L. Stewart found that two out of three farm real estate transfers made in 1924 were voluntary sales, but in 58 per cent of the cases the purchaser was related to the former owner. Twelve per cent of the transfers were due to deaths, 8 per cent to bankruptcy or foreclosure, 5 per cent to voluntary relinquishment in satisfaction of mortgage debts, less than 1 per cent to tax sales, and 8 per cent to other compulsory circumstances, such as condemnation.

[Rural economics investigations at the Ohio Station] (*Ohio Sta. Bimo. Bul.*, 11 (1926), No. 6, pp. 245-254).—The results of work in rural economics are given.

Farm machinery costs in Ohio, J. I. Falconer.—A table is given showing the sales price of 12 farm implements and 5 gas-driven machines in 1914 and in each of the years 1920 to 1926, inclusive. Excluding gas-driven machines, the weighted index for the price of farm machinery in 1923 was 148; in 1924, 178; 1925, 168; and in 1926, 167. Assuming that 30 per cent of the machinery cost is for gas-driven machines, the index number in 1923 was 125; in 1924, 146; and in 1925 and 1926, 138.

Summary of 4,666 farm records in Ohio from 1910-1925, J. I. Falconer.—Data from 4,666 financial summaries of the year's business on Ohio farms are tabulated under the following headings: County, principal sources of receipts in order of importance, year covered, number of farms, receipts per farm, expenses per farm, and labor income.

Feed prices, J. I. Falconer.—Tables are given showing (1) the average price in 1910-1914, and the prices in March, 1923-1926, and in September, 1926, of corn, oats, bran, tankage, oil meal, and cottonseed meal; and (2) the index of these prices using the average 1910-1914=100. The weighted index of these feeds in July, 1926, was 130 as compared with an index of 161 for all farm expenses.

Freight rates on Ohio butter, cheese, and condensed milk, C. G. McBride.—Tables are given showing the freight rates on butter and cheese from different Ohio points to different destinations during different periods from 1915 to 1926. The index of the present freight rates compared with those effective before 1915 was 190, while the index of prices paid to farmers for butter in 1925 was 170.

Index number of production, wages, and prices, J. I. Falconer.—This is a continuation through September, 1926, of the index numbers previously noted (*E. S. R.* 56, p. 183).

An economic study of irrigated farming in Twin Falls County, Idaho, B. HUNTER and S. B. NUCKOLS (*U. S. Dept. Agr. Bul.* 1421 (1926), pp. 75, figs.

23).—This investigation was conducted by the Bureau of Agricultural Economics and Plant Industry, U. S. D. A., and the Idaho Agricultural Experiment Station, and covers the years 1919 to 1922, inclusive. It includes (1) a study of the agricultural development and readjustments of the Twin Falls South Side project, (2) a business analysis of the farms studied during each of the years 1919–1922, (3) the cost of producing each of the 7 primary crops grown in 1919 to 1921, inclusive, and (4) the average cost of keeping work horses and the cost of horse labor per hour in 1921. The information was obtained by the survey method. The farms studied varied in size from 17 to 345 acres, the most frequent sizes being 40-acre, 80-acre, and 20-acre, in the order named. Cash crop farming predominated. Of the farms studied, 87 per cent were general crop farms, 7 per cent dairy and general crop farms, and 6 per cent orchard and general crop farms. The orchard and general crop farms carried very little productive livestock.

The return to capital varied during the 4 years from 1.5 to 7.2 per cent, averaging 4.1 per cent, for general crop farms; from 3.7 to 10.9 per cent, averaging 5.8 per cent, for dairy and general crop farms; and from -0.4 to 12 per cent, averaging 5.2 per cent, for orchard and general crop farms. The size of farm had considerable influence on the economical organization and operation of the general crop farms. The 40-acre farms had 5 per cent more of the total capital tied up in buildings and equipment than had the 80-acre farms. On the 80-acre farms a little over 15 acres of crops were handled per work horse and 4.2 crop acres per month of man labor, as compared with 10 and 2.8 acres, respectively, on the 40-acre farms. Yields were slightly higher on the 40-acre farms, but the net returns per acre for use of real estate for the 4-year period varied from $-\$1$ to $\$24$, averaging $\$7.75$, for 40-acre farms, and from $\$3$ to $\$33$, averaging $\$14.25$, for 80-acre farms.

None of the 7 leading field crops showed an average net return per acre in more than 2 of the 4 years studied, no one of them showed a loss each year, and in no year did all the crops show losses. The average number of hours of man labor used per acre in producing the different crops in 1919–1921 were for wheat 25.1, alfalfa hay 30.8, sugar beets 131.6, potatoes 101.4, beans 57.2, red clover seed 24.9, and alsike clover seed 21.7. The average number of hours of horse labor were 44.3, 32, 117.6, 100.2, 57.1, 22.6, and 15.1, respectively, for the different crops.

The 151 farms on which cost of horse labor was studied in 1921 averaged 75 acres, and there was an average of 4.7 work horses per farm. An average of 703 hours of work was done per horse at a cost of 7.8 cts. per hour. The average cost per horse per year was $\$55.15$, of which 63 per cent went for feed.

Farming for profits: Anderson and similar areas of South Carolina, W. C. JENSEN (*South Carolina Sta. Bul. 230 (1926), pp. 69, figs. 22*).—This bulletin is based upon surveys made by the station from 1922 to 1925, inclusive, to determine the most economic farm organizations and practices in Anderson County, S. C., and a study made by the Office of Farm Management, U. S. D. A., in the same area in 1914. The results of the work in 1922 have been previously noted (E. S. R., 52, p. 588).

Farm organization or combination of crops and livestock, acres of cotton per farm, and value of cotton per acre are deemed the most important factors determining the financial success of this area. In the years 1922, 1924, and 1925 the best farms averaged 103 acres in crops, 22.9 acres of crops per mule, and 12.9 acres of cotton per mule; the average farms 75 acres in crops per farm, 19.7 acres of crops per mule, and 10.9 acres of cotton per mule; and the poorest farms 66 acres in crops, 18.3 acres of crops per mule, and 10.1 acres of cotton per mule. Each 1.5 acres of cotton per mule increased the

gross cash income per mule approximately \$100, using 1924 prices. A multiple correlation analysis shows that operator's earnings increased rapidly with the increase in the acreage of cotton grown from 5 acres up to nearly 200 acres, and also with the increase in the acreage value of cotton from \$40 or less to \$130.

The cost of producing cotton in 1924 decreased 3.2 cts. per pound with each 100 lbs. per acre increase in the yields of lint cotton. Large increases in yields resulted from increased mixed fertilizer applications of over 300 lbs. up to approximately 600 lbs. per acre, and with increased applications of nitrate of soda from 40 to approximately 160 lbs. per acre.

For each mule used on the farm the following acreages are recommended: Cotton 12.5, corn 5, oats 2.5, wheat 0.8, cowpea hay after grain 2.5, alfalfa hay 0.3, miscellaneous and other crops 1.4, and winter cover crops 8.5 acres. Sufficient livestock should be carried on each farm to supply meat, eggs, and dairy products for family needs.

Tables are given showing the recommended crop plan for a 4-mule farm, best-average-poorest farm data, production cost of different crops, and returns from using different amounts of fertilizer with cotton and fertilizers at different prices. Tables of average quantity expenditures and costs in 1924 are given for 20 dairy, 20 poultry, and several truck farms in the Greenville area.

Economic studies of dairy farming in New York, VI, VII, E. G. MISNER (*New York Cornell Sta. Buls.* 452 (1926), pp. 3-58, figs. 2; 455 (1926), pp. 3-51).—These bulletins report the results for the years ended April 30, 1923 and 1924, of the study previously noted (E. S. R., 54, pp. 584, 585). Eighty-eight farms were studied the first year and 95 farms the second year. Some of the more important data for the two years are summarized in the following table:

Averages per farm of important business factors for the years ended April 30, 1923 and 1924

Kind of business factor	1923	1924
Size of farm.....acres.....	151	162.8
Acreage in crops.....	59	59.2
Acreage pastured.....	66.4	78
Number of cows, average.....	22	23
Capital.....	\$16,080	\$15,546
Receipts:		
Crops.....	\$592	\$1,027
Livestock sold.....	\$713	\$682
Milk sold.....	\$2,761	\$3,061
Miscellaneous.....	\$484	\$477
Expenses:		
Total.....	\$3,714	\$4,087
Operating.....	\$3,221	\$3,509
Farm income.....	\$836	\$1,160
Labor income.....	\$32	\$383
Net income.....per cent.....	None.	1.2
Monthly cash living costs of operator.....	\$62	\$60
Number of men, including operator.....	2.19	2.2
Percentage of labor done by operator and family.....	67.1	66
Rate per hour for operator's labor.....	\$0.31	\$0.33
Rate per hour for hired labor.....	\$0.20	\$0.23
Rate per hour for horse labor.....	\$0.18	\$0.17
Returns above all other costs per hour of labor:		
Summer dairies.....	\$0.133	\$0.099
Winter dairies.....	\$0.284	\$0.127
Milk per cow.....pounds.....	6,305	6,753
Price received per 100 pounds of milk.....	\$2.12	\$2.12
Cost of producing 100 pounds of milk.....	\$2.35	\$2.44
Cost per pound of butterfat.....	\$0.70	\$0.73
Loss per cow.....	\$13.35	\$20.25
Cost of raising a heifer to age of freshening.....	\$109	\$116
Productive man-work units per man.....	247	238
Productive horse-work units per work animal.....	64	63
Acreage of crops per man.....	26.9	26.7
Acreage of crops per work animal.....	16.3	16.5

In 1922, 40 farmers failed to make interest, 33 made labor incomes of from \$1 to \$1,000, and 15 made labor incomes over \$1,000. In 1923, 33 did not make interest, 38 made from \$1 to \$1,000, and 24 made over \$1,000.

Tables are included in each bulletin summarizing the uses of fertilizer, lime, and manure for different crops; giving the labor distribution; and showing important business factors for each farm studied. Each bulletin has a tabulated summary for use in comparing individual farms with the average. Bulletin 452 briefly discusses 5 farms successfully operated in 1922, and 3 farms out of 76 in the Earlville region having labor incomes of over \$1,000 in 3 consecutive years.

Factors in the cost of producing beef in the Flint Hills section of Kansas, R. H. WILCOX, W. E. GRIMES, M. EVANS, and H. J. HENNEY (U. S. Dept. Agr. Bul. 1454 (1926), pp. 27, figs. 9).—This bulletin presents the results of a study made from 1921 through 1923 by the Department and the Kansas Experiment Station of the cattle industry in the Flint Hills section—a rough section of over 3,000,000 acres in the central and southern part of the eastern half of Kansas. The study was made to ascertain the number of acres of grass required to put normal gains on steers, the methods used in handling steers, the factors in the costs of grazing, and the economic position of summer grazing in Kansas in relation to the beef-cattle industry and to the markets for livestock.

Methods and practices of retailing meat, W. C. DAVIS (U. S. Dept. Agr. Bul. 1441 (1926), pp. 24, figs. 9).—This bulletin is the first of a series of three giving the results of a survey of the retail marketing of meat conducted by the Bureau of Agricultural Economics. The study of methods and practices covered by this bulletin was made in 1924 and 1925 in 20 cities scattered throughout the United States. A total of 1,404 stores were studied, of which about 600 belonged to chain systems and 800 were independent shops. The number of stores in relation to population, their location, volume and character of business, practical knowledge of the proprietor, sources of supplies and methods of buying, facilities and equipment, selling and operation practices, frequency of turnover, price determinations, spread between wholesale cost and retail prices, and other factors were studied and recommendations made for eliminating the weaknesses and deficiencies of the industry.

The number of persons per store ranged from 300 to 700 in the different cities. Efficiency in operation was found to be due more to the qualifications and practical knowledge of the management than to the size, number of units, or capital employed.

Margins, expenses, and profits in retailing meat, K. B. GARDNER (U. S. Dept. Agr. Bul. 1442 (1926), pp. 56, figs. 3).—This bulletin is the second of the series on the retail marketing of meat noted above and is based upon data collected in 16 cities of the United States. These data were obtained from 142 individual retail straight meat markets in 1923, 111 such markets in 1924, and from a smaller number of semiwholesale markets, combination stores, retail chain stores, and semiwholesale and retail chain meat markets.

Data were obtained from 74 individual straight retail markets in both years and showed that the percentage of gross margins, expenses, and profits based on net sales was practically the same in the two years. An analysis based on 129 of these shops in 1923 which had net sales of over \$14,000 showed the various items of margin, expense, and profit in the percentages of net sales to be as follows: Gross margin between cost and receipts 23.56 per cent, profits 3.01, total expenses 20.55 divided into salaries and wages 13.16, rent 2.18, wrapping 0.97, refrigerating 1, light and power 0.33, depreciation 0.42, and

other expenses 2.49 per cent. Of these 129 markets, 21.7 per cent were operated at a loss when proprietor wages were included, 30.2 per cent showed a profit of less than 3 per cent of the sales, 27.1 per cent profits of from 3 to 6 per cent, 14.7 per cent profits of from 6 to 9 per cent, and 6.3 per cent profits of over 9 per cent. The average profits for carry stores were 3.24 per cent, limited delivery stores 2.29, and unlimited delivery stores 3.23 per cent.

Delivery costs amounted to 5 per cent of the delivered sales. The absolute cost of retailing meat was found to have changed but little from 1919 to 1923, when gross margins, expenses, and profits were related to a common base (1913).

An analysis of the data gathered from other than individual retail straight meat markets is also made.

Crops and Markets [for November, 1926] (*U. S. Dept. Agr., Crops and Markets*, 6 (1926), Nos. 20, pp. 305-320; 21, pp. 321-336; 22, pp. 337-352; 23, pp. 353-368).—The usual tabulations, notes, summaries, etc., are given for livestock, meats, wool, fruits, vegetables, grain, hay, cotton, feed, dairy and poultry products, and foreign crops and markets by weeks from November 1 to 27, 1926.

Monthly Supplement to Crops and Markets [November, 1926] (*U. S. Dept. Agr., Crops and Markets*, 3 (1926), Sup. 11, pp. 345-384, figs. 5).—The usual tables, charts, comments, and summaries are included for crops, dairy products, fruit and vegetable shipments, livestock and livestock products, seeds, cold storage holdings, prices, world agriculture, etc. Special reports are given for the cattle and lamb feeding situations October 1 and November 1. Special tables are presented showing the acreage and condition of the cotton crop October 18 and November 1; the acreage and yield per acre of cotton; the production, value, and annual prices of cotton and cottonseed by States, 1910-1926; the estimated monthly marketings of cotton by States, 1922-1925, and by years, 1910-1926; and the monthly farm prices of cotton and cottonseed by years, 1910-1926.

FOODS—HUMAN NUTRITION

Nutritional physiology, P. G. STILES (*Philadelphia and London: W. B. Saunders Co., 1924, 5. ed., pp. 307, pls. 3, figs. 20*).—A revision of the work previously noted (*E. S. R.*, 51, p. 163).

Food selection and expenditure in a college community, M. M. KRAMER and E. GRUNDMEIER (*Jour. Home Econ.*, 18 (1926), No. 1, pp. 18-23).—This paper summarizes the results of a dietary survey conducted in a late fall or winter month on 465 students at the Kansas State Agricultural College in 10 sorority and 7 fraternity houses and 3 boarding houses for men. All of the houses represented were managed without the assistance of a dietitian. In all cases records were kept of the meals served and of foods used in the specific time, with quantity, quality, and retail costs. From these figures calculations were made of calories of energy, grams of protein, phosphorus, calcium, and iron, and cost per man per day.

The energy figures ranged from 1,856 to 3,761 calories, with an average of 2,889 per day. The protein averaged 85 gm., or 340 calories per 3,000 calories, and in no case furnished less than 10 per cent of the total energy. As judged by the Sherman standards, calcium was inadequate in 75 per cent, phosphorus in 70 per cent, and iron in 50 or 60 per cent of the groups. The cost per man per day ranged from 24.1 to 52.6 cts., with an average of 35.6 cts. The five dietaries having the highest cost per 100 calories had more mineral deficiencies than the five showing the lowest cost. A comparison of the cost distribution among the different classes of foods with the Sherman standards indicated that

the deficiencies in the diet could be made up without more cost by more careful selection, including a more liberal use of milk and cheese and of whole grain products and a wiser choice of fruits and vegetables.

Feeding problems in college communities, E. I. RAITT (*Western Dietitian*, 1 (1926), No. 6, pp. 11-13, 38, 39, figs. 4).—A dietary survey similar to the foregoing has been made at the University of Washington in 12 organized houses for college women, serving a total of 1,200 meals daily. The records were made in January and February, 1926, and were collected and summarized by R. S. Godfrey.

Averaged by houses, the minimum, maximum, and average energy values were 2,249, 3,160, and 2,667 calories per person per day. The protein averaged 80 gm. per person, or 120 gm. per 3,000 calories, and an average of 65 per cent of it was of animal origin. Five of the 12 groups fell below the 0.67 gm. per day of calcium recommended by Sherman as the minimum allowance, 8 below 1.32 gm. of phosphorus, and all but 1 below 0.015 gm. of iron. Estimated for 3,000 calories only 1 group was short on calcium, 3 on phosphorus, and 5 on iron. The minimum, maximum, and average expenditures for food were 32, 49, and 42.7 cts. The houses least successful in the mineral allowance all spent above the average, while of those furnishing a sufficient supply of minerals 2 were above and 3 below the average total expenditure.

On the basis of the distribution of total food expenditures among the different classes of foods as compared with the standards recommended by Sherman, it is considered that the present diets might be improved by a slight reduction in the meat and an increase in vegetables and fruits in season and in eggs, milk, and cheese.

A square meal, R. H. A. and V. G. PLIMMER (*Hygeia [Chicago]*, 4 (1926), No. 11, pp. 611-614, figs. 11).—A novel scheme for the diagrammatic representation of complete and incomplete diets is explained and illustrated. A balanced diet supplying all the materials needed by the body is represented by a circle inclosed in a square. The upper half of the circle represents the calories supplied by fat and carbohydrates and the lower half water and salts. Three of the four corners of the square not filled by the circle represent vitamins A and D, B, and C, and the fourth protein. The absence or shortage of these constituents of the diet can be shown by the removal or cutting off of the corners, and an excess of any constituent inside or outside the circle by suitable enlargements. Examples of poorly balanced diets are given with accompanying diagrams.

Nutritive value of protein in beef extract, ox blood, ox palates, calf lungs, hog snouts, and cracklings, R. HOAGLAND and G. G. SNIDER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 9, pp. 829-843, figs. 8).—Following the method employed in previous studies along the same line (E. S. R., 55, p. 487), the authors have determined the nutritive value of various meat products having limited use as human food.

With the exception of calf lungs, the protein of which proved to be of fair quality, all of the products tested were inadequate as the sole source of protein for young rats. Dried blood and hemoglobin were so distasteful to the rats that the food consumption was too low to afford any evidence of the nutritive value of the protein. Of the other materials, serum protein, hog snouts, and pork cracklings fed at a 15 per cent level proved adequate for maintenance but not for satisfactory growth, and beef extract was inadequate for maintenance at an 18 per cent level.

The biological value of bread-protein, M. HINDHEDE (*Biochem. Jour.*, 20 (1926), No. 2, pp. 330-334).—The author takes exception to the low figures

reported by Martin and Robison for the biological value of the proteins of wheat from a 25-day test (E. S. R., 47, p. 765), and presents data from metabolism experiments conducted on two subjects for a period of 126 days showing that nitrogen equilibrium is possible on a diet furnishing only 22 gm. daily of digestible protein in the form of rye bread. The ability to continue for such a long period on a low nitrogen diet and at the same time maintain the caloric requirements is attributed to the use of a comparatively large amount of fruit.

A study of the laxative action of wheat bran, G. A. WILLIAMS (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 8, pp. 630, 631).—Preliminary studies conducted on dogs are reported which indicate that the laxative effect of wheat bran is largely due to its content of crude fiber, this being a more powerful laxative than an equal amount of powdered agar.

Peas in the diet, A. L. MARLATT (*Canner*, 63 (1926), No. 22, pp. 29, 32).—This paper contains a brief description of the commercial process of canning peas, an explanation of the meaning of the various trade names for canned peas, and suggestions for the selection of various types of canned peas for different uses in the diet.

Cellulose sausage casings, W. F. HENDERSON and H. E. DIETRICH (*Indus. and Engin. Chem.*, 18 (1926), No. 11, pp. 1190-1194, figs. 2).—A brief description is given of the various stages in the research work which has been conducted for the past 10 years at the Mellon Institute of Industrial Research under the Food Container Fellowship for the purpose of devising an edible synthetic substitute for the animal casings used for packing sausages. The material finally adopted is cellulose derived from high grade purified cotton linters. This is treated by the viscose process and manufactured by the use of specially designed machinery into thin-walled seamless tubes. The cellulose cases have the advantage over the intestinal casings from the standpoint of the manufacturer in requiring no preliminary treatment and being easier to fill, and from the standpoint of the consumer in being more satisfactory from every hygienic and sanitary angle.

Studies on the effect of heat on milk, I, II, H. E. MAGEE and D. HARVEY (*Biochem. Jour.*, 20 (1926), No. 4, pp. 873-891, figs. 4).—The question of the nutritive properties of pasteurized milk as compared with fresh milk is considered in a series of papers, the first two of which are noted below.

I. *Some physico-chemical changes induced in milk by heat*.—In this study of the changes brought about in the state of some of the constituents of milk by varying amounts of heat, whole fresh milk and whole milk pasteurized at 65° C. (149° F.) for 30 minutes were compared for their content of soluble calcium after precipitation of the proteins with colloidal ferric hydroxide. As thus determined 85 per cent of the total CaO was found in solution in the whole fresh milk and 71 per cent in the pasteurized milk. In the other experiments reported, three kinds of milk were used—fresh milk, consisting of skim milk 3 hours after milking; pasteurized milk, prepared by holding skim milk at a temperature of 70° for 30 minutes in a flask immersed in a water bath; and boiled milk, prepared by holding the milk in a flask immersed in a water bath for an hour at boiling temperature. After coagulation by rennin an average of 22.72 per cent of the total CaO was found in the whey in the case of fresh milk, 20.73 in the pasteurized, and 18.52 per cent in the boiled milk. On dialysis against running water, the percentages of total CaO in diffusible form in the fresh, pasteurized, and boiled milk were about 26, 20, and 15 per cent, respectively. A study of the colloidal properties of the three samples suggested the probability that the losses in CaO after heating are due to the formation

of colloidal $\text{Ca}_3(\text{PO}_4)_2$ from the soluble CaHPO_4 . Precipitation of amorphous or crystalline $\text{Ca}_3(\text{PO}_4)_2$ could not be detected.

Tryptic digestion experiments in vitro showed no change in the digestibility of the milk as the result of heating.

II. *The influence of diets of fresh and treated cow's milk on the calcium, phosphorus, and nitrogen metabolism of the young pig.*—Metabolism experiments conducted on young pigs are reported, the results of which indicate that "the retention of calcium, phosphorus, and nitrogen by young animals is lower on a diet containing heated milk than on one containing fresh or sour milk, and further that the addition of soluble calcium to the heated milk ration increases the amount of calcium, phosphorus, and nitrogen retained by more than the weight of the calcium added. The changes in the state of the colloids described in our first paper had evidently no effect on the assimilation of nitrogen. It is therefore suggested that the reduction in the soluble calcium by heat is an important factor in the lowering of the retention of calcium, phosphorus, and nitrogen of young animals fed on heated milk as compared with raw milk."

Peptic digestion of cow's milk, J. H. HESS, E. M. KOCH, and Z. C. SENNEWALD (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 17, pp. 1360-1364, figs. 4).—Various milk modifications commonly used in infant feeding have been compared with reference to the rate of gastric digestion and to the relative importance in the digestion process of the character of the curd and the H-ion concentration. The digestion experiments were conducted in vitro, with quantitative determinations of the increase in soluble nitrogen as the result of digestion and with an examination of the curd and a determination of the H-ion concentration. The results were checked by feeding the milk to young puppies and obtaining the curds at 0.5, 2, and 3 hours by induced vomiting.

The experiments in vitro showed that the solubility of milk proteins is decreased by boiling and by such increased acidity as occurred in the range of the experiments, and is increased by the introduction of weakly acid anions, by buffer salts, and by autolysis. Aside from the physical character of the curd, a lowered pH and previous denaturization of the protein are considered to be important factors in influencing the peptic digestion of milk proteins. The excellent results obtained with cultured lactic acid milk are attributed to the combination of small curd formation, low pH, and the tendency to denaturization of the protein. Orange juice milk (56 cc. of orange juice per liter of milk) gave the highest total soluble nitrogen. Lemon juice milk (21 cc. per liter) was not as readily digested in vitro as other acid milks of similar pH.

In the feeding experiments the curds obtained with raw and pasteurized milk were large and tough and those with boiled and acidified milk small. The alkaline modifications prevented curd formation until the milk had been in the stomach for half an hour.

Although cultured lactic acid milk proved superior to all other acid milks in digestibility, orange or lemon juice is recommended as the most logical addition to raw, pasteurized, or boiled milk for continued feeding on account of its high content of vitamins and mineral constituents and additional buffer salts. Raw egg yolk as previously suggested by Hess and Mitzner (*E. S. R.*, 51, p. 867) is also recommended in addition to one of the fruit juices.

The production and handling of human milk, H. D. CHAPIN (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 17, pp. 1364-1366).—This is a discussion of the production and handling of human milk by the Children's Welfare Federation of New York since October 6, 1921, with data on the specific gravity and the fat, protein, and lactose content of 44 different samples of pooled milk and on its keeping qualities.

The nutritive value of inorganic substances.—I, A study of the normal zinc metabolism, with particular reference to the calcium metabolism, L. T. FAIRHALL (*Jour. Biol. Chem.*, 70 (1926), No. 2, pp. 495–512, figs. 6).—In this investigation the metabolism of zinc in rats has been studied under conditions of normal, acid, and alkaline feeding. The diet used throughout consisted of cracked wheat 21.3, corn meal 21.3, rolled oats 35.6, milk powder (Klim) 14.2, liver powder 4.7, and yeast powder 2.8 per cent, with a small weekly allowance of fresh lettuce. During the normal periods the animals drank distilled water from burettes, and during the acid and alkaline periods ammonium chloride (1 M decreasing to 0.4 M) and sodium bicarbonate (0.1 M), respectively. The experiment continued 3 weeks on the normal, 7 on the alkaline, 1 on the normal, and 15 on the acid feeding. The food mixture was analyzed frequently for zinc and calcium and the weekly output of urine and feces tested separately for zinc and calcium.

The average daily intake per rat during the water periods amounted to 0.48 mg. of zinc and 19.1 mg. of calcium and the excretion 0.44 and 15.1 mg., respectively. The calcium storage was of the same order as reported by Sherman and MacLeod for adult rats (*E. S. R.*, 54, p. 593) and the storage of zinc about 1 per cent of that of calcium. A further proof of the storage of zinc in the organism of the growing rat is afforded by analyses for calcium and zinc of the bodies of rats at various ages of from 7 to 210 days. During this time the calcium content rose from 0.069 to 3.016 gm. and the zinc from 0.37 to 8.2 mg. Values obtained for the zinc content of the blood of 2 adult rats were 0.68 and 0.79 mg. per 100 gm. and of calcium 10.2 and 10.4 mg., respectively.

During the alkaline feeding the excretion of zinc in both the urine and feces was at first increased and later returned to normal. During the acid feeding there was a similar increase in excretion, but the balance continued to remain negative until normal feeding was resumed. The calcium metabolism was not affected by the alkaline diet, but the excretion of calcium was slightly increased on the acid diet. These data indicate that zinc is less firmly retained in the body than calcium.

Data are also given on the zinc content of a number of foods and on the fecal zinc excretion of a man on normal diets. It is estimated that man consumes from 10 to 15 mg. of zinc daily and excretes about 1 mg. daily in the urine. The fecal excretion as judged by the data presented fluctuates widely with the amount of zinc ingested.

The value of egg yolk in supplementing diets deficient in calcium, E. Tso (*Amer. Jour. Physiol.*, 77 (1926), No. 1, pp. 192–198, figs. 6).—In this complete report of a study previously noted from a preliminary report (*E. S. R.*, 52, p. 260), further evidence is given of the value of egg yolk in supplementing diets deficient in calcium. In the feeding experiments reported, 5 per cent of egg yolk proved as satisfactory a supplement to the deficient diet as 2 per cent of cod-liver oil.

“The results of these experiments have a practical bearing of fundamental significance on the problem of feeding young children in such a country as China where cow’s milk is little used. To most households the cost of milk seems almost prohibitive. On the other hand, the cost of eggs is extremely low. Therefore, the addition of one or two eggs a day to the diet of Chinese children should be of immense value not only in enhancing its vitamin A and vitamin B content and its protein quality, but in improving the calcium metabolism and safeguarding the body against calcium starvation.”

The relation of anemia, primary and secondary, to vitamin A deficiency, K. K. KOESSLER, S. MAURER, and R. LOUGHLIN (*Jour. Amer. Med. Assoc.*,

87 (1926), No. 7, pp. 476-482, figs. 3).—The theory upon which the experimental work and specific recommendations for the dietary treatment of pernicious anemia reported in this paper are based is that in pernicious and other severe anemias "the blood changes and the changes in the gastrointestinal tract may be due to vitamin A underfeeding over a long period of years. The nervous symptoms might be related to an absence or deficient quantity of vitamin B. The tendency to hemorrhages found in severe anemias may be due to the partial or complete lack of vitamin C. This theory does not assume to invalidate the importance of bacterial poisons for the pathogenesis of pernicious anemia. The tissue changes brought about by the chronic vitamin deficiency may facilitate the action of these poisons."

In support of this theory, particularly in respect to the effect of deprivation of vitamin A, data are given on the blood changes in rats following variations in the vitamin A content of the diet, including total lack, chronic deficiency or underfeeding, and an abundant supply. These data are thought to prove that "the addition of a small quantity of vitamin A to the diet of an animal, long depleted in its vitamin reserve, brings about rapid formation of new red blood cells. The rate and intensity of this regeneration is, within reasonable limits, a function of the quantity of the vitamin added. Blood regeneration can not take place without the presence of vitamin A. Rats while in a state of chronic vitamin A deficiency develop a severe anemia, which, after ample vitamins are added to the diet, shows the typical blood picture of an early Addison anemia, characterized by all the features of rapid blood regeneration."

Assuming that the same conditions hold in human beings, it is recommended that the treatment of pernicious and other severe anemias be based upon the replenishment of the body with vitamins through a proper dietary management. Included in the specific recommendations for dietary treatment are cod-liver oil (5 cc. four times daily), 6 yeast tablets equivalent to 200 mg. of concentrated yeast extract, 50 or 60 gm. of butter, 6 or 7 glasses of milk, $\frac{1}{2}$ pint of cream, 2 or 3 egg yolks or whole eggs, together with an abundance of fruits and vegetables, whole-wheat bread made with milk, and in place of muscle meat liver, kidney, sweetbreads, or brains.

Treatment of pernicious anemia by a special diet, G. R. MINOT and W. P. MURPHY (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 7, pp. 470-476, fig. 1.)—A diet composed especially of foods rich in complete protein and iron, particularly liver, and containing an abundance of fruits and fresh vegetables and very little fat, has been given to a series of 45 patients with pernicious anemia for periods varying from 6 weeks to 2½ years, with promising results in prompt remission of the anemia, rapid increase in red blood corpuscles and hemoglobin count, and improvement in clinical appearance. The use of an abundance of liver and muscle meat was suggested by the experimental work of Whipple and Robscheit-Robbins on blood regeneration in severe anemia (*E. S. R.*, 53, p. 867), as well as other observations in the literature, abundant references to which are given as footnotes.

A differentiation between the water-soluble growth-promoting and anti-neuritic substances, S. M. HAUGE and C. W. CARRICK (*Jour. Biol. Chem.*, 69 (1926), No. 2, pp. 403-413, figs. 5.)—The literature on the identity or non-identity of the water-soluble growth-promoting vitamin B and the anti-neuritic vitamin is reviewed briefly, and a further study of the question is reported in which corn and yeast were compared as to both of these properties by carefully controlled feeding experiments conducted on baby chicks.

On 30 per cent corn as the sole source of vitamin B in an otherwise complete diet, the chicks grew slowly and showed no symptoms of polyneuritis during

the 18 weeks of the test. On the same amount of yeast the chicks grew rapidly, but nearly all developed polyneuritis during the tenth week and died within 2 weeks thereafter. On 20 per cent corn and 10 per cent yeast, growth was rapid and only a few cases of polyneuritis developed. On lower levels of corn and yeast some polyneuritis developed in all of the lots. Growth was rapid with as small an amount as 10 per cent of yeast, and slow even with large amounts of corn. That the superior growth-promoting properties of the yeast were not due to its protein was demonstrated by equally favorable results when a water extract of the yeast was used in place of the dried yeast, and when purified casein to the extent of 25 per cent was substituted for the 20 per cent meat residue and 5 per cent degerminated corn of the basal ration.

The authors conclude that the antineuritic vitamin and the water-soluble growth-promoting vitamin are not identical and that the yeast used was low in the antineuritic vitamin and rich in the water-soluble growth-promoting vitamin, while the corn was relatively rich in the antineuritic vitamin but poor in the growth-promoting vitamin.

The production of antirachitic properties in human milk resulting from irradiation of the mother, A. F. HESS, M. WEINSTOCK, and E. SHERMAN (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 8, pp. 636-638).—The authors have demonstrated the possibility of increasing the antirachitic properties of human milk by irradiation of the mother. While human milk in 25-cc. daily doses proved incapable of healing rickets or increasing the inorganic phosphorus content of the blood in rats made definitely rachitic by means of the Sherman-Pappenheimer low phosphorus diet, the same amount of milk from the same woman brought about definite healing and raised the inorganic phosphorus content of the blood of another series of rachitic rats after the woman had been irradiated every other day for a month by means of a mercury vapor lamp.

"It seems that an experiment of this kind has a definite application to pediatrics. It clearly indicates the value of ultra-violet irradiation of the mother during lactation as a preventive of rickets in the baby. Probably during the winter months when the infant is most in need of protection from rickets the intensity of sunlight is insufficient to produce this property in the milk."

The effect of irradiation of the environment with ultra-violet light upon the growth and calcification of rats, fed on a diet deficient in fat-soluble vitamins.—The part played by irradiated sawdust, II, E. M. HUME and H. H. SMITH (*Biochem. Jour.*, 20 (1926), No. 2, pp. 335-339).—The favorable effect of irradiated sawdust on the growth and calcification of the bones of young rats on a diet deficient in fat-soluble vitamins (E. S. R., 53, p. 264) is attributed to the consumption of small amounts of the sawdust, a conclusion previously reached by Nelson and Steenbock (E. S. R., 53, p. 264).

A note on the production by irradiation with ultra-violet light of antirachitic properties in sterols derived from the small Siak Illipe nut (*Palaquium burckii*), E. M. HUME and H. H. SMITH (*Biochem. Jour.*, 20 (1926), No. 2, pp. 340-342).—It is reported that mixed sterols prepared from the fat of the small Siak Illipe nut, *P. burckii*, acquire antirachitic properties on irradiation in the same way as cholesterol and phytosterol, but contain no appreciable amount of vitamin A either before or after irradiation. The authors' technique for determining vitamin D is as follows:

Young rats are placed on a diet deficient in fat-soluble vitamins at a weight of about 40 gm. and are kept on this diet for 33 days, at which time they are growing very slowly. Under these conditions the application of an antirachitic stimulant through irradiation or food is followed by growth at a much more

rapid rate for a time, followed by a decline in weight and death. The bones of such rats are more highly calcified than the controls. The basal diet is composed of inactivated caseinogen, starch, hardened cottonseed oil, marmite, lemon juice, and a salt mixture. The material to be tested is given embedded in a small pellet of white bread and hardened cottonseed oil, the control rats receiving the pellet without the material to be tested.

Puffer fish oil; a very potent antirachitic; its elaboration by fish deprived of sunlight, A. F. HESS and M. WEINSTOCK (*Soc. Expt. Biol. and Med. Proc.*, 23 (1926), No. 6, pp. 407, 408).—This brief note is of interest as indicating that the antirachitic potency of fish liver oil is dependent on the diet of the fish rather than on the action of ultra-violet radiations. Puffer fish from a batch some of which had been used for tests for antirachitic vitamin were kept for three months in an aquarium away from sunlight. During this time the livers became exceptionally rich in oil, the average amount increasing from 5 to 55 per cent. The oil at the end of three months was as rich in vitamin A as that tested at the beginning of the experiment. The diet of the fish consisted largely of herring, which is rich in antirachitic vitamin, and this is thought to account for the richness of the oil in this vitamin.

Studies on experimental rickets.—XXVII, Variation of vitamin D content of butterfat as a factor in the development of rickets induced by diets suitable for preparing rats for the line test, E. V. MCCOLLUM, N. SIMMONDS, J. E. BECKER, and P. G. SHIPLEY (*Jour. Biol. Chem.*, 70 (1926), No. 2, pp. 437, 438).—Attention is briefly called to the necessity of keeping the butterfat in rickets-producing diets as low as possible on account of its varying content of vitamin D. On changing the source of butterfat in experiments in which the diets recommended in the previous paper of the series (E. S. R., 54, p. 295) were used, protection against rickets was secured with 5 per cent of the butter, but not when this was lowered to 1 and 2 per cent. The necessity is also pointed out of maintaining a constant phosphorus and calcium content in rickets-producing diets when used for testing natural foods for vitamin D. "Regulation of the phosphorus content can be accomplished by replacing a part of either the casein, gelatin, or egg albumin and a part of the dextrin if necessary by such an amount of the food to be studied as will equal these in protein and phosphorus content."

Concentrated orange juice, source of vitamine C, C. P. WILSON (*Calif. Citrogr.*, 12 (1926), No. 1, pp. 2, 20, 21).—This paper consists chiefly of a review of papers by Goss (E. S. R., 53, p. 458) and Priston (E. S. R., 55, p. 194) on the preparation and antiscorbutic properties of a commercial concentrated orange juice preparation, "Califorange."

The present status of our knowledge of the etiology of pellagra, J. GOLDBERGER (*Medicine*, 5 (1926), No. 2, pp. 79-104, figs. 5).—This is a discussion of various theories concerning the etiology of pellagra, leading up to the author's present theory that it is due to the lack of a pellagra-preventing vitamin P-P, possibly identical with vitamin B.

Simple goiter and its prevention, D. MARINE (*Jour. Amer. Med. Assoc.*, 87 (1926), No. 18, pp. 1463, 1464).—A brief summary of modern views concerning the cause of simple goiter and the best means for its prevention. "One can say that the factors which cause simple goiter center about the supply of iodine and the needs, normal and abnormal, of the thyroid gland for iodine. Supplying this element in amounts that can be considered as roughly approximating the physiologic needs of the body has resulted in completely controlling the disease both in man and in animals."

TEXTILES AND CLOTHING

Collecting the literature of textiles, C. F. GOLDTHWAIT (*Amer. Dyestuff Rptr.*, 15 (1926), No. 20, pp. 802, 803).—The filing system outlined has been applied to almost the whole textile field from raw materials to clothing, including textile chemistry.

The flax, hemp, and jute year book, compiled by H. R. CARTER (*Belfast: H. R. Carter, 1926, 3. ed., rev., pp. 276, pls. 35, figs. 27*).—This manual reviews the history and commercial status of flax, hemp, and jute, and describes in some detail the processes involved in preparing textiles therefrom. Mechanical information and a technical glossary in English, French, and German are also included.

Application of X-rays in the textile industry, G. L. CLARK (*Amer. Dyestuff Rptr.*, 15 (1926), No. 20, pp. 788-795, figs. 10).—This contribution from the Massachusetts Institute of Technology shows the nature of X-rays and the types of information to be gained from X-ray photographs of textile materials. The results of X-ray studies on cellulose are summarized, and it is shown that information of value may also be obtained by the use of X-ray methods in the study of dyes.

Molecular structure of plant fibers determined by X-rays, O. L. SPONSLER (*Jour. Gen. Physiol.*, 9 (1926), No. 5, pp. 677-695, figs. 10).—According to this contribution from the southern branch of the University of California, the wall of the plant fiber is probably built up of unit groups of atoms which have assumed the form of a space lattice. The elementary cell of the lattice is an orthorhombic structure with the dimensions $6.10 \times 5.40 \times 10.30$ Å. u., and contains two unit groups equal in size to two $C_6H_{10}O_5$ groups. The crystallographic unit cell would contain four of these elementary cells. The groups of atoms, $C_6H_{10}O_5$, are arranged in parallel chains running lengthwise of the fiber, and in each chain the odd-numbered groups have a different orientation from the even numbered. The chains parallel to one another are spaced 6.10 Å. u. in one direction and 5.40 Å. u. at right angles to that. In these two directions the odd-numbered chains also would differ in orientation from the even. On account of the cylindrical shape of the fiber, the elementary cells are arranged in the form of concentric cylinders or layers. The dimensions of the fibers are such that the fiber wall is about 40,000 elementary cells in thickness, i. e., is composed of that many concentric layers.

Studies of the bacterial decomposition of textile fibres.—IV, Note on the action of *B. subtilis* and *B. mesentericus* on cellulose, A. C. THAYSEN and H. J. BUNKER (*Biochem. Jour.*, 20 (1926), No. 4, pp. 692-694).—Experiments at the Royal Naval Cordite Factory at Dorset, England, failed to show that either *B. subtilis* or *B. mesentericus* is capable of decomposing cotton fibers.

The swelling of cotton fibres, A. J. HALL (*Textile Colorist*, 48 (1926), No. 575, pp. 744-746, figs. 7).—The changes in the diameter of cotton fibers caused by the atmosphere, mercerization, washing, drying, alkalies, and acids are discussed briefly.

A test for mercerised cotton, H. MENNELL (*Jour. Textile Inst.*, 17 (1926), No. 5, p. T247).—The test described consists in immersing a sample of the material, together with standard mercerized and unmercerized samples, for 2 minutes at room temperature in a mixture of 320 cc. of sulfuric acid, specific gravity 1.6, and 260 cc. of 40 per cent formaldehyde solution, washing the samples, and neutralizing with hot dilute sodium carbonate solution. The samples are then dyed in a dilute boiling bath of Chlorazol Sky Blue GW made alkaline with sodium carbonate and the colors compared. If the sample to be tested is already dyed, the color may be removed with sodium hypochlorite or hot alkaline hydrosulfite without affecting the test in any way.

On the question of the standardisation of wool in the preparation of international wool statistics, H. HENSELER (*Internatl. Rev. Sci. and Pract. Agr.* [Rome], n. ser., 4 (1926), No. 3, pp. 513-534, pls. 9).—A detailed discussion of the method of judging the fleece and wool of sheep, used at the Technischen Hochschule of Munich.

Dyes not fast to ironing [trans. title], R. HALLER (*Kolloid Ztschr.*, 38 (1926), No. 3, pp. 248-253; *abs. in Chem. Abs.*, 20 (1926), No. 18, p. 3086).—Investigation of the nature of the dyeing process when blue and violet benzidine dyes are used on cotton, wool, and acetate-silk fibers, with special reference to the reversible color change (blue to corinth red) when the dyed cotton is touched with a hot iron, confirmed the view that these dyes form colloidal solutions of different degrees of dispersion, the larger particles coloring cotton fiber blue and the smaller particles corinth red. Solutions with a low degree of dispersion are particularly sensitive to temperature changes or to variations in the medium employed. Thus in hot dye baths wool and cotton are dyed red by aqueous solutions but on cooling the color on the cotton becomes blue-violet. Alcoholic solutions hardly affect wool, but dye cotton a permanent corinth red. The effect of touching the dyed cotton with heated metal is to increase the degree of dispersion of the dye on the fabric, with change of color from blue to red.

The largest particles, which are colorless, are first deposited, then a layer of smaller violet particles, and lastly a small zone of corinth red particles. This indicates a fixed relationship between the degree of dispersion of the coloring matter and that of the adsorbent. The surface of the adsorbent plays a decisive part also when fibers are used, for swelling causes inner micellar surfaces to come into play, the difference in the sizes of these accounting for the different behavior of different adsorbents. Wool and acetate silk after swelling have larger inner surfaces than cotton. The reddening of blue dyed cotton is also produced by desiccation over sulfuric acid but to a less extent than by heating. The hypothesis of Justin-Mueller that two forms of the dye exist, one containing water and the other water free, while not consistent with all experimental facts, is applicable to the portion of the dye existing in a low degree of dispersion. The observed color changes on heating and drying may thus be connected with dehydration and simultaneous increase in the degree of dispersion.

Principles of window curtaining, M. A. DAVIS (*U. S. Dept. Agr., Farmers' Bul.* 1516 (1926), pp. II+38, figs. 34).—This contribution from the Textiles and Clothing Division of the Bureau of Home Economics has been planned as a guide to the home maker in selecting, making, and hanging curtains suitable for the different rooms of an average home. The art principles of lines, proportion, balance, color, and texture and pattern with relation to window curtaining are first discussed, after which the recognized curtains for windows are classified, with the kinds of materials best suited to each. The proper selection as to type and materials of curtains for the different rooms of a house, specific directions for making the various types of curtains, and a classified list of curtain materials complete the publication, which is illustrated throughout with half tones of interiors and line drawings.

HOME MANAGEMENT AND EQUIPMENT

Convenient kitchens, G. GRAY (*U. S. Dept. Agr., Farmers' Bul.* 1513 (1926), pp. II+30, figs. 31).—This supersedes Farmers' Bulletin 607 (E. S. R., 32, p. 65). It contains practical information on the planning and arrangement of convenient kitchens and includes numerous working drawings.

MISCELLANEOUS

Report of the Guam Agricultural Experiment Station, 1925, C. W. EDWARDS ET AL. (*Guam Sta. Rpt. 1925, pp. II+20, figs. 13*).—This contains reports of the director, the assistant in agronomy and horticulture, and the entomologist, and meteorological observations. The experimental work recorded is for the most part abstracted elsewhere in this issue.

A year's progress in solving some farm problems of Illinois: Thirty-eighth Annual Report [of Illinois Station, 1925], compiled and edited by F. J. KELHOLZ (*Illinois Sta. Rpt. 1925, pp. 191, figs. 42*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1925, a summary of the principal lines of work and publications of the year. The experimental work reported and not previously noted is for the most part abstracted elsewhere in this issue.

Abstracts of papers not included in bulletins, finances, meteorology, index (*Maine Sta. Bul. 328 (1925), pp. 253-275+XV, pl. 1*).—This contains the organization list of the station; abstracts of 9 papers, 6 of which were previously noted and another abstracted elsewhere in this issue; meteorological observations, noted on page 207; a financial statement for the fiscal year ended June 30, 1925; an index to Bulletins 322-328, inclusive, which collectively constitute the forty-first annual report of the station; a tribute by W. H. Jordan to former Director C. D. Woods; and announcements as to the work and publications of the station.

Annual Report of [Nevada Station], 1925 [S. B. DOTEN] (*Nevada Sta. Rpt. 1925, pp. 20, figs. 2*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1925, lists of station projects and publications, and a report of the director discussing the work and problems of the station during the year. The experimental work reported is for the most part abstracted elsewhere in this issue.

Forty-fifth Annual Report of the New York State Agricultural Experiment Station [1926], R. W. THATCHER (*New York State Sta. Rpt. 1926, pp. 69*).—This contains the organization list, a review of the work and publications of the station, meteorological observations noted on page 207, and a financial statement for the fiscal year ended June 30, 1926. The experimental work reported is for the most part abstracted elsewhere in this issue.

Bimonthly Bulletin of the Ohio Agricultural Experiment Station [November-December, 1926] (*Ohio Sta. Bimo. Bul., 11 (1926), No. 6, pp. 209-256, figs. 17*).—This number contains, in addition to several articles abstracted elsewhere in this issue, the following: Meat Meal Versus Meat Scraps for Egg Production, by D. C. Kennard, and Storage of Potatoes.

NOTES

Arizona University and Station.—A wool laboratory has been completed for use in the animal husbandry work. This will enable the station to make careful studies of wool and mohair produced in Arizona in relation to quality, strength, shrinkage, and scouring.

Dr. O. C. Magistad, soil chemist for a commercial fruit company in Honduras, has been appointed associate professor of agricultural chemistry and associate chemist in the station, beginning March 1.

Cornell University.—A gift of \$130,000 for the endowment of a research professorship in forest soils has been made by the Charles Lathrop Pack Forestry Trust, together with additional funds for operating expenses in the advanced line of investigation to be undertaken. The chair will be named for Mr. Pack, founder of the trust and the maker of other large gifts for the promotion and support of education in forestry. Among these are the Charles Lathrop Pack Demonstration Forest, a 2,500-acre tract of white pine land on the main Adirondack highway near Lake George, and land or endowments to the New York State College of Forestry, the Yale Forest School, and the University of Washington.

The research work contemplated will be done in the College of Agriculture, and it is hoped to select its head in the near future. The proposed line of investigation is a new development in forest research in this country. Although in the northeastern hardwood area, extending over the Middle Atlantic States and as far west as Indiana and Illinois, the question of proper forest care and operation depends very largely upon a study of soil conditions, practically no data on forest soils are at present available. The attempt will be made to coordinate studies in several fields of science, applying what is learned to the special soil problems involved in growing healthy forests. As the announcement states, "this research will necessarily deal with the chemistry and biology of soils. It will naturally have intimate relation with the field of heredity in tree growth, particularly as it should help to solve problems of adapting certain varieties of trees to given soils. And it will similarly have a bearing on the field of plant pathology, because of the relation that soil conditions bear to diseases of trees."

International Congress of Agriculture.—The thirteenth congress is scheduled to meet at Rome from May 23 to 28. Its program will be divided into six sections, termed, respectively, international conference of agricultural associations, which will consider the position of agriculture and the work of agricultural associations; agricultural cultivation and industry, which will discuss the cultivation of cereals from an economic and social point of view; zootechny, which will deal with the problem of the world production of meat and milk from an economic and social viewpoint; training and cooperation in the agricultural industry, which will consider the scientific organization of agricultural work; agricultural geology and climatology; and the women's section, which will deal with women's organizations in rural districts, domestic economy, training for rural women, and the development of rural life.

EXPERIMENT STATION RECORD

Editor: H. L. KNIGHT

EDITORIAL DEPARTMENTS

Agricultural and Biological Chemistry—SYBIL L. SMITH.
Meteorology—W. H. BEAL.
Soils and Fertilizers—R. W. TRULLINGER.
Agricultural Botany and Diseases of Plants—W. H. EVANS, Ph. D., W. E. BOYD.
Genetics—H. M. STEECE, J. W. WELLINGTON, G. HAINES.
Field Crops—H. M. STEECE.
Horticulture and Forestry—J. W. WELLINGTON.
Economic Zoology and Entomology—W. A. HOOKER, D. V. M.
Animal Husbandry, Dairying, and Dairy Farming—G. HAINES.
Veterinary Medicine—W. A. HOOKER.
Agricultural Engineering—R. W. TRULLINGER.
Rural Economics and Sociology, Agricultural and Home Economics Education—
F. G. HARDEN.
Foods and Human Nutrition—SYBIL L. SMITH.
Textiles and Clothing—H. M. STEECE, SYBIL L. SMITH.
Home Management and Equipment—F. G. HARDEN, R. W. TRULLINGER.
Indexes—MARTHA C. GUNDLACH.
Bibliographies—ANNA HOWARD.

CONTENTS OF VOL. 56 NO. 4

	Page
Editorial notes:	
The agricultural appropriation act, 1927-28.....	301
Recent work in agricultural science.....	309
Notes.....	399

SUBJECT LIST OF ABSTRACTS

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

A half-century of chemistry in America, 1876-1926, edited by Browne.....	309
Recent advances in biochemistry, Pryde.....	309
Practical organic and bio-chemistry, Plimmer.....	309
A text-book of organic chemistry, Holleman, edited by Walker and Mott.....	309
Progress of applied chemistry, 1923, [1924, and 1925], edited by Burton.....	309
Chemical synonyms and trade names, Gardner.....	309
Manual for the dairy chemist, Labarre.....	310
The fats, Leathes and Raper.....	310
Substitutes for ethyl alcohol in citrus flavors, Schuette and Domogalla.....	310
The phytosterols of corn oil, Anderson and Shriner.....	310
The phytosterols of rice bran fat, Nabenhauer and Anderson.....	310
The phytosterols of wheat germ oil, Anderson, Shriner, and Burr.....	310
The viscosity of pectin sols, Ohn.....	310
Acetyl groups in pectin, Nelson.....	311
The chemistry of grape pigments, IV, Anderson and Nabenhauer.....	311
The antiscorbutic fraction of lemon juice, IV, Daubney and Zilva.....	311
Non-volatile constituents of the cotton plant, Power and Chesnut.....	311
A modification of the deflection balance, Trevan.....	312
Indicators: Their use, Kolthoff, trans. by Furman.....	312
A rapid colorimetric method of estimating pentoses, McCance.....	312

	Page
Fat content of breads and cereals, Cormack.....	312
Estimation of iodine in foodstuffs and body fluids, Leitch and Henderson.....	312
The search for colour reactions of vitamin "A," Cocking and Price.....	313
The estimation of calcium in blood-serum, Trevan and Bainbridge.....	313
The analysis of pigments, paints, and varnishes, Fox and Bowles.....	313
Furfural steps into industry, Killeffer.....	313

METEOROLOGY

Monthly Weather Review, [September-October, 1926].....	313
Solarimeters and solarigraphs, Gorczyński.....	314
Forecasting precipitation from local data, Ray.....	314
Persistence of weather types in the Hawaiian Islands, Loveridge.....	314
Weather and sugar cane in Louisiana, McDonald.....	314
Wind as motive power for electrical generators, Carter.....	315

SOILS—FERTILIZERS

Biophysical and biochemical investigation of soil, Stoklasa and Doerell.....	315
Simplification of mechanical analysis of soil, Smolik.....	315
Soil survey of Garrett County, Maryland, Snyder et al.....	315
Soil survey of Ottawa County, Michigan, Veatch et al.....	315
Soil survey of the Las Vegas area, Nevada, Carpenter and Youngs.....	316
Soil survey of Cayuga County, New York, Lewis et al.....	316
Soil survey of Grant and Mineral Counties, West Virginia, Phillips.....	316
Terracing in Alabama, LeBron and Nichols.....	316
Behavior of moist, air-dried, and repeatedly dried soils, Káš.....	316
The movement of soil moisture in the vapor phase, Parts I, II.....	317
Soil moisture in relation to the growth of crop plants, Shantz.....	317
Soil reactions in relation to plant successions, Geisler.....	317
Relation of soil to plant cell sap, McCool.....	318
Growth of microorganisms in soil, Wilson and Lyon.....	318
[Soil bacteriology work at the Delaware Station], Manns.....	318
Distribution of Azotobacter in Bavarian soils, Niklas et al.....	319
Nitrate studies on a manured and unmanured soil, Murphy.....	319
[Soil fertility studies at the Arkansas Station].....	319
[Soil management and fertility studies at the Illinois Station].....	319
Soil treatment and production in Nelson district, 1924-25, Rigg et al.....	319
The absorption of fertilizers by Ceylon soils, Joachim.....	320
Decomposition of manure in soil and its utilization by plants, Bach.....	320
Substances in rains and snows, Ribble and Bowman.....	321
Some tests with Soilgro, Leonard.....	321
Spreading of lime nitrogen with soil, Blanck and Giesecke.....	321
Mixtures of urea with phosphatic and potassic fertilizers, Boischot.....	321
Test soils for water-soluble phosphorus, Spurway.....	321
Colloidal phosphate, Bottini.....	321
Cropping experiments with sericite, Blanck and Alten.....	322
Degree of resistance of different limes toward acid solutions, Bottini.....	322
Residual effects of 40 years manurial treatment, III, White and Hoiben.....	322
The Missouri fertilizer law, Mumford and Haigh.....	322
Testing fertilizers—spring, 1926, Haigh.....	322
Inspection of commercial fertilizers for 1926, Phillips et al.....	323

AGRICULTURAL BOTANY

Corn stalks vs. field plots as a guide to fertility, Welton et al.....	323
Influence of potash on cotton bolls and foliage, Skinner and Pate.....	323
Essential nature of aluminum and silicon for plant growth, Sommer.....	323
Soluble aluminium in relation to plant growth, Line.....	323
The toxicity of water distilled in metallic vessels, Lesage.....	323
Copper injury to cabbage plants, Detjen and Gray.....	324
Theory of regeneration based on mass action, II, Loeb.....	324
[Studies on the plasma membrane], Weis.....	324
Permeability in <i>Beggiatoa mirabilis</i> , Ruhland and Hoffmann.....	324
Changes in H-ion concentration in nutrient solutions, I, II, Jacobson.....	324
Effects on plasma of H ions, Sakamura and Loo.....	325

	Page
The genesis of starch in cereals, Belval.....	325
The influence of chemical agencies on starch content and osmotic values in stomatal guard cells, Arends.....	325
A new product of sugar transformation by fungi, Butkewitsch.....	325
Significance of acid amids for nitrogen exchange in plants, Mothes.....	325
Asparagine in transformations of nitrogenous materials, Prianichnikov.....	325
Light and growth, Priestley.....	325
The daily course of photosynthesis in land plants, Kostytshew et al.....	325
The physiology of paraheliotropism, Nuernbergk.....	326
Geotropic sensitivity in negatively geotropic plant organs, Herzog.....	326
Temperature relations in wound reactions, Potter.....	326
The injection of lacunae as a sign of death in aquatic plants, Devaux.....	326
[Seeds and X-rays], Ancel.....	326
Torsion in developmental movements of leaves, Seybold.....	326
Accessory buds, Sandt.....	326
Biological study of blooming of flowers, Davy de Virville and Obaton.....	326
Seeds and plants imported from January 1 to March 31, 1924.....	326
Bergey's manual of determinative bacteriology, Bergey et al.....	326

GENETICS

Genetics in South Africa: Heredity and environment, Duerden.....	327
The nature of hereditary factors, Lübbischew.....	327
The new preformationist doctrine, Yampolsky.....	327
Recent advances in cytology, Sharp.....	327
Cytological studies in the genus <i>crataegus</i> , Longley.....	327
Soy bean investigations, Schuster.....	327
Maturation divisions and segregation of chromosomes, Carothers.....	327
Chromosome numbers in crop plants, Aase and Powers.....	327
Chromosome VIII in maize, Eyster.....	328
A chemical conception of genes, Schmalfluss.....	328
Mutations in the sweet potato, Rosa.....	328
The irrelevant nature of the question whether new characters can be produced by fresh combinations of pre-existing ones, Lotsy.....	328
Some wool characters and their inheritance, Davenport and Ritzman.....	328
Lethal factors with regard to behavior in animals and man, Mohr.....	329
A case of pollen dimorphism in maize, Demerec.....	329
Nature and conditions of formation of esculent roots, Sinskaia.....	329
Barley with orange lemmas, Bauman.....	329
The variability of crossing over in maize, Stadler.....	330
Hybrid vigor in cow peas, Hofmann.....	330
The segregation of <i>Oenothera nanella-brevistylis</i> from crosses with <i>nanella</i> and with <i>lamarckiana</i> , Davis.....	330
A haploid wheat plant, Gaines and Aase.....	330
On the actual existence of leporides, Kuiper.....	330
Correlation and machine calculation, Wallace and Snedecor.....	330
Weight of new-born, growing, and full-grown rabbits, Kopeć.....	330
Ovulation in the rabbit, Snyder.....	331
Anthropological studies of single and double ovum twins, Verschuer.....	331
Invariable production of deciduomata in the virgin rat with anterior hypophyseal fluid, Teel.....	331
On the analysis of the morphogenesis in animals, Zawadowsky.....	331
Chemical differences in blood as related to sex, Needels.....	331

FIELD CROPS

Mathematics and agronomy, Student.....	332
The arrangement of field experiments, Fisher.....	332
[Field crops experiments in Arkansas].....	332
[Field crops experiments in Illinois].....	333
[Field crops work in Northumberland County, England], Gilchrist.....	334
[Report of the] Scottish Society for Research in Plant-breeding, Robb.....	334
Maori agriculture, Best.....	334
East African pasture plants.—I, East African grasses, Hubbard et al.....	334
Pasture studies, Wiggans.....	334

	Page
[Experiments with legumes in Illinois]-----	335
Sunflowers as compared with corn as a silage crop for New York, Wiggins-----	336
The barley crop, Hunter-----	337
Some observations on white clover, Adams-----	337
Corn production in Kansas, Salmon-----	337
Relation of weather to date of planting potatoes in Ohio, Bushnell-----	337
Potato spraying and dusting experiments, 1921 to 1925, Folsom and Bonde-----	338
Proceedings of twelfth meeting of Potato Association of America-----	338
The germination of lowland rice, Suzuta-----	339
Date of seeding winter rye when the ground is dry or wet, Hume et al-----	339
Tobacco from Palestine, Nigeria, and Mauritius-----	339
Relation of yield of wheat to nitrogen of soil, Neidig and Snyder-----	339
Characteristics of wheats grown under identical environment, Herman-----	340
The commercial protein test of wheat, Whitcomb and Lewis-----	340

HORTICULTURE

[Horticultural investigations at the Arkansas Station]-----	340
[Horticultural investigations at the Delaware Station]-----	341
[Horticultural investigations at the Illinois Station]-----	342
Research in vegetable gardening, Thompson-----	344
Nitrate utilization by asparagus in the absence of light, Nightingale and Schermerhorn-----	344
Government inspection of nurseries to eliminate variety mixtures, Upshall-----	344
Notes on hardy orchard cover crops, Barnett-----	344
The nitrogen and carbohydrate composition of the developing flowers and young fruits of the apple, Howlett-----	345
Picking maturity of apples in relation to storage, Magness et al-----	345
Use of plant characters in identification of raspberry varieties, Winter-----	345
Experiments with fertilizers for coffee in Porto Rico, McClelland-----	345
Trees and shrubs of California gardens, Saunders-----	346

FORESTRY

Soil and moisture relationships of sweet gum and river birch, Trenk-----	346
The occurrence of hickories in Iowa in relation to soil types, Trenk-----	346
Mixed white pine and hardwood, Cline and Lockard-----	346
Germination of some pines and other trees, Pammel and King-----	347
Scotch pine pollen in Copenhagen, May 25, 1804, Oppermann-----	347
Douglas fir in Poland, Suchocki-----	347

DISEASES OF PLANTS

Plant diseases-----	347
Department of plant pathology, Manns and Adams-----	348
[Plant disease investigations at the Illinois Station]-----	348
Economic plant diseases common in Kansas and their control, Melchers-----	349
Destruction of insect and fungus or fungoid pests, Benson-----	349
Metabolism in Botrytis, Hunter and Berkeley-----	349
Mosaic studies, IV, Dickson-----	349
Effects of salt and H-ion concentration on bacteria and moulds, Reed-----	350
Equipment and methods for studying relation of soil temperature, Leukel-----	350
Simultaneous surveys for stem rust, Freeman and Melander-----	350
Seed treatment for smut control, Fraser and Simmonds-----	350
Experiments in oat smut control in 1923, Howitt and Stone-----	350
Smut control experiments in hull-less oats during 1923, Dickson et al-----	350
Pickling wheat with carbonate of copper, Quodling-----	350
"Take-all" of wheat in western Canada, Fraser-----	350
<i>Sclerotinia intermedia</i> n. sp. in salsify and carrots, Ramsey-----	350
A native weed host for bacterial blight of bean, Gardner-----	351
Bacterial rot of cauliflower, Géray-----	351
Cotton diseases in Porto Rico, Cook-----	351
A leaf spot of <i>Phaseolus aureus</i> new to the Philippine Islands, Welles-----	351
White rot of Allium in Europe and America, Walker-----	351
Root rot and blight of canning peas, Stone-----	351
Copper dusts and sprays in control of potato diseases and insects, Boyd-----	351

	Page
Results of experiments to prevent potato Rhizoctonia, Howitt.....	352
Potato varieties resistant to wart disease, De Vilmorin.....	352
Witches' broom of potatoes in the Northwest, Hungerford and Dana.....	352
Sugar production and cane diseases, Cook.....	353
Cane pests and diseases, Cottrell-Dorner.....	353
Rust resistance in timothy, Barker and Hayes.....	353
Tomato diseases, Berkeley.....	353
The physiological drop of fruits in Delaware, Detjen and Gray.....	353
<i>Sphaeropsis matorum</i> and <i>Myxosporium corticola</i> in Oregon, Zellar.....	353
Apple measles in Missouri, Rhoads.....	353
Note on an Exoascus disease on <i>Prunus amygdalus</i> var. <i>amara</i> , Campbell.....	354
Raspberry diseases, Berkeley and Jackson.....	354
A note on raspberry canker (<i>Nectria rubi</i> Osterwalder), Alcock.....	354
Blue stem of red and black raspberry, Berkeley and Jackson.....	354
Strawberry black root, Berkeley and Jackson.....	354
Bunchy top in bananas, Goddard, Magee, and Collard.....	354
Pineapple chlorosis, Cook.....	354
The aecial stage of <i>Hyalospora aspidiotus</i> , Faull and Darker.....	354
<i>Stereum sanguinolentum</i> as the cause of "sapin rouge" or red heart rot of balsam, Faull and Mounce.....	355
The pathological anatomy of tissue produced in <i>Abies balsamea</i> following an attack of the spruce budworm, McLeod.....	355
Chestnut blight in Ontario, Stone.....	355
Some silvicultural aspects of the chestnut blight situation, Frothingham.....	355
Coryneum twig bight of Manitoba maple, Howitt.....	355
The self pruning of western yellow pine, Long.....	355

ECONOMIC ZOOLOGY—ENTOMOLOGY

Animal pests of useful plants, I, Blunck et al.....	355
Rabbit and mouse control in the orchard, Talbert.....	355
Analysis of the growth curves of the insect larvae, Yagi.....	355
Entomology [at the Arkansas Station].....	355
[Investigations of economic insects], Dozier.....	356
[Insect control investigations at the Illinois Station].....	357
Biological control of pests in the Hawaiian Islands, Imms.....	357
[Reports of the entomologist for the years 1924 and 1925], Jarvis.....	358
Catalogue of Indian insects. IV-X.....	358
Utilization of calcium cyanide in control of pests in India, Brittain.....	358
Calcium cyanide and control of pests in Ceylon, Brittain.....	358
Studies on contact insecticides, IV, Tattersfield.....	358
Toxicity of 3:5-dinitro-o-cresol to insect eggs, Gimmingham et al.....	359
Fruit insect problems for 1925, Cory.....	359
Control of Porto Rican mole-cricket, or changa, on golf courses, Thomas.....	359
The influence of temperature on <i>Locusta migratoria</i> L., Pospelov.....	360
Life history of <i>Helopeltis</i> on cotton in Southern Nigeria, Lean.....	360
Controlling mealybugs on ornamental plants, Doane.....	360
The silver fir chermes, Chrystal.....	360
The development of the ovary in the silkworm (<i>Bombyx mori</i>), Machida.....	360
Sixth year's work against gipsy moth in New Jersey, Weiss et al.....	360
The potato tuber moth, Cory.....	360
Biology of the green bud worm and eye-spotted budmoth, Woroniecka.....	360
The peach tree borer, Pepper.....	360
<i>Theresia ampelophaga</i> Bayle in Crimean vineyards, Fedorov.....	360
The European corn borer: Relation of larvae to submergence, Crowell.....	360
Notes on the sweet potato pyralid moth, <i>Megastes grandalis</i> , Cowland.....	361
The European pine-shoot moth (<i>Evetria buoliana</i> Schiff.), Tempel.....	361
Development of <i>Simaethis</i> (<i>Hemerophila</i>) <i>pariana</i> , Minkiewicz.....	361
The larger narcissus bulb-fly, McDaniel.....	361
The Queensland fruit fly (<i>Chaetodacus tryoni</i> Froggatt), Jarvis.....	361
North American cerambycid larvae, Craighead.....	361
The coffee berry-borer (<i>Sephanoderes hampei</i>) in Uganda, Hargreaves.....	362
The tuart bud weevil (<i>Haplonyx tibialis</i>), Newman and Clark.....	362
Hymenoptera and paratyphoid (?), Müller.....	362
Studies of <i>Bacillus larvae</i> , the cause of American foulbrood, Lochhead.....	362
Notes on encyrtidae bred from psyllids, Gahan and Waterston.....	362

	Page
A new trichogrammatid parasite of the cotton stemborer, Waterston.....	362
Descriptions of new coccid-inhabiting chalcidoid parasites, Compere.....	362
The woolly aphis parasite (<i>Aphelinus mali</i> Hald.), Gurney.....	362
The woolly aphis parasite (<i>Aphelinus mali</i> Hald.), Jarvis.....	362
British spiders: Their haunts and habits, Savory.....	362
A new invertebrate host of <i>Trypanosoma cruzi</i> Chagas, Uribe.....	362

ANIMAL PRODUCTION

[The biological values of proteins].....	363
Dietary requirements for reproduction.....	363
Fowler's solution cuts size of rabbit litters.....	363
Effects of fluorine on bone formation.....	363
Tests show best type of corn to use for silage.....	363
Inspection of commercial feeding-stuffs, Phillips et al.....	363
Cattle feeding investigations, 1924-25, McCampbell et al.....	364
Cattle feeding investigations, 1925-26, Anderson and Marston.....	364
Economic beef production investigation.....	365
Wintering stock steers, Potter and Withycombe.....	365
Sweet clover fell short in 1925 as beef pasture.....	366
A mineral deficiency in the rations of cattle, Eckles et al.....	366
[Feeding experiments with sheep at the Illinois Station].....	367
Lamb feeding experiments, 1925-1926, Johnson.....	368
Lamb feeding investigations, 1925-26, Reed and Marston.....	368
[Feeding experiments with swine at the Arkansas Station].....	369
[Feeding experiments with swine at the Delaware Station], Tomhave.....	369
[Experiments with swine at the Illinois Station].....	370
Hogging down corn, Robison.....	371
Fillies wintered well on oats, soybean roughage.....	371
[Experiments with poultry at Delaware Station], Tomhave and Mumford.....	372
[Experiments with poultry at the Illinois Station].....	372
The effect of various sources of animal protein, Kistler et al.....	373
Relative value of certain root crops and salmon oil as sources of vitamin A for poultry, Davis and Beach.....	373
Feeding chickens, Sherwood.....	373
Fitting and exhibiting standard-bred poultry, Steup.....	374

DAIRY FARMING—DAIRYING

Composition and feeding value of hydrolyzed sawdust, Archibald.....	374
[Feeding experiments with dairy cattle at the Arkansas Station].....	375
[Experiments with dairy cattle at the Illinois Station].....	375
[Experiments in dairying at the Illinois Station].....	376
Control of market milk sold by a Michigan dairy, 1922-1925, Cooledge.....	376
[Experiments at the Arkansas Station with neutralizers and starters].....	376
A suggested bacteriological standard for ice cream, Fabian.....	377

VETERINARY MEDICINE

[Animal disease investigations at Delaware Station], Palmer and Baker.....	377
Anti-abortion vaccines.....	377
Anthrax prophylaxis.....	378
Foot-and-mouth disease, Mohler.....	378
Inclusion bodies in foot-and-mouth disease, Trautwein.....	378
Immunization against foot-and-mouth disease, Vallée et al.....	378
Foot-and-mouth disease: Control by chemotherapy, Walker and Taylor.....	378
Foot-and-mouth disease, Vendel.....	379
Avian tuberculosis can be transmitted to calves.....	379
[Investigations of swine diseases at the Illinois Station].....	379
Bacillary white diarrhea in fowl, Bushnell et al.....	380
[Bacillary white diarrhea investigations at the Illinois Station].....	381
Avian diphtheria, roup, and bird pox vaccines and bacterins, Pyle.....	381

AGRICULTURAL ENGINEERING

[Agricultural engineering studies at the Arkansas Station].....	381
[Agricultural engineering studies at the Illinois Station].....	382
Surface water supply of St. Lawrence River basin, 1923.....	382

	Page
Surface water supply of Hawaii, July 1, 1921, to June 30, 1922.....	382
Quality of water and industrial development in United States, Collins.....	382
The flow of water through culverts, Yarnell et al.....	383
Public Roads, [November, 1926].....	384
Binder and knotter troubles, Smith.....	384
Electric ploughing, Matthews.....	384
Dissipation of heat by cast-iron water radiators, Giesecke.....	384
Choosing a home electric lighting plant, Fogle.....	385
Septic tanks for farm sewage disposal, Cooper.....	385

RURAL ECONOMICS AND SOCIOLOGY

[Investigations in agricultural economics at Illinois Station, 1926].....	385
Rural economics and sociology.....	386
Farming in the Big Bend country, Spillman.....	386
Returns from the Arkansas radish crop in 1926, Brannen and Dickey.....	387
Woodlot taxation in Michigan, Dressel.....	387
Crops and Markets, [December, 1926].....	387
Cotton facts, compiled by Shepperson, rev. by Shepperson.....	387
Report on the grain trade of Canada . . . 1925, Dougan and Ursell.....	387
Report on the marketing of pigs in England and Wales.....	387
Report on the marketing of poultry in England and Wales.....	387
Expense factors in city distribution of perishables, Artman.....	387
Consumer habits and preferences in meat, Gardner and Adams.....	388
Possibilities of cooperative marketing, Thomsen and Hensley.....	388
Co-operative ideals and problems, Örne, trans. by Downie.....	388
Price fixing by governments, compiled by Lacy et al.....	388
Needed readjustments in rural life.....	389

AGRICULTURAL AND HOME ECONOMICS EDUCATION

Handbook of educational associations and foundations in United States..	389
Vocational agriculture in the present agricultural situation, Lane.....	389
The folk high schools of Denmark, Begtrup et al.....	389
The story of the women's institute movement, Robertson Scott.....	389
Report on the educational work of women's rural institutes.....	389
Source book for the economic geography of North America, Colby.....	389
The botany of sugar cane, Mameli de Calvino.....	389
An animal feeding experiment, Spencer.....	390
Agricultural journalism, Crawford and Rogers.....	390

FOODS—HUMAN NUTRITION

Nutritive value of Oriental foods, Ohn.....	390
Studies in Chinese economic botany, Shih.....	390
Influence of granulation on flour, Shollenberger and Coleman.....	390
Use of Missouri soft wheat flour in making light bread, Davis and Cline..	391
A bakery infection with <i>Monilia sitophila</i> , Reed.....	391
The dietetic value of oatmeal proteins, Hartwell.....	391
[Studies at the Illinois Station on milk composition and energy].....	392
Acidophilus milk proves desirable beverage.....	392
Fruit jellies—the rôle of pectin, Myers and Baker.....	392
The science of making sauerkraut, Fabian.....	392
Remedies being found for canned corn defects.....	393
Commercial varieties of dextrin and use in diets, Randoïn and Lecoq....	393
Calcium balance with hydrochloric acid milk, Flood.....	393
The antirachitic vitamin.....	393
Contributions to tropical physiology, Sundstroem.....	393
Growth standards for private school boys, Gray and Fraley.....	394
Metabolism of undernourished children, I-III, Wang et al.....	395
Goiter in children in New York City, Cohen.....	396

TEXTILES AND CLOTHING

Strength tests at any atmospheric conditions, Morrill.....	396
Result of light-fastness tests.....	396
Odors in woolen goods, Textus.....	397
Fur-dyeing and fur dyes in America, Austin.....	397

	Page
Quilts: Their story and how to make them, Webster-----	397
A book of hand-woven coverlets, Hall-----	397
Clothing: Choice, care, cost, Woolman-----	397
Standard hosiery lengths, Schenke and Schoffstall-----	397

MISCELLANEOUS

Thirty-eighth Annual Report [of Arkansas Station], 1926, Gray-----	397
Annual report of the director for 1926, McCue et al-----	397
Thirty-ninth Report [of Illinois Station, 1926], compiled by Keilholz-----	397
Michigan Station Quarterly Bulletin, edited by Shaw and Hill-----	398
Publications available for free distribution-----	398

LIST OF EXPERIMENT STATION AND DEPARTMENT PUBLICATIONS ABSTRACTED

Stations in the United States

	Page
Arkansas Station:	
Bul. 214.....	387
Bul. 215 (Thirty-eighth Ann. Rpt. 1926).....	319,
332, 340, 347, 355, 363, 365, 369, 375, 376, 377, 378, 381, 386, 398.	
California Station:	
Bul 412.....	373
Delaware Station:	
Bul. 147 (Ann. Rpt. 1926).....	318,
324, 327, 341, 348, 353, 356, 369, 372, 377, 392, 398.	
Idaho Station:	
Research Bul. 5.....	339
Circ. 40.....	368
Circ. 41.....	398
Illinois Station:	
Thirty - ninth Ann. Rpt. 1926.....	319,
333, 335, 342, 348, 357, 363, 366, 367, 370, 371, 372, 375, 376, 379, 381, 382, 385, 392, 393, 398.	
Kansas Station:	
Bul. 238.....	337
Tech Bul. 21.....	380
Circ. 127.....	374
Circ. 128.....	364
Circ. 129.....	349
Circ. 130.....	364
Circ. 131.....	368
Maine Station:	
Bul. 334.....	338
Massachusetts Station:	
Tech. Bul. 10.....	381
Michigan Station:	
Spec. Bul. 158.....	377
Quart. Bul., vol. 9, No. 2, Nov., 1926.....	318,

EXPERIMENT STATION RECORD

VOL. 56

MARCH, 1927

No. 4

When presenting in these columns an interpretation of the successive acts making appropriations for the support of the Federal Department of Agriculture, reference has often been made to the general interest which seems to exist in the prospective financial resources and lines of development of the Department and the difficulties which are commonly encountered in attempting to utilize the appropriation acts as a basis of information without considerable explanation. Although the general form of this legislation has become relatively stabilized, seldom is the act for one year directly comparable with that of another because of the omission or inclusion of numerous items. An even more deceptive factor is the fact that some of the Department's funds come from other sources. Among these are the so-called "permanent" and "deficiency" appropriations and the variable but often important special appropriations provided in other legislation.

All of these complications enter into a comparison of the latest of these acts, covering the fiscal year ending June 30, 1928, with its immediate predecessor. The total amount available under the new act will be \$128,511,739, or including the permanent appropriations of \$11,351,250, which are continued unchanged, \$139,862,989. This is an apparent increase of \$227,166. However, it fails to take into account a special appropriation of \$10,000,000 for combating the European corn borer and certain deficiency items approved February 28, 1927, aggregating \$3,808,000 and in part available for the work of both fiscal years. Taken collectively these allotments swell the total appropriations to the Department to \$153,670,989, by far the largest amount ever granted.

From the standpoint of agriculture, the real situation is further obscured by the large proportion of these appropriations which is devoted to road construction. The total for this purpose carried in the act is \$77,500,000, with \$1,400,000 more in the First Deficiency Act, or slightly more than half of the total funds accredited to the Department. Viewed from another angle, as the roads funds in the act represent a decrease of \$2,500,000 from the previous act, there is a corresponding increase in the funds available for other purposes.

Including the large emergency corn borer appropriation and the deficiency allotment of \$2,155,000 for fighting forest fires during the fiscal year 1927, the net increase becomes \$14,380,166, or slightly less than 19 per cent.

This increase, which is perhaps the most significant figure which can be adopted for the purposes of this discussion, is for the most part concentrated in a few large items. Among these are \$1,200,000 additional for the payment of indemnities to farmers in connection with tuberculosis eradication work, \$1,192,000 being made immediately available; \$480,000 additional for the increased payment to the States under the Purnell Act; \$290,000 additional for cooperative forest fire protection; \$200,120 additional in the allotment to the Bureau of Entomology for its work in the prevention of the spread of the European corn borer; \$180,000 additional for the Japanese and Asiatic beetle campaign; and \$100,000 additional for white pine blister rust control. There are also many smaller items of increase and some reductions.

The formulation of the new act received unusually prompt consideration by Congress, and its approval by President Coolidge on January 18, 1927, took place earlier in the session than for many years. None the less its provisions received the usual detailed scrutiny by the Bureau of the Budget, and the testimony in the hearings before the House and Senate subcommittees aggregated nearly 1,000 printed pages. In the main the recommendations of the Bureau of the Budget were adhered to, the principal deviation being the appropriation of \$5,000,000 less than the recommendation for the Federal aid highway system and forest roads and trails.

Following the precedents of recent years, the act contains little general legislation, the most important innovation being a reorganization and regrouping of some of the activities of the Department. Chief among these is the establishment of a Bureau of Chemistry and Soils, which will take over on July 1, 1927, all of the research work of the Department in these two subjects. This will include the entire Bureau of Soils as at present constituted, the soil bacteriology and soil fertility investigations of the Bureau of Plant Industry, and the entire Bureau of Chemistry with the exception of those units having to do with the enforcement of the regulatory laws dealing with food and drugs, tea, and naval stores and the analytical work conducted in collaboration with other departments. These phases are to be joined with the work of the Insecticide and Fungicide Board into a regulatory unit to be known as the Food, Drug, and Insecticide Administration. The reorganization, advocated by Secretary Jardine as a logical development, will serve to differentiate more clearly the research and regulatory functions of the Depart-

ment and will concentrate closely related chemical and biochemical research into a single bureau.

Another innovation in the form of the bill needs special explanation in considering the allotments for specific undertakings of the Department. This consists in eliminating the so-called "general salaries allotments" of the several bureaus and offices and reappportioning these sums to the various projects and investigations. The practice now to be discarded was a survival from the "statutory rolls" required prior to the Classification Act of 1923 and from the standpoint of the general public was extremely confusing, since the act indicated certain amounts for specific projects while the "general salaries allotment" also was used to supplement the same projects to an indefinite degree. The change thus affords much more complete information as to the total funds actually available for the various investigations than has hitherto been obtainable from the act, but there is the disadvantage of preventing a direct comparison of the new allotments with those for the previous years. This difficulty, however, does not extend to the totals for the bureaus and need be reckoned with chiefly as the explanation of many apparent project increases.

Taking up the various branches of the Department in turn, the Office of the Secretary receives \$8,874,977. This includes as its principal items the usual payments to the States of \$1,440,000 under the Hatch and Adams Acts, \$1,920,000 under the Purnell Act, \$1,300,000 for the supplementary extension work under the Smith-Lever Act, and \$1,424,000 for the Department's own cooperative extension work, but not the Smith-Lever funds themselves of \$4,580,000 as these are provided for in the permanent appropriations. There is an apparent increase of \$308,157, but since the Department Library, hitherto appropriated for separately, is now included as a unit of the Office of the Secretary the net increase is really \$223,977. This sum is the resultant of a number of increases and decreases, the former including as its principal item the additional \$480,000 under the Purnell Act, while the latter is due in part to reductions of \$200,000 in the Department's allotment of \$938,000 for printing and binding by the omission of the special appropriation for reprinting the publications of the Department dealing with the diseases of horses and cattle and \$35,000 for the purchase, recently completed, of over 1,000 acres of land at Beltsville, Md. There is also a net reduction of \$25,000 in the funds for rent of buildings in the District of Columbia, this resulting from a purchase for the Department in October, 1926, of a four-story brick building erected for its use and acquired under the comprehensive public buildings program initiated last year.

The funds available for the Office of Experiment Stations are continued at \$124,566, of which \$117,140 may be expended for salaries in the District of Columbia. The respective allotments for the maintenance of the experiment stations in Alaska, Hawaii, and Porto Rico of \$76,240, \$54,940, and \$56,460 are unchanged, while the Guam and Virgin Islands Stations each receive \$25,000. An increase of \$840 for the Guam Station will provide for the continuation of entomological studies previously undertaken, and one of \$2,820 for the Virgin Islands will enable that station to continue demonstration work recently begun on St. Thomas and St. John.

The Weather Bureau is granted \$2,646,073, a net increase of \$1,993. The funds for investigating atmospheric phenomena from the special point of view of aviation were enlarged by \$44,600, making available for the purpose \$241,500, and those for the frost warning service by \$4,000, but these are offset by the omission of \$38,000 previously appropriated to erect a building at East Lansing, Mich., now completed and a reduction of \$8,607 in certain administrative funds.

The new appropriations for the Bureau of Animal Industry aggregate \$10,671,470, and these are as usual supplemented by the \$3,000,000 permanent appropriation for meat inspection. The net increase from \$4,653,000 to \$5,964,000 in the funds for tuberculosis eradication already referred to is the principal change. Large appropriations estimated at over \$11,000,000 are also expected to be available from the States under the cooperative understanding in effect for several years, forecasting a campaign of much activity. It is of interest to note that during the past year over 8,000,000 cattle were tested, of which a little over 3 per cent were reactors, and that the number of accredited cattle was in excess of 1,500,000, while over 10,500,000 cattle had passed one of the two clean tests required. The phraseology of the act is modified to include work with paratuberculosis and to permit the payment of indemnities to owners of animals which after condemnation for tuberculosis have died prior to slaughter from natural or other causes.

The allotments for combating other animal diseases were reduced. For the cattle tick campaign \$24,450 less is given, the new appropriation aggregating \$712,390. During the calendar year 1925, the last for which data are available, eradication was completed in 72 additional counties, making a total of 601 of the 984 counties originally infested. The hog cholera campaign receives \$451,320 (a reduction of \$3,263) and that against dourine \$26,970 (a reduction of \$5,000), while the emergency appropriation for the eradication of foot-and-mouth and other contagious diseases is decreased from \$5,000 to the nominal sum of \$100. The last outbreak of foot-and-

mouth disease was suppressed June 10, 1926, and it is estimated that on July 1, 1927, a balance will remain from the appropriation for this purpose of over \$2,000,000. Permission is granted in the new act to utilize \$10,000 from this balance in an attempt to control or eradicate European fowl pest and similar diseases of poultry. An increase of \$10,000 in the allotment for the bureau's inspection and quarantine service will enable a more comprehensive examination of animals imported over the Mexican border and the enforcement of new regulations governing imports in secondhand bags, suspected of being potential carriers of various diseases.

The animal husbandry allotment is increased by \$27,420 to a total of \$441,670. A portion of this increase is for the livestock experimental station at Miles City, Mont., \$7,500 for studies of the factors affecting the quality and color of meat, and the remainder to extend the poultry feeding and breeding experiments at Glendale, Ariz.

The Bureau of Dairy Industry receives \$499,734, an increase of \$4,640. There is also carried elsewhere in the act an increase of \$2,000 for the experimental work at Huntley, Mont., and an initial appropriation of \$25,000 toward the immediate establishment of the dairying and livestock experiment station in connection with the Great Plains Experiment Station at Mandan, N. Dak., authorized by an act approved July 3, 1926.

The total for the Bureau of Plant Industry is \$3,945,425, an increase from \$3,801,015, and with a considerable number of relatively small readjustments of funds. The additional allotments include \$20,745 for forest pathological studies, \$11,905 of which is for work with blight-resistant chestnuts; \$100,000 for the white pine blister rust campaign, previously noted, to provide for an extension in the Northwest; \$10,000 for the development of desirable disease-resistant varieties of sugar cane; \$5,000 for a study of the commercial possibilities of levulose production from Jerusalem artichokes; \$17,000 for cotton and truck diseases, of which \$7,500 is made available for studies of the root rot of cotton and the remainder is for studies of curly top of truck crops; \$5,000 for fruit improvement; and \$2,000 for forage crop investigations. On the other hand, there are decreases of \$1,000 for the pathological laboratory, \$3,630 for citrus canker eradication, now completed except for small plantings in Louisiana and Texas, and \$1,412 for the studies of drug and miscellaneous plants.

The Forest Service receives \$8,608,570, together with \$1,000,000 for the acquisition of additional land at the headwaters of navigable streams, \$75,000 for the cooperative distribution of planting stock, \$1,000,000 (an increase of \$290,000) for cooperative forest fire protection and suppression, \$60,000 (an increase of \$10,000) for assistance to farm owners on forest problems, and \$6,500,000 (an increase

of \$1,500,000) for the construction of forest roads and trails. These various appropriations, together with \$3,771,250 from the permanent appropriations, make a total of \$21,014,820 available for forestry work. This expenditure will be offset to a considerable degree, as usual, by the receipts from the national forests, which in 1926 amounted to \$5,155,661.02.

An increase of \$65,000 for silvical investigations will be utilized mainly in establishing two additional forest experiment stations authorized July 3, 1926. One of these stations will be so located as to serve the Mississippi and Ohio Valleys and the other those of Pennsylvania and neighboring States. These stations will bring to eleven the number of regional stations now in operation.

The Forest Service funds for the administration of the national forests, which now include 158,759,000 acres and are valued at over \$1,500,000,000, were increased by \$130,027. Of this amount \$77,285 is to provide additional fire protection and \$40,717 is for the administration of commercial timber sales, while a new item of \$3,000 is for the purchase and maintenance at the Wichita National Forest in Oklahoma of a herd of long-horned or Spanish cattle as a means of preserving this historic breed against complete extinction. There is also an increase of \$9,736 in the allotment of \$500,000 for the forest products investigations.

The new Bureau of Chemistry and Soils receives \$1,115,005, an increase of \$38,005 over the comparable lines of work for the previous year. The allotment for general chemistry studies is increased from \$191,347 to \$195,947 and that for soil fertility studies from \$66,200 to \$71,200. An increase of \$10,200 in the funds for investigations of plant dust explosions and fires is provided for a study of farm fires, the losses from which during the past fiscal year are estimated at \$150,000,000 and 3,500 lives. On the other hand, the insecticide and fungicide investigations are decreased by \$580, and the soil survey, which has now covered about 35 per cent of the agricultural lands, by \$3,220.

The Bureau of Entomology receives an increase from \$2,640,168 to \$3,078,265. This is, of course, independent of the emergency \$10,000,000 European corn borer appropriation already referred to, but includes an increase from \$485,000 to \$685,120 for the bureau's research on this insect. Of this amount \$50,000 is made immediately available, and in the discretion of the Secretary of Agriculture the expenditure of \$300,000 may be made only when an equal amount becomes available from other sources. For the Japanese beetle control an increase from \$285,000 to \$465,000 is provided, while for the gipsy and brown-tail moth campaign the previous allotment of \$670,000 is continued unchanged. The remaining increases are those of \$11,980 for combating deciduous fruit insects, \$20,400 for insects

affecting southern field crops, especially the cotton hopper; \$2,835 for insects affecting tropical and subtropical plants; and \$26,575 for miscellaneous insects.

For the Bureau of Biological Survey there is an increase from \$987,365 to \$1,035,020. Of this increase \$22,000 is for the maintenance of mammal and bird reservations, \$15,000 for the studies of North American birds and other animals (to be devoted to investigations of the breeding and diseases of fur-bearing and meat-producing animals), \$10,000 for reindeer breeding and protection in Alaska, and \$5,000 toward the acquisition of additional areas of land and water for the Upper Mississippi River Wild Life and Fish Refuge. There is also a reduction of \$4,345 in the allotment of \$158,000 for the protection of migratory birds.

The total for the Bureau of Agricultural Economics, \$5,016,251, represents a net increase of \$119,854. Of this sum \$50,000 is to extend the cotton statistics to include estimates of the amount of the various grades produced, while \$11,245 additional for the market inspection of perishable farm produce will provide two more inspectors for fruits and vegetables, one for eggs, and one for meats, in response to a steadily growing demand for this service. Of somewhat similar nature are the increases of \$11,060 for the enforcement of the U. S. Grain Standards Act, \$24,940 for the U. S. Warehouse Act, and \$13,470 for the Grain Futures Act. In consequence of the passage on July 2, 1926, of an act creating a division of cooperative marketing in the bureau, the funds available for this work have been increased from \$163,440 to \$220,000. On the other hand, there are reductions from \$617,768 to \$596,780 in the funds for studies of marketing farm products, from \$6,290 to \$3,000 in those for the completion of the wool work of the War Industries Board, and from \$440,000 to \$420,000 in those for the enforcement of the Packers and Stockyards Act.

The enforcement of the Plant Quarantine Act by the Federal Horticultural Board is strengthened by an allotment of \$25,000 additional for port inspection service, while for the *Thurberia* weevil quarantine \$32,800 is added as a new item. In the campaigns for the eradication of the pink bollworm and the *Parlatoria* date scale reductions are made of \$50,000 and \$2,760, respectively.

The work of the remaining branches of the Department is continued substantially on the present basis. The Bureau of Home Economics again receives \$127,244, and in addition to its large appropriations for road construction already discussed the Bureau of Public Roads is allotted \$457,170, a decrease of \$6,509. The newly established Food, Drug, and Insecticide Administration is granted as its initial appropriation \$1,311,385. Its allotment for the enforcement of the Naval Stores Act is increased by \$10,000,

while those for the tea importation and insecticide acts are decreased by \$2,690 and \$795, respectively.

The closing days of the final session of the Sixty-ninth Congress were noteworthy for the passage of a number of other acts enlarging the duties and responsibilities of the Department. In most cases appropriations to carry out this legislation were authorized but the failure of the second deficiency appropriation bill to receive consideration in the Senate prevented the actual appropriation of the funds. Among these measures were an act to prevent the destruction or dumping without sufficient cause of farm produce received in interstate commerce by commission merchants, to enforce which during the fiscal year 1927 the Secretary of Agriculture was to have been given \$25,000; another act regulates the importation of milk and cream and carries an authorization of \$50,000 per annum; a third measure authorizes the Department to collect and publish additional statistics as to the grade and staple length of cotton; and a fourth amended the Cotton Futures Act to facilitate the adjustment of differences above and below "middling" in future contracts. Other appropriations authorized but not completed were \$100,000 to enable the Department to construct and maintain highways in the Virgin Islands, \$50,000 for cooperation with the South Carolina Experiment Station in investigating the dairying and livestock industries and developing agriculture in the Sand Hill region, and \$8,600,000 for loans by the Department to farmers in the drought and storm stricken areas of the Northwestern and cotton States for the purchase of seed grain, feed, and fertilizer.

Legislation was also passed, authorizing acceptance by the Secretary of a gift of about 1,760 acres of land in Wyoming, to be known as the Izaak Walton League Addition to the winter elk refuge maintained by the Biological Survey at Jackson Hole, and establishing a national arboretum, at a cost for land of \$300,000, to be located within or adjacent to the District of Columbia.

Taken as a whole the appropriation act and the various supplementary measures present few spectacular innovations other than the European corn borer campaign, which is doubtless the largest operation of the sort ever to be attempted. There are, however, many smaller increases looking toward the more adequate control of specific pests and diseases and similar undertakings, and but few decreases in any direction. The importance of an uninterrupted development of existing projects is quite clearly recognized throughout the act, and even the failure of the second deficiency act, although postponing the operation of the various measures just referred to, will cause much less inconvenience than in the case of several other branches of the Government. Under the general conditions the outlook for the new fiscal year is very promising.

RECENT WORK IN AGRICULTURAL SCIENCE

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

A half-century of chemistry in America, 1876-1926, edited by C. A. BROWNE (*Jour. Amer. Chem. Soc.*, 48 (1926), No. 8-A, pp. XIV+254, figs. 61).—This historical review commemorating the fiftieth anniversary of the founding of the American Chemical Society consists of two parts, the first dealing with the origins and developments of the American Chemical Society and the second with reviews of progress in various branches of chemistry in America. Of particular interest in the second part are the reviews of The Chemistry of Physiology and Nutrition, by G. Lusk, and Agricultural Chemistry, by Browne.

Recent advances in biochemistry, J. PRYDE (*London: J. & A. Churchill, 1926, pp. VIII+348, pls. 4, figs. 34*).—Recent progress in various fields of biological chemistry is summarized in 11 chapters dealing, respectively, with aspects of protein catabolism, colloids and the physical chemistry of proteins, the nucleoproteins, the carbohydrates, the biochemistry of the fats, the biochemistry of phosphorus compounds, the rôle of sulfur in biochemistry, the vitamins, hemoglobin and related natural pigments, the chemical basis of specific immunological reactions, and chemotherapy. A list of literature references is given at the end of each chapter.

Practical organic and bio-chemistry, R. H. A. PLIMMER (*London and New York: Longmans, Green & Co., 1926, new ed., pp. X+568, pl. 1, figs. 67*).—In the present edition of this volume, originally compiled as a practical handbook for medical students (*E. S. R.*, 39, p. 607), the theoretical part of organic chemistry has been enlarged in order that the book might serve as a text as well as a laboratory manual. Additional material has been added to the section on physiological chemistry, but in spite of these additions the book is reduced somewhat in size through the omission of advanced portions considered non-essential in a general course.

A text-book of organic chemistry, A. F. HOLLEMAN, edited by A. J. WALKER and O. E. MOTT (*New York: John Wiley & Sons; London: Chapman & Hall, 1925, 6. ed., rewritten, pp. XX+581, figs. 77*).—In the present revision of this well-known textbook (*E. S. R.*, 44, p. 409) still more space has been allotted to the applications in organic chemistry of various physicochemical methods. An account has been added of the work of Irvine and his collaborators on the constitution of the dioses, and in connection with dyestuffs a review of the relationship between constitution and color has been introduced.

Reports of the progress of applied chemistry, 1923, [1924, and 1925], edited by T. F. BURTON (*Soc. Chem. Indus. [London], Ann. Rpts. Prov. Appl. Chem.*, 8 (1923), pp. 618, fig. 1; 9 (1924), pp. 700, figs. 2; 10 (1925), pp. 723).—These volumes continue for 1923-1925 the survey of progress in various fields of applied chemistry (*E. S. R.*, 49, p. 608).

Chemical synonyms and trade names, W. GARDNER (*London: Crosby Lockwood & Son, 1925, 2. ed., enl., pp. VI+271+56*).—An appendix containing an additional 2,700 definitions has been added to the original edition of this reference work (*E. S. R.*, 52, p. 108).

Manual for the dairy chemist, F. LABARRE (*Manuel du Chimiste de Laiterie. Gauthier-Villars & Co., 1926, pp. [3]+168*).—A laboratory manual on the analysis of milk and detection of various adulterants and the analysis of butter, cheese, condensed milk, dried milk, and casein. Necessary tables and French laws and official methods are included.

The fats, J. B. LEATHES and H. S. RAPER (*London and New York: Longmans, Green & Co., 1925, 2. ed., [enl.], pp. VII+242, fig. 1*).—The most important change in the present revision of this monograph (E. S. R., 23, p. 704) has been the extension of the section on the physiology of fats from about 20 pages to seven chapters.

Fatty oils as substitutes for ethyl alcohol in citrus flavors, H. A. SCHUETTE and B. P. DOMOGALLA (*Indus. and Engin. Chem., 18 (1926), No. 12, pp. 1254-1257, figs. 2*).—This study of the suitability of various fatty oils, including corn, cottonseed, olive, and peanut, for solvents of lemon and orange oils to be used as flavoring agents includes the effect of the solvent upon the rotation of the essential oil and the keeping qualities of the solution.

When used soon after preparation, the oils proved satisfactory as judged by the flavor of the baked products in which they had been used, but on standing the acidity of the oils developed to such a degree that in less than a year the taste was so objectionable that the oils could not be utilized. With age and increasing acidity there was a reduction in the optical rotation of the essential oils indicating decomposition.

The phytosterols of corn oil, R. J. ANDERSON and R. L. SHRINER (*Jour. Amer. Chem. Soc., 48 (1926), No. 11, pp. 2976-2986*).—In addition to the results given in a progress report of this study (E. S. R., 54, p. 502), further evidence is given of the presence in corn oil of a mixture of at least three isomeric sterols corresponding in composition to sitosterol, $C_{27}H_{46}OH$. The names α -, β -, and γ -sitosterols are proposed for these isomers of which only one, the γ form, has as yet been obtained in a pure condition, crystallizing in colorless plates melting at 145-146° C.

The phytosterols of rice bran fat, F. P. NABENHAUER and R. J. ANDERSON (*Jour. Amer. Chem. Soc., 48 (1926), No. 11, pp. 2972-2976*).—Essentially noted from a progress report (E. S. R., 54, p. 502).

The phytosterols of wheat germ oil, R. J. ANDERSON, R. L. SHRINER, and G. O. BURE (*Jour. Amer. Chem. Soc., 48 (1926), No. 11, pp. 2987-2996*).—The sterols of wheat germ were found to consist of dihydrositosterol and at least three sterols isomeric with sitosterol and apparently identical with those isolated from corn oil as noted above.

The viscosity of pectin sols, A. OHN (*Indus. and Engin. Chem., 18 (1926), No. 12, pp. 1295-1298, fig. 1*).—A pectin preparation made from a distilled water extract of orange albedo by alcohol precipitation was used to determine the relative viscosity of sols prepared from varying proportions of the pectin, citric acid, cane sugar, and distilled water. The viscosity measurements were made with the Stormer viscosimeter at varying temperatures from 60 to 103° C. The results obtained are summarized as follows:

“The optimum ratio for a good jelly using this pectin preparation is 0.40 gm. pectin and 62.5 gm. sugar per 100 cc. at pH 2.60. The relative viscosity of this sol at 103° is 0.560. At 100° a pectin-acid-sugar sol having a viscosity greater than 0.556 relative to a glycerol standard at 60° will jell. When the amounts of acid, pectin, and sugar are sufficient to cause jelly formation, sudden increases in the relative viscosity occur below 80°. The temperature at which the sol shows a sudden increase of the relative viscosity may be called its jelling point. Thus measurements of the relative viscosity may be used as an indication of jelling power. Within certain limits the surface tension

decreases as the relative viscosity of the sol increases, depending apparently upon the lowering of the pH."

Acetyl groups in pectin, E. K. NELSON (*Jour. Amer. Chem. Soc.*, 48 (1926), No. 11, pp. 2945, 2946).—Determinations of the content of acetyl groups in various pectins prepared in the laboratory by the method of Ehrlich and Sommerfeld (*E. S. R.*, 55, p. 407) are reported.

Lemon pectin yielded only 0.37 per cent of acid calculated as acetic after deducting the formic acid formed in the distillation, apple pectin 0.45, and tomato pectin 0.79 per cent, while sugar-beet pectin yielded 6 per cent. It is concluded that the acetyl group is not an essential constituent of pectins in general. Its presence in root pectins, such as beet pectin, is attributed to the presence in the original material of lignin, lignocellulose, or cell materials containing acetyl groups.

A contribution to the chemistry of grape pigments.—IV, The anthocyanins in Isabella grapes, R. J. ANDERSON and F. P. NABENHAUER (*Jour. Amer. Chem. Soc.*, 48 (1926), No. 11, pp. 2997–3003).—This continuation of the chemical study of the pigments of grapes (*E. S. R.*, 52, p. 803) has been noted briefly from a progress report (*E. S. R.*, 54, p. 503).

The antiscorbutic fraction of lemon juice, IV, C. G. DAUBNEY and S. S. ZILVA (*Biochem. Jour.*, 20 (1926), No. 5, pp. 1955–1959).—Continuing the investigation of the chemical nature of vitamin C (*E. S. R.*, 55, p. 309), the authors have determined the ash content of six batches of lemon juice and of the purest fraction as yet obtained from it, with the following results: 0.1503 and 0.00262, 0.2124 and 0.00069, 0.1732 and 0.00252, 0.2034 and 0.00790, 0.1896 and 0.00601, and 0.2084 and 0.002742 per cent for the original juice and purified fractions, respectively.

The ash of the concentrate was examined for nickel, cobalt, boron, iodine, and phosphorus, with negative results for the first three. Iodine was present in amounts corresponding to from 0.1 to 0.2 mg. per liter, but was excluded from being a part of the antiscorbutic substance itself, since it did not diffuse through collodion membranes soaked in 95 per cent alcohol through which the active material passed readily. As determined by the Neumann method, phosphorus was present in all of the samples to the extent of from 0.0005 to 0.0009 per cent.

Non-volatile constituents of the cotton plant, F. B. POWER and V. K. CHESNUT (*Jour. Amer. Chem. Soc.*, 48 (1926), No. 10, pp. 2721–2737).—The investigation previously noted (*E. S. R.*, 54, p. 803) has been extended to include the nonvolatile constituents of the branches of the cotton plant stripped from the coarse, woody stems and with all bolls removed. From this material, after extraction with alcohol and distillation with steam, a dark-colored aqueous liquid and a black, oily resin were obtained. From the former were isolated considerable amounts of potassium nitrate and potassium chloride, quercetin, betaine, choline, succinic acid, and a small amount of salicylic acid, together with a nonidentified crystalline acid melting at 105 to 106° C. and a neutral crystalline substance melting at 140 to 143°. The liquid from which these substances have been obtained reduced Fehling's solution strongly, thus indicating the presence of a considerable proportion of a reducing sugar.

From the oily resin, amounting to 3.134 per cent of the dry material, the following substances were obtained: A phytosterol, $C_{27}H_{46}O.H_2O$ (m. p., 135°); a phytosterolin (phytosterol glucoside), $C_{28}H_{50}O_3$ (m. p., 218–223°), which yielded on hydrolysis a phytosterol (m. p., 135°) and a sugar which undoubtedly was glucose; pentatriacontane, $C_{35}H_{72}$ (m. p., 75°); palmitic acid; an acid of phenolic character (m. p., 188–189°); a mixture of volatile acids, consisting apparently of butyric, valeric, and caproic acids, the first two predominating;

and a small amount of a phenolic substance, which could not be identified with any of the phenols which have thus far been examined spectrophotometrically. By the distillation in a vacuum of a portion of the unsaponifiable material a mixture of terpenes was obtained from which the following substances were isolated: Dipentene, $C_{10}H_{16}$ (tetrabromide, m. p., 122–123°); an oxygenated compound (b. p., 200–220) which appears to possess the formula $C_8H_{10}O$; an optically active, dicyclic sesquiterpene, $C_{15}H_{24}$; and a product (b. p., 300–350°) which evidently consisted of diterpenes, $C_{20}H_{32}$.

A modification of the deflection balance for use in biochemical laboratories, J. W. TREVAN (*Biochem. Jour.*, 20 (1926), No. 2, pp. 419–422, fig. 1).—“A cheap and simple form of balance is described, the action of which depends on the bending of a steel wire. By its means 1 to 30 mg. can be weighed to ± 0.01 mg. in 30 seconds. By using a series of wires of different thicknesses on the same instrument, the replacement of the wire by another taking only a few seconds, any range of weights from 1 mg. to 1 gm. can be weighed with an accuracy of ± 1 in 10,000.”

Indicators: Their use in quantitative analysis and in the colorimetric determination of hydrogen-ion concentration, I. M. KOLTHOFF, trans. by N. H. FURMAN (*New York: John Wiley & Sons; London: Chapman & Hall, 1926, pp. XII+269, pl. 1, figs. 23*).—This translation is based upon the second German edition, but contains a new chapter on amphoteric compounds and numerous additions distributed through the text.

A rapid colorimetric method of estimating pentoses, R. A. McCANCE (*Biochem. Jour.*, 20 (1926), No. 5, pp. 1111–1113).—In the method described, varying amounts of the pentose material to be tested are heated for two hours in the water bath with concentrated hydrochloric acid in test tubes fitted with glass tubes to act as condensers. After cooling, the furfural formed is shaken out with benzene and the color developed with a benzidine reagent prepared by dissolving 0.5 gm. of benzidine in 100 cc. of equal parts of absolute alcohol and glacial acetic acid. A deep violet color is said to develop in about 15 minutes and to persist for nearly two hours. Standards for comparison are prepared from arabinose treated in the same way. The method, while having definite limitations, is recommended for certain purposes, particularly the examination of the urine, on account of its simplicity and rapidity.

Fat content of breads and cereals, G. A. CORMACK (*Biochem. Jour.*, 20 (1926), No. 5, pp. 1052–1054).—A comparison is reported of the ether-soluble material in flours prepared from wheat, oats, barley, and soy beans as determined by Soxhlet extraction before and after pepsin digestion of the flour.

From two to three times as much fat was removed from the flour after peptic digestion as before. Repeated extraction of the flour was also found to increase considerably the amount of fat obtained, and it is concluded that the fat content usually reported for flour and bread is too low. The values obtained for various types of bread before and after digestion are Scotch white bread 0.29 and 0.93, English white bread 0.27 and 0.61, Scotch pan loaf 0.96 and 1.6, and Scotch brown bread 1.4 and 2.8 per cent, respectively.

The estimation of iodine in foodstuffs and body fluids, I. LEITCH and J. MCA. HENDERSON (*Biochem. Jour.*, 20 (1926), No. 5, pp. 1003–1007, fig. 1).—The Fellenberg method of determining iodine in biological materials (E. S. R., 53, p. 201) has been modified by the elimination of the colorimetric, and slight changes in the titrimetric, determinations. Nickel crucibles are used in place of iron for the preliminary ashing of the material. Potassium nitrite is omitted, and 2 N sulfuric acid used for the acidification and bromine water in place of chlorine water for the liberation of the iodine. The method is described in full, with data on its accuracy. It is estimated that the error is

about ± 10 per cent when iodine is present in such minute quantities as from 0.5γ to 2γ .

The search for colour reactions of vitamin "A," T. T. COCKING and E. A. PRICE (*Pharm. Jour. and Pharm.* [London], 4. ser., 63 (1926), No. 3275, pp. 175-178).—Further experience in the use of antimony trichloride dissolved in chloroform as a color reagent for vitamin A (E. S. R., 56, p. 10) is reported, substantiating the earlier conclusions that this reagent is superior to others which have been recommended for this test. The advantages of the antimony trichloride reagent are thought to be that the reaction is not interfered with by traces of water or alcohol in the chloroform, that a fully saturated solution is not essential, that the blue color produced is more permanent and intense than the colors given by any other reagents tested, and that the reagent is relatively innocuous and does not lose its activity for several months if kept in a stoppered bottle.

Data are tabulated on the original color as determined by the Lovibond tintometer and the color developed by the antimony trichloride reagent in 17 samples of Norwegian cod-liver oil and 6 of Newfoundland oil. The percentages of unsaponifiable matter in some of the oils were also determined. As judged by these data, the color of the oil itself and the amount of unsaponifiable matter present are not criteria of the vitamin A content, the activity of cod-liver oils with respect to vitamin A may vary as much as 8 to 1, and the Newfoundland oils examined have on an average a higher content of vitamin A than the Norwegian oils.

An alphabetical summary is given of the various reagents which have been used for the color test, with the color yielded, and the advantages and disadvantages in the test.

The estimation of calcium in blood serum, J. W. TREVAN and H. W. BAINBRIDGE (*Biochem. Jour.*, 20 (1926), No. 2, pp. 423-426, fig. 1).—A method of determining calcium in blood serum is described in which the calcium is precipitated as oxalate as in the method of Kramer and Tisdall (E. S. R., 46, p. 203), washed with saturated ammonium oxalate in place of water, and then converted into calcium carbonate by heating in the centrifuge tube in which it is separated and washed. The calcium carbonate is finally titrated with $N/100$ phosphoric acid, H_3PO_4 , using bromophenol blue as indicator. By the use of a special micrometer syringe devised by the senior author only 1 cc. of serum is required, and smaller quantities down to 0.1 cc. are said to give results sufficiently accurate for most purposes.

The analysis of pigments, paints, and varnishes, J. J. FOX and T. H. BOWLES (*London: Ernest Benn, 1927, pp. X+11-179, figs. 9*).—This is one of the oil and color chemistry monographs edited by R. S. Morrell.

Furfural steps into industry, D. H. KILLEFFER (*Indus. and Engin. Chem.*, 18 (1926), No. 12, pp. 1217-1219, figs. 2).—A description is given of the commercial manufacture of furfural from oat hulls by a method similar to that developed at the U. S. Department of Agriculture for its production from corn-cobs (E. S. R., 51, p. 809). A flow sheet for furfural production from the original oats to the technical product is included. It is noted that before 1922 furfural was obtainable with difficulty at prices varying from \$6.50 to \$30 per pound, while in May, 1926, the price was 15 cts. per pound. Various uses of furfural are listed.

METEOROLOGY

Monthly Weather Review, [September-October, 1926] (*U. S. Mo. Weather Rev.*, 54 (1926), Nos. 9, pp. 367-408, pls. 15, figs. 9; 10, pp. 409-452, pls. 14, figs. 4).—In addition to detailed summaries of meteorological and climatological data and weather conditions for September and October, 1926, and

bibliographical information, notes, abstracts, and reviews, these numbers contain the following contributions:

No. 9.—Weather and Sugar Cane in Louisiana (illus.), by W. F. McDonald (abs.) (see below); the Tropical Storm of August 25–26, 1926, in Southern Louisiana, by R. A. Dyke; Persistence of Weather Types in the Hawaiian Islands (illus.), by E. F. Loveridge (see below); Forecasting Precipitation from Local Data (illus.), by C. L. Ray (see below); Wind as Motive Power for Electrical Generators (illus.), by H. G. Carter (see p. 315); Climatological Data for Andagoya, Republic of Colombia, South America, by P. C. Day; C. E. P. Brooks on Variations of Pressure from Month to Month in the Region of the British Isles, by A. J. Henry; Part 2 of Gregg's Aerological Survey of the United States; Results of Observations by Means of Pilot Balloons, by B. M. Varney; and Solarimeters and Solarigraphs (illus.), by L. Gorczyński (see below).

No. 10.—The West Indian Hurricanes of September 14–22, 1926 (illus.), by C. L. Mitchell; An Interpretation of the Wind Velocity Record at Miami Beach, Fla., September 17–18, 1926, by B. C. Kadel; Destructive Gust at Jupiter, Fla., Following the Miami Hurricane, by H. B. Boyer; The Hurricane at Turks Island, September 16, 1926, by G. Goodwin; A. Ångström on "Radiation and Climate," by H. H. Kimball; Broadcasting Weather Maps by Radio (illus.), by B. F. Dashiell; Horizontal Ground Day Visibility at Ellendale, N. Dak., by L. A. Warren; A Graphic and Tabular Aid to Interpreting Correlation Coefficients (illus.), by J. F. Voorhees; Substances in Rains and Snows, by H. Ribble and P. Bowman (see p. 321); and Climate and Weather at Kerguelen Island, by B. M. Varney.

Solarimeters and solarigraphs, L. GORCZYŃSKI (*U. S. Mo. Weather Rev.*, 54 (1926), *No. 9*, pp. 381–384, *pl. 1*, *fig. 1*).—Simple instruments for direct readings of solar radiation intensity from sun and sky are described.

Forecasting precipitation from local data, C. L. RAY (*U. S. Mo. Weather Rev.*, 54 (1926), *No. 9*, pp. 372–374, *figs. 2*).—A statistical and graphic study of the probability of rain following different pressure heights, wind directions, pressure changes, and the several combinations of these factors are presented, but "do not show a sufficiently high average of probability to serve . . . as an aid in forecasting."

Persistence of weather types in the Hawaiian Islands, E. F. LOVERIDGE (*U. S. Mo. Weather Rev.*, 54 (1926), *No. 9*, pp. 370–372 *fig. 1*).—The study reported in this article shows a systematic and persistent tendency in weather variations in the Hawaiian Islands greater than has been observed at places in higher latitudes. Temperatures show a remarkable tendency to persist. In case of rainfall, atmospheric pressure, and wind velocity the persistence is less but still clearly apparent. It is suggested that the fact that wet and dry weather tend to persist in summer might be of some value in long-range forecasting.

Weather and sugar cane in Louisiana, W. F. McDONALD (*U. S. Mo. Weather Rev.*, 54 (1926), *No. 9*, pp. 367–369, *fig. 1*).—This is a summary of a much fuller discussion of the subject previously noted (*E. S. R.*, 55, p. 715).

There was found to be a linear correlation of +0.53 between sugar yield and the preceding March temperature, of -0.51 between the sugar yield and the preceding January rainfall, and of -0.54 between sugar yield and the August rainfall. A correlation coefficient of +0.50 between the molasses-sugar ratio and November sunshine (at New Orleans) is taken to indicate a large influence of sunshine on the ripening processes, and this appears to be in accord with general observation. The high correlations between seasonal rainfall and sugar yield in Louisiana as compared with those of tropical sugar-

producing countries indicate that "those years or terms of years when Louisiana rainfall most closely approximated the seasonal type of the Tropics, with accentuation of wet and dry seasons, produced the best yields. In Louisiana increased rainfall during spring until June, and rainfall below normal from August through harvest, produces such an accentuation and increases yields, whereas years or periods of more uniformly wet character, or with the seasonal type reversed, reduce yields." "It seems reasonable to suppose that the evolutionary responses of cane, a plant of tropical origin, must be closely bound up with the rainfall regimen, seasonally the most variable climatic feature of its native habitat."

Wind as motive power for electrical generators, H. G. CARTER (*U. S. Mo. Weather Rev.*, 54 (1926), No. 9, pp. 374-376, figs. 4).—A study at Lincoln, Nebr., of wind velocity and force leads to the conclusion that "while the data presented may not prove the feasibility of operating electrical generators by wind power, they at least show the possibilities."

SOILS—FERTILIZERS

Biophysical and biochemical investigation of soil, J. STOKLASA and E. G. DOERELL (*Handbuch der Biophysikalischen und Biochemischen Durchforschung des Bodens*. Berlin: Paul Parey, 1926, pp. XV+812, figs. 91).—This book deals with the biophysical and biochemical investigation of soil, and especially with methods for biological study.

Simplification of mechanical analysis of soil [trans. title], I. SMOLIK (*Ann. Sci. Agron. Franç. et Étrang.*, 43 (1926), No. 1, pp. 29-34).—A simplification of the Kopecky process is described.

Soil survey of Garrett County, Maryland, J. M. SNYDER ET AL. (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils*, 1922, pp. III+957-982, fig. 1, map 1).—This survey, made in cooperation with the Maryland Geological Survey and Experiment Station, deals with the soils of an area of 427,520 acres in western Maryland. The area is composed of two physiographic divisions, the mountain section occupying approximately three-fourths of the county, and the high rolling plateau. The county is said to be well drained.

The soils are said to be all light colored and are prevailingly deficient in organic matter. There is much uniformity in texture in both the surface and subsoil throughout the area, and nearly all of the soils contain much fragmental rock. Including rough stony land, 15 soil types of 5 series are mapped, of which the Dekalb stony silt loam and gravelly silt loam cover 36 and 22.4 per cent of the area, respectively.

Soil survey of Ottawa County, Michigan, J. O. VEATCH ET AL. (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils*, 1922, pp. III+921-955, figs. 3, map 1).—This survey, made in cooperation with the Michigan Experiment Station, deals with the soils of an area of 361,600 acres, located in the Great Lakes Plains in southwestern Michigan. The topography is characterized by nearly level plains, partly dry and partly wet and swampy, and low rounded hills, basins, and shallow valleys of glacial origin. The greater part of the area is said to be naturally sufficiently well drained for agriculture.

The soils exhibit a diversity in texture and other characteristics. The sands or light soils occupy the greatest acreage, but the loams, silt loams, and clay loams are but slightly less in the aggregate. There are only a few small areas of gravelly soils and only negligible acreages of very stony soils and heavy clay soils. Including muck and marsh, 29 soil types of 18 series are mapped, of which the Plainfield sand and the Newton loamy fine sand cover 20.9 and 10 per cent of the area, respectively.

Soil survey of the Las Vegas area, Nevada, E. J. CARPENTER and F. O. YOUNGS (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1923, pp. III+201-245, pls. 4, fig. 1, maps 2*).—This survey deals with the soils of an area of 197,120 acres situated in Clark County in southern Nevada and which embraces the greater part of the Las Vegas Valley. The greater part of the area consists of broad gently sloping alluvial fans, with a smaller flatter area in the central part of the valley.

The soils of the valley are derived mainly from limestone, with slight admixtures of materials derived from basalt and other crystalline igneous rocks. Alkali is of widespread distribution in the valley, but generally of low concentration, except in places in the lower, more poorly drained central part of the valley. Including dune sand and rough stony land, 21 soil types of 9 series are mapped, of which the Las Vegas loam, gravelly fine sandy loam, and loamy fine sand and the Gila gravelly fine sand cover 18.8, 13.5, 12.9, and 11 per cent of the area, respectively.

Soil survey of Cayuga County, New York, H. G. LEWIS ET AL. (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1922, pp. IV+1023-1082, pls. 4, fig. 1, map 1*).—This survey, made in cooperation with the New York State College of Agriculture, deals with the soils of an area of 449,920 acres lying near the center of the Finger Lakes region in central New York. The topography of the area varies from smooth, nearly level, gently sloping, undulating, hilly, and morainic to steep and broken. As a whole the county is well drained, although some areas need drainage.

The soils are variable in texture, color, mode of formation, and content of lime and organic matter. The most extensive soils represent partly weathered till material of varying thickness, with some residual material from the underlying geological formations. Including muck, marsh, meadow, and steep broken land, 39 soil types of 27 series are mapped, of which the Ontario loam and the Honeoye silt loam cover 18.9 and 18.3 per cent of the area, respectively.

Soil survey of Grant and Mineral Counties, West Virginia, S. W. PHILLIPS (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1922, pp. III+983-1022, pls. 2, fig. 1, maps 2*).—This survey, made in cooperation with the West Virginia Geological Survey, deals with the soils of an area of 517,120 acres comprising two counties in the Appalachian Mountain region in eastern West Virginia. The topography varies from rolling to mountainous. The area is drained into the north branch of the Potomac River.

The soils of the area are grouped as the smoother upland soils having a rolling to hilly topography, the first bottom and second bottom soils, and the rough mountainous areas. Including rough stony land, 20 soil types of 11 series are mapped, of which the Dekalb shale loam, rough stony land, and Dekalb stony silt loam cover 33.8, 22.6, and 12.4 per cent of the area, respectively.

Terracing in Alabama, L. C. LEBRON and M. L. NICHOLS (*Ala. Polytech. Inst. Ext. Circ. 94 (1926), pp. 11, figs. 5*).—Practical information on terracing for the prevention of soil erosion under Alabama conditions is presented.

Physiologically variable behavior of moist, air-dried, and repeatedly dried soils [trans. title], V. KÁŠ (*Sborn. Českoslov. Akad. Zeměděl. (Ann. Czechoslovak Acad. Agr.), 1 (1926), No. 1, pp. 89-152, figs. 11; Ger. abs., pp. 150-152*).—Studies are reported which showed that drying or alternate wetting and drying of soil and also freezing change its physical, chemical, and biological properties. The resulting flocculation of the colloidal material and the accompanying increase in the degree of dispersity were found to improve the conditions for bacterial life in heavy soils. Air-dried sandy clay soil

showed decreased hygroscopicity and water evaporating power. Freezing had the same effect.

Drying or freezing of heavy soils rich in colloids caused a regular increase in the catalytic power, which disappeared, however, as a result of repeated wetting. Boiling or centrifuging moist soils suspended in distilled water produced the same results as drying.

Air-dried soil suspended in distilled water and boiled or centrifuged had a lower catalytic power than moist soil. An increasing addition of colloidal potassium silicate solution to sandy clay soil depressed the catalytic power. The opposite effect was obtained with ordinary sand.

The view that physical soil properties exercise no influence in liquid cultures is considered incorrect, since the filter paper used to separate the colloidal materials from their dispersion medium is not adequate for this purpose.

Nitrification was markedly depressed by both drying and freezing. Acid formation was found to be chemically irregular in dried soils, but proceeded rapidly and reached a maximum earlier and decreased more markedly than in moist soil.

Carbon dioxide formation was found to be greater in dry soils than in moist soils, especially in the early stages. Repeated drying of a humus clayey sand garden soil further increased the carbon dioxide formation. Progressive repetition of this treatment, however, eventually strongly depressed the carbon dioxide formation.

The difference between the behavior of a dried soil and that of a moist soil is considered to be directly proportional to the soil productivity.

The movement of soil moisture in the vapor phase, Parts I, II (*Abs. in Jour. Amer. Soc. Agron., 17 (1925), No. 10, pp. 642, 643*).—This is an abstract of two papers presented at the ninth annual meeting of the American Society of Agronomy at Fort Collins, Colo., June 18–20, 1925. The first, by J. C. Russel, deals with some theoretical considerations, and the second, by H. E. Weakley, with experimental observations.

Laboratory and field data, from studies conducted at the Nebraska Experiment Station, were presented to show the magnitude and importance of vapor movements. The evaporation of water from a free water surface into the atmosphere directly or through dry porous material, either soil or sand, was shown to be a linear function of saturation deficit. The rate of evaporation varied with the porosity of the material, but was not affected by its hygroscopicity. As much water passed from a free water surface through dry, coarse sand as through dry, coarse granular soil of identical permeability coefficient. The size rather than the quantity of pore space determined the extent of the water lost. Cracks in a soil mass seemed to allow very rapid vapor movement.

The evaporation of water from a wet mass of soil when not more moist than the field carrying capacity seemed to follow all of the laws of vapor movement. As much water was lost from wet soil columns when they were broken by air gaps as when they were continuous.

Soil moisture in relation to the growth of crop plants, H. L. SHANTZ (*Jour. Amer. Soc. Agron., 17 (1925), No. 11, pp. 705–711*).—In a contribution from the U. S. D. A. Bureau of Plant Industry data are presented on the utilization of water by plants as a basis for studies of the movement and retention of water in soils.

Soil reactions in relation to plant successions in the Cincinnati region, S. GEISLER (*Ecology, 7 (1926), No. 2, pp. 163–184, figs. 8*).—Studies conducted at the University of Cincinnati are reported which indicate that the type

of soil which prevails in the successional stages is readily detected in the climax.

A prevailing acid or alkaline condition was noted in the reactions of each of the successions. The soils of the upland successions were acid in reaction due to lack of drainage and poor aeration. All successions except the upland were found to be essentially alkaline in reaction due to the nature of the underlying rocks. The influence of the rock materials was more marked in earlier than in later stages of succession. In every succession the earliest stages were found to be rather limited in their range of reaction, while the later stages had a wider range.

The results indicate that many species grow under widely varying soil conditions, and that there is nothing to indicate that the soil reactions are responsible for species distributed in the Cincinnati region. There seems to be no definite progression of soil reactions in relation to the plant successions in the region, but rather a widening of the range of reactions as the climax is approached.

Relation of soil to plant cell sap, M. M. McCool (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 60-64).—Studies are briefly reported which indicate that the use of fertilizers lowers the freezing point of cell sap, and that the phosphorus content of the cell sap of plants is affected by soils and their fertilization. The addition of potash to muck soil increases the concentration of the juice of the leaves of such crops as sugar beets and carrots. It appears further that the amount of inorganic phosphorus in the cell sap varies with the time of day, being greater in the morning than later on in the day.

The growth of certain microorganisms in planted and in unplanted soil, J. K. Wilson and T. L. Lyon (*New York Cornell Sta. Mem.* 103 (1926), pp. 3-25).—Studies are reported in which soil was placed in large tubes, and after these had been heated in an autoclave and inoculated with pure cultures of selected organisms, sterilized seeds of maize or timothy were planted in some of the tubes, while others remained unplanted. After the plants had grown for periods varying from several days to a few months, the soil was removed from both the planted and unplanted tubes, dilute infusions were plated, and colonies were counted after incubation.

With few exceptions the soil in which plants were grown contained a larger number of organisms than did the unplanted soil. The organisms used were in every case those known to be active in changing nitrogen from one form to another.

The conclusion is drawn that at least some crop plants produce a condition in the soil surrounding their roots which favors the growth of certain microorganisms that consume nitrate nitrogen, thus accounting for the disappearance of nitrate nitrogen not absorbed by plants.

[**Soil bacteriology work at the Delaware Station**], T. F. Manns (*Delaware Sta. Bul.* 147 (1926), pp. 35-37).—Studies by P. Mautz showed that certain of the sulfates strongly stimulate sulfur oxidation. Potassium sulfate was the most active in this respect, while iron, aluminum, ammonium, and magnesium sulfates showed some stimulation. Sulfur oxidation was found to take place rapidly whether in soil or organic composts.

Pot studies with wheat to learn the relative availability to plants of phosphorus made citrate soluble by the sulfur oxidation process and that in commercial fertilizer showed that the noncomposted, nonavailable phosphorus sulfur mixtures with activators to stimulate sulfur oxidation gave as good results as commercial fertilizer, with only one exception.

Distribution of Azotobacter in Bavarian soils with reference to their reaction and lime and phosphoric acid contents [trans. title], H. NIKLAS, H. POSCHENRIEDER, and A. HOCK (*Centbl. Bakt. [etc.]*, 2. Abt., 66 (1926), No. 1-7, pp. 16-28).—Studies are reported of a number of Bavarian soils. The results are taken to indicate that the natural occurrence of Azotobacter in soils is governed very largely by reaction and lime content, and that many soils, in spite of their favorable reaction and high lime content, contain no active Azotobacter because of a deficiency in phosphoric acid. Apparently such soils can contain Azotobacter, but these are unable to assimilate nitrogen.

Nitrate studies on a manured and unmanured soil under continuous wheat culture, H. F. MURPHY (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 11, pp. 734-741).—Studies conducted at the Oklahoma Experiment Station are reported which showed that nitrates were produced in much larger quantities in manured soil than in unmanured soil. Nitrification experiments showed that the manured soil produced 1.68 times more nitrates than the unmanured soil for a period of two months in the greenhouse and 2.24 times as much nitrates as the unmanured soil under open-room conditions. During July, with optimum moisture present, the manured soil produced under open-room conditions 1.74 times the amount of nitrates produced by the unmanured soil.

Nitrification was greater under greenhouse conditions than outdoors for both manured and unmanured soils. Similar ratios existed in both cases favoring the manured soil. Spring growth started later on the unmanured plot, and the manured soil was superior to the unmanured soil with reference to nitrates present, nitrification, moisture retention, and plant growth. It was found that the amount of nitrates present in the soil under each treatment is rapidly reduced as soon as the spring growth of wheat begins.

[Soil fertility studies at the Arkansas Station] (*Arkansas Sta. Bul.* 215 (1926), pp. 3-7).—The progress of soil fertility studies is briefly reported (E. S. R., 55, p. 17). Data are presented on forms of lime and phosphorus and sources of nitrogen and on the effect of cultivation on the accumulation of nitrates and moisture in the soil.

[Soil management and fertility studies at the Illinois Station] (*Illinois Sta. Rpt.* 1926, pp. 8, 9-27, fig. 1).—The progress results of a large number of soil fertility studies are very briefly summarized (E. S. R., 56, p. 212), which include data on the comparative value of livestock and grain systems of farming, the fertilizing value of crop residues and farm manure, the influence of limestone of different degrees of fineness on soil productivity, lime sources and liming practices, phosphate sources and fertilization practices, potash and sulfur fertilization practices, and the effect of legumes on soil productivity.

Some of the outstanding results obtained are that extreme fineness in limestone is not necessary on Illinois soils, and that moderate liming is more profitable than excessive liming. The soils of the State vary in their phosphate requirements, and apparently no one carrier of phosphate gives the best results. In practically all sections of the State responses to rock phosphate used with manure are much less than when it is used with crop residues in grain systems of farming. Except on certain peaty or alkali soils, the use of potassium salts on the soils of central or northern Illinois does not give economic returns. In the southern part of the State economic increases have been noted, especially in the corn crop. Sulfur apparently fails to increase crop yields on the soils of the State.

Soil treatment and crop production in the Nelson district, 1924-25, T. RIGG ET AL. (*Cawthron Inst., Nelson, N. Z., Dept. Chem. and Agr. Bul.* 2, n. ser. (1926), pp. [19]).—A series of short papers dealing with some of the soil problems of the Nelson district are presented. These are: Liming and Manu-

rial Experiments on Stoke Soils; Cropping on the Hope Plains, Nelson District; Scientific Treatment of the Soil, Motupiko and Motueka Valleys; Hay Experiments, Waimea Plains, Nelson; Lucern Experiments, Waimea Plains, Nelson; and Soil Treatment for Nelson Tomato Houses.

A preliminary investigation on the absorption of fertilizers by Ceylon soils, A. W. R. JOACHIM (*Ceylon Dept. Agr. Bul. 75 (1926), pp. 19, pls. 3*).—Four series of experiments are reported, the purposes of which were (1) to ascertain the absorptive power of Ceylon soils, and (2) to estimate the losses of fertilizers added to them through leaching by rainfall.

The absorptive power of soils for fertilizers was found to vary with the nature, compactive power, porosity, and moisture content. The fertilizer losses were slightly greater from moist soils than from air-dried soils. The nitrates of sodium and potassium were least absorbed, while soluble superphosphate and the sulfates of potassium and ammonium were most absorbed. Potassium sulfate was absorbed to a greater degree than potassium chloride.

It was found that the amount of fertilizer absorbed by a soil increases with time, but that by far the greater part of the absorption takes place during the first 2 hours. When the fertilizer was incorporated in the upper 3 in. of a 6-in. layer of soil, the loss of fertilizer due to a 2-in. rainfall during 2 hours was hardly appreciable. If 24 hours afterward a further rainfall of 1 in. occurred, only a very small proportion of the fertilizer was leached from the top 6 in. of the soil. However, in the case of nitrates of sodium and potassium the amounts lost in the drainage water were greater, being 6 per cent in the case of the latter and 15 per cent in the case of the former. Hardly any losses of the other fertilizers were observed.

Decomposition of stable manure in soil and its utilization by plants [trans. title], M. BACH (*Landw. Vers. Sta., 104 (1926), No. 5-6, pp. 245-284*).—Studies are reported on (1) the decomposition of stable manure in soils, (2) the influence of stable manure on the content of available nutrients in soil, (3) the utilization of the total soil nutrients by plants, and (4) the utilization of the nutrient content of stable manure.

The main oxidation of carbon was found to occur during the first year after the application of stable manure to soils. During this period approximately 75 per cent of the total carbon added was decomposed. After that period the oxidation of the stable manure carbon proceeded more slowly. Decomposition of the organic constituents of the stable manure naturally was more rapid during the warmer than during the colder periods of the year.

The carbonaceous material disappeared more rapidly in sand, clay, and shale soils than in other soils. The pentosans decreased more rapidly than the total carbon. The decomposition of lignin was much more slow than that of the pentosans.

After fertilization with stable manure the total and soluble nitrogen contents of the soil showed a considerable decrease due to denitrification and leaching. The content of phosphoric acid soluble in 1 per cent citric acid in soils was only slightly decreased after fertilization with stable manure, after which it remained uniformly the same. The soluble potash gradually decreased, however, due to leaching and fixation.

Soils planted to beets and rye naturally showed a decrease in nutrient materials. The beet crop was doubled by manuring. The rye yield was also considerably increased.

About 30 per cent of the nitrogen, 20 per cent of the phosphoric acid, and 50 per cent of the potash contents of stable manure additions were utilized by the rye and beet crops during the first two years after fertilization.

Substances in rains and snows, H. RIBBLE and P. BOWMAN (*U. S. Mo. Weather Rev.*, 54 (1926), No. 10, p. 424).—Results of determinations of nitrogen compounds, sulfates, and chlorine in 57 samples of rain and 13 of snow at Cornell College, Iowa, are summarized. The 15.1 in. of precipitation from September 19, 1924, to June 3, 1925, carried in solution 4.65 lbs. per acre of nitrates, 0.07 of nitrites, 15.79 of free ammonia, 11.45 of albuminoid ammonia, 165.64 of sulfates, and 29.79 of chlorine. The 32.46 in. of precipitation from June 15, 1925, to May 31, 1926, carried in solution 5.9 lbs. per acre of nitrates, 0.27 of nitrites, 2.5 of free ammonia, 1.63 of albuminoid ammonia, 72.61 of sulfates, and 83.84 lbs. of chlorine. The chlorine content varied widely and is thought to be probably due to salt particles carried from the Atlantic Ocean.

Some tests with Soilgro, L. T. LEONARD (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 10, pp. 623-629).—Tests conducted by the U. S. D. A. Bureau of Plant Industry of Soilgro, a so-called culture of soil bacteria, are briefly reported.

The total numbers of bacteria in the Soilgro cultures tested were found to be much lower than those in the so-called bacterial food accompanying the liquid cultures. Soil and manure samples plated for comparison gave higher figures. The numbers of ammonifying and cellulose-destroying bacteria were also larger in the bacterial food, soil, and manure samples than in the Soilgro cultures. The presence of *Azotobacter* in the culture was not indicated by the tests made. Certain strains of legume bacteria were found in Soilgro, but in less number than in the potting soil used for comparison.

Nitrogen fixation by potting soil was superior to the fixation by a Soilgro culture, and the mixtures of Soilgro gave a lower fixation in two cases than the culture from which they were made. The nitrification of ammonium salts in liquid and in soil cultures was better by potting soil than by any of the Soilgro preparations.

Soilgro showed no superiority in the production of radishes, either in the stimulation of germination, earliness of crop, or weight of crop, collectively or individually. Tests made with peas were likewise negative. Two tests on lawns did not produce results favorable to Soilgro. Quantitative tests on soil cuttings made from treated plats bore out the results of the superficial examination.

Spreading of lime nitrogen with soil [trans. title], E. BLANCK and F. GIESECKE (*Jour. Landw.*, 73 (1925), No. 4, pp. 305-316).—Studies conducted at the University of Göttingen are reported which showed that composting lime nitrogen with soil and subsequent application of the mixture in the usual manner caused a considerable increase in crop yields. The conclusion is drawn that the injurious products of the decomposition of lime nitrogen exist only a short time as such and may be transformed into harmless and useful compounds during composting.

Mixtures of urea with phosphatic and potassic fertilizers [trans. title], P. BOISCHOT (*Ann. Sci. Agron. Franç. et Étrang.*, 43 (1926), No. 1, pp. 45-50).—Studies conducted at the National Institute of Agronomy of France are reported which showed that urea may be mixed with the majority of phosphatic and potassic fertilizers. Mixtures of urea with alkaline fertilizers are not recommended owing to the resulting nitrogen losses.

Test soils for water-soluble phosphorus, C. H. SPURWAY (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 64-67).—Data on a simple field test are presented which are said to give information on fertilization needs.

Colloidal phosphate [trans. title], E. BOTTINI (*Staz. Sper. Agr. Ital.*, 58 (1925), No. 7-9, pp. 209-216).—Studies of the physical and chemical properties of a finely pulverized phosphatic fertilizer are reported.

Only 9.79 per cent of the material showed apparent colloidal properties. About 63.06 per cent of the material consisted of particles 80 μ in diameter. The coarse material contained more phosphoric acid than did the fine material. The colloidal portion contained hardly a trace of phosphoric acid, and it consisted mainly of organic matter.

Treatment of this material with distilled water, saturated solutions of carbon dioxide, and solutions of neutral salts, both organic and mineral, dissolved out only traces of phosphoric acid, and only small quantities were soluble in ammonium citrate. Apparently solutions of citric and of citroformic acids were capable of dissolving out considerable phosphoric acid.

These results are taken to indicate that this so-called colloidal phosphate has no greater fertilizing value than other pulverized natural phosphates.

Cropping experiments with sericite as a source of potash [trans. title], E. BLANCK and F. ALTEN (*Landw. Vers. Sta.*, 104 (1926), No. 5-6, pp. 237-243).—Experiments conducted at the University of Göttingen are briefly reported which showed that pulverized sericite as a source of potash increased the yield of peas and oats but apparently had little effect on mustard.

Degree of resistance of different limes toward acid solutions circulating in cultivated soils [trans. title], E. BOTTINI (*Staz. Sper. Agr. Ital.*, 58 (1925), No. 7-9, pp. 268-288).—Studies are reported the results of which indicate that different forms of lime may be placed in three groups with reference to their resistance to decomposition by acid solutions of soils.

The first group comprises calcareous marls, concretions, sands, and fossils which are rather easily decomposed. The second group comprises the calcareous clays which present a higher degree of resistance to decomposition. The third and apparently most resistant group includes the dolomites and other hard lime compounds.

It was found that resistance to decomposition bears a relation to specific weight, a low specific weight corresponding to a low resistance. Resistance to decomposition was also found to bear a relation to geologic distribution. Compact lime formations found at the greater depths were less easily decomposed than more recent formations at less depths.

Residual effects of forty years continuous manurial treatment.—III, Ultimate fate and some physical and chemical effects of applied lime, J. W. WHITE and F. J. HOLBEN (*Soil Sci.*, 22 (1926), No. 1, pp. 61-74).—In this third contribution (E. S. R., 55, p. 220), studies of the fate of two forms of lime and of the physical and chemical effects of continuous liming of soils are reported.

The results showed that the actual loss of calcium oxide from the normal plowed depth is not necessarily confined to that removed by drainage. It was found that the rate of limestone decomposition is influenced by the soil reaction.

H-ion studies showed that a soil treated with burnt lime had an average OH-ion concentration of 7.88, as compared to 7.68 where limestone was applied. Three months after burnt lime was applied the OH-ion concentration was 7.91, as compared to 7.81 39 months after lime application. This is taken to indicate that lime has therefore not maintained a high OH-ion concentration on this soil. Lime was found to have a tendency to reduce the water-soluble potassium by 7.1 per cent when used alone and 6.7 per cent when used with manure.

The Missouri fertilizer law, F. B. MUMFORD and L. D. HAIGH (*Missouri Sta. Circ.* 152 (1926), pp. 4).—The text of the law is presented and briefly discussed.

Testing fertilizers—spring, 1926, L. D. HAIGH (*Missouri Sta. Circ.* 149 (1926), pp. 8).—Guaranties and actual analyses of 102 samples of fertilizers

and fertilizer materials collected for inspection in Missouri in the spring of 1926 are presented.

Inspection of commercial fertilizers for 1926, T. G. PHILLIPS, T. O. SMITH, and A. W. PETRE (*New Hampshire Sta. Bul.* 225 (1926), pp. [1]+16).—Guaranties and actual analyses of samples of 103 brands of fertilizers and fertilizer materials collected for inspection in New Hampshire during 1926 are presented.

AGRICULTURAL BOTANY

Corn stalks vs. field plots as a guide to the fertility requirements of the corn crop, F. A. WELTON, V. H. MORRIS, and R. W. GERDEL (*Ohio Sta. Bul.* 397 (1926), pp. 284-302, figs. 5).—A report is given of a study of the Hoffer method of estimating plant food deficiencies by chemical tests of cornstalks (E. S. R., 56, p. 220), the tests being applied to corn plants grown on fertility plats on six soil types. The results of the chemical tests are tabulated in comparison with the yields.

The authors consider the results of their investigations as unfavorable for the method, as sometimes the tests were quite variable and often were conflicting when compared with the history of the fertilizer treatments of the plats.

The influence of potash on cotton bolls and foliage on a potash deficient soil, J. J. SKINNER and W. F. PATE (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 9, pp. 550-556, figs. 3).—The results are given in detailed and tabular form of fertilizer experiments made in 1923 and repeated in 1924 with cotton on a Coastal Plain soil formed of Piedmont material brought down by water action. These results show striking needs of the soil for certain plant food materials for cotton production, also the influence of certain fertilizer elements on the character of the cotton plant and on the fiber produced by it.

Studies concerning the essential nature of aluminum and silicon for plant growth, A. L. SOMMER (*Calif. Univ. Pubs. Agr. Sci.*, 5 (1926), No. 2, pp. 57-81, figs. 2).—Experimentation to determine whether aluminum and silicon are essential to plant growth employed especially purified salts and redistilled water, all containers being coated with paraffin or Valspar deprived so far as possible by special treatment of any soluble constituent.

Addition of aluminum to pea cultures gave a small increase in total dry weight and a greater increase in seed amount. Aluminum with millet increased growth markedly, especially in case of the seed, these experiments suggesting that aluminum may be essential to millet. Silicon may also be essential to the growth of rice. Seeds of millet grown without silicon were seriously infected by fungi, those grown with silicon not being attacked.

Soluble aluminium in relation to plant growth in culture solutions and in acid soils, J. LINE (*Brit. Assoc. Adv. Sci. Rpt.* 93 (1925), p. 364).—As here outlined, this account deals with the evidence on which the toxic aluminum theory of acid soils is based; the conditions under which aluminum is precipitated as hydroxide and as phosphate; the addition of aluminum salts to culture solutions and interaction of the plant and such culture solutions; and amounts of soluble aluminum found in acid soils and the growth of plants in soils so treated.

The toxicity of water distilled in metallic vessels, and its neutralization [trans. title], P. LESAGE (*Rev. Gén. Bot.*, 36 (1924), No. 424, pp. 145-158).—Experimentation with dwarf peas is described. Magnesium choride is thought to exert an antitoxic influence.

Copper injury to cabbage plants, L. R. DETJEN and G. F. GRAY (*Delaware Sta. Bul.* 147 (1926), p. 26).—Injury to cabbage grown in a greenhouse behind copper screens was traced to watering the plants through the screens, sufficient copper having been carried to the plants to cause their injury. Generally a soft rot followed the copper injury, and the plants died quickly.

Theory of regeneration based on mass action, II, J. LOEB (*Jour. Gen. Physiol.*, 6 (1923), No. 2, pp. 207-214, figs. 2).—The polarity in the regeneration of an isolated piece of stem of *Bryophyllum calycinum* expresses itself by the characteristic facts first, that regeneration occurs only at the extreme ends, and, second, that the character of the regenerated organs is different at the opposite ends, shoots being formed at the most apical nodes and roots at the extreme basal end of the piece. Explanation which has been offered is discussed in view of facts set forth previously (E. S. R., 51, p. 731).

Quantitative proof is furnished that all the material available for shoot and root formation in an isolated leaf of *B. calycinum* flows to those notches where, through the influence of gravity or by a more abundant supply of water, growth is accelerated. As soon as acceleration of growth in these notches commences, the growth of the shoots and roots in the other notches which may already have started ceases. "Analogy with the behavior of regeneration in a leaf in which the growth in one set of notches is accelerated suggests that in an isolated stem a more rapid growth is favored at the extreme ends (probably by a block of the sap flow at the extreme ends), and that when this happens the total flow of ascending sap goes to the most apical buds and the total flow of the descending sap goes to the most basal roots. As soon as this occurs, the growth of the other roots and shoots is suppressed."

[Studies on the plasma membrane], A. WEIS (*Ztschr. Wiss. Biol., Abt. E, Arch. Wiss. Bot.*, 1 (1925), No. 1, pp. 145-186, figs. 9).—This account of plasma membrane and plasma threads in the epidermis of *Allium cepa* resulted from work done toward a dissertation in the Botanical Institute of the University of Leipzig, 1922-1924.

Permeability in *Beggiatoa mirabilis* [trans. title], W. RUHLAND and C. HOFFMANN (*Ztschr. Wiss. Biol., Abt. E, Arch. Wiss. Bot.*, 1 (1925), No. 1, pp. 1-83, figs. 10).—This is a contribution bearing upon the ultrafilter theory of plasma.

Changes in hydrogen-ion concentration in nutrient solutions.—I, In a culture with wheat. II, In cultures with rice, H. G. M. JACOBSON (*Jour. Amer. Soc. Agron.*, 17 (1925), No. 9, pp. 577-586).—Experimentation is described in the first part of this report as carried out with wheat plantlets in dilutions of Group III solution R₂S₁ of the National Research Council series. Considerable change occurred in this solution when subjected to 100-day plants for 3 days. Increase in pH values in the solution was thought to be due to the anion of KNO₃ being taken up more rapidly than the cation, thus leaving potassium to form a basic compound which in turn tended to neutralize some of the existing acidity. The changes in pH values and nitrogen concentrations were not due to biological activities. Root excretions were probably also a partial cause for the increase in pH values.

In the second part of this report an account is given of a similar investigation with the rice plant. Approximately 80 per cent of the total nitrogen of the solutions was removed gradually during the 3 days of the experiment. The pH values of the solutions changed from pH 5.0 to 3.0 after growing rice plants for one 3-day period. The decrease in pH was more marked after the cessation of photosynthesis. The main cause of the reaction changes noted

is thought to be the CO_2 given off by the rice plant roots and absorbed by the cultural solution. A partial cause was, supposedly, the taking up of cations of salts having SO_4 anions by the rice plants, resulting in the formation of H_2SO_4 .

The effects on plant plasma of H ions in different concentrations [trans. title], T. SAKAMURA and T. L. Loo (*Bot. Mag. [Tokyo]*, 39 (1925), No. 460, pp. 61-76, fig. 1).—This contribution bears upon the concept of an isoelectric point for protoplasm. The work basing this account was done with *Spirogyra* sp. The results are given in tabular and graphical form, with discussion.

The genesis of starch in cereals [trans. title], H. BELVAL (*Rev. Gén. Bot.*, 36 (1924), Nos. 427, pp. 308-324; 428, pp. 337-356; 429, pp. 395-411).—Starch of cereals is formed apparently from carbohydrate substance elaborated by the leaves, which is delivered to the stem principally in the form of hexoses. One part of this is utilized immediately, a second part being held as reserve pending the appearance of the grain, to which the carbohydrates then migrate, undergoing transformation. Starch is lacking in green parenchyma, though sugar is evident. As regards the character of the reserves, maize and wheat are separable so as to constitute distinct classes, which are dealt with in some detail.

The influence of chemical agencies on starch content and osmotic values in stomatal guard cells [trans. title], J. ARENDS (*Ztschr. Wiss. Biol., Abt. E, Arch. Wiss. Bot.*, 1 (1925), No. 1, pp. 84-115).—The effects of widely different chemical substances on osmotic values in stomatal guard cells are detailed, with generalizations.

A new product of sugar transformation by fungi [trans. title], W. S. BUTKEWITSCH (*Ztschr. Wiss. Biol., Abt. E, Planta, Arch. Wiss. Bot.*, 1 (1926), No. 5, pp. 657-665).—The substance herein described was obtained from saccharine cultures of *Aspergillus oryzae*.

The significance of acid amids for nitrogen exchange in higher plants [trans. title], K. MOTHES (*Ztschr. Wiss. Biol., Abt. E, Arch. Wiss. Bot.*, 1 (1925), No. 2, pp. 317-320).—Amids in older plants play as significant a rôle as in plants during germination. Details are given.

The rôle of asparagine in the transformations of nitrogenous materials in plants [trans. title], PRIANICHNIKOV (*Rev. Gén. Bot.*, 36 (1924), Nos. 423, pp. 108-122, figs. 3; 424, pp. 159-181).—Ammonia constitutes both the beginning and the end of nitrogen transformations in the plant. Asparagine is an important phase in synthesis at a certain stage, the subsequent relations of which are outlined.

Light and growth, J. PRIESTLEY (*Brit. Assoc. Adv. Sci. Rpt.* 93 (1925), p. 357).—"An attempt is made to bring to one common focus the phenomena of etiolation, including the remarkable morphological and structural changes included by very brief exposures of etiolated plants to light, and the facts of phototropism, as exhibited both in the higher plants and in fungus hyphae. An attempt is made to interpret the phenomena of phototropism without the employment of the terms 'stimulus' and 'response.'"

The daily course of photosynthesis in land plants [trans. title], S. KOSTYTSCHEW, M. KUDRIAVZEWA, W. MOISSEJEWA, and M. SMIRNOWA (*Ztschr. Wiss. Biol., Abt. E, Planta, Arch. Wiss. Bot.*, 1 (1926), No. 5, pp. 679-699, figs. 6).—The authors have studied photosynthesis in *Lappa tomentosa*, *Phragmites communis*, and *Betula pubescens* as to its daily normal course and as to modifying causes. On cloudy days the rate of photosynthesis is significantly lower than on clear days.

The physiology of paraheliotropism, E. NUERNBERGK (*Beiträge zur Physiologie des Tagesschlafs der Pflanzen*. Jena: Gustav Fischer, 1925, pp. 138, figs. 8).—Discussing the so-called diurnal sleep of leaves as seen in 17 plants, the author holds that the phenomena usually dealt with under this term include as regards causation two distinct processes, diurnal sleep (in the strict sense of that expression) due to illumination and another phase here called heat sleep.

The distribution of geotropic sensitivity in negatively geotropic plant organs [trans. title], W. HERZOG (*Ztschr. Wiss. Biol., Abt. E, Arch. Wiss. Bot.*, 1 (1925), No. 1, pp. 116-144, fig. 1).—Experimentation with parts of different plants is systematically reported. In all objects studied there was a local concurrence of sensitive zone and statolith starch.

Temperature relations in wound reactions, M. C. POTTER (*Brit. Assoc. Adv. Sci. Rpt.* 93 (1925), p. 361).—Temperature raising and temperature lowering factors are considered.

The injection of lacunae as a sign of death in aquatic plants [trans. title], H. DEVAUX (*Rev. Gén. Bot.*, 36 (1924), No. 423, pp. 99-107).—The spontaneous injection of aeriferous spaces in aquatic plants is always an accompaniment of death, being strictly localized in the parts which are dead. The injection of the spaces indicates, indirectly, a disorganization of the protoplasm more profound than simple coagulation.

[**Seeds and X-rays**], S. ANCEL (*Bul. Soc. Bot. France*, 72 (1925), No. 1-2, pp. 195-199).—The germination period of seeds of *Phaseolus vulgaris* was not affected by exposure to X-rays of different intensities.

Torsion in developmental movements of leaves, A. SEYBOLD (*Über die Drehung bei der Entfaltungsbewegung der Blätter*. Jena: Gustav Fischer, 1925, pp. 80, figs. 64).—A study, featuring the viewpoint of Goebel (*E. S. R.*, 53, p. 324), regarding teleology and actual causation in floral developmental movements is detailed.

Accessory buds, W. SANDT (*Zur Kenntnis der Beiknospen*. Jena: Gustav Fischer, 1925, pp. 160, figs. 50).—An extended study of accessory buds deals also with problems of correlation.

Biological study of the blooming of flowers [trans. title], A. DAVY DE VIRVILLE and F. OBATON (*Rev. Gén. Bot.*, 36 (1924), No. 422, pp. 49-67, pls. 3).—These experiments are claimed to have enabled the authors, by a study of the isolated action of each of the different meteorological factors, to ascertain the part played by each factor as influencing the opening and closure of flowers.

Seeds and plants imported by the Office of Foreign Plant Introduction, Bureau of Plant Industry, during the period from January 1 to March 31, 1924 (*U. S. Dept. Agr., Inventory* 78 (1926), pp. 34).—Lists are given, together with economic notes, on about 475 lots of seeds and plants introduced for testing in various parts of the United States.

Bergey's manual of determinative bacteriology, D. H. BERGEY ET AL. (*Baltimore: Williams & Wilkins Co.*, 1925, 2. ed., pp. XVI+462).—A key for the identification of organisms of the class Schizomycetes was arranged by a committee of the Society of American Bacteriologists, consisting of D. H. Bergey as chairman, with F. C. Harrison, R. S. Breed, B. W. Hammer, and F. M. Huntoon. "The committee does not regard the classification of species offered here as in any sense final, but merely a progress report leading to more satisfactory classification in the future." As no bacteriological code had been formulated for bacteriologists, the committee used the International Rules of

Botanical Nomenclature adopted by the International Congress of Vienna, 1905, and Brussels, 1910, in so far as these rules were applicable to bacteriology. An index prepared by R. S. Breed concludes the volume.

GENETICS

Genetics and eugenics in South Africa: Heredity and environment, J. E. DUERDEN (*So. African Jour. Sci.*, 22 (1925), pp. 59-72, pl. 1).—The author calls attention to marked differences in the development of hereditary characters under varying conditions of environment, with special reference to the effects of environment on the development of the European and native races in South Africa.

A critical study of the nature of hereditary factors [trans. title], A. A. LIÜBISCHCHEV (LUBISCHEW) (*Izv. Biol. Nauch. Issledov. Inst. Permsk. Gosud. Univ. (Bul. Inst. Recherches Biol. Univ. Perm)*, 4 (1925), *Sup. 1*, pp. 142; *Eng. abs.*, pp. 126-142).—A critical analysis is presented of the various conceptions of the nature and potentialities of hereditary factors which have been presented by various investigators, many of which are more or less contradictory.

The new preformationist doctrine, C. YAMPOLSKY (*Genetica [The Hague]*, 7 (1925), Nos. 5-6, pp. 507-516).—In contrast to the original preformationist doctrine that the individual was present in miniature in the germ cells the new doctrine assumes the organization of determiners for the various characters within the nuclei of the egg and sperm cells.

Recent advances in cytology, L. W. SHARP (*Amer. Jour. Bot.*, 11 (1924), No. 10, pp. 610-616).—A brief outline, with concluding remarks, presents phases of recent progress in cytological interests.

Cytological studies in the genus *Crataegus*, A. E. LONGLEY (*Amer. Jour. Bot.*, 11 (1924), No. 5, pp. 295-317, pls. 3, figs. 8).—Study of material collected at the Arnold Arboretum of Harvard University gave indications that the members of the polymorphic genus *Crataegus* can be grouped into diploid species with the chromosome number 16, triploid and tetraploid species able to develop their pollen mother cells to the tetrad stage, and triploid and tetraploid species in which the pollen mother cells have thin and vacuolated cytoplasm and seldom develop to the tetrad stage. These are discussed as to characters and behavior.

Soy bean investigations, G. L. SCHUSTER (*Delaware Sta. Bul.* 147 (1926), p. 6).—Cytological studies of the soy bean showed the presence of seven chromosomes and that they are short and thick.

The maturation divisions in relation to the segregation of homologous chromosomes, E. E. CAROTHERS (*Quart. Rev. Biol.*, 1 (1926), No. 3, pp. 419-435, figs. 2).—From a discussion of the literature bearing on the maturation division in which reduction occurs, it is concluded that neither maturation division may be rightly called a segregation division, but that the two maturation divisions are essentially a unit process and segregation may occur in either.

Chromosome numbers in crop plants, H. C. AASE and L. POWERS (*Amer. Jour. Bot.*, 13 (1926), No. 6 pp. 367-372, pls. 2).—Counts at the Washington Experiment Station showed the chromosome numbers of *Triticum monococcum* to be 7, *T. dicoccoides*, *T. turgidum*, *T. dicocum*, and *T. durum* 14, *T. spelta*, *T. compactum*, and *T. vulgare* 21, *Avena viestii*, *A. brevis*, and *A. strigosa* 7, *A. sativa* 21, *Hordeum spontaneum* and *H. vulgare* 7, *H. murinum* and *H. jubatum* 14, *Secale cereale* 7, and *Aegilops cylindrica*, *A. triuncialis*, *A. squarrosa*, *A. ovata*, and *Arrhenatherum elatius* 14. A summary of chromosome

counts in crop plants and related forms, omitting species counted by the authors, is also included.

Chromosome VIII in maize, W. H. EYSTER (*Science*, 64 (1926), No. 1644, p. 22).—At least five factor pairs, of which four are described as new, were found at the University of Maine to be linked with *Pr pr* factor pair, which modifies aleurone color in corn from red to purple and which does not seem to belong to any of the seven linkage groups already reported in corn. These factor pairs include *Bm bm*, which, when homozygous recessive, causes a water-soluble, yellowish-brown pigment to develop in the cells of the midrib and sheath of the leaves; *Sc₁ sc₁*, for scarred endosperm (E. S. R., 48, p. 437); *Fi₂ fi₂*, for a fine striping of the chlorophyll, which appears in young seedlings and persists through the life of the plant; *Yg yg*, which, when homozygous recessive, causes the seedling as well as the growing plant to be distinctly yellowish-green in color, due to a deficiency in the chloroplastid pigments; and *Tn tn*, which, when homozygous recessive, produces a small slender plant with a usually very small ear shoot, a small unbranched tassel, and leaves always strongly tinged with anthocyanin.

"This group of linked factors is especially interesting in that it represents a new chromosome in maize, to be designated as chromosome VIII."

A chemical conception of genes [trans. title], H. SCHMALFUSS (*Ztschr. Induktive Abstam. u. Vererbungslehre*, 41 (1926), No. 1, pp. 111, 112).—The author considers the gene in the light of a catalytic agent in chemistry.

Mutations in the sweet potato, J. T. ROSA (*Jour. Heredity*, 17 (1926), No. 5, pp. 167, 168, pl. 1).—A root longitudinally striped with white and yellow, two white roots, and several normal yellow roots were borne on a plant of the Yellow Jersey sweet-potato variety at the California Experiment Station. The striped root is considered a sectorial chimera. In the crop from the mutant plants the plants having white roots were inferior in yield to their yellow brethren. A hill of Nancy Hall bearing white potatoes and its progeny are also described.

On the irrelevant nature of the question whether new characters can be produced by fresh combinations of pre-existing ones, J. P. LOTSY (*Genetica [The Hague]*, 7 (1925), Nos. 5-6, pp. 517-520).—The author compares the production of new characters by recombinations of preexisting ones to the ability of the chemist to produce new substances by recombinations of elements.

Some wool characters and their inheritance, C. B. DAVENPORT and E. G. RITZMAN (*New Hampshire Sta. Tech. Bul.* 31 (1926), pp. 58, figs. 3).—Studies of the wool characters of the animals used in the cross-breeding experiments, of which the inheritance of traits of conformation was previously noted (E. S. R., 50, p. 26), are reported.

Fleece weight was found to be considerably affected by age, feeding, and general environmental conditions, and was therefore very difficult to analyze genetically. In the F_1 hybrids of Rambouillet ewes with Hampshire and Southdown rams and of Oxford ewes with Rambouillet ram, the fleece weight was nearer to that of the Down parent, but exceeded it slightly except in the Oxford cross where the fleece was lighter than that of either parent. In later generations the fleece was improved by selection and there was evidence of segregation, especially in the scoured fleece weight.

The diameter of the wool fibers of the F_1 crosses was variable but intermediate between the parents, indicating that the parental races, especially the Hampshires, are heterozygous with regard to the factors responsible. In the Southdown \times Rambouillet cross the F_2 generation was less variable with respect to the diameter of the fiber than the F_1 , due to the fact that both sires and

dams were selected for intermediate wool diameter. The variability was again reduced in the F_3 generation by the same means. There was no evidence of a permanent blend in the F_1 generation, but the F_2 average may be moved in either direction according to the genotype of the parents. Fineness of wool is evidently controlled by multiple factors. As in the case of the fineness of wool, the variability of the length of fiber tended to diminish in successive generations, but there seemed to be no physiological dependence of small diameter on shortness of fiber.

Crimpiness was also intermediate in its mode of inheritance, though there was an inclination of the F_1 toward the more crimping parent. Correlation coefficients indicated that there was no significant relation between crimp and diameter of fiber though a positive correlation between percentage of crimp and length of fiber was indicated, probably due to the fact that the more crimp there is the more the fiber can be elongated.

Lethal factors with regard to their behavior in domestic animals and in man [trans. title], O. L. MOHR (*Ztschr. Induktive Abstam. u. Vererbungslehre*, 41 (1926), No. 1, pp. 59-109, figs. 10).—This is a discussion of the various lethal and semilethal factors in man, animals, and *Drosophila*, including their mode of inheritance.

A case of pollen dimorphism in maize, M. DEMEREC (*Amer. Jour. Bot.*, 11 (1924), No. 7, pp. 461-464, fig. 1).—By treating the pollen of heterozygous corn plants with iodine, it was found that segregation could be detected in the gametophytic generation. Plants heterozygous for waxy endosperm had about 50 per cent waxy and 50 per cent starchy pollen grains in one and the same pollen sac. The case resembled that described by Parnell (*E. S. R.*, 48, p. 28) for rice.

On the nature and the conditions of the formation of esculent roots.—**Preliminary report** [trans. title], E. SINSKAFĀ (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 1, pp. 3-35, figs. 4; *Eng. abs.*, pp. 26-35).—Crosses between the edible radish with esculent roots and a wild form without enlarged roots yielded in the F_1 generation all thin roots, followed by segregation into thin, intermediate, and esculent types in the F_2 . On the other hand, crosses between the oleiferous radish (thin root) and the common radish yielded enlarged roots in the F_1 and no regular splitting in the F_2 . Apparently the thin root of the wild radish and the thin root of the oleiferous radish are of different genetic nature.

In crosses between *Brassica campestris* and *B. napus*, both thin rooted forms, the F_1 forms were generally intermediate. The occurrence of enlarged roots in a stock of *B. juncea*, a normally thin-root species, is believed to be due to natural hybridization. In the F_2 generation of crosses between *B. juncea* and *B. chinensis*, both thin-root forms, there was noted one strain with esculent roots.

Pointing out that soil fertility and moisture and the source of seed also function in the production of enlarged roots, the author concludes that the ability to produce edible roots is the product of the interaction of genotype and environment.

Barley with orange lemmas [trans. title], A. BAUMAN (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 3, pp. 181-186; *Eng. abs.*, p. 186).—Crossing a hulled 2-row barley (*Hordeum distichum ucrainicum*), showing lemmas colored a distinct orange, which was also spread over the rachis, with other varieties gave rise to a series of new constant orange-pigmented forms. The orange color is evidently recessive.

The variability of crossing over in maize, L. J. STADLER (*Genetics*, 11 (1926), No. 1, pp. 1-37, figs. 6).—Significant observations in this contribution from the University of Missouri have been recorded from another source (E. S. R., 54, p. 728).

Hybrid vigor in cowpeas, F. W. HOFMANN (*Jour. Heredity*, 17 (1926), No. 6, pp. 209-211, figs. 2).—F₁ reciprocal hybrids from California Black Eye × Blue Goose cowpeas were intermediate in flower color in greenhouse and field cultures at the University of Illinois but exhibited heterosis in diameter of stem, plant height, and potential seed yield. The hybrids bloomed much later than either parent.

The segregation of *Oenothera nanella-brevistylis* from crosses with *nanella* and with *lamarckiana*, B. M. DAVIS (*Genetics*, 11 (1926), No. 1, pp. 57-72).—The studies reported were carried on at the University of Michigan.

A haploid wheat plant, E. F. GAINES and H. C. AASE (*Amer. Jour. Bot.*, 13 (1926), No. 6, pp. 373-385, figs. 10).—Pollination of Hybrid 128, *Triticum compactum humboldtii*, with pollen of *Aegilops cylindrica* at the Washington Experiment Station resulted in a plant resembling the female parent but almost completely (99.8 per cent) sterile, producing 9 seeds.

Cytological studies revealed that the nuclei of the spore mother cells and of the somatic cells of the stamens and pistils contained 21 single chromosomes. Sporogenesis was irregular, the 21 unpaired chromosomes were distributed in the first division, apparently by chance, to the two poles, and chromosomes frequently strayed into the cytoplasm. Pollen grains varied greatly as to size and as to the number of nuclei contained. Giant multinucleate pollen grains were sometimes found as a result of the coalescence of contiguous pollen mother cells. Fusion of somatic nuclei in pairs, and subsequent mitosis, frequently occurred in ovaries and anthers.

The haploid Hybrid 128 is triploid in respect to the genus *Triticum*, and its nuclei probably contain 3 dissimilar sets of 7 chromosomes each. Synapsis fails, possibly on account of the absence of homologous chromosomes. The absence of homologous mates seems to be as fatal to orderly meiosis as the presence of inharmonious chromosomes in hybrid offspring.

On the actual existence of leporides, K. KUIPER (*Genetica [The Hague]*, 7 (1925), Nos. 5-6, pp. 471-474).—The author describes several crosses of rabbits and hares which have produced offspring in the experimental garden of Mr. Houwink in the Netherlands. The leporides produced also proved to be fertile.

Correlation and machine calculation, H. A. WALLACE and G. W. SNEDECOR (*Iowa Agr. Col. Off. Pub.*, 23 (1925), No. 35, pp. 47, figs. 6).—The meaning and uses of the various correlation coefficients, simple, partial, and multiple, are presented in nontechnical language, and explicit directions are set forth for the use of the usual commercial forms of calculating machines, either key-driven or crank-driven, in finding correlation coefficients or related constants.

On the correlation between the weight of new-born and that of growing and of full-grown rabbits [trans. title], S. KOPEĆ (*Pam. Państw. Inst. Nauk. Gosp. Wiejsk. Puławach (Mém. Inst. Natl. Polon. Écon. Rurale Puławy)*, 6 (1925), A, pp. 288-329, figs. 2; *Eng. abs.*, pp. 325-329).—In continuing the studies of the inheritance of weight in rabbits (E. S. R., 52, p. 331), weights at birth and at 10-day intervals to 90 days and at 30-day intervals to 390 days are reported on 30 male and 30 female F₂ rabbits from the cross Himalayan ♀ × Silver ♂. By classifying the individuals into five groups according to their birth weights, it was found that the mature weights ranked in the same order as the birth weights. Significant positive correlation coefficients were calculated between the birth weights and the weights at the different ages in prac-

tically all cases for males and females. It is, therefore, concluded that inferences as to the inheritance of mature size may be drawn from the weights at birth. When grouped according to litter size there was no such relation between birth weights and the weights at the different ages, and part of the correlation coefficients were positive while others were negative. Females were generally slightly heavier than males.

Studies of growth according to the percentage monthly increment in live weight showed, when plotted, that the curve was bimodal, the one mode occurring in the second month and the other in the seventh month. Four periods are distinguished by the author for the rates of growth of the rabbits under investigation, i. e., first month, second to sixth month, seventh to ninth month, and tenth to thirteenth month. Growth was completed by the end of the third period. The percentage monthly increment in weight was inversely related to the birth weights.

Ovulation in the rabbit, F. F. SNYDER (*Abs. in Anat. Rec.*, 32 (1926), No. 3, p. 242).—Studies of the oestrous cycle and ovulation in 18 rabbits between 6 and 12 months of age indicated that no regular cyclic changes occurred in the vaginal smears or in the vaginal wall, but mating occurred readily in nonpregnant animals at all times and was followed by ovulation. Ovulation was indicated by the recovery of ova from the Fallopian tubes. Ovulation without mating was not observed.

Anthropological studies of single and double ovum twins [trans. title], O. V. VERSCHUER (*Ztschr. Induktive Abstam. u. Vererbungslehre*, 41 (1926), No. 1, pp. 115-119).—The differences in the weights and measurements at various ages of 93 single ovum and 43 double ovum twins have been determined. The average and percentage differences between the individuals of the pairs were obviously greater in the twins from 2 ova than in the twins from a single ovum, though wide variations in the relation of these differences were found in the several parts measured. Attention is called to a possible relation between the left- or right-handedness of males and the comparative placement of the left and right testicles, as well as to the corresponding location and pressure on double ovum twins in utero.

Invariable production of deciduomata in the virgin rat with anterior hypophyseal fluid, H. M. TEEL (*Abs. in Anat. Rec.*, 32 (1926), No. 3, p. 243).—Deciduomata were regularly produced in virgin rats by the insertion of silk threads into the uterus after the administration of anterior hypophyseal fluid, though under ordinary conditions without the administration of this substance deciduomata are relatively impossible to produce in the virgin rat. Such results did not follow in spayed rats.

On the analysis of the morphogenesis in animals, M. ZAWADOWSKY (*Biol. Gen.*, 2 (1926), No. 3, pp. 352, 353).—From the results of experiments with various breeds of fowls, ducks, pheasants, antelopes, bulls, deer, and rams, in which gonad tissue from one sex was transplanted to the other sex, the author concludes in general that both sexes have the same potentialities for development, except that certain modifications are brought about by the hormones produced by the sex glands. A partial inequality of the potentialities of the characters independent of sex is, however, admitted.

Chemical differences in blood as related to sex, L. J. NEEDELS (*Abs. in Anat. Rec.*, 32 (1926), No. 3, pp. 238, 239).—In studies with rats and monkeys at the University of Missouri School of Medicine, the sex glands have been found to play an important rôle in the Manoilov reaction. The animals used consisted of females at different stages of the oestrous and menstrual cycles, castrated males and spayed females, and spayed females in which oestrus was

produced by injection of ovarian and placental hormones. From these studies it was concluded that the degree of decolorization of the blood was greater in males and in young animals than in females and older animals. The oxidation was greatest in rats during oestrus and in monkeys during the intermenstruum period. The reaction was decreased by the removal of the ovaries, but increased by the injection of ovarian and placental hormones into spayed animals. Castrated males tended to react as females, while stunted and diseased animals gave atypical results.

FIELD CROPS

Mathematics and agronomy, STUDENT (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 703-719, figs. 3).—A discussion of the mathematical analysis of the results of agronomic experiments.

The arrangement of field experiments, R. A. FISHER (*Jour. Min. Agr. [Gt. Brit.]*, 33 (1926), No. 6, pp. 503-513, fig. 1).—In dealing with the class of error held due to soil heterogeneity, the author questions the significance of a result and discusses the measurement of accuracy by replication, wrongly estimated errors, distinction between errors, random plot arrangement, the Latin square, and complex experimentation.

[**Field crops experiments in Arkansas**] (*Arkansas Sta. Bul.* 215 (1926), pp. 7-23, 49-51).—Among continued experiments (E. S. R., 55, p. 29) reported on were varietal trials with cotton, corn, wheat, oats, rye, barley, sorgho, soy beans, cowpeas, alfalfa, peanuts, potatoes, and sweet potatoes and breeding work with cotton, corn, oats, wheat, and sweet potatoes.

In nutrition studies with rice an abandoned rice soil gave the best growth through the period up to May 15; from then to maturity a typical rice soil which had been growing rice for several years appeared to excel in crop growth and development. A virgin rice soil showed the poorest growth and matured the rice later than the two other soils. In greenhouse fertilizer tests the abandoned soil made its highest yield with an application of ammonium sulfate with acid phosphate, the cropped soil with cottonseed meal in combination with acid phosphate and potassium, and the virgin soil with cottonseed meal, phosphoric acid, potassium, and lime.

Marked progress was reported in breeding for oil and nitrogen content of cotton seed. The season apparently tended to augment the protein content of the seed, whereas the reverse was observed as to oil content. Selections from commercial cotton varieties were noted for their increase in yield and in earliness over the parent stocks. Spacing results for the year favored a thick stand resulting from light thinning.

Cultivation of corn to a medium depth again surpassed other methods at the station, losses being recorded from very shallow cultivation, delayed cultivation, no cultivation, and none except weeds hoed off. Some yield increases followed deep cultivation at Scott, whereas delayed cultivation, no cultivation, and laying by early resulted in marked reduction. Planting experiments over a period indicated April 15 as the surest date at the station and from June 1 to 15 at Scott. Corn grown with cowpeas, soy beans, and velvet beans averaged 33.3 bu. per acre, while corn grown alone made 46.4 bu. Interplanting of legumes may have a certain merit on very small farms where small fields are cultivated, especially in hilly areas where much hand work is involved. Tests at Scott indicated that corn row widths may be increased advantageously to some extent with legumes between the rows. However, with rows at about twice the normal width corn yields declined.

Several legumes were grown in separate blocks, some being seeded in spring oats, and were cut off for hay or plowed under and corn grown subsequently

to measure the effects. Data thus far obtained showed that, when no other crop is grown on the land in the season, using the legumes for hay results most profitably, whereas when legumes can be grown after a crop such as early harvested oats, it is well to plow under the legumes. Peanuts seemed to yield best in close plantings, i. e., 8 to 12 in. apart in 2.5-ft. rows. The merits of lespedeza, bur clover, hairy vetch, sweet clover, beggar weed, Canadian and Austrian field peas, and velvet beans are detailed from the results of tests.

Frequent cutting of alfalfa resulted in slightly larger annual hay production and a noticeable reduction of stand. Permitting the alfalfa to remain as long as feasible without heavy loss of foliage seemed desirable for lasting stands. Manure was more effective than commercial fertilizer, although both helped to prolong the duration of the stand. Cultivation after each cutting with a loaded spike tooth harrow was not very effective. Apparently alfalfa first gives out and weeds follow closely in its wake instead of the weeds crowding out the alfalfa. Grimm alfalfa has proved superior to other alfalfas tested.

Fertilizer recommendations are made for potatoes (E. S. R., 55, p. 435) on different soil types. Certified northern seed again outyielded good commercial northern stock. During attempts to obtain immediate growth in freshly dug potatoes, the ethylene chlorohydrin method developed by Denny (E. S. R., 55, p. 829) resulted in 100 per cent germination of freshly dug potatoes within 10 days after treatment. It appeared that the ethylene treatment should be made below 70° F., although the germination of the treated seed proceeds most rapidly at soil temperatures of about 80°. Of the other methods tried, storing freshly dug tubers in a dry place at 80 to 90° with free air circulation has excelled. Tubers stored 4 weeks will sprout in 5 to 7 days provided the soil temperature is high.

The residue from acid phosphate applied to a previous crop of potatoes, tomatoes, or cotton is recommended for sweet potatoes. Where such land is not available from 300 to 500 lbs. of 12-4-4 fertilizer may be applied under the ridges or beds. The best stands and yields resulted from early plantings, and spacing slips from 12 to 16 in. apart in 30- to 36-in. rows reduced the proportion of oversized roots. Attempts to improve strains by hill selection resulted negatively. Storage studies showed the need of careful and rapid handling in the marketing of cured stock. Sweet potatoes cut and bruised at digging kept perfectly until spring with little more shrinkage than sound roots, but when injured after being stored until February rotted in from a few days to 2 weeks, depending on whether a high or medium low temperature was maintained.

[Field crops experiments in Illinois] (*Illinois Sta. Rpt. 1926, pp. 8, 9, 27, 34-38, 42-49, 133-136, figs. 2*).—Continued investigations (E. S. R., 56, p. 229) reported on embraced varietal trials with corn, oats, winter and spring wheat and barley, breeding work with these crops and rye, a storage test with potatoes, and rotations.

The 1925 crop from the high protein and low protein corn strains analyzed 18.3 and 7.43 per cent protein, respectively, and the high and low oil strains 10.21 and 1.43 per cent of oil. The respective heights of ear of the high ear and low ear strains were 99.8 and 9.7 in., and on the 2-ear strain 60 per cent of the stalks bore two or more ears. "Barren-sterile," a type of plant without shoot or tassel, appeared to be a simple recessive to the normal type in work by C. M. Woodworth and F. L. Winter.

In line with previous years, G. H. Dungan, W. L. Burlison, and B. Koehler found corn harvested for seed when mature to outyield corn picked in earlier stages. Seed corn placed in bangers November 30 and December 1 and

containing about 23 per cent of moisture in the grain was dried in several ways by E. W. Lehmann and R. C. Kelleher. The corn dried by 79.4 hours of forced heated air at 93° F. was not damaged in germination according to tests made April 24, whereas the seed dried by 207.6 hours of forced unheated air germinated 19.2 per cent below its December 1 record. Seed allowed to dry by natural ventilation suffered an 18 per cent reduction in germination. Experiments by J. C. Hackleman showed that the farmer can construct a satisfactory cabinet for corn germination at a moderate cost. Dungan observed that early maturing corn varieties again produced their highest yields when planted at an intermediate date, while the later sorts yielded best when planted early.

Increased yields due to mulching winter wheat with straw may not be expected every year, according to results obtained by O. H. Sears; however, the crop following the wheat may be improved. In barley improvement work by Woodworth and Winter the characters hooded, black, and rough awned differed from their respective allelomorphs bearded, white, and smooth awned by a single factor in each case.

In tests by J. J. Pieper a mixture of oats and peas and one of oats and vetch gave the highest hay yields of the early emergency hays, while soy beans and Sudan grass led in the late emergency hay series. In another series alfalfa grown alone yielded better than when grown with either red clover, winter vetch, timothy, or orchard grass. Timothy and orchard grass with alfalfa yielded little more than half the yield of alfalfa alone. A mixture of two alfalfa varieties did not outyield either variety grown alone.

[Field crops work in Northumberland County, England], D. A. GILCHRIST (*Northumb. Co. Ed. Com. Bul. 38 (1926), pp. 10-58*).—The progress of previous experiments with field crops (E. S. R., 54, p. 231) is described.

[Report of the] Scottish Society for Research in Plant-breeding, W. ROBB (*Scot. Soc. Research Plant Breeding Rpt., 1926, pp. 26, figs. 4*).—The progress of breeding work with different field crops is described as heretofore (E. S. R., 54, p. 231.)

Maori agriculture, E. BEST (*New Zeal. Dominion Mus. Bul. 9 (1925), pp. VIII+172, pls. 27, figs. 23*).—An account of the cultivated food crops of the New Zealand natives, including the sweet potato, yam, taro, *Lagenaria vulgaris*, and *Cordyline* spp., with information on native agricultural methods, rituals, and origin myths.

East African pasture plants.—I, East African grasses, C. E. HUBBARD, W. E. TREVITHICK, and J. HUTCHINSON (*London: Crown Agents for Colonies, 1926, pp. 56, figs. 28*).—Twenty grasses which commonly occur in East Africa (Kenya, Uganda, Tanganyika, etc.) are described and illustrated, with a description of a typical grass plant and details of the floral structure.

Pasture studies, R. G. WIGGANS (*New York Cornell Sta. Mem. 104 (1926), pp. 3-59, pls. 4, figs. 3*).—The effects of fertilizers, lime, manure, seeding, and cultural treatments on the production and botanical composition of pasture areas representative of the most depleted (Turkey Hill), the generally unproductive (Bald Hill), and the high-grade pasture areas (university plats) of New York were studied during 5 years.

Acid phosphate resulted in significant increases in total vegetation under each of the conditions studied, the increases averaging about 20 per cent. Particularly on the poorer areas, the increase appeared almost wholly due to the higher proportion of grass and clover with increasingly fewer weeds.

Sodium nitrate, used only on the Bald Hill plats, produced a significant increase in total vegetation, largely by increases in grass and weeds with an

actual decrease in the clover. Apparently nitrogen might better be added to pastures through stimulation of legume production rather than by nitrogenous fertilizers. Potash, likewise used only on the Bald Hill plats, failed to give conclusive results and seemed of doubtful value as a fertilizer for pastures. On unlimed areas the increases consisted mostly of weeds, whereas on the limed areas an improvement in the quality of the product was apparent.

Lime gave very positive results in each of the tests. On the poorer areas the increases varied but averaged more than 100 per cent, while on areas previously limed the increase was consistent and was about 10 per cent. The average composition of the herbage on the Bald Hill plats changed from 5.3 per cent of clover, 26.6 of grass, and 68.1 per cent of weeds to 26.6, 43.7, and 29.7 per cent, respectively. The increases in grasses and clovers comprised the actual increases in total production and seemed to cause the decreases in weeds. A similar change was noted on Turkey Hill but not on the university pasture plats, where desirable vegetation was already established. Lime may give decided increases in production and improvement in quality on previously untreated pastures over a large area in New York.

Manure, used only in the Turkey Hill tests, resulted in an increase approaching 100 per cent in yield and in an improvement of the vegetation quality by a stimulation of white clover in particular.

Of the cultural methods tested on the low production areas, plowing decidedly altered the vegetative composition of the area for a short time after treatment by increasing grass and clover and decreasing weeds. However, the effect largely disappeared after 5 years, and the total production over several years was influenced only slightly. Greater benefits accrued from the manure on the cultivated than on the uncultivated plats. Plowing and cultivation of old pastures failed to be of distinct advantage in these trials, nor could reseeding be recommended as a means of renovating old pastures. Cutting trials showed that well-established pasture areas will usually produce more green weight and almost as certainly less dry weight when cut often as pasture than when cut once a season as hay.

[Experiments with legumes in Illinois] (*Illinois Sta. Rpt. 1926, pp. 26, 27, 28-34, fig. 1*).—Sweet clover grown on brown silt loam in studies by F. C. Bauer, H. J. Snider, E. E. DeTurk, and H. A. Lunt contained a high percentage of nitrogen, and consequently more than three times as much nitrogen per acre was obtained as in sweet clover on gray silt loam. Sweet clover on brown silt loam developed a single taproot system penetrating from 24 to more than 40 in., while that on gray silt loam produced a branching-root system penetrating from about 8 to 14 in. O. H. Sears found that late spring plowing of sweet clover for use as a green manure crop had no immediate advantage over earlier plowing. On the Sidell field early-plowed plats yielded 14.2 more bushels of corn per acre than those plowed later. Greenhouse studies with soil from the Ewing (Franklin County) field showed that sweet clover may be made more efficient as a green-manure crop for that soil by fertilizing with potassium salts.

Alfalfa studies by W. L. Burlison and J. C. Hackelman indicated that hardiness alone does not suffice to insure a good yield. Alfalfa cut in full bloom was killed out completely, while that cut in one-tenth bloom survived the winter in good shape. Grimm and Cossack, both variegated alfalfas, showed practically no winterkilling, Kansas-, Colorado-, and Idaho-grown common alfalfas were intermediate, while the already poor stand of Argentine alfalfa became even thinner. Variegated alfalfa continued to excel under northern Illinois conditions. Spring-seeded plats remained considerably better than late summer or fall-seeded plats at De Kalb.

Clipping red clover in the fall of the first year continued to increase the yield of seed considerably in tests by J. J. Pieper and W. P. Flint, although hay yields were not materially enhanced thereby. One or two spring clippings were both prejudicial to seed yields. If the first crop is used for hay and the second for seed the yield of seed probably will be high enough to justify the practice. Poor seed production of alsike and Mammoth clover was also observed.

Illini and A. K. 2, selections from A. K. soy beans, were noteworthy for their seed production and Hong Kong, A. K., and Virginia led in hay yields. In tests by Sears the increases in soy bean yields as a result of inoculation have ranged from 5 per cent on fertile brown silt loam soils to more than 300 per cent on a dune sand soil. Proper inoculation also materially increased the protein content of hay and seed. Sears also found pure cultures of legume bacteria grown on artificial or laboratory media to be superior to soil for inoculating legumes when judged by the number of nodules obtained per plant. When the same legume is grown again in the same field good nodule development is had both from pure cultures and from soil. Either method of inoculation is rendered less effective by failure to sow the seed soon after inoculation. For best results bacteria should be applied to the seed within 24 hours of planting. The yields of wheat following soy beans cut for hay or for seed were found by Sears to be larger than the yields obtained from land on which oats or corn preceded the wheat.

In soy bean improvement investigations by C. M. Woodworth yellow seed coat in a cross between Sable and Manchu proved to be dominant to black, and in 15 crosses between yellow and green cotyledon varieties the segregation in cotyledon color indicated that the yellow parents carried two factors for yellow. But one yellow variety has been found possessing a single factor only. Further evidence of linkage between tawny pubescence and black hilum was obtained.

Sunflowers as compared with corn as a silage crop for New York, R. G. WIGGANS (*New York Cornell Sta. Bul.* 456 (1926), pp. 3-29, figs. 10).—Experiments on the growing for silage of sunflowers and corn, alone and in combination, are described, with observations on the merits of sunflowers in controlling weeds and a brief report on breeding work with sunflowers. The work of others on the composition of sunflowers and their feeding value as silage is reviewed, and objections to sunflowers as a silage crop are cited.

During 4 years various mixtures of corn and sunflowers harvested for silage resulted in yields of sunflowers disproportionate to the sunflower plants in the combination. Mixtures containing 25, 50, and 75 per cent, respectively, of sunflower plants resulted in from 50 to 75, from 80 to 90, and from 90 to 96 per cent by weight of sunflowers in the harvest. The dry matter percentage in the two corn varieties tested averaged materially higher than in the sunflowers. The percentage of grain in the corn decidedly decreased as the sunflower percentage in the mixture rose, being of slight significance when as high as 50 per cent of sunflower plants was in the mixture.

Sunflowers alone averaged 52 per cent more green weight and 33 per cent more dry weight than did corn grown alone. Mixtures of corn and sunflowers generally outyielded an equal area grown one-half to corn and one-half to sunflowers. In these tests the optimum spacing for sunflowers ranged from 6 to 9 in. apart in 36-in. rows. A greater percentage of dry matter was noted in the sunflowers as the planting rate increased.

While the experimental results did not recommend sunflowers for silage in areas well suited for corn production, under certain conditions sunflowers may be very useful. These may include areas where late spring frosts and early

fall frosts make corn uncertain for silage, where very limited areas of highly productive land are available for crops and the most food possible on the given area is desired, and areas where a smother crop is wanted to aid in controlling grass and weeds.

The barley crop, H. HUNTER (*London: Ernest Benn, 1926, pp. VIII+166, pls. 2, figs. 6*).—This book describes the results of a series of experiments on barley culture conducted cooperatively since 1901 by the Department of Agriculture and Technical Instruction of Ireland.

The successive chapters deal with the botanical classification of the genus *Hordeum*, Irish barley soils, quality in malting barley, variety comparisons, selection experiments, the Danish barley experiments, the production of new varieties by hybridization, some conditions influencing the yield of grain, and economic results. Information regarding the technique of hybridization and conducting yield trials is appended.

Some observations on white clover and a method of distinguishing between the seeds of wild white and Dutch clover, F. M. J. ADAMS (*Ann. Appl. Biol., 13 (1926), No. 3, pp. 339-357, pls. 2, figs. 5*).—The frequency of certain shape types of seed, the average ratio of long diameter of seed to short diameter, the area of cotyledon, and the length of petiole of first foliage leaf were found useful in distinguishing samples of wild white from Dutch clover seed. At a later growth stage, prostrate habit and formation of axillary shoots characterize wild white clover. Permanence in wild white clover is due to a strongly developed power of vegetative propagation variously lacking in Dutch clovers.

Corn production in Kansas, S. C. SALMON (*Kansas Sta. Bul. 233 (1926), pp. 3-42, figs. 19*).—This is largely a revision of an earlier publication (E. S. R., 34, p. 529), and gives information on the adaptation of corn in Kansas, rotations, varieties, cultural and harvest methods, seed, and insects and control methods.

The relation of weather to the date of planting potatoes in northern Ohio, J. BUSHNELL (*Ohio Sta. Bul. 399 (1926), pp. 343-384, figs. 12*).—Efforts to harmonize the time of planting potatoes with climatic conditions in northern Ohio to insure maximum production are reported on, and planting dates are recommended for different sections of the State. The literature on the effect of weather on the potato crop and on date of planting experiments and practices is reviewed.

The growing season in northern Ohio is longer than required by the Rural group of varieties, which predominate in that section. Since tuber growth seems to be retarded by such high temperatures as occur during summer in Ohio and appear to depress potato yields there more than drought, for highest yields tuber development should proceed during cool weather as much as possible. This may be accomplished with the Rural varieties by planting at such a time that tubers develop during the cool fall weather and maturity coincides with the end of the growing season.

Field experiments during four seasons showed the highest yields to come from plantings made between May 13 and June 2. The Wooster records indicate that the average date of frost severe enough to kill potato tops is October 16. Plantings between May 15 and 25, adequately sprayed, will mature about October 16 and theoretically give the maximum average yields. General recommendations are to plant the last three weeks in May and follow by thorough spraying.

Since an unsprayed crop often dies prematurely from hopperburn, thus shortening the growing period, unsprayed potatoes should probably be planted

3 or 4 weeks later than sprayed crops. Several economic factors, particularly price at harvest, favor early April planting and at Wooster often outweigh the advantage in yield gained from May planting. Where the fall weather is more favorable for potatoes than at Wooster, early planting is less common.

Potato spraying and dusting experiments, 1921 to 1925, D. FOLSOM and R. BONDE (*Maine Sta. Bul. 334 (1926)*, pp. 205-284, pls. 8, figs. 2).—Spraying and dusting experiments with potatoes from 1921 to 1925 are reported, with reviews of previous work in Maine and elsewhere and outlines of methods of spraying and dusting. Records available for the period 1892-1921 indicate that to attempt effective spraying against early blight and late blight, and incidentally flea beetles and leaf hoppers, would be justified if the estimated cost would be less than the increase in net returns expected from a fifth larger crop.

The accounts of the 1921-1925 tests also discuss the incidence of blight and flea beetle, the effectiveness of dusting, yields, and rot in subsequent storage of the crop. These tests considered with others carried on from 1916 to 1919 show an average increase of about 5 per cent over the 332 bu. produced by unsprayed potatoes in a healthy crop at digging, enough increase to justify spraying in 1926. Although Bordeaux spraying in many regions is usually profitable, this does not hold in all cases. In Aroostook County the several factors which generally tend to reduce profits indicate the desirability of more economical methods of spraying, on some farms at least.

The results from using a vine protector were not enough to seem significant under the conditions of field variations in the tests. The use of 5-50 copper sulfate solution to hasten maturity appeared to be an entire waste of effort and materials.

Comparison of copper lime dust and Bordeaux mixture during 4 years showed that, with equivalent amounts of metallic copper, dust is practically as good for controlling late blight, is markedly inferior for controlling flea beetles and early blight, and permits earlier maturity and about the same yield production even with some prematuring. The hopperburn question seemed irrelevant to the region. Dust was considerably more expensive due to the cost of factory mixed materials. The timeliness of applications and the human factor are also commented on in regard to dusting.

Proceedings of the twelfth annual meeting of The Potato Association of America (*Potato Assoc. Amer. Proc.*, 12 (1925), pp. 164, figs. 3).—The twelfth annual meeting of the association held in Kansas City, Mo., in December, 1925, is reported on, and the activities of the organization and of its committees in 1925 are summarized. Among the papers included are The Development of Potato Varieties in the United States, by C. F. Clark; The Present Status of Potato Breeding, and Genetic Studies in Potatoes.—I, The Inheritance of Parti-Color and Suffused Tuber Color, both by F. A. Krantz; Relation of Environmental Factors to Productiveness of Seed Potatoes, by H. O. Werner; Northern Versus Southern Grown Seed, by W. H. Martin, W. M. Peacock, and P. M. Lombard; Some Problems of a Local Supply of Potatoes for the Corn-belt, and Some Suggestions from the Iowa Yield Tests of Seed Potatoes, both by C. L. Fitch; Some Studies in Hollow Heart of Potatoes, and Problems Confronting the Certification Authorities in the Great Lake States, both by H. C. Moore; Potatoes in Irrigated Rotation Experiments at the Scottsbluff, Nebraska, Experiment Farm, by J. A. Holden; Date of Planting a Factor in Size of Seed Piece Studies, by J. Bushnell; Time of Irrigation an Important Factor in Potato Production, by W. C. Edmundson; The Value of the Seed Source or Sample Plot in Certification of Potatoes, by M. F. Barrus; Methods of Conducting the Seed Plot and Its Importance in Potato Improvement Work,

by D. Folsom and E. S. Schultz; Administration of Seed Potato Certification, by A. G. Tolaas; Problems Confronting the Certification Authorities in Canada, by D. J. MacLeod; Factors Influencing Certification Work in the Great Plains States, by H. O. Werner and W. Morrow; Problems Confronting Certification Authorities in the Inter-Mountain States, by F. M. Harrington; Problems Confronting Seed Potato Certification Authorities in the Pacific States, by J. E. Curry; The Hot Formaldehyde Dip of Seed Potatoes, by I. E. Melhus; Missouri's Adoption of the Hot Formaldehyde Method on a Commercial and Community Scale, by E. M. Page; Disinfecting Seed Potatoes by the Dry Method, by W. H. Martin; Some Experiments on the Control of Potato Scab (*Actinomyces scabies*) with Semesan and Other Organic Mercury Compounds, by F. J. Funk and J. H. Gooding; The Relation of Some Soil Factors to the Development of Common Scab of Potatoes, by G. B. Sanford; and Methods of Treating Seed Potatoes, by B. Ball.

The germination of lowland rice [trans. title], I. SUZUTA (*Abs. in Japan. Jour. Bot.*, 3 (1926), No. 2, pp. (38), (39)).—Hulled and unhulled rice subjected to temperatures of from 30 to 100° C. for from 1- to 5-day periods did not show a subsequent reduction in germination for temperatures up to 80°. At 90° coagulation of the protoplasm was apparent. Rapid germination follows a more or less prolonged after-ripening period, which may be shortened by storage in direct sunlight, artificial heating, or by the use of hydrogen peroxide.

The date of seeding winter rye when the ground is dry or wet, A. N. HUME, E. W. HARDIES, and C. FRANZKE (*South Dakota Sta. Bul.* 220 (1926), pp. 4).—Substantial acreages of winter rye are sown in South Dakota each year, it being a comparatively sure crop and capable of producing fair yields when seeded over a wide range of time and conditions. Seeding tests at the Highmore Substation indicated that ordinarily maximum yields can be obtained from seeding the optimum date, September 15. In seasons with abnormally high or low rainfall, delaying seeding for some weeks after September 15 until conditions are favorable seems advisable. Such delay to avoid possible loss of valuable seed appears warranted by fairly good yields had from later seeding.

Tobacco from Palestine, Nigeria, and Mauritius (*Bul. Imp. Inst. [London]*, 24 (1926), No. 2, pp. 187-205).—The merits of samples of Turkish tobacco from Palestine, pipe tobacco from Nigeria, and cigar filler tobaccos from Mauritius are pointed out, with brief comment on the status of the crop in these colonies.

The relation of the yield and protein content of wheat to the nitrogen content of the soil under ten years of different systems of cropping, R. E. NEIDIG and R. S. SNYDER (*Idaho Sta. Research Bul.* 5 (1926), pp. 3-32, fig. 1).—In reporting the progress during the period 1914-1923 of work outlined heretofore (*E. S. R.*, 43, p. 227) the authors discuss the effect of the several rotations upon the wheat yield, the protein content of wheat, and the nitrogen content of the soil. Conclusions held applicable to the section of the Palouse country receiving an average annual rainfall of about 22 in., may be summarized as follows:

Continuous cropping of soil to wheat for 10 years without manure showed yields fluctuating from year to year, annual precipitation, especially that falling in May, June, and July, being a material factor in such variation. Continuous cropping to wheat with 20 tons of manure per acre applied every third year resulted in increased yields from year to year, with only a slightly higher protein content. After 10 years the nitrogen-carbon ratio was higher in the continuous plats manured than in unmanured.

The rotation wheat, oats, and corn drew heaviest on the soil nitrogen and carbon and was followed by (1) wheat, oats, and peas, and (2) wheat, oats, and potatoes. The last rotation affected the total nitrogen of the soil less than others including intertilled crops, and slightly exceeded the wheat, oats, and fallow rotation in average wheat yields. The wheat, oats, and pea rotation produced more wheat and with a lower protein content than the wheat, oats, and corn.

The corn and pea rotations receiving manure made a large increase in wheat yields with higher protein contents, while the wheat, oats, and fallow system showed high wheat yields and high protein content without manure applications. Manure increased the protein content materially and the yield only slightly, indicating that the best utilization of manure was not had on summer fallow under the experimental conditions. While plant foods, especially nitrogen, are made more available and larger crop yields result, nutrients and organic matter are more rapidly depleted by summer fallowing, and the poor physical condition of the soil resulting ends in greater erosion. The legume used in the rotations did not suffice to maintain the nitrogen and organic content of the soil.

The decreasing amounts of total nitrogen for the years 1920, 1922, and 1923 indicated that none of these rotations will maintain the nitrogen and organic content of the soil. Additional proof appeared in the narrow nitrogen-carbon ratio, which lies between 1:9.3 and 1:10.9. The fact that all applications of manure resulted in higher yields of wheat and in higher protein content is held to show that the protein content of wheat is influenced by manure. The results obtained seemed to indicate the close correlation of moisture and available plant foods, chiefly nitrogen, and their effect on the yield and protein content of wheat.

Varying characteristics of three types of wheat grown under the influence of identical environment, R. S. HERMAN (*Cereal Chem.*, 3 (1926), No. 4, pp. 244-252, figs. 6).—Samples of Kharkof, Blackhull, and Kanred wheats from plats at the Kansas Experiment Station varied only slightly in milling qualities, while they differed widely in baking characteristics, and analytical variations were decidedly evident as regards ash and protein content, absorption, pH, and viscosity measurements. The unusually high protein content of Kanred and Blackhull gave no indication of fermentation period or possible margin of safety as relating to commercial usage of the flours. The three wheats gave practically identical baking results, with the exception of crumb color and absorption, when handled on their individual approximate optimum fermentation period.

The commercial protein test on wheat and some of its problems, W. O. WHITCOMB and J. P. LEWIS (*Cereal Chem.*, 3 (1926), No. 4, pp. 232-243).—This contribution from the Montana Experiment Station deals with the history of the commercial protein test on wheat and some of the problems encountered in its application.

HORTICULTURE

[**Horticultural investigations at the Arkansas Station**] (*Arkansas Sta. Bul.* 215 (1926), pp. 42-49, 52, figs. 3).—As in the preceding annual report (*E. S. R.*, 55, p. 36) the pollination of the apple is discussed. Following a brief review of methods of technique employed it is reported that Rome, Delicious, and Yellow Transparent pollen proved good and Ben Davis and Stayman Winesap pollen inferior for fertilizing Ben Davis flowers. In similar environment pollen which made the most vigorous growth was the most effective. Where one

flower in a cluster was pollinated considerably in advance the others often dropped even though fertilized. The unfavorable results with Ben Davis pollen are thought due to incompatibility, since the pollen grew well on media. Pollen kept dry in the laboratory germinated well for from 20 to 25 days. Arkansas and Stayman Winesap pollen was short-lived, while that of Rome, Ingram, and Delicious survived 41 days. In the presence of moisture pollen germinated rapidly. Up to 22-27° C. there was an increase in germination and growth of pollen tubes, with a slight reduction at 30° and considerable reduction at 35°. The optimum temperature for Yellow Transparent was about 24°, Delicious 18-24, King David 20, Arkansas 24-30, Stayman Winesap 24-27, and Ben Davis 22°, indicating a greater adaptability of certain varieties to southern temperatures. The bursting of pollen grains and the disintegration of tubes proceeded more rapidly at high temperatures.

Above 15 per cent, sugar decreased pollen germination and tube elongation. Germination is deemed largely a matter of moisture absorption. Pollen viability appeared to be affected by the vigor of the tree and of the spur rather than by any treatment the tree may receive. Sterility in the Winesap group is due to abortion of pollen grains and of ovules.

Measurements showed a greater average length in the case of Yellow Transparent and of Ben Davis for fruiting than for nonfruiting spurs. However, no definite standards of length and diameter could be associated with fruitfulness nor could any differences be correlated with fertilizer treatments. There was found in Ben Davis and Yellow Transparent an association between fruiting spur and terminal shoot growth, and generally spurs under 1 cm. in length were nonfruitful. Approximately 21 per cent of Yellow Transparent and 37 per cent of Ben Davis spurs bloomed in two successive seasons. A striking correlation was found between the number of apples remaining on the spur until the third week in June and the number of primary leaves on the spur. However, with new leaves the results were conflicting. That only a very small number of apples abscise on account of lack of fertilization was indicated in an examination of dropped fruits. Frequently, as in the Winesap group, fertilization is apparently prevented by ovule abortion as well as a failure of the pollen. Later dropping is considered largely a matter of competition between fruits.

Fertilizer studies with apples further emphasized the fact that nitrogen is the only element to effect appreciable results. It is believed that trees making from 6 to 8 in. terminal growth need no fertilizer, and the lack of water or humus may easily become a limiting factor.

Fertilizer studies with the peach are again discussed (E. S. R., 55, p. 341).

Fertilizers did not increase the yield of grapes. Pruning decreased the yield of grape vines in direct proportion to the amount of fruiting wood removed. Vines with 65 buds gave better yields than those reduced to 50. Fertilizers had no effect on the sugar content of grapes. Cynthiana gave promise as a stock for Campbell Early. A study of clusters borne on shoots arising from primary and secondary buds showed more and more and larger clusters from the primary buds but with no significant gain in size of individual berries.

A comparison of hotbed and outdoor-grown tomato plants gave results greatly in favor of the former.

[Horticultural investigations at the Delaware Station] (*Delaware Sta. Bul.* 147 (1926), pp. 22-26, 27-29).—This is the usual annual report (E. S. R., 54, p. 641).

As reported by C. A. McCue and L. R. Detjen long-continued studies show the need of fertilizers for the production of profitable crops of apples.

Nitrogen was apparently the most important limiting factor, as trees receiving potash and phosphorous alone showed marked deterioration. That nitrogen is essential to peaches was indicated in observations recorded by G. F. Gray, McCue, and Detjen.

Cabbage breeding studies reported by Detjen and Gray showed the difficulty of isolating fixed types by self-pollination. The first generation plants resulting from reciprocal crosses of dissimilar parents were similar. Tall plants crossed with dwarfs yielded all tall progeny. Wide plants crossed with narrow ones yielded for the most part wide progeny. Large diameter of stem appeared also to be a dominant character. Crosses between head and loose-leaf types yielded all gradations, with headless types in the approximate ratio of 3 to 1 to heads. Bolting by nonbolting plants also yielded an intergrading progeny. The factor for blooming the first season appeared dominant to nonblooming. Bolting and heading appeared to be affected by a multiple factor for season. The time of maturity of cabbage seemed to be a complex character determined by a multiple factor. Various conditions of self and cross incompatibility are recorded and classified.

Observations by F. S. Lagassé upon the effect of 5 and 10 lb. applications of nitrate of soda to 20-year-old Paragon apple trees showed an increased growth and color with 10-lb. applications without any inhibiting effect upon fruit bud formation. In propagation studies with Stayman Winesap apples Lagassé found that scion wood taken from 2-year-old trees gave somewhat better survival than that taken from 1-year trees, Three-in. scions were slightly better than those 2 in. in length. The Crimson Beauty apple was largely self-sterile. The set of fruit in a solid block of Early Ripe apples was greatly increased by the introduction of bees and flowers of Yellow Transparent. Preliminary observations on the J. H. Hale peach showed this variety to be self-sterile, but when crossed with Belle of Georgia, Hiley, Early Elberta, and Elberta yielded 31.4, 23.9, 15.9, and 15.6 per cent of set, respectively.

[Horticultural investigations at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 137-142, 144, 145, 150-160, 162, 164-166, 166-168, figs. 6*).—This is the usual annual report (E. S. R., 56, p. 233).

Apple breeding studies conducted by C. S. Crandall have yielded approximately 30,000 hybrid seedlings, the fruits of 4,600 of which have been described. Self-pollination studies have been seriously handicapped by self-sterility and a lack of vigor in such seedlings as have been produced. Disbudding of young apple trees to prevent the growth of undesirable limbs or summer tipping to check growth was found by W. A. Ruth and V. W. Kelley to check the development of the trees. On the other hand early summer tipping of the central leader encouraged the early formation of sufficient framework branches.

In studies at Olney, Ruth found nitrogenous fertilizers applied in the spring over a period of 3 years to be of little importance to Grimes and Jonathan trees of early bearing age. At Urbana, Ruth found the yield of mature Jonathan and Grimes trees was not reduced by severe dormant pruning in the two preceding seasons. Reduced number of fruits is compensated in the case of Jonathan by larger size. A high correlation was noted between bloom and crop in Grimes (the off year) and a low correlation in Jonathan (the on year). In a study by Ruth and Kelley of the effect of various types of pruning upon young apple trees, unpruned Duchess trees yielded the most fruit, followed in order by moderate thinning, moderately headed and thinned, and with heavily thinned the least productive.

Studies by J. W. Lloyd and H. M. Newell of the apple situation in Calhoun County, in which area approximately half the commercial apple crop of Illinois is produced in spite of a total absence of railroads, showed that much of the fruit is not properly graded, with the result that prices are forced down. Peach breeding studies conducted by Crandall have resulted in several thousand seedlings, 238 of which are still continued under test as promising.

Small fruit tests conducted by A. S. Colby show the Quillen black raspberry, Van Fleet red raspberry, Wilder currant, and Glendale gooseberry to be promising on account of vigor. In storage at 35 to 40° F. Brighton grapes kept 153 and Delaware 141 days. Other good keepers were Barry, Diamond, Herbert, Caco, Agawam, and Vergennes. Chasselas Rose and Sweetwater, vinifera varieties, did well when accorded winter protection. Based on 3 years' records, vines trained according to the Kniffin system yielded the most clusters of maximum size when left with 45 to 50 buds to the vine. The results of a comparison of the Kniffin, Munson, Fan, and Chautauqua systems of training is given in tabular form. A study of the accumulative effect of 3 years' pruning upon the 1925 crop showed that when the number of buds is increased the number of pounds of fruit per vine increases up to a certain unestablished point. The rate of increase after 45 buds is reached becomes much slower. The greater the number of buds per vine the less the weight of individual clusters, particularly after 50 buds are reached. Worden and Moore Early were comparably productive whether trained to a single, a Y, or a double trunk. In the abnormally dry season of 1925 strawberry yields were increased more than 300 per cent by overhead irrigation. Selected strains of Juneberry and Elaeagnus were found to have value both as food and ornamental plants.

Vegetable fertility investigations conducted by Lloyd show that commercial fertilizers supplemented with cover crops are sufficient to produce satisfactory tomato yields except in very dry seasons, at which time manure proved a much better source of humus. Maximum yields of tomatoes and sweet corn were secured with manure supplemented by phosphorus or phosphorus plus potash. In 1925 the best yield of muskmelons was obtained with manure and phosphorus. Fertilizer tests were seriously hampered in 1925 by the early summer drought, but studies by Lloyd and E. P. Lewis in Cook County showed the value of phosphorus for truck crops. In some instances commercial fertilizers gave results comparable to those from manure. Apparently the amount of manure used by commercial growers could be greatly reduced if supplemented by commercial fertilizers. Of various manure substitutes a 4-8-6 fertilizer was most effective. Of single elements, acid phosphate gave the best results. Raw rock phosphate was decidedly less effective than either acid phosphate or bone meal.

Experiments by W. A. Huelsen and M. C. Gillis with sweet corn have resulted in selected strains of Country Gentleman and Evergreen possessing valuable canning qualities. Pure line studies with corn have reached the recombination stage. Sweet corn fertilizer tests reported in tabular form indicate that a combination of 400 lbs. of acid phosphate and 50 lbs. of muriate of potash is a particularly effective application. Huelsen and Gillis found that wilt-resistant tomatoes are far more productive than ordinary canning varieties when grown on infected soil. Selection studies indicated that resistance can be increased in practically all the main crop varieties by continued selection.

Studies by F. F. Weinard and S. W. Hall again showed the superior value of fresh soil in greenhouse flower production. Two-year grafted roses in new soil yielded 12 per cent more blossoms than comparable plants grown for two successive seasons in the same soil. Carnations produced approximately 8 per

cent more bloom in new soil. Whereas grafted Premier rose plants in new soil outyielded those in old soil, own-rooted plants were equal in productivity. Observations upon the behavior of gladiolus corms which had been used for forcing indicated that these may be successfully forced a second time. In the case of Ophelia roses slight gains in yield of blossoms were recorded in favor of the progeny of high-yielding plants. Orchid seedlings were grown successfully on agar media containing nutrient minerals and sugars.

Research in vegetable gardening, H. C. THOMPSON (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 287-295).—This, the presidential address of the 1925 meeting of the American Society for Horticultural Science, outlines various important groups of vegetable problems whose solution is essential to the industry, discusses methods of attacking problems, and urges concentration on research having a practical as well as a purely scientific value.

Nitrate utilization by asparagus in the absence of light, G. T. NIGHTINGALE and L. G. SCHERMERHORN (*Science*, 64 (1926), No. 1655, p. 282).—Microchemical determinations at the New Jersey Experiment Stations in the winter and spring of 1926 upon asparagus growing in complete nutrient cultures and subject to continuous darkness consistently showed an abundance of nitrates in the fibrous absorbing roots, with none or very slight amounts in the storage roots. In continued darkness, the rapidly growing spears or shoots contained no nitrates save occasional traces near the bases. No nitrates were found in rapidly growing spears of plants grown under normal light conditions. In the case of plants growing in a minus nitrogen solution, no nitrates were found in any part of the plants. In the minus nitrogen series growth was associated with a decrease of protein and an increase of the nitrate-free soluble nitrogen fraction.

Analysis of the roots of the several series showed a considerable loss of carbohydrates associated with the growth of the spears. In continuous darkness this loss was much larger in the complete than in the minus nitrogen series, leading the authors to suggest that carbohydrates were used in the assimilation of the nitrates.

Government inspection of nurseries to eliminate variety mixtures, W. H. UPSHALL (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 276-283).—Investigations conducted at the Horticultural Experiment Station, Vineland, Ont., showed that pears, plums, cherries, and peaches, as well as apples, may be identified by a careful study of various leaf and shoot characters. In the summer of 1925 over 850,000 trees were inspected, with an average percentage of mixture of only 1.5.

Notes on hardy orchard cover crops, R. J. BARNETT (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 283-286).—In tests conducted at the Kansas Experiment Station, rye and winter vetch proved more valuable orchard cover crops than wheat, soy beans, cowpeas, or alfalfa. Observations indicated that the time of planting should be varied from season to season according to rainfall conditions. Winter vetch seeded at the rate of 40 lbs. per acre yielded more dry matter than when sown at the rate of either 20 or 30 lbs. Leguminous cover crops left the soil in a better physical condition than did cereal crops.

The nitrogen and carbohydrate composition of the developing flowers and young fruits of the apple, F. S. HOWLETT (*New York Cornell Sta. Mem.* 99 (1926), pp. 3-79, figs. 20).—A fuller report upon studies which have been previously discussed (*E. S. R.*, 50, p. 835). Chemical analyses of apple flowers in various stages of development showed the total nitrogen in young emerging blossoms to be low on the basis of the average number of milligrams per flower but relatively high on the basis of the percentage of green and of dry weight,

a condition due, in the author's belief, to the large proportion of meristematic tissue in the young flowers. On the basis of percentage of green and dry weight, the flowers at the same stage as above were low in free reducing substances, total sugars, and the acid-hydrolyzable fraction, but with the approach of full bloom the flowers increased very greatly in all types of carbohydrates.

At full bloom the petals, comprising little more than one-third of the green weight of the entire blossom, contained approximately two-thirds of the free reducing substances. The rapid growth and enlargement of the petals was accompanied by a decrease of total nitrogen on the basis of the percentage of green and of dry weight. There was relatively little withdrawal of nitrogen and carbohydrates by the flowers during the period of full bloom.

The rapidly enlarging fruits that set withdrew progressively greater amounts of total nitrogen and of carbohydrates. Flowers that were about to drop showed decided losses of nitrogen after petal fall, comparable to the losses that occur in abscising leaves. The decrease, consistently ranging from 28 to 49 per cent of the entire amount present in the flower just after petals had fallen, is thought to be quite possibly due to a backward translocation. A decrease in various types of carbohydrates in the abscising flowers is deemed due to a change into an undetermined form, to increased respiration, or to a backward translocation.

Picking maturity of apples in relation to storage, J. R. MAGNESS, H. C. DIEHL, and M. H. HALLER (*U. S. Dept. Agr. Bul. 1448 (1926), pp. 20, pl. 1, fig. 1*).—This paper, taken in large part from an earlier and more comprehensive discussion (*E. S. R.*, 55, p. 538), is devoted principally to the changes occurring in various important commercial apple varieties just prior to their ripening on the tree and during storage. It is emphasized that firmness of the flesh, the amount of yellowing on unblushed portions of the surface, and the tenacity with which fruits hold to the tree are in many instances the most dependable indexes to picking maturity. A color chart is presented for determining the rate of yellowing in the uncolored portion of the apple surface, and mention is again made (*E. S. R.*, 54, p. 39) of the pressure tester designed by the Department for determining changes in resistance of the flesh.

Use of plant characters in identification of red raspberry varieties, J. D. WINTER (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 261-264).—Studies conducted by the Minnesota Experiment Station during the growing season upon plants of a large number of raspberry varieties showed that certain plant characters, such as the abundance, color, and structure of the spines on the canes and on the petioles, the number of leaflets to each petiole, the relative height of the canes and whether or not they are conspicuously glaucous, and the color of the foliage are relatively constant under varying conditions of growth and may be used in the identification of varieties. A key is presented for important Minnesota varieties based upon these characters.

Experiments with fertilizers for coffee in Porto Rico, T. B. McCLELLAND (*Porto Rico Sta. Bul. 31 (1926), pp. 34, pls. 3, figs. 18*).—Records taken upon the growth and yield of coffee shrubs fertilized with nitrogen, phosphorus, and potash, singly and in various combinations, showed potash to be distinctly beneficial, especially when combined with nitrogen. On the other hand, heavy applications of nitrogen alone or nitrogen combined with phosphorus had in this test a distinctly deleterious effect upon growth and yield. An examination by J. O. Carrero of the changes occurring in the soil solutions of the various plats showed the most productive plat, nitrogen and potash, to be the highest in acidity, indicating that coffee is an acid tolerant plant.

On another location complete fertilizers were most effective in increasing coffee yields, indicating that nitrogen, phosphorus, and potash all were of benefit. Observations upon the berries from the various plats showed that notable increases in yield were accompanied by a reduction in size of the berries.

In both field and pot tests ammonium sulfate applied semiannually proved more effective than sodium nitrate in increasing both growth and yield of Bourbon coffee. Heavy applications of lime failed to exert any appreciable effect on coffee yields. In pot experiments equal quantities of sodium nitrate were much more effective when applied monthly rather than in large semi-annual doses. Monthly applications of sodium nitrate supplemented with sulfur proved superior to semiannual applications of ammonium sulfate.

General suggestions for fertilizing coffee are presented.

Trees and shrubs of California gardens, C. F. SAUNDERS (*New York: Robert M. McBride & Co., 1926, pp. XIV+323, pls. 33*).—This book contains popular information concerning the history, culture, and attractive characteristics of native and exotic trees, shrubs, and vines of California.

FORESTRY

Some soil and moisture relationships of sweet gum and river birch in southern Maryland, F. B. TRENK (*Iowa Acad. Sci. Proc., 32 (1925), pp. 133-142, figs. 3*).—Noting the frequent existence in southern Maryland of adjacent but sharply demarcated stands of sweet gum and river birch, a study was made of the soil and moisture relations in the contrasting areas to determine, if possible, the underlying differences. In every instance the water-holding capacity of the sweet gum soils, both surface and substratum, exceeded that of the river birch.

The occurrence of hickories in Iowa in relation to soil types, F. B. TRENK (*Iowa Acad. Sci. Proc., 32 (1925), pp. 143-155, figs. 7*).—A study of the relation between the distribution of hickories and the character of the soil show that only a relatively small number of the 115 recognized soil types of Iowa support a growth of hickory.

Mixed white pine and hardwood, A. C. CLINE and C. R. LOCKARD (*Harvard Forest Bul. 8 (1925), pp. 67, figs. 13*).—Noting that the original forests of central New England were largely a mixture of hard and soft woods and also that pure stands of white pine have a tendency to revert to hardwoods, a study was made of various forest types in north central Massachusetts and southwestern New Hampshire to determine the best methods of handling the existing forests.

It was found that in second growth stands pine suffers severely in competition with sprout hardwoods, but that the few pines which attain maturity are of exceptional quality, suggesting the desirability of selective cutting which would favor both pines and hardwoods. The problem is chiefly confined to soils of medium quality, as these are better adapted than are heavier or lighter types to the pine-hardwood mixture. The pine was observed to thrive better when planted in small groups distributed among the hardwoods than as individual trees. With this plan the pines and hardwoods can be allowed to develop according to their own habits, without the necessity of liberation cuttings except perhaps along the marginal zone.

A study of possible returns from the different types leads to the assumption that greater net profits may result from mixed stands than from pure pine. Furthermore, the mixed stand is more natural and has a tendency to maintain the fertility of the soil, and is less susceptible to external injuries such as

wind storms, insect scourges, etc. As the region studied is naturally adapted to hardwoods, it is deemed much wiser to supplement the hardwoods with groups of pine rather than to work against nature.

Germination of some pines and other trees, L. H. PAMMEL and C. M. KING (*Iowa Acad. Sci. Proc.*, 32 (1925), pp. 123-132, figs. 15).—This comprises brief technical descriptions of the newly-germinated seedlings of several species of *Pinus*, *Larix*, *Picea*, and *Sequoia*.

Scotch pine pollen in Copenhagen, May 25, 1804 [trans. title], A. OPPERMANN (*Tharandter Forstl. Jahrb.*, 77 (1926), No. 12, pp. 404-408).—Mention is made of a heavy fall of rain mixed with a yellow dust which under the microscope proved to be Scotch-pine pollen, a fact which was all the more astonishing since the nearest large Scotch-pine forests were more than 184 miles distant.

Douglas fir in Poland [trans. title], S. SUCHOCKI (*Rocz. Nauk Rolnicz. i Leśnych*, 15 (1926), No. 1, pp. 150-205, figs. 13; *Ger. abs.*, pp. 202-204).—Of two types of Douglas fir introduced into Poland from North America the green Coastal form has been found much superior to the blue Colorado because of its greater frost resistance and more rapid growth, and on account of its tolerance to shade was found favorable for planting in older stands. As compared with the other conifers it was found to be less exacting on the soil. Preferably, the soil should be better than that required for Scotch pine but not necessarily equal to that preferred by oak. The site should be as free as possible from early and late killing frosts. Growth and volume tables are included.

DISEASES OF PLANTS

Plant diseases (*Arkansas Sta. Bul.* 215 (1926), pp. 52-59, figs. 4).—In continuation of work previously reported on the development of wilt resistant strains of cotton (E. S. R., 55, p. 41), tests were made of a large number of strains and varieties of cotton grown in heavily infested soil, but very little wilt resulted. In seeking for a possible explanation of the lack of wilting, physiological studies were made of the parasite, and it was found that in cultures in the absence of organic nitrogen the fungus was able to produce at least two substances which were toxic to cotton, while in the presence of organic nitrogen either no toxic substances were produced or they were in such dilution as to exert no injurious effect. The breeding work of the station is said to have shown marked differences in types of cotton in reference to their susceptibility to wilt. In connection with the plant breeding experiments, delimiting the seed with sulfuric acid proved a good means of controlling angular leaf spot.

Using soil temperature control tanks, it was found that cotton wilt develops to only a slight extent at temperatures above 35° C., and it is believed that it will not develop to any appreciable extent below 25°. The optimum for growth is considered probably about 27 or 28°.

A summary account is given of investigations on a bacterial stalk rot of corn in continuation of work previously reported (E. S. R., 55, p. 847).

Stem rot of rice, due to *Sclerotium oryzae*, is said to have become one of the principal limiting factors in rice production in some parts of Arkansas. Rotation with some cultivated dry-land crop and the prevention of spreading the disease by straw, etc., or by drainage or overflow waters are suggested as means to be adopted for the control of this disease.

Apple spraying experiments are briefly reported upon which are said to indicate the need for more definite information on the relation of environmental factors to fruit diseases as a means for simplifying spraying directions.

A brief account is given of sweet potato mosaic, a more detailed description of which has been noted (E. S. R., 56, p. 51).

Notes are given on the morphology and life cycles of a number of species of bacteria.

Department of plant pathology, T. F. MANNS and J. F. ADAMS (*Delaware Sta. Bul. 147 (1926), pp. 29-35*).—Laboratory studies have again indicated that sweet potato pox is caused by a species of *Actinomyces*.

Studies made on the possibility of insect carriers of the virus of yellows or little peach have given negative results with the peach curculio. Spring and fall dormant applications of fungicides failed to control the bacterial leaf spot of peach, and summer spraying gave little difference in leaf infection. Bagging experiments with Elberta and Hale varieties gave no indication of the possibilities of bud infection. Special attention was given to the problem of the overwintering of the disease, and a heavy twig infection of the Elberta variety is said to have materially assisted in this study. Peach twigs, the 1925 growth, were collected on October 29, 1925, and March 24, 1926, and plum twigs on February 5, 1926. From these twigs conclusive evidence was found that the organism overwinters in cankers. As a means of control toxicity studies were made to determine whether paradichlorobenzene and carbon tetrachloride, sodium fluoride, calcium fluoride, cresol, and chlorophenol mercury would destroy the bacteria. From the preliminary results field experiments were undertaken in which sodium fluoride, cresol, and chlorophenol mercury were given further test.

In tests for the control of diseases of cucurbits, two commercial dusts and two other copper preparations were tested, comparisons being made of 15 and 9 per cent copper dusts. Downy mildew did not appear, but leaf-blight infection was heavy on the untreated vines. All four dusts gave equally good control for leaf blight. Laboratory studies on cantaloupe diseases are said to have shown that *Alternaria brassicae nigrescens* was not associated with the leaf blight in the experiments described.

In the study of soy bean diseases there is said to have been shown a general increase in the State of leaf spot caused by *Septoria glycines*. Downy mildew and bacterial leaf spot (*Bacterium phaseoli sojense*) were not of common occurrence, and negative results were obtained in treating seed with chlorophenol mercury as no disease appeared on any of the plantings. A collection of seed made from plants showing mosaic when planted in the greenhouse in the fall showed no evidence of the disease symptoms on the foliage. It is thought probable that what had been considered mosaic was associated with a deficiency in potash. A spot disease due to *B. vignae* was reported in the State for the first time on Lima beans, and the same organism has been recognized as occurring on cowpeas.

In an experiment to control die-back on apples a natural mulch of pine needles and an unperforated thermogen paper were employed to cover the ground about the trees. When examined at later periods no die-back symptoms were observed, while in unmulched trees symptoms were conspicuous by the last of July.

In continuation of a study of the longevity of corn root diseases (E. S. R., 52, p. 844), additional tests of samples of the crop of 1922 have shown the persistence of *Diplodia zeae*, while *Gibberella saubinetii*, *Fusarium moniliforme*, and *Cephalosporium sacchari* showed a conspicuous dropping off in vitality.

[Plant disease investigations at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 38-42, 143, 144, 147-149, 153, 166, fig. 1*).—Continuing investigations of seed-borne diseases of corn (E. S. R., 56, p. 240), experiments by B. Koehler et al. indicate that the time usually adopted for planting corn, that is, about

the middle of May, is best when diseased seed is used, but with disease-free seed planting a week earlier is advised. Studies by E. E. DeTurk, E. G. Sieveking, and J. R. Holbert are said to show that the protein reserve in seed corn infected with *Diplodia* is inadequate to carry over the plant through the germination and early seedling stages in the absence of other sources of nitrogen. The complete withdrawal of phosphate had little or no effect on the early growth of the corn seedling. Koehler et al. found that four commercial compounds were of some value in combating *Diplodia* and *Gibberella* root rot diseases, but the common methods of seed treatment were of no value.

Investigations of H. W. Anderson on fire blight have been extended to include a study of the hold-over blight cankers on the apple variety Willow Twig and have resulted in the recommendation of definite control measures. These include cutting out the cankers, disinfecting and protecting the wounded surfaces, inspection of orchards, and immediate removal of new infections.

Studies by the same investigator are said to show that lime sulfur of dormant strength applied in the fall or Bordeaux mixture oil emulsion applied in the fall or early spring will control peach leaf curl. If applied in the spring after the buds swell neither will control the disease, nor will oil emulsion applied in the fall or spring.

The black root rot of orchard trees caused by *Xylaria* sp. is said to be increasing in Illinois, and this fungus is believed to be a common cause of the dying of young trees in the southern part of the State. A type of root rot associated with weakness in the graft is briefly described. Root or collar rot of apple trees caused by the fire blight organism is reported.

Continued studies by A. S. Colby are said to have shown that two seasonal applications of lime sulfur controlled gooseberry leaf spot when conditions were not favorable for the spread of the disease.

Experiments of F. F. Weinard and S. W. Decker showed that neither seed nor seed-bed treatments controlled aster yellows after the plants were transferred to the field.

Economic plant diseases common in Kansas and their control, L. E. MELCHERS (*Kansas Sta. Circ. 129 (1926)*, pp. 23).—In tabular form descriptions are given of the more striking characteristics of many of the diseases occurring on economic plants in Kansas, and suggestions are offered for their control or prevention. In a separate part of the publication seed treatments for the control of seed-borne diseases are described, and formulas and directions are given for the preparation of various sprays and other fungicides.

Destruction of insect and fungus or fungoid pests, A. H. BENSON (*Queensland Agr. Jour.*, 24 (1925), No. 5, pp. 465-467, fig. 1).—A comparison is made of methods for control of pests and diseases affecting various agricultural plants.

Metabolism in Botrytis, A. HUNTER and G. H. BERKELEY (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 349).—A study of the metabolism of four *Botrytis* forms of the *B. cinerea* group was made by analyzing for total nitrogen, ammonia nitrogen, amino nitrogen, sugar content, and titratable acidity of the medium, along with total nitrogen and dry weight values of the mycelium. The results are said to show important and interesting aspects of metabolism, and to indicate that two of the four forms are closely related and comprise a group distinct from the other forms. A correlation between physiology and morphology, in so far as grouping of the forms was concerned, was established.

Mosaic studies, IV, B. T. DICKSON (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 346).—Mosaic of *Pisum sativum* is said to be transmitted through seed. Soy bean mosaic is reported for the first time in Quebec, also a case of transmission of tomato mosaic to healthy tomato by the flea beetle (*Epitrix cucumeris*).

A transmission of mosaic from *Physalis* sp. to *Browallia* sp. is said to have occurred under uncontrolled conditions.

Effects of salt and hydrogen-ion concentration upon the growth and structure of certain bacteria and moulds, G. B. REED (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 348).—The growth of *Vibrio comma* in dilute peptone is said to be increased with the addition of sodium chloride up to 0.2 M. The addition of the salt widens the pH tolerance, and further increase in the concentration of salt is said to decrease the growth and to decrease the pH tolerance. The optimum growth of *Oidium lactis* was similarly influenced by salt concentration and pH value.

Equipment and methods for studying the relation of soil temperature to diseases in plants, R. W. LEUKEL (*Phytopathology*, 14 (1924), No. 8, pp. 384–397, figs. 5).—A detailed description is given of the equipment, together with the operation and methods employed, for the study of the relation of soil temperature to cereal diseases at the Arlington Experimental Farm.

Simultaneous surveys for stem rust: A method of locating sources of inoculum, E. M. FREEMAN and L. W. MELANDER (*Phytopathology*, 14 (1924), No. 8, pp. 359–362, fig. 1).—The authors describe a method for the location of barberry bushes that have escaped detection in surveys for their eradication.

Seed treatment for smut control, W. P. FRASER and P. M. SIMMONDS (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 347).—Experiments on smut control with wheat and hull-less oats were carried on at the Dominion Experimental Farms in Saskatchewan and Alberta, in which copper carbonate, a mixture of copper sulfate and calcium carbonate, and sulfur in the form of dusts, and also solutions of formaldehyde, Semesan, and Chlorophol gave good control except in the case of sulfur in some experiments. Copper carbonate dust was most satisfactory for hull-less oats.

Experiments in oat smut control in 1923, J. E. HOWITT and R. E. STONE (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 346).—Formaldehyde sprinkle treatment is said to have reduced both germination and yield, while formaldehyde spray almost entirely prevented smut and was followed by the largest yield of any of the methods tested. Neither copper carbonate dust nor copper sulfate-lime dust was effective in eliminating smut. Copper sulfate dip reduced germination slightly but was effective in the control of smut.

Smut control experiments in hull-less oats during 1923, B. T. DICKSON, R. SUMMERBY, and J. G. COULSON (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 350).—Formalin, copper sulfate, copper carbonate, and copper sulfate-lime dust were tested for the control of smut. While all greatly reduced the percentage of smut, copper carbonate proved the most efficient method of control and the most simple in its application.

Pickling wheat with carbonate of copper, H. C. QUODLING (*Queensland Agr. Jour.*, 24 (1925), No. 5, pp. 456, 457, fig. 1).—The advantages and method are outlined of applying copper carbonate to wheat seed to prevent stinking smut, as are also directions for constructing conveniently and inexpensively "the petrol case seed pickler."

"Take-all" of wheat in western Canada, W. P. FRASER (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 347).—The occurrence of *Ophiobolus cariceti* on Marquis wheat in northern Saskatchewan is reported.

Sclerotinia intermedia n. sp., a cause of decay of salsify and carrots, G. B. RAMSEY (*Phytopathology*, 14 (1924), No. 7, pp. 323–327, pl. 1, figs. 6).—A description is given of a strain of *Sclerotinia* found causing decay of the roots of salsify and carrots on the Chicago market. The sclerotia are said to be intermediate in size between those produced by *S. libertiana* and *S. minor*,

and an intermediate amount of mycelium is produced. Hence the descriptive name *S. intermedia* is proposed for this species.

A native weed host for bacterial blight of bean, M. W. GARDNER (*Phytopathology*, 14 (1924), No. 7, p. 341).—The author reports *Bacterium phaseoli* occurring in leaf lesions on *Strophostyles helvola*, a common weed plant in many regions.

Bacterial rot of cauliflower [trans. title], GÉRAY (*Jour. Agr. Prat.*, n. ser., 44 (1925), No. 51, pp. 501, 502).—Cauliflower culture has suffered severe losses during the previous 20 years owing to a rot due to a bacterium said to have been described by Delacroix (*E. S. R.*, 17, p. 876) and Griffon. Varieties indicated as having abundant water are more susceptible than are less watery kinds, which are less desirable. Apparently soil alkalinity is favorable to the disease.

Cotton diseases in Porto Rico [trans. title], M. T. COOK (*Rev. Agr. Puerto Rico*, 15 (1925), No. 6, pp. 300, 301).—Cotton disease-causing fungi named include *Cercospora gossypina*, *Ramularia areola*, *Kuehneola gossypii*, *Glomerella gossypii*, *Diplodia gossypina*, *Sclerotium rolfsii*, and one or two species of *Fusarium*.

Studies on a leaf spot of Phaseolus aureus new to the Philippine Islands, C. G. WELLES (*Phytopathology*, 14 (1924), No. 8, pp. 351–358, pl. 1, figs. 3).—A leaf, stem, and pod disease of mungo bean (*P. aureus*) is described, the causal organism being *Cercospora cruenta*.

White rot of Allium in Europe and America, J. C. WALKER (*Phytopathology*, 14 (1924), No. 7, pp. 315–322, pl. 1; abs. in same, No. 1, p. 26).—An account is given of an investigation of the white rot of onion caused by *Sclerotium cepivorum*, the presence of which in this country had been recently reported. The fungus is known to affect common onion, Welsh onion, leek, shallot, and garlic, and the causal organism is believed to overwinter and persist indefinitely in the soil under European conditions.

Observations made in Europe and laboratory experiments by the author are said to indicate the disease to be most destructive in moderately cool soil (15 to 18° C.) having a medium moisture content. These conditions are said to prevail for the winter crop of onions in the Southern States, and this region is considered favorable for the disease. The chief mode of widespread dissemination of the fungus is on diseased bulbs or seedlings.

Root rot and blight of canning peas, R. E. STONE (*Abs. in Phytopathology*, 14 (1924), No. 7, pp. 348, 349).—It is claimed that in certain sections of Ontario root rot and blight cause serious loss to canning peas. Two fungi have been found closely associated with the disease, one a species of *Fusarium* and the other a *Pythium*. Attempts have been made to secure disease-resistant strains of peas, and several strains have been developed that appear promising.

The relative efficiency of some copper dusts and sprays in the control of potato diseases and insect pests, O. C. BOYD (*New York Cornell Sta. Bul.* 451 (1926), pp. 3–68, figs. 8).—A report is given of an investigation made to compare certain dusts and sprays, particularly copper-lime dust with Bordeaux mixture, for the control of potato diseases and insect pests, especially late blight and flea beetle control.

Laboratory experiments are said to show that the membranes formed when copper-lime dust is wetted are similar to those in Bordeaux mixtures rich in lime, but they remain entire and are not broken and scattered as in the spray. When light applications were made of copper-lime dust and of dilute Bordeaux mixture to give the same amount of copper per unit of area, a larger percentage

of this area was covered by the spray membranes, due to their greater number and greater surface area, than by the dust membranes.

Under field conditions, it was found that about 44 per cent more copper for each unit amount applied per acre was retained by the foliage sprayed with Bordeaux mixture than by the dusted foliage, and laboratory experiments showed that the spray coating was more resistant to washings than copper-lime dust coverings. Under both greenhouse and field conditions only about one-half as much dust was retained by dry potato foliage as by thoroughly moistened leaves, and under field conditions the rate of loss from the dry-dusted foliage was higher. When equal amounts of copper were applied to damp foliage, in the copper-lime dust with a good hand machine or the best power dusters and in the Bordeaux mixture with exceptionally good sprayers, the control of early and late blight and of aphids appeared to be about equal in the two methods. The spray coating appeared to be superior in the control of flea beetles, leafhoppers, and tipburn. Copper-lime dust when applied to dry foliage was less effective in controlling diseases and insect pests than when applied at the same rate to damp foliage.

The results of three years' experimentation in the comparison of copper-lime dust with Bordeaux mixture are said to show that the sprayed plats produced an average gain in yield over the dusted plats of 7.2 bu. per acre, and this is considered indicative of the difference between the effectiveness of the two methods of protection. Sulfur, used either alone or with hydrated lime, gave only slight protective properties against late blight, flea beetles, and tipburn. When freshly mixed copper-lime dusts containing from 10 to 20 per cent of copper were applied to wet foliage, a slight burning of the leaves followed the use of the 10 per cent dust and a severe injury from the 20 per cent mixture. Dusts which contained less than 10 per cent of metallic copper produced no injury.

Some evidence was obtained which is believed to indicate that heavy coatings of either dust or spray produced a dwarfing or a stunting effect on the plants, and this was entirely independent of the occurrence of copper injury on the leaflets. Based on the price of dusting and spraying materials in 1922, when 3 lbs. of copper was applied per acre in each application, it is said that it cost about \$2 to dust an acre once with home-mixed copper-lime dusts, \$1.50 to spray an acre once, and from \$3.75 to \$4 to treat an acre once with commercial brands of dust.

Results of experiments to prevent potato Rhizoctonia, J. E. HOWITT (*Abs. in Phytopathology, 14 (1924), No. 7, p. 349*).—Five years' experiments on the control of Rhizoctonia have indicated that in Ontario corrosive sublimate materially reduces the amount of Rhizoctonia, and that stronger solutions than those usually recommended can be used.

Potato varieties resistant to wart disease [trans. title], H. L. DE VILMORIN (*Jour. Agr. Prat., n. ser., 44 (1925), Nos. 49, pp. 453, 454; 50, pp. 475-478; 51, pp. 493-496*).—Information is given regarding potatoes resistant to wart disease, more particularly English and German varieties.

Witches' broom of potatoes in the Northwest, C. W. HUNGERFORD and B. F. DANA (*Phytopathology, 14 (1924), No. 8, pp. 372-383, pl. 1, figs. 4*).—A description is given of a potato disease that made its appearance in the Pacific Northwest in 1923. The disease is said to have occurred under a wide range of conditions, and while the cause was not definitely determined the infection was found to be constantly transmitted by the tubers. Witches'-broom of potatoes is said to have some resemblances to leaf roll, spindle sprout, and net-necrosis, but from the evidence at hand the authors consider it a distinct disease.

Sugar production and cane diseases [trans. title], M. T. COOK (*Rev. Agr. Puerto Rico*, 15 (1925), No. 6, pp. 273-276).—A brief discussion relative to sugar cane diseases affecting production, and to preventives, including disease-free stock and ground, roguing, and immune or highly resistant varieties.

Cane pests and diseases, W. COTTRELL-DORMER (*Queensland Agr. Jour.*, 24 (1925), No. 5, pp. 441-443).—Leaf scald is the most serious cane disease of the Mossman district, Clark Seedling appearing very susceptible. Leaf stripe injured greatly ratoon B. 147, but was resisted by Q. 813. Foot rot is favored by too early covering. Leaf scald shows varietal preferences.

Rust resistance in timothy, H. D. BARKER and H. K. HAYES (*Phytopathology*, 14 (1924), No. 8, pp. 363-371, fig. 1).—Previous investigations having indicated that certain timothy selections were quite resistant to rust (E. S. R., 42, p. 247), further selections were made of various clonal lines which were inoculated with timothy rust from different localities in the United States and Canada. No definite indications were found showing the existence of biological strains of *Puccinia graminis phleipratensis*. The occurrence of resistant clonal lines of timothy which were not infected by the rust collected from widely separated localities is said to lend encouragement to the production of rust-resistant varieties. Inoculation experiments on seedlings produced from self-fertilized clonal lines, and from crosses between clonal lines, indicated that resistance or susceptibility in the selections of timothy studied is dependent upon a single differential factor pair. Resistance is said to be a dominant, and a close approximation to a 3:1 ratio was obtained in the progeny of self-fertilized resistant plants.

Tomato diseases, G. H. BERKELEY (*Canada Dept. Agr. Bul.* 51, n. ser. (1925), pp. 14, pls. 3).—This is said to be a revised edition of Bulletin 35, second series, prepared by McCubbin and noted previously (E. S. R., 43, p. 348).

A study of the physiological drop of fruits in Delaware, L. R. DETJEN and G. F. GRAY (*Delaware Sta. Bul.* 147 (1926), pp. 20, 21).—In continuation of studies on the physiological drop of fruits (E. S. R., 55, p. 451), a brief account is given of studies on the correlation existing between the time and mode of shedding of fruits and the genetic relation of the trees. It was found that trees of the same variety under similar conditions shed their immature fruits in similar and parallel waves, while trees of different varieties and different kinds of fruits shed their fruits in dissimilar waves. Strong evidence is said to have been secured that indicates the stability of the wave character in relation to the variety or kind of fruit. Neither widely different fertilizer treatments, crown gall disease, rootstocks, nor early or late applications of nitrogen disturb the balance of the genetic factor.

Sphaeropsis malorum and Myxosporium corticola on apple and pear in Oregon, S. M. ZELLER (*Phytopathology*, 14 (1924), No. 7, pp. 329-333).—The author confirms the statement of Stillinger relative to the occurrence of apple black rot in Oregon (E. S. R., 46, p. 849), but the disease is considered of limited economic importance because of the dry summer climate. The fungus has usually been found as a bark canker, although it is said to occur also as a leaf spot and may cause a black rot of apples rather frequently.

M. corticola is said to occur in Oregon as a superficial bark canker, and apparently it produces no lasting or damaging effect on trees which have bark infections due to this organism. No decay of fruit was induced by artificial inoculation.

Apple measles, with special reference to the comparative susceptibility and resistance of apple varieties to this disease in Missouri, A. S. RHOADS (*Phytopathology*, 14 (1924), No. 7, pp. 289-314, pls. 5, fig. 1).—The author

describes an obscure bark disease of apple trees, reviews the literature regarding this disease, and gives an account of his own investigations concerning it. Marked differences in the susceptibility and resistance of different varieties to measles are pointed out. Various explanations have been advanced to explain the cause of the disease, but the author found no relation between drainage of soil, application of fertilizers, tillage, and cover crops, or the method of pruning and the prevalence of the disease. Thus far no causal organism has been discovered, and the author believes that the trouble is purely a physiological one. From his observations of the disease in Missouri he does not consider it responsible for a more or less rapid decline of the tree. In many instances young and vigorous trees were found to outgrow the trouble ultimately without any special treatment.

Note on an Exoascus disease on *Prunus amygdalus* var. *amara*, W. G. CAMPBELL (*Bot. Soc. Edinb. Trans. and Proc.*, 29 (1924-25), pt. 2, pp. 186-191, figs. 4).—*P. amygdalus amara* in St. Andrews University Botanic Garden has for some years shown disease, which has recently spread to *P. amygdalus dulcis*. Dieback is a prominent feature, as is also an increase in all dimensions of the leaves, the average weight of which is about eleven times the normal. The fungus, which hibernates in the walls of the phloem elements of the shoots, is claimed to be other than the true *Exoascus deformans*, as it differs from that form in several details.

Raspberry diseases, G. H. BERKELEY and A. B. JACKSON (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 347).—The authors report that the average amount of mosaic for the Niagara Peninsula is from 15 to 20 per cent. Nicotine sulfate may be used to check the spread of the disease, and heavy fertilizing tends to mask its presence. The chief method of control suggested is the use of certified stock. Leaf curl of raspberries in the Niagara Peninsula is said to vary from 0 to 5 per cent, and the disease is believed to be on the decrease.

A note on raspberry canker (*Nectria rubi* Osterwalder), N. L. ALCOCK (*Bot. Soc. Edinb. Trans. and Proc.*, 29 (1924-25), pt. 2, pp. 197, 198).—At two points named raspberry cane roots showed disease in association with *N. rubi*.

Blue stem of red and black raspberry, G. H. BERKELEY and A. B. JACKSON (*Abs. in Phytopathology*, 14 (1924), No. 7, pp. 347, 348).—The presence of blue stem on black raspberries has been reported, and the authors give an account of the disease as prevalent throughout the Niagara Peninsula, Ontario, on both red and black raspberries. Isolations from the wood of infected canes are said to have given characteristic cultures of *Acrostalagmus caulophagus*.

Strawberry black root, G. H. BERKELEY and A. B. JACKSON (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 348).—The presence of this disease in one or two districts of the Niagara Peninsula is reported. Preliminary inoculation tests are said to indicate that at least one type of injury may be caused by soil bacteria.

Bunchy top in bananas, E. J. GODDARD, C. J. P. MAGEE, and H. COLLARD (*Queensland Agr. Jour.*, 24 (1925), No. 5, pp. 424-429).—Tests in insect-proof inclosures showed 100 per cent infection within one month following contact of banana plants with insects (*Pentalonia nigronervosa*) from infected plants, but no infection in plants not exposed.

Pineapple chlorosis [trans. title], M. T. COOK (*Rev. Agr. Puerto Rico*, 15 (1925), No. 6, pp. 296, 297).—Pineapple chlorosis appears most frequently in the gravelly coastal soils of alkaline reaction between San Juan and Arecibo. Iron sulfate at different rates gives marked improvement in case of young plants.

The aecial stage of *Hyalopeziza aspidiotus*, J. H. FAULL and G. D. DARKER (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 350).—This fungus, which is a

fern parasite, is said to have *Abies balsamea* for its alternate host, an observation which was confirmed by inoculation experiments of the authors.

Stereum sanguinolentum as the cause of "sapin rouge" or red heart rot of balsam, J. H. FAULL and I. MOUNCE (*Abs. in Phytopathology*, 14 (1924), No. 7, pp. 349, 350).—A description is given of a rot of balsam trees due to *S. sanguinolentum*. The fungus is said to fruit abundantly on dead trees and slash, and on this account they should be destroyed.

The pathological anatomy of tissue produced in *Abies balsamea* following an attack of the spruce budworm, C. H. MCLEOD (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 345).—A description is given of young shoots of *A. balsamea* attacked by the spruce or balsam bud worm. The abnormalities are said to appear in any part of the growth ring, and several types may appear in the same ring.

Chestnut blight in Ontario, R. E. STONE (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 345).—Chestnut blight due to *Endothia parasitica* is said to occur in Ontario. In Norfolk County, 25 per cent of the trees are reported diseased.

Some silvicultural aspects of the chestnut blight situation, E. H. FROTHINGHAM (*Jour. Forestry*, 22 (1924), No. 8, pp. 861-872).—In this account with discussion (mainly from a silvicultural point of view) of chestnut blight, chiefly in the southern Appalachian region, it is concluded that efforts to stop or even control its spread are not justified by experience. Chestnut utilization is the first need. Successive short-lived generations of sprouts from blight-killed chestnuts, with the tendency of such to spread, also the reproduction of inferior species and shading, constitute a menace to the more valuable hardwoods.

Coryneum twig blight of Manitoba maple, J. E. HOWITT (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 345).—The Manitoba maples in the vicinity of the Ontario Agricultural College are reported as affected by *C. negundinis*.

The self pruning of western yellow pine, W. H. LONG (*Phytopathology*, 14 (1924), No. 7, pp. 336, 337).—Attention is called to the presence of *Oenangium abietis* on the lower parts of the western yellow pine, where it causes self-pruning through its destruction of the lower branches. Only the lower weakened branches are attacked, the fungus rarely being found more than 30 ft. from the ground. It is considered a valuable asset to the lumbering industry in New Mexico and Arizona.

ECONOMIC ZOOLOGY—ENTOMOLOGY

Animal pests of useful plants, I, H. BLUNCK, K. FRIEDERICHS, F. STELLWAAG, S. WILKE, and F. ZACHER, rev. by L. REH (*Handbuch der Pflanzenkrankheiten*, founded by P. SORAUER. IV, *Tierische Schädlinge an Nutzpflanzen*, 1. Teil. Berlin: Paul Parey, 1925, 4. ed., vol. 4, pp. XVI+483, figs. 218).—In this volume the authors deal with the insect and other animal pests of economic plants.

Rabbit and mouse control in the orchard, T. J. TALBERT (*Missouri Sta. Circ. 151* (1926), pp. 14, figs. 7).—This includes an account of the treatment of injured trees.

Analysis of the growth curves of the insect larvae, N. YAGI (*Mem. Col. Agr., Kyoto Imp. Univ.*, No. 1 (1926), pp. 35, figs. 9).—This is a contribution from the entomological laboratory of the Kyoto Imperial University.

Entomology [at the Arkansas Station] (*Arkansas Sta. Bul. 215* (1926), pp. 39-41, fig. 1).—In reporting upon the boll weevil, reference is made to work previously reported in Bulletins 203 and 204 (E. S. R., 55, pp. 50, 55).

The insect injury to cotton which attracted most attention during 1926 was caused by three species of plant bugs, the cotton hopper, the tarnished plant

bug, and the cotton leaf bug." A survey made at representative points in the State at the height of the outbreak showed that the majority of all infestations of the cotton hopper could be traced to patches of croton or of evening primrose. These infestations were generally local, although in some instances they were spread over the greater part of large plantations. Dusting cotton with both sublimed and superfine sulfur gave fairly satisfactory control of the hopper in experimental plats, and was also apparently successful in large fields where used by the growers.

The codling moth life history studies were continued, and the rate of emergence of spring brood moths in 3-day periods, a hypothetical curve of rate of oviposition, and dates recommended for making cover sprays to control first brood larvae are graphically illustrated by a chart. In addition to the calyx spray, three cover sprays were recommended for the control of first brood larvae, and four were recommended for the control of the later broods.

"In the best plat 90.24 per cent of all fruit set was free from worms, in contrast with 10.87 per cent free from worms on the unsprayed check. An average of 2,024 apples, 94.79 per cent of which were free from worms, was harvested on each of the trees on this sprayed plat, while an average of only 152 apples was harvested on the check trees. Trees on which the last spray application was omitted were distinctly more wormy than trees given the full schedule, resulting on the average in a loss of nearly 8 per cent of the harvested fruit."

Brief reference is made to a 2-year study of the birds of the State.

[Investigations of economic insects], H. L. DOZIER (*Delaware Sta. Bul.* 147 (1926), pp. 17-20).—The investigations of the year dealt particularly with the bionomics and control of the codling moth, its control in the State, due to "side worm" injury, being the outstanding problem in this field. An attempt was made to determine the degree of variety susceptibility to attack, and a distinct preference was found to be shown for the Stayman Winesap, Paragon, and King David. The Nero, Rome Beauty, Delicious, and York Imperial were attacked to a much less degree, and the Lily of Kent, Jonathan, and Missouri Pippin showed a decided resistance to attack, their fruit being almost uninjured while other varieties on adjacent and surrounding trees were badly damaged. It is pointed out that the degree to which a variety is attacked seems to be connected with the toughness of the skin.

A study was made of the various sources of infestation and carry-over of the pest, and it was clearly shown that old picking baskets in the packing houses and sheds were the greatest source. The old picking baskets were found to be heavily infested with worms, which, upon leaving the picked fruit, cocooned up in the crevices and between the staves. On May 5 several hundred worms were collected from baskets at a packing house, and up to this date only one individual had pupated. In the outdoor insectary at Newark, however, about 10 per cent of the worms in pupation sticks had pupated by May 7. The first adult moths began issuing in a packing house at Woodside on May 20, the majority of these being oriental peach moth adults at that time, and as the season advanced the numbers of the oriental peach moths decreased and the codling moth adults increased. In the cellar of one grower the moths started emerging in abundant numbers by June 10, and adults caught on Tanglefoot exposed the last 48 hours at the windows showed 535 oriental peach moths and 85 codling moth adults. On June 23 more Tanglefoot had caught 322 oriental peach moths and 142 codling moths; on July 1, 121 codling moths and 101 oriental peach moths; and on July 8, 253 codling moths and only 41 oriental peach moths. This shows the oriental

peach moth to be slightly earlier in spring emergence than the codling moth and also indicates a mixed infestation of both species on the apple. Some interesting data were obtained on the abundance of wasp parasites of the codling moth, the following species having been taken in the packing house in order of their abundance: *Ascogaster carpocapsae* (Vier.), *Phanerotoma tibialis* Hald., *Bracon carpocapsae* (Cush.), and *Dibrachys boucheanus* (Ratz.).

From 389 old picking baskets stored in the cellar of a packing house at Camden in the early spring, 11,602 worms were found, an average of 29.08 worms per basket. Out of approximately 3,000 baskets at Woodside, 224 showed 4,895 worms, or an average of 21.4 worms per basket. One hundred baskets in the cellar of a grower at Rising Sun gave 1,373 worms, or an average of 13.73 worms per basket.

In a large cage in an orchard near Camden, the first stung fruit of the season was observed on June 7, and by June 10 only 35 out of 94 set fruit on the tree were unstung, some of the young apples having as many as 6 or 7 stings. On June 24 a careful examination of this orchard showed stung fruit outside the cage to be extremely scarce, while in the cage all the fruit was heavily stung, some having as many as 27 stings. It was stated that instead of entering through the calyx cup end of the fruit, as usually occurs, the newly hatched worms entered from the side, and it was rare to find an attempt at entry through the calyx.

The grape leafhopper has for a number of years taken a heavy annual toll in the vineyards of the State, and, gradually increasing in numbers, has proved to be the worst grape pest in the State. A study has been made of its life history in the outdoor insectary, with seasonal observations of conditions in the field. The fungus *Entomophthora sphaerosperma* was observed to be killing large numbers of adults on grape foliage in the fall of 1925, and during the latter part of May, 1926, they were as abundant as in the preceding July. Liquid nicotine did not prove very successful against the adults, and strong winds in the vineyards rendered dusting impracticable. Calcium cyanide dust was demonstrated to have better killing powers than the nicotine lime dust, but on the few hot, quiet days that occurred some growers used 2 per cent nicotine lime dust with good practical results at a cost of about \$5 per acre.

[Insect control investigations at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 163, 164*).—In control work by J. W. Lloyd and W. P. Flint with insects on eggplants, the best yields in 1925 were obtained from plants dusted with arsenate of lead (1 lb.) and hydrated lime (4 lbs.) Spraying with calcium arsenate (1.5 lbs.) and lime (1 lb. to 50 gal. water) resulted in nearly as high yields. The results of the year indicated that the arsenical is the active agent in the control since the spraying material, consisting of calcium arsenate and lime alone, was more effective than the combined mixture of Bordeaux and arsenate; and the weaker the Bordeaux the greater was the yield of eggplants.

In control work with the striped cucumber beetle, the best results were obtained by dusting plants with a mixture consisting of 1 lb. of calcium arsenate and 20 lbs. of gypsum. The yield from the plats so treated was 4 times the average yield of all untreated check plats and was higher than the yields resulting from any of the other treatments.

The biological control of insect pests and injurious plants in the Hawaiian Islands, A. D. IMMS (*Ann. Appl. Biol., 13 (1926), No. 3, pp. 402-423, pl. 1*).—This is a summary of information based upon investigations in the islands in 1925.

(Annual reports of the entomologist for the years 1924 and 1925), E. JARVIS (*Queensland Bur. Sugar Expt. Stas. Ann. Rpts.*, 24 (1924), pp. 13-18; 25 (1925), pp. 17-23).—These are the usual annual reports (E. S. R., 52, p. 853). They deal with work with sugar-cane insects, particular attention being given to the control of the gray-back cockchafer (*Lepidoderma albohirtum* Waterh.), including the use of paradichlorobenzene, calcium cyanide, and carbon disulfide; the weevil borer *Rhabdocnemis obscurus* Boisld.; and the termite *Mastotermes darwiniensis* Frogg.

Catalogue of Indian insects, IV—X (*Calcutta: Govt.*, 1924, pts. 4, pp. 33; 5, pp. IV+40; 1925, pts. 6, pp. 126; 7, pp. 29; 8, pp. 35; 9, pp. 92; 1926, pt. 10, pp. 14).—This is in continuation of the catalogue previously noted (E. S. R., 51, p. 54). Part 4, by R. Senior-White, deals with Trypetidae (Trypaneidae); part 5, by S. N. Chatterjee, with Nitidulidae; part 6, by M. Cameron, with Staphylinidae; parts 7, 8, and 9, all by T. B. Fletcher, with Lasiocampidae, Amatidae, and Zygaenidae, respectively; and part 10, by G. R. Dutt, with Stephanidae. Systematic arrangements of the genera and species, bibliographies, and distributional data are given for each family.

The utilization of calcium cyanide in the control of insect and rodent pests in India, W. H. BRITAIN (*Planters' Chron.*, 21 (1926), No. 33, pp. 538-544).—The author concludes that calcium cyanide has a wide range of usefulness as an insecticide and rodent killer in India. It is easily transported, simply and quickly applied, requires no mixing, and after exposure the poisonous property disappears leaving a nonpoisonous residue.

Calcium cyanide and its utilization in the control of insect pests in Ceylon, W. H. BRITAIN (*Trop. Agr. [Ceylon]*, 67 (1926), No. 1, pp. 45-49, pl. 1).—A discussion of the use of this insecticide as applied to pest control in Ceylon.

Studies on contact insecticides.—Part IV, A quantitative examination of the toxicity of certain plants and plant products to *Aphis rumicis* L. (the bean aphid), F. TATTERSFIELD, C. T. GIMINGHAM, and H. M. MORRIS (*Ann. Appl. Biol.*, 13 (1926), No. 3, pp. 424-445, figs. 6).—The authors here continue earlier work (E. S. R., 55, p. 852), with an account of laboratory experiments on the toxicity to *A. rumicis* of extracts of a considerable number of plants, including some tropical fish poisons, lupines, broom, gorse, lobelia, and others.

"Alcoholic extracts of certain tropical plants used as fish poisons are shown to have a high toxicity under the conditions of the experiments. The roots and stems of white haiari and the stems of black haiari (both species of *Lonchocarpus* from British Guiana), the roots of *Tephrosia toxicaria*, and the leaves of *T. vogelii* all possess notable insecticidal properties. The roots and stems of *T. candida* are less toxic. Preliminary experiments indicate that the haiaris and *T. vogelii* and *T. toxicaria*, when tested as stomach poisons, exert both a repellent and toxic action to caterpillars. Certain derivatives isolated from these plants were tested. The most toxic substance obtained from the haiaris is shown to be identical with tubatoxin, the crystalline poison found in *Derris elliptica*. Tubatoxin proved to be several times more toxic than nicotine. In the case of *T. vogelii* and *T. toxicaria*, the most toxic substances isolated were resinous in nature. Crystals closely corresponding to tephrosin, as isolated by Hanriot, were less toxic. A number of alkaloids were also investigated. Cytisine and lobeline, known to have a physiological action on higher animals similar to that of nicotine, were found somewhat less toxic than nicotine to aphides. Eserine was the only other alkaloid tested which approached nicotine in toxicity."

A quantitative examination of the toxicity of 3:5-dinitro-o-cresol and other compounds to insect eggs under laboratory and field conditions, C. T. GIMMINGHAM, A. M. MASSE, and F. TATTERSFIELD (*Ann. Appl. Biol.*, 13 (1926), No. 3, pp. 446-465, pl. 1, figs. 2).—In this special paper on the subject (see above) the authors report upon quantitative determinations, under controlled conditions in the laboratory, of the toxicity of 3:5-dinitro-o-cresol and its sodium salt to eggs of the geometrid moth *Selenia tetralunaria* Hüfn.

The results show that these compounds have a very high toxicity to insect eggs, and that the sodium salt of dinitro-o-cresol is only slightly less toxic than dinitro-o-cresol in the uncombined state. Preliminary laboratory experiments indicate that dinitro-o-cresol is also highly toxic to insect eggs of a more resistant type than those of *S. tetralunaria*. Spray fluids containing dinitro-o-cresol or the sodium salt showed a high efficiency against eggs of the hop aphid on plum trees on a larger scale under field conditions. The trees sprayed with these compounds remained almost free from aphids during the following spring when the control trees were badly infested. The spray fluids containing dinitro-o-cresol and its sodium salt had a marked general cleansing effect on the trees. No injury to the trees was observed.

A quantitative method for judging the results of the field experiments was worked out. This involved recording details of large numbers of eggs on selected shoots on sprayed and control trees before and after spraying, a numerical measure of the effect of the various treatments being thus obtained. The method gave consistent and reliable results.

Fruit insect problems for 1925, E. N. CORY (*Peninsula Hort. Soc. [Del.] Trans.*, 39 (1925), pp. 34-38).—This is a brief discussion of the more important insect enemies of fruit in the year, particularly relating to the oriental peach moth.

The control of the Porto Rican mole-cricket, or changa, on golf courses, W. A. THOMAS (*Bul. U. S. Golf Assoc. Green Sect.*, 6 (1926), No. 9, pp. 197-200, figs. 2).—It is pointed out that many complaints have been received from golf clubs in the southeastern United States, the West Indies, and even from South America relating to the destruction wrought to greens and fairways by the changa. In experiments conducted at the Jekyl Island Club, of Brunswick, Ga., it was found that a commercial product, a carbon disulfide emulsion containing 75 per cent of carbon disulfide, used at the rate of 1 part of the emulsion to 400 parts of water and sprinkled over the green at the rate of 2 qt. to the square foot of area as rapidly as the ground would absorb it, resulted in a control of slightly more than 95 per cent. In the course of from four to six weeks the infestation was sufficiently heavy to justify an additional treatment.

Thirty lbs. of a commercial cyanide dust, which contained approximately 40 per cent actual calcium cyanide, was mixed with 500 gal. of water and poured as evenly as possible over the entire green (about 4,400 sq. ft.) through a 0.75-in. hose. While applying the solution it was kept thoroughly agitated, and after the application sprinklers were set running to carry the material into the soil. This treatment also gave more than 95 per cent control, but like the emulsion its effects lasted for only about a month.

It was found that three applications of a poison bait consisting of 100 lbs. of cottonseed meal, 100 lbs. of rice flour, and 10 lbs. of calcium arsenate, moistened with a cheap molasses solution (1 part of molasses to 10 parts of water) to make the bait crumbly, gave excellent control. The bait was used at the rate of 15 lbs. to the green, or 150 lbs. per acre, at weekly or 10-day intervals. Although the effect was not as immediate as with the carbon disulfide and calcium cyanide treatments, the low cost of the material and

the ease of application made it practicable to treat not only the green but also the adjacent infested fairways, thus preventing early reinfestation of the green. Late afternoon was found to be the most satisfactory time for making treatments.

The influence of temperature on the maturation and general health of *Locusta migratoria* L., V. P. POSPELOV (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 363-367, pls. 3).—This is a contribution from the State Institute of Experimental Agronomy, Leningrad.

Observations on the life history of *Helopeltis* on cotton in Southern Nigeria, O. B. LEAN (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 319-324).—The life history, habits, and control of the capsids *H. bergrothi* Reut. and *H. sanguineus* Popp. are considered.

Controlling mealybugs on ornamental plants, R. W. DOANE (*Pan-Pacific Ent.*, 2 (1926), No. 4, pp. 213, 214).—In control work with the common mealybug, *Pseudococcus gahani*, the author has found a spray consisting of 1 gal. Volk oil (orange oil), 7.5 lbs. Gold Dust washing powder, 0.5 pint nicotine (Blackleaf 40), and 50 gal. of water to be effective.

The silver fir chermes, R. N. CHRYSTAL ([*Gt. Brit.*] *Forestry Comm. Bul.* 7 (1926), pp. 27, pls. 9).—This bulletin gives a general account of the chief species of silver fir used for forest planting in Britain, including a discussion of *Abies grandis* and *A. nobilis* in relation to chermes attack. This is followed by accounts of the silver fir chermes *Dreyfusia nüsslini* Bör. and *D. piceae* Bör. and their relation to the forest, the silver fir in Denmark, the silver fir chermes in Denmark, and the control of chermes in Denmark, and a general discussion of the Danish results in relation to British conditions.

The development of the ovary in the silkworm (*Bombyx mori*), J. MACHIDA (*Jour. Col. Agr., Imp. Univ. Tokyo*, 7 (1926), No. 4, pp. 293-351, pls. 4, figs. 2).—This report of the author's studies includes 64 references to the literature.

Results of the sixth year's work against the gipsy moth in New Jersey, H. B. WEISS ET AL. (*N. J. Dept. Agr. Circ.* 105 (1926), pp. 32, figs. 28).—Details of the work of the year (E. S. R., 54, p. 156) are presented, largely in tabular form. But three colonies, containing a total of 54 egg masses, were found.

The potato tuber moth, E. N. CORY (*Peninsula Hort. Soc. [Del.] Trans.*, 39 (1925), pp. 51-56).—A brief discussion of the status of the potato tuber worm and means for its control (E. S. R., 55, p. 356).

A study on the biology of the green bud worm (*Argyroploce variegana* Hb.) and the eye-spotted budmoth [trans. title], J. WORONIECKA (*Pam. Państw. Inst. Nauk. Gosp. Wiejsk. Puławach (Mém. Inst. Natl. Polon. Écon. Rurale Puławy)*, 6 (1925), A, pp. 366-394, pl. 1; *Eng. abs.*, pp. 390-394).—Of a large number of tortricids injurious to orchards in the environs of Puławy and in all the district of Lublin, *A. variegana* and the eye-spotted budmoth are said to do the most damage. In this paper the author deals with their biology, natural enemies, and means of control.

The peach tree borer, J. O. PEPPER (*Clemson Agr. Col. S. C., Ext. Circ.* 81 (1926), pp. 8, figs. 10).—A practical account of this pest and means of control.

Theresia ampelophaga Bayle in Crimean vineyards, S. M. FEDOROV (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 393-397, pls. 2).—An account of the distribution and ecology, bionomics, nature of the damage, and control measures for this lepidopteran, one of the most important pests of the vine in various countries.

The European corn borer: The relation of the larvae to submergence, M. F. CROWELL (*New Hampshire Sta. Tech. Bul.* 30 (1926), pp. 20, figs. 7).—In this paper the author records the results of a study commenced in the winter

of 1924-25 and continued until the spring of 1926. He discusses resistance of larvae to submergence, the structure of the spiracles, closing apparatus, tracheal system, penetration of liquids into the tracheal system, etc.

It was found that the hibernating larvae of the European corn borer can withstand periods of submergence in water from six to seven times as long as can the active larvae. This ability appears to be due to the fact that the tracheal closing apparatus is closed during the period of hibernation, since there is no other anatomical adaptation to account for it. Their ability to withstand submergence is not sufficient to account for the records of survival after prolonged submergence in the stalks in which they enter hibernation, but this survival may be accounted for by the fact that a considerable time elapses before a submerged stalk becomes saturated with water. A comparison of this pest with others shows that the hibernating larvae of other Lepidoptera can also withstand longer periods of submergence than can the active larvae.

Notes on the sweet potato pyralid moth, *Megastes grandalis* Guen., J. W. COWLAND (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 369-372, figs. 2).—It is pointed out that since *M. grandalis* was first reported from Brazil in 1854 there has been no record until 1919, when it was reported by Ulrich from Trinidad. It is well distributed throughout the island, and during certain seasons is a very serious pest of the sweet potato, which is the only known food plant. The author gives descriptions of the immature stages, notes on its life history and habits and on its parasites, including the egg parasite *Trichogramma minutum* Ril., the sarcophagid larval parasite *Sarcophaga sternodonta* Towns., and the tachinid *Masicera? abdominalis* Wulp.

The European pine-shoot moth (*Evetria buoliana* Schiff.) [trans. title], W. TEMPEL (*Kranke Pflanze*, 2 (1925), No. 8, pp. 166, 167, pl. 1; abs. in *Rev. Appl. Ent.*, 13 (1925), Ser. A, No. 12, p. 603).—In an old infestation of the pine-shoot moth near Chemnitz, Saxony, the author observed parasitism by the tachinid *Actia (Thryptocera) pilipennis* Fall., and the homenopterans *Pimpla examinator* F., *P. turionella* L., *P. detrita* Hb., *Cremastus confluens* Gr., and *Orgilus obscuratus* Hal.

On the development and biology of *Simaethis (Hemerophila) pariana* Clerck [trans. title], S. MINKIEWICZ (*Pam. Państw. Inst. Nauk. Gosp. Wiejsk. Puławach (Mém. Inst. Natl. Polon. Écon. Rurale Puławy)*, 6 (1925), A, pp. 330-365, pls. 2; Eng. abs., pp. 357-364).—This is a report of a pest which in 1920 emerged in large numbers and severely injured a young apple orchard of the National Institute of Agriculture in Puławy. Studies of its life history and habits, natural enemies, and means of control are dealt with.

The larger narcissus bulb-fly, E. McDANIEL (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 54, 55).—This is a brief account of the narcissus bulb fly, found during the year for the first time in Michigan bulbs. It includes a reference to the hot-water treatment for bulb flies and eelworms.

The Queensland fruit fly (*Chaetodacus tryoni* Froggatt), H. JARVIS (*Queensland Agr. Jour.*, 26 (1926), No. 2, pp. 101-104, pl. 1).—A brief summarized account of this fruit fly, which was first discovered by Tryon in 1889.

North American cerambycid larvae, F. C. CRAIGHEAD (*Canada Dept. Agr. Bul.* 27, n. ser. (1923), pp. 239, pls. 44, figs. 8).—This work deals with the classification and the biology of North American cerambycid larvae. The subject is dealt with under the headings of introduction (pp. 3, 4), classification of the larvae as correlated with that of the adults (pp. 5-7), biological characteristics as correlated with anatomical structures and their use in taxonomy (pp. 7-9), summary of biological habits (pp. 9-13), anatomical characterization (pp. 13-25), brief characterization of larvae of the family

Cerambycidae, including keys to the subfamilies, genera, species, etc. (pp. 26-138), appendix with additional species (pp. 138-144), literature cited (pp. 145, 146), index to species, genera, and higher groups (pp. 147-149), abbreviations used in plates and text figures (p. 150), and plates (pp. 151-239).

Notes on the coffee berry-borer (*Stephanoderes hampei* Ferr.) in Uganda, H. HARGREAVES (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 347-354, figs. 3).—The author gives a summary of the life history of this borer and a description of the early stages, and discusses the habits of the adults, nature of the damage, natural control, and artificial control.

The tuart bud weevil (*Haplonyx tibialis*), L. J. NEWMAN and J. CLARK (*Aust. Forestry Jour.*, 9 (1926), No. 7, pp. 191, 192, 194, 195, figs. 4).—An account of *H. tibialis* and its injury to the tuart (*Eucalyptus gomphocephala*), one of the most useful hardwoods grown in Western Australia.

Hymenoptera and paratyphoid? The intestinal bacteria of bees and wasps [trans. title], K. MÜLLER (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 97 (1926), No. 2-3, pp. 214-218).—None of the 75 strains of Gram-negative bacteria obtained from bees and wasps and cultivated on Endo agar which resembled paratyphoid colonies was agglutinated by the typhoid or paratyphoid B serum. Reference is made to the investigations of Bahr (*E. S. R.*, 47, p. 259) and others on the subject.

Studies of *Bacillus* larvae, the cause of American foulbrood of bees, A. G. LOCHHEAD (*Canada Expt. Farms, Div. Bact. Rpt. 1925*, pp. 19, 20).—The author has tabulated the growth of *B. larvae* on different media and also the effect of plant extracts on the growth of *B. larvae*.

Notes on encyrtidae (Hym., Chalcidoidea) bred from psyllids, with description of a new species, A. B. GAHAN and J. WATERSTON (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 373-375, fig. 1).—*Psyllaephagus arbuticola*, reared from a psyllid on *Arbutus* in San Mateo and Alameda Counties and from *Euphyllura arbuti* at Palo Alto, Calif., is described as new.

On a new trichogrammatid (Hym., Chalcidoidea) parasite of the cotton stemborer (*Sphenoptera* sp.), J. WATERSTON (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 309-313, figs. 2).—Under the name *Lathromeris johnstoni* n. sp., the author describes and reports upon a new egg parasite of the cotton stem borer (*Sphenoptera* sp.). It has been reared from Khartum, Anglo-Egyptian Sudan, to 100 miles south.

Descriptions of new coccid-inhabiting chalcidoid parasites (Hymenoptera), H. COMPERE (*Calif. Univ. Pubs. Ent.*, 4 (1926), No. 1, pp. 31, figs. 10).—In this paper eight parasites are described as new, including two aphelinids, one eulophid, three Ectromatini (encyrtids), and two Mirini.

The woolly aphid parasite (*Aphelinus mali* Hald.), W. B. GURNEY (*Agr. Gaz. N. S. Wales*, 37 (1926), No. 8, pp. 620-626, figs. 3).—This is an account of the introduction and establishment of *A. mali* in New South Wales.

The woolly aphid parasite (*Aphelinus mali* Hald.), H. JARVIS (*Queensland Agr. Jour.*, 26 (1926), No. 2, pp. 105-108, figs. 5).—This is a brief summary of the life history of this parasite in Queensland.

British spiders: Their haunts and habits, T. H. SAVORY (*Oxford, Eng.: Clarendon Press, 1926*, pp. XII+180, figs. 34).—A small handbook on British spiders.

A new invertebrate host of *Trypanosoma cruzi* Chagas, C. URIBE (*Jour. Parasitol.*, 12 (1926), No. 4, pp. 213-215, fig. 1).—The author reports the discovery that the reduviid bug *Apiomerus pilipes* Fab. is a host of *T. cruzi* in Venezuela. This bug was found to feed readily upon *Rhodnius prolixus* Stahl and also upon the house fly.

ANIMAL PRODUCTION

[The biological values of proteins] (*Illinois Sta. Rpt. 1926, p. 65*).—In continuing the studies of the biological values of proteins (E. S. R., 51, p. 570), H. H. Mitchell found that corn protein had an average value of 55 with swine as compared with an average value of 60 obtained in numerous experiments with rats. Tankage protein proved to have a distinctly inferior value of 48, 47, and 30 in individual experiments with swine as compared with the proteins of other feeds. In agreement with earlier work, mixtures of corn and tankage had an average value higher than that of corn alone.

Dietary requirements for reproduction (*Arkansas Sta. Bul. 215 (1926), pp. 23, 24, 25, figs. 4*).—In continuing this study (E. S. R., 54, p. 561), the potency of wheat oil as a source of vitamin E, both for fertility and lactation, has been demonstrated by use in connection with a skim milk powder sterility-producing ration.

Two types of sterility have been encountered, one form being observed in the first generation females, which is characterized by a resorption of the fetus, while the second form occurs in the second-generation animals receiving a diet of skim milk powder prepared from winter milk, and can be prevented by incorporating in the basal diet 3 per cent of wheat oil, and 0.05 per cent of equal amounts of $\text{AlK}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, NaF, MnSO_4 , and Na_2SiO_3 . Illustrations of uteri containing resorbed young are presented.

An unusually high requirement of vitamin B for normal milk secretion has likewise been brought out in these studies.

Fowler's solution cuts size of rabbit litters (*Illinois Sta. Rpt. 1926, p. 82*).—In continuing the studies of the effect of Fowler's solution on reproduction in rabbits, E. Roberts and G. A. Lindsey found that the average size of 28 litters produced before treating the females with this substance was 6.3, while the average size of 34 litters produced after feeding Fowler's solution was 5.3. It was also further indicated that the animals to which this drug was administered were more susceptible to disease, and many were rendered sterile.

Effects of fluorine on bone formation (*Arkansas Sta. Bul. 215 (1926), pp. 23, 26, 27*).—Preliminary studies of the function of the inorganic elements of the diet have indicated that the utilization of calcium and phosphorus compounds is influenced by the relative amounts of vitamins and magnesium present, and by their state of division and degree of solubility.

Fluorine has been found to be a disturbing element in bone formation in the amounts which are present in rock phosphate. In excessive amounts it interferes particularly with calcium formation. In rats, fluorine, in amounts varying from 0.1 to 0.5 gm. per kilogram of the ration, has been found to produce a marked elongation of the upper incisors.

Tests show best type of corn to use for silage (*Illinois Sta. Rpt. 1926, pp. 90, 91*).—Studies by W. B. Nevens indicated that corn containing from 25 to 35 per cent dry matter at the time of harvest made silage having better keeping qualities and a higher feeding value than corn in which the dry matter content was without these limits. The digestion coefficients of one variety of early and two varieties of late maturing corn are presented for comparison.

Inspection of commercial feeding-stuffs, T. G. PHILLIPS, T. O. SMITH, and A. W. PETRE (*New Hampshire Sta. Bul. 224 (1926), pp. 51*).—The usual report of the guaranties and analyses of feeding stuffs officially inspected between December, 1925, and May, 1926 (E. S. R., 54, p. 264).

Cattle feeding investigations, 1924-25, C. W. McCAMPBELL, B. M. ANDERSON, and H. W. MARSTON (*Kansas Sta. Circ. 128 (1926), pp. 14, fig 1*).—An experiment with baby beef steers and two with yearling steers are reported.

To what extent may one depend upon silage as a roughage for baby beef?—Six lots of calves were selected for a 195-day experiment ended May 18, 1925. All lots were fed shelled corn. The roughage of one lot consisted of alfalfa hay, while another lot received cane silage as the only roughage. The other four lots received a full-feed of cane silage through the entire experiment, but during the last 75 and 135 days and for the entire feeding period, respectively, 2 lbs. of alfalfa hay per head daily were allowed. The fourth lot received a full-feed of alfalfa hay during the entire experiment. The rations were supplemented with cottonseed meal in amounts varying inversely with the amount of alfalfa hay fed.

The results showed that the inclusion of both cottonseed meal and cane silage in the ration of corn and alfalfa produced the best finish and the largest returns over feed costs. Gains were slightly more rapid on the rations of corn and unlimited amounts of alfalfa, with or without the cane silage. Fairly satisfactory baby beef was also produced on the ration of corn, cane silage, and cottonseed meal, but supplementing this ration with alfalfa hay throughout the feeding period materially increased the calculated value of the silage.

Cottonseed meal v. ground corn as a fattening feed.—Two lots of yearling steers, averaging approximately 550 lbs. in weight, were fed on a ration of alfalfa hay and silage plus cottonseed meal in one lot, while the other lot received 1 lb. of cottonseed meal per head daily and sufficient corn to make the combined amounts of concentrates in the two lots equal. For the 140-day feeding period the former consumed 11.04 lbs. of cottonseed meal per head daily, and the latter 10.04 lbs. of corn and 1 lb. of cottonseed meal. The average daily gains of the respective lots were 2.39 and 2.43 lbs., but the former lot was a little better finished. Ground corn fed in this way proved to be worth approximately 95 per cent as much as cottonseed meal, though its ordinary market price is relatively much below that proportion.

Wintering yearling steers preparatory to grazing without grain the first half of the grazing season and full feeding the last half.—Three lots of 10 yearling steers, averaging approximately 540 lbs. in weight, were selected for this test. Lots 1 and 2 were wintered on a limited grain ration, averaging 4.83 lbs. of corn and 1 lb. of cottonseed meal per head daily, with alfalfa hay and cane silage. Lot 3 received the same amounts of cane silage and cottonseed meal, but no corn or alfalfa. Following the winter feeding period, the three lots were grazed without grain from May 5 to August 3. After this pasturing period lot 1 was then finished by 90 days' feeding in dry lot on corn, cottonseed meal, and alfalfa, while the other two lots were finished with corn and cottonseed meal on pasture.

The results showed that the steers which were wintered without grain were fed at a considerable loss per head according to the calculated prices, but this loss was considerably reduced by the more rapid gains on pasture. When the finished period was included the calculated profits were greater than for the other lot finished on grass, but the returns were not as great as for those finished in dry lot.

Cattle feeding investigations, 1925-26, B. M. ANDERSON and H. W. MARSTON (*Kansas Sta. Circ. 130 (1926), pp. 5, fig 1*).—Six lots of calves, averaging approximately 420 lbs. in weight, were selected for studying the results which could be obtained with prairie hay when supplemented with cottonseed meal, linseed meal, or calcium carbonate, and fed with shelled corn

and cane silage. A control lot for comparison received a ration of shelled corn, cane silage, alfalfa hay, and cottonseed meal, which proved most satisfactory in the above experiments.

The results indicated that the addition of 0.11 lb. per head daily of calcium carbonate to a ration of shelled corn, cane silage, prairie hay, and cottonseed meal increased the rate of gain from 2.12 to 2.31 lbs. per head daily. When alfalfa hay replaced the prairie hay without calcium carbonate the rate of gain was 2.30 lbs. Another lot receiving the same ration, except that the corn was self-fed, made an average daily gain of 2.42 lbs. per head, and showed the largest calculated profits over feed costs of any of the lots. Linseed meal proved slightly superior to cottonseed meal as a supplement to the prairie-hay ration in the rate of gain, feed required per unit of gain, and finish of the steers. Feeding half alfalfa and half prairie hay did not give as good results as where prairie hay was fed alone and supplemented with calcium carbonate.

Economic beef production investigation (*Arkansas Sta. Bul. 215 (1926)*, pp. 29, 30).—Calves from grade Angus cows bred to purebred Angus bulls weighed an average of 430.4 lbs. at weaning and 661.6 lbs. after 140 days' feeding on alfalfa, silage, brewers' rice, and cottonseed meal. Purebred Angus calves averaged 433.4 lbs. at weaning and 666.4 lbs. at the end of the experiment. The corresponding weights of calves from scrub cows sired by purebred bulls were 374.3 and 589 lbs., respectively, and for calves from scrub cows sired by scrub bulls 366.4 and 579.4 lbs., respectively.

The calves were rated as to quality in the order of purebreds, calves from scrub cows and purebred bulls, calves from grade cows and purebred bulls, and scrub calves whose sires and dams were scrub animals.

Wintering stock steers, E. L. POTTER and R. WITHYCOMBE (*Oregon Sta. Bul. 224 (1926)*, pp. 16, figs. 13).—From the results of 10 years' experiments in wintering 33 lots of calves and heifers at Eastern Oregon Substation (E. S. R., 55, p. 665), general suggestions for the wintering of stock steers are presented.

The studies have shown that calves in particular may gain in weight but at the same time lose in fat and relative finish when short of feed. The same is also true of yearlings but to a less extent, due to the decreased tendency of yearlings to grow as compared with calves. The gains made the following summer on pasture were found to be directly related to the winter gains, irrespective of the kinds of feeds used. Calves making average winter gains of 21, 63, 115, 162, and 187 lbs. made the following respective summer gains: 238, 247, 219, 195, and 182 lbs. Similar results were obtained in experiments with yearlings. The amount of feed required to produce an average daily gain of 2 lbs. per head was approximately twice that required for maintenance in both calves and yearlings.

In a discussion of the value of alfalfa, straw, silage, and grain for wintering stock cattle, it is pointed out that approximately 2 lbs. of alfalfa per 100 lbs. of live weight daily was required to maintain weight, while each additional 7 to 7.5 lbs. produced 1 lb. of gain. Straw appeared to have no place in the winter ration where any appreciable gain was expected, but for maintenance purposes 2,100 to 2,200 lbs. of barley straw supplemented with 165 lbs. of cottonseed cake or 650 lbs. of alfalfa was equivalent to 1 ton of alfalfa. Silage proved to have approximately 40 per cent the economic value of alfalfa pound for pound when included in an alfalfa hay ration for wintering stock. It is therefore recommended that silage be saved for fattening cattle, where its value has been estimated at approximately twice that for maintenance. Nor with its high cost and relatively low value for maintenance purposes, did it

appear to be advisable to include grain in the winter ration of steers that are to be turned out on grass.

Sweet clover fell short in 1925 as beef pasture (*Illinois Sta. Rpt. 1926*, pp. 62, 63).—In continuing the study of the maintenance of the breeding herd (*E. S. R.*, 56, p. 262), H. P. Rusk found that the backward spring of 1925 greatly retarded the growth of sweet clover, making it necessary to add oat straw to the ration of cows carried through the grazing season on this pasture. By furnishing this supplement the length of the pasturage season was extended from 90 to 100 days, and the cows made an average daily gain of 0.38 lb. in weight as compared with a loss of 0.81 lb. when no oat straw supplement was furnished.

Data collected during the following winter indicated that dry stover silage was a satisfactory basal ration for dry beef cows during the winter months. When supplemented with 1 lb. of soy bean oil meal and 5 lbs. of oat straw the cows were maintained in a good breeding condition.

A mineral deficiency in the rations of cattle, C. H. ECKLES, R. B. BECKER, and L. S. PALMER (*Minnesota Sta. Bul. 229 (1926)*, pp. 4-49, figs. 18).—A survey indicated that mineral deficiency in cattle was particularly prevalent in certain regions of Minnesota, and that the symptoms of depraved appetite, stiffness, and very soft bones were most pronounced in the late winter or early spring, and were least pronounced when the animals were on pasture, especially in wet seasons.

Analyses of timothy, alfalfa, and prairie hay grown in regions where mineral deficiency was observed indicated that the calcium and magnesium contents were fully equal to the normal, but the phosphorus content was lower. During two years in which the rainfall differed considerably, the mineral content of the forage appeared to be associated with the rainfall. The water in the affected regions was high in its content of magnesium and sulfates.

After making the survey, three experiments were conducted. The first was concerned with the prevention of depraved appetite by feeding bone meal on 6 different farms with 119 cattle. Access to bone meal was allowed during a 150-day period. The average consumption per 30-day period on these different farms varied from 1.92 to 8.24 lbs. per head, but salt was mixed with the bone meal on the farm where the very high consumption occurred, and the average consumption on the other 5 farms was 3.57 lbs. per head per month. No indications of depraved appetite were apparent in the herds receiving bone meal, the cattle were reported as in better condition, and less difficulty was experienced with breeding.

The second experiment was concerned with the wintering at the station of 6 cows from a section where depraved appetite was especially severe on a basal ration of prairie hay, ground oats, salt, and water to which magnesium sulfate was added. Two of the cows receiving the basal ration only showed depraved appetite in 186 and 194 days, respectively. Of the 2 receiving a supplement of 150 gm. of calcium carbonate daily, depraved appetite was evidenced in 1 in 118 days, while the other failed to show it, as did the other 2 which received 100 gm. of monobasic sodium phosphate per head daily. This experiment showed that symptoms similar to those occurring in affected areas, though less severe, were produced by the use of feeds from farms where mineral deficiency was prevalent. More liberal feeding probably reduced the severity of the symptoms.

The third experiment involved the effect of mineral supplements in curing 7 animals showing depraved appetite. Four individuals receiving 103 gm. of tricalcium phosphate or 128 gm. of monobasic sodium phosphate recovered

rapidly, as did one receiving tricalcium phosphate and 85 gm. of magnesium sulfate daily. The animals recovering also gained in body weight or milk production, or both. The results with two animals indicated that calcium carbonate was ineffective when used as a mineral supplement to the basal ration, but that when these two animals were supplied with monobasic sodium phosphate they improved steadily. The addition of 85 gm. of magnesium sulfate to the ration of one normal animal which was also receiving monobasic sodium phosphate did not induce depraved appetite, even after 360 days' feeding, indicating that large amounts of magnesium sulfate in the drinking water in affected regions is incidental rather than a direct cause of depraved appetite and associated conditions. The chief cause appears to be a lack of phosphorus in the roughage.

From the records of production and analyses of milk, it was found that production appeared to be increased by the use of phosphate supplements, but there was no evidence that the ash of the milk was in any way changed. The conditions of mineral deficiency were reflected in a lowered rate of reproduction and relatively infrequent ovulation. Reproduction was considerably improved by the phosphate supplement.

[Feeding experiments with sheep at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 68-76, fig. 1*).—The results of feeding and nutrition experiments with sheep, mostly in continuation of those previously noted, are briefly reported (E. S. R., 56, p. 263).

Tests concluded on energy values of sheep feeds.—The results of tests conducted by W. G. Kammlade and H. H. Mitchell of the relative net energy values of timothy, clover, and alfalfa hay and oat straw have indicated that these feeds are distinctly different when expressed in terms of total digestible nutrients and when expressed in terms of net energy. The roughages were supplemented with 0.15 lb. of linseed oil meal daily per 100 lbs. of live weight, and the timothy hay lot further had free access to mineral supplements. Hay was allowed in sufficient amounts to maintain live weight. The average metabolizable energy per kilogram of dry matter was 2.292 therms for alfalfa hay, 1.944 therms for clover hay, and 2.177 therms for the timothy hay ration. An average of 1.917 lbs. of alfalfa, 1.824 lbs. of clover, or 1.593 lbs. of timothy were required daily per 100 lbs. of live weight for maintenance.

The average results showed that per 100 lbs. of live weight the maintenance requirement of metabolizable energy was 1,864 calories for the alfalfa hay ration, 1,521 calories for the clover hay ration, and 1,507 calories for the timothy hay ration. From this it is concluded that timothy hay has a distinctly higher net energy value than either alfalfa hay or clover hay, and that clover hay has a slightly higher net energy value than alfalfa. The net availability of the metabolizable energy of alfalfa was distinctly lower than that of clover or timothy.

Field and dry lot compared for lamb feeding.—In studying the practice of feeding lambs wholly or partially in the fields, Kammlade and J. H. Knox selected 6 lots of 25 lambs each. Two lots were fed in dry lot throughout the 95 days of the experiment on rations of shelled corn and alfalfa hay and shelled corn and soy bean hay, respectively. The results showed that those receiving alfalfa hay made an average daily gain of 0.32 lb. as compared with 0.36 lb. for those receiving soy bean hay, the latter requiring less corn per 100 lbs. of gain than the former.

Two of the other four lots were fed for 23 days in a corn and soy bean field, while the other two were fed for a similar time in a cornfield. One lot from each field was then finished in dry lot on a ration of shelled corn and

soy bean hay, and shelled corn and alfalfa hay, respectively, while the other lot was left in the field to finish the standing corn when the ration was supplemented with soy bean hay in case of those which had run on corn and soy beans, and with alfalfa for those which had run on the cornfield. Judging from the poor gains secured during the first 28 days and the unusually good gains made during the rest of the feeding period, lambing down corn alone did not prove satisfactory unless supplemented with a legume roughage. Those lambing down corn and soy beans made greater gains than those receiving corn alone. Supplementing corn alone with alfalfa hay gave greater gains than feeding corn and soy beans and then supplementing with soy bean hay.

Soy bean study yields only results of their kind.—The results of digestion experiments with sheep, using rations of alfalfa hay alone, soy bean oil meal alone, and combinations of the two feeds, are reported by T. S. Hamilton and Kammlade.

Comparing the results obtained with those in which the soy bean concentrates were fed with oat straw and soy bean straw, it was evident that a marked associated digestibility existed between the concentrates and roughages when fed in the same ration. The digestibility of the ether extract was found to vary directly with the fat content of the ration. The coefficients obtained in the single trial with soy bean oil meal alone were higher for dry matter and crude protein than any of the average estimated coefficients from other experiments, while the coefficient for nitrogen-free extract agreed fairly well. The digestibility of the crude fiber was 55 per cent, while the estimated coefficients were either negative or above 100 per cent in all cases. Of the gross energy of the meal 73 per cent was metabolizable.

Lamb feeding experiments, 1925-1926, R. F. JOHNSON (*Idaho Sta. Circ. 40 (1926), pp. 4*).—The results of a 100-day test of the relative value of alfalfa seed screenings and beet pulp as supplements to a ration of alfalfa hay and 1 lb. of barley per head daily for fattening western lambs of Rambouillet breeding, averaging 62 lbs. in live weight, are reported.

The 124 lambs on the basal ration of alfalfa and barley made an average daily gain of 0.24 lb. per head and required 937 lbs. of hay and 357 lbs. of barley per 100 lbs. of gain. When the ration was supplemented with alfalfa screenings the lambs made an average daily gain of 0.25 lb. per head, but considerable difficulty was experienced in getting the lambs to consume the screenings due to the presence of unpalatable weed seeds.

Supplementing the alfalfa and barley ration with 1.05 and 2.09 lbs. of beet pulp per head daily produced an average daily gain of 0.27 lb. by each method of feeding, but the inclusion of the larger amount of beet pulp reduced the calculated feed costs per 100 lbs. of gain, which were lower in these 2 lots than in the other 2 lots fed in this experiment. The consumption of hay and barley were both reduced by the inclusion of the beet pulp in the ration.

Lamb feeding investigations, 1925-26, H. E. REED and H. W. MARSTON (*Kansas Sta. Circ. 131 (1926), pp. 3, fig. 1*).—Since alfalfa hay appears to be the best Kansas roughage for fattening lambs, a test was conducted with 3 lots of 52 67-lb. lambs each to determine the amount of alfalfa hay that could be most efficiently included in the ration. For this purpose the rations of hay were limited in the different lots to 0.5, 1.0, and 1.5 lbs., respectively, per head daily. Shelled corn was full-fed in all lots.

The results showed that during the first 20 days the gains increased with the amount of hay fed, but during the last two 20-day periods of the 60-day experiment the gains increased with the amount of corn fed. The average gains per head in the 3 lots for the entire test differed by less than 1 lb. but

were in favor of the lot consuming the smallest amount of alfalfa hay. The best finish and the lowest feed cost per unit of gain were also associated with the smallest consumption of alfalfa.

It is concluded that the feeding of 1.5 lbs. of alfalfa per head daily throughout the fattening period prevented the consumption of proper amounts of corn, though larger amounts of hay could be fed more advantageously during the first than during the last part of the fattening period.

[Feeding experiments with swine at the Arkansas Station] (*Arkansas Sta. Bul. 215 (1926)*, pp. 32-35).—The results of three experiments are noted.

Soft pork investigations with rice by-products.—After 8 weeks' feeding on rice bran and tankage and on rice polish and tankage, pigs averaging 67.5 lbs. in weight were divided into two lots, one of which received brewers' rice and tankage while the other pair received corn and tankage for hardening in a final 8 weeks' period. Access to minerals was allowed throughout the experiment. The pigs made average daily gains of 0.42 and 0.52 lb. while on the rice bran and rice polish rations, respectively, due to the fact that the bran contained an abnormal amount of rice hulls and the polish produced scouring. Replacing these feeds with brewers' rice or corn resulted in very satisfactory gains. Carcass analyses of the animals at the end of the experiment indicated that corn was slightly more effective than brewers' rice for hardening soft pork. More economical results were obtained with corn, largely due to its lower cost.

Legume hay v. tankage for wintering brood sows.—Gilts receiving soy-bean hay with corn farrowed extra good litters, while only one gilt in the lot receiving corn and tankage farrowed a satisfactory litter. These results indicated that the soy bean hay was not responsible for previous troubles with abortion which have been experienced with animals receiving this roughage.

In checking the results with albino rats it was found that rations made up of corn and soy bean hay with and without tankage allowed the production of normal litters of young, but difficulties in rearing were evident when these rations were used during the lactation period.

Forage crops for fattening swine.—Pasture trials with Sudan grass and sweet clover have indicated that there is very little difference in the values of these two crops, though the pasturing season was very short. A protein supplement to corn was necessary even when the hogs are on fairly good pasture, and a mineral mixture will not replace the protein supplements under such conditions.

[Feeding experiments with swine at the Delaware Station], A. E. TOMHAVE (*Delaware Sta. Bul. 147 (1926)*, pp. 10, 11, 12).—The results of the following experiments are briefly reported:

Alfalfa hay in the winter ration for brood sows.—In continuing this experiment (E. S. R., 54, p. 665), two groups of sows were again fed alfalfa leaves or tankage as protein supplements to a ration of white ear corn and minerals. The results indicated that the alfalfa leaves supplied some essential that was evidently lacking in the white ear corn, tankage, and mineral ration, as the sows receiving alfalfa produced pigs averaging 2.55 lbs. when farrowed as compared with 2.38 lbs. on the tankage ration; 40.6 per cent of the former and only 10.7 per cent of the latter were classified as strong, and at the end of the first 7 days only 3 per cent of the pigs farrowed were dead due to weakness in the alfalfa lot, as compared with 32.3 per cent of the pigs in the tankage lot. The average daily consumption of the alfalfa leaves was 2.27 lbs. per head, and their use materially reduced the cost of wintering.

Protein supplements for growing fattening pigs.—In a test of the relative value of soy beans as protein supplements, 3 lots of 10 57-lb. pigs were selected,

one lot receiving a ration of yellow hominy, middlings, and tankage, while in the other lots the tankage was replaced by ground soy beans or a mixture of ground soy beans and bone meal 85:15. During the 92-day experiment the following average daily gains were made with the different protein supplements: Tankage 1.02 lbs., ground soy beans 0.65 lb., and ground soy beans and bone meal 0.75 lb. There were required 35.2 and 21.4 per cent more concentrates to produce 100 lbs. of gain on the ground soy bean and ground soy bean and mineral rations than on the tankage ration. Ground soy beans were evidently not as efficient as tankage for pork production, but their efficiency was considerably improved by the addition of bone meal.

Forage crops for swine in Delaware.—In one trial alfalfa forage was found to be distinctly superior to rape, due to the fact that 320 lbs. of feed were required per 100 lbs. of gain on alfalfa, as compared with 349 lbs. on rape. The pork produced per acre of forage was calculated at 3,547 and 2,082 lbs. on the respective crops.

In another experiment pigs fed to an average weight of 150 lbs, required 350 lbs. of feed per 100 lbs. of gain when full-fed on pasture, but only 325 lbs. of feed per 100 lbs. of gain when receiving a limited ration of 3 per cent of their live weight until they reached 100 lbs., after which they were full-fed. Limited feeding of late farrowed pigs allowed for utilization of an abundance of forage as well as considerable new corn, while full-feeding usually allows for marketing earlier in the fall.

In a comparison of cowpeas and soy beans as forage crops, average daily gains of 1.1 lbs. and 1.43 lbs. were produced on the respective types of forage. Only 340 lbs. of feed were required per 100 lbs. of gain on soy beans as compared with 428 lbs. on cowpeas.

[Experiments with swine at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 49-59, figs. 3*).—The results of experiments, mostly continuations of those previously noted (*E. S. R., 56, p. 264*), are briefly reported.

Sow's gaining power not inherited by litter.—Twenty Poland China gilts were hand-fed individually a full ration by W. E. Carroll, R. A. Smith, and E. Roberts in order to determine the rate and economy of gains of each. The pigs produced by six of these sows after mating them to the same boar were similarly fed, but the rate and economy of gain made by the litters showed no close agreement when compared with the feed records of their dams.

Crossbred pigs made no greater gains this year.—Roberts and Carroll found that crossbred and purebred offspring produced by double matings of a Duroc-Jersey and Poland China boar with 5 Duroc-Jersey and 5 Poland China gilts showed no significant difference in the vigor or size of the crossbred and purebred pigs at birth, and no marked superiority of the crossbred pigs over the purebreds was apparent in their capacity to make rapid and economical gains when fed out to a weight of approximately 200 lbs.

Oats give good results in brood sow ration.—In experiments to determine the advisability of including oats in rations of ear corn and minerals with or without tankage or alfalfa hay for brood sows and gilts, Carroll and Smith found that such rations met the requirements of the sows and produced strong vigorous pigs, from which it is concluded that oats may be used rather extensively in the brood sow ration with satisfactory results.

Oil in soy beans found to be cause of soft pork.—In studying the relative feeding value of soy beans and soy bean products for pork production, Carroll, Smith, S. Bull, and J. H. Longwell self-fed 4 lots of 20 pigs each, averaging 63 to 64 lbs. in live weight, to a final weight of 230 lbs. The rations of 3 of the lots consisted of ground corn, alfalfa meal, and minerals with supplements of

tankage, ground soy beans, and soy bean oil meal, respectively. The fourth lot received shelled corn, whole soy beans, minerals, and blue grass pasture. The results showed that the poorest gains were made by the lot receiving ground soy beans, 0.96 lb. per day, while with soy bean oil meal the gains were 1.13 lbs. per day as compared with 1.55 lbs. by the lot receiving tankage and 1.44 lbs. by the lot receiving whole soy beans with blue grass pasture. The soy beans did not appear to be palatable.

At the conclusion of the experiment the pigs were slaughtered and studied for the hardness of fat in the carcasses. The soy bean oil produced carcasses lacking in firmness, while tankage or soy bean oil meal produced firm carcasses. The fresh cuts from the soy bean oil carcasses were soft, flabby, difficult to cut, and oily in appearance, and the lard was soft.

In a second experiment three lots of 15 pigs each, averaging 66 lbs. in live weight, and one lot of 19 pigs, averaging 74 lbs. in live weight, were fed to a final weight of 232 to 235 lbs. to determine the amount of soy bean oil which could be included in the ration without producing soft pork. All lots received a basal ration of corn and alfalfa meal supplemented in one lot with tankage, in another with soy bean oil meal, and in the other two with soy bean oil meal and different amounts of soy bean oil. The results showed that the hogs in these respective lots made average daily gains of 1.59, 1.39, 1.30, and 1.40 lbs. The average dressing percentages were 82.1, 78, 78.4, and 78.6 per cent, or distinctly a higher dressing percentage for the tankage-fed pigs. All of the carcasses in the lot receiving tankage were hard, while only three were hard in the lot receiving soy bean oil meal, and those receiving the soy bean oil were largely soft, 14 out of the 15 pigs being soft in the lot receiving soy bean oil equivalent to the amount in 19 per cent of soy beans.

Hogging down corn, W. L. ROBISON (*Ohio Sta. Bul.* 398 (1926), pp. 301-339, figs. 9).—The combined results of several years' experiments in hogging down corn, relating particularly to comparisons of mineral and protein supplements, are presented and analyzed in connection with tests at other stations.

With standing corn, soy beans, tankage, and minerals more rapid and greater gains per bushel of corn consumed were produced than with standing corn, tankage, and minerals, but the returns per acre were greater with the latter ration, as the soy beans reduced the yield of corn. Rape proved slightly superior to soy beans in the combination of corn and tankage or corn and minerals in favorable seasons, but in dry seasons made little growth when seeded at the time of the last cultivation. Access to clover pasture with standing corn and tankage improved the rate and economy of gain.

The results of 9 experiments at Wooster and 6 at the Miami County Experiment Farm consistently indicated a larger return per bushel of corn when the corn was harvested and fed rather than hogged down. Hogging down immature corn reduced the gains produced per acre, but allowed the hogs to be marketed at a time when prices were more satisfactory than when the corn had matured.

Fillies wintered well on oats, soy bean roughage (*Illinois Sta. Rpt.* 1926, pp. 66, 68).—In continuing the studies of relative values of rations for draft fillies (*E. S. R.*, 56, p. 270), J. L. Edmonds and C. W. Crawford found that equal parts of sheaf oats and soy bean hay supplemented with a light feeding of crushed oats and bran were satisfactory for both growth and economical wintering of weanling and yearling Percheron fillies. A pasture combination of blue grass in the spring and fall and sweet clover during the hot, dry months was satisfactory.

[Feeding experiments with poultry at the Delaware Station], A. E. TOMHAVE and C. W. MUMFORD (*Delaware Sta. Bul.* 147 (1926), pp. 13, 14).—The results of three experiments are briefly reported.

Soy beans for baby chicks.—Three pens of 350 chicks each were used for comparing protein supplements of meat scrap and dried buttermilk, ground soy beans and dried buttermilk, and ground soy beans. At 7 weeks of age the average weights of the males and females receiving the two types of animal protein were 1.020 and 0.957 lbs., while those receiving ground soy beans and dried buttermilk averaged 0.860 and 0.740 lbs., and those receiving ground soy beans as the only protein supplement averaged 0.433 and 0.557 lbs.

Ground soy beans in the ration for laying pullets.—Preliminary results of a comparative test of meat scrap and ground soy beans as protein supplements in a mash of laying hens showed that those receiving meat scrap laid larger numbers of eggs and consumed considerably more feed.

Artificial illumination for pullets.—Under good management unlighted pens were made to produce nearly as many eggs as lighted pens in two years' experiments.

[Experiments with poultry at the Illinois Station] (*Illinois Sta. Rpt.* 1926, pp. 78-81).—In studies of the necessary amount of turning of eggs during incubation, by L. E. Card, eggs not turned at all hatched poorly, while those turned only during the first 6 days hatched almost as well as eggs turned twice daily throughout the incubation period.

Continuing the study of the energy values of feed for chickens (E. S. R., 56, p. 270), H. H. Mitchell conducted a series of 25 determinations on the heating effect of corn with Rhode Island Red hens. The average results showed that 100 gm. of corn containing approximately 89 per cent of dry matter had a heating effect of 52 calories, though considerable variation was shown in the individual determinations.

From these data it is concluded that 1 lb. of corn has a total gross energy content of 1,761 calories, 15 per cent of which is lost to the chicken in intestinal and urinary excretions. As 236 calories represents the heating effect of the corn, the net energy value per pound becomes 1,261 calories. Thus only 72 per cent is available to the chicken for maintaining its life activities, for muscular activity, or for the production of new body tissue in growth and fattening. As compared with other animals the chicken converts the energy of corn to its own use much more efficiently than the steer and probably more efficiently than the pig.

In studies by Card, M. H. Keith, and Mitchell of the rate of digestion of a whole corn ration, a ground corn ration, and a ration composed of ground corn and tankage 4:1, 25 birds were killed at intervals varying from 11 to 35 hours after consuming 50 gm. of each of these rations. Though considerable variability was observed in the proportionate amounts of feed found in the different segments of the alimentary canal, the results indicated that the dry matter content of the different segments was not affected by the kind of ration furnished. The type of ration tended to influence the time required for the crop to empty. Of the whole corn ration the crop emptied in about 11 hours, but an appreciably longer time was required for the ground feeds to pass on through the crop, and as the crop emptied the gizzard also quickly emptied.

The moisture content of the material in the different segments of the alimentary canal showed some variability. The percentage of moisture in the contents of the gizzard averaged 44.2, in the small intestine 83.0, in the ceca 76.8, and in the contents of the large intestine 78.9. The contents of the small intestine were most constant with respect to the percentage of moisture.

The effect of various sources of animal protein on the egg production and condition of Single Comb White Leghorn pullets, P. T. KISTLER, T. B. CHARLES, and H. C. KNADEL (*Pennsylvania Sta. Bul. 206 (1926), pp. 23, figs. 3*).—The results of two experiments comparing protein supplements for egg production, which have been previously referred to (*E. S. R., 54, p. 368*), are reported.

In the first experiment 7 lots of 50 birds each were used for comparing meat scrap and condensed or dried buttermilk when fed separately or in combinations as protein supplements to a basal mash. The protein was supplied in equal amounts in the mash but from the various sources.

In the second experiment 6 lots of 50 birds each were used for comparing similar sources of protein, but in combinations of meat scrap and dried or condensed buttermilk. Coconut oil meal was also used with one lot. The results of the second experiment were somewhat complicated by parasites, early winter molt, and an epidemic of chicken pox and roup.

In general, however, the two experiments indicated that dried and condensed buttermilks were efficient and economical sources of protein for egg production when used in proper combinations with meat scrap, due to the increased egg production which is obtained and which more than compensates for the increased feed cost. The advantages suggested for the milk products are that they maintain the body weight of the fowls in the most efficient manner, increase the size of the eggs, reduce the tendency toward early molting by increasing production, and maintain a more even production throughout the year.

A study of the relative value of certain root crops and salmon oil as sources of vitamin A for poultry, D. E. DAVIS and J. R. BEACH (*California Sta. Bul. 412 (1926), pp. 3-15*).—In continuing the studies of the relative value of succulent feeds as sources of vitamin A for poultry (*E. S. R., 52, p. 875*), lots of 10 pullets each were fed a vitamin A deficient ration supplemented with one variety in each lot of yellow, red, or white carrots, red, yellow, or white mangels, or yellow or white turnips. Salmon oil was the only source of vitamin A for one lot, and another lot received the basal ration only. At the start of the experiment the roots were allowed at the rate of 1 gm. per bird daily and the salmon oil at the rate of 1 cc., but the amount was doubled when the birds of a lot showed signs of ophthalmia, or pustules in the mouth, or esophagus, and redoubled with the further appearance of lesions indicating a vitamin A deficiency in the ration. The experiment lasted 96 days.

The results showed that none of the birds receiving the yellow or red carrots or the salmon oil in minimum doses developed the nutritional diseases. Their live weight increases varied from 41 to 44.5 per cent, and they laid at 30, 33, and 26 per cent rates, respectively, during the last 41 days of the test. Salmon oil in 1 cc. doses also cured birds showing lesions of vitamin A deficiency, and compared favorably with cod-liver oil as a source of vitamin A. It is, therefore, concluded that yellow and red carrots are as good sources of vitamin A as the common varieties of green feeds used for poultry.

With a few individual exceptions, practically all the birds in the other lots developed symptoms of vitamin A deficiency even though the amounts of the roots were increased to 8 to 32 gm. per bird daily. The first symptoms of the deficiency occurred on the thirty-second day in the control lot and on the thirty-third day with yellow turnips. One bird in the white turnip lot showed characteristic lesions on the fifty-fourth day.

Feeding chickens, R. M. SHERWOOD (*Texas Sta. Circ. 42 (1926), pp. 3-7*).—This consists mainly of suggested rations for chicks, fattening cockerels, pullets, and laying hens.

Fitting and exhibiting standard-bred poultry, H. H. STEUP (*Kansas Sta. Circ. 127* (1926), pp. 39, figs. 18).—General directions for fitting, exhibiting, and judging poultry, including illustrations and descriptions of ideal and defective characters and other data, are given.

DAIRY FARMING—DAIRYING

The composition, digestibility, and feeding value of hydrolyzed sawdust, J. G. ARCHIBALD (*Jour. Dairy Sci.*, 9 (1926), No. 3, pp. 257-271).—In an investigation conducted at the Massachusetts Experiment Station with the cooperation of the U. S. D. A. Forest Products Laboratory, the nutritive properties of sawdust cooked with dilute sulfuric acid under 120 lbs. pressure were studied. Analyses of hydrolyzed Douglas fir and eastern white pine sawdust showed that approximately 95 per cent of the dry matter was composed of nitrogen-free extract and crude fiber. About 21 per cent of the original sawdust was converted into sugar by the treatment.

In a test of the palatability of this feed the rations of 11 cows were supplemented with amounts of Douglas fir sawdust not exceeding 5 lbs. daily. All refused the hydrolyzed sawdust when it was fed alone, but 8 showed no dislike for it when it was mixed with the grain.

Six digestion trials, each of 16 days' duration, were carried on with 3 sheep each. The daily rations fed in all experiments consisted of 400 gm. of hay, 125 gm. of gluten feed, 100 gm. of hydrolyzed sawdust, and 10 gm. of salt. The results of the digestion trials with the two kinds of sawdust showed that the digestible nutrients were principally confined to nitrogen-free extract, as the other constituents were practically unattacked. Omitting the results of the 2 experiments showing the greatest deviation with each kind of sawdust, 32.73 per cent of the dry matter and 60.21 per cent of the nitrogen-free extract of the Douglas fir sawdust and 46.22 per cent of the dry matter and 66.42 per cent of the nitrogen-free extract of the eastern white pine sawdust were digestible. The fiber of the latter appeared to be somewhat more digestible than that of the former. Calculations of the net energy values of these feeds indicated that the eastern white pine sawdust had an apparent value of 18.6 therms of net energy per 100 lbs., while the net energy value of the Douglas fir sawdust was a minus quantity. The digestibility of the sawdust residue was so low and so variable that this part of the product evidently had no food value.

Trials of the feeding value of both kinds of treated sawdust were conducted with 6 cows, comparing this feed with cornstarch by the double reversal method in 11-week periods. The amounts of cornstarch and sawdust fed were equalized on the basis of the digestible nutrients of each. The basal ration consisted of mixed hay and a grain mixture of which 20 per cent was composed of cornstarch or an equivalent amount of sawdust. The combined results with 4 cows which completed the test normally show that those receiving the Douglas fir sawdust produced 98.5 lbs. less milk in 28 days than those receiving the cornstarch ration. The 5 cows on the white pine sawdust ration produced 42 lbs. less milk than on the starch ration.

The net decreases in milk production during the first 10 days after the ration was changed were 41.3 lbs. on starch and 127.8 lbs. on the Douglas fir sawdust, and in the second experiment 9.0 lbs. on starch and 43.3 lbs. on the eastern white pine sawdust. All groups showed a net gain in weight, but the amounts were larger on the starch rations than on the sawdust rations.

Though the animals evidently derived some benefit from the sawdust, it is not believed that hydrolyzed sawdust as now prepared has any economic value, considering the present cost of carbohydrate feeds.

[Feeding experiments with dairy cattle at the Arkansas Station] (*Arkansas Sta. Bul.* 215 (1926), pp. 30-32).—Two lots of three cows each were selected for comparing by the reversal method rice bran and wheat bran added to the rations of corn silage, alfalfa hay, and a grain mixture of yellow corn, cottonseed meal, linseed oil meal, and gluten feed. The feeding periods were 8 weeks in duration with transition periods of 1 week. The cows produced 7 per cent more milk and 5 per cent more butterfat on the rice bran ration with practically the same consumption of feed, and also made slightly greater gains in body weight than when wheat bran was included in the ration.

Three lots of heifers, consisting of a total of 3 Holsteins and 6 Jerseys, were used for comparing alfalfa and soy bean hay when fed with a grain mixture. One lot receiving soy bean hay also received 2 per cent of finely ground steamed bone meal added to the grain mixture and 10 cc. of cod-liver oil twice weekly. The heifers receiving soy bean hay and grain without the additional supplements made the largest daily gain and required the least feed per unit of gain, though the advantage over alfalfa hay was very slight. The same animals also showed the largest increase in most body measurements. The lot receiving the mineral supplement and cod-liver oil occupied the third place with respect to percentage of increase, except in case of shank circumference, in which the alfalfa-hay lot excelled and the lot receiving soy bean hay with supplements was third. It is concluded that leafy bright colored soy bean hay cut before the stems become mature is equal to alfalfa hay for growing heifers. Additions of bone meal and cod-liver oil to soy bean hay and grain were of no particular benefit.

[Experiments with dairy cattle at the Illinois Station] (*Illinois Sta. Rpt.* 1926, pp. 89, 90, 91, 92, 93, 94).—In studies of the relation between variations in temperature and humidity from day to day and the amount and quality of milk produced by individual cows, F. A. Davidson found that in general a falling temperature from day to day increased the percentage of total solids in the milk, while a rising temperature decreased this percentage without noticeably affecting the yield of the milk.

Comparative feeding tests of ground, chaffed, and whole soy-bean hay for dairy cattle, conducted by W. B. Nevens, indicated that chaffed hay produced a gain of approximately 54 lbs. and grinding a gain of about 50 lbs. of digestible dry matter per ton of hay fed, but the economy of the extra preparation was questioned.

The results of a continued study of the effect of self-feeding on dairy cattle by Nevens (*E. S. R.*, 56, p. 271) indicated that the high protein rations consumed had a depressing effect on milk production, and that milk production was not stimulated beyond what would be expected with good feeding methods. Self-feeding has proved uneconomical as the cows remain in high condition and use feed uneconomically.

Studies of the comparative persistency of lactation in Guernsey and Holstein cattle by W. L. Gaines indicated that both breeds showed normal distribution curves for the persistency values, which were in both cases quite closely related to the initial rate of production. Persistency was not affected by age, except as age affected the initial rate of production. Persistency, however, was greatly affected by environmental factors, and to a slight extent by genetic factors. This character did not appear to be a promising one for genetic improvement.

Short-time tests at approximately 6 months after calving appeared to be the best stage of lactation for affording an index of the year's yield.

A commercial preparation containing edestin obtained from cottonseed and claimed to stimulate milk secretion in nursing mothers, when fed at the rate of 5 oz. per day per 1,000 lbs. of live weight to 4 cows in various stages of lactation, had no appreciable effect on the rate of milk secretion.

[Experiments in dairying at the Illinois Station] (*Illinois Sta. Rpt. 1926*, pp. 93, 95, 96, 97).—M. H. Campbell found that the size of fat globules in milk could be measured by diluting the milk to 100 times its volume with a solution of water and glycerin and placing this solution in a Newbauer hemacytometer. The fat globule was then directly measured under the microscope by means of the euscope.

Studies by M. J. Prucha indicated that the use of sodium hypochlorite, calcium hypochlorite, or chloramine-T will practically sterilize dairy utensils. A solution containing at least 150 parts of chlorine per million of water is recommended for cans and similar utensils.

Prucha and J. M. Brannon found that butter passed through certain printing machines in which it was crushed did not keep as well as butter not so treated, and that undesirable flavors developed in such print butter.

Studies of the factors relating to shrinkage in ice cream by H. A. Ruehe and P. H. Tracy indicated that some commercial improvers cause an enzymic change in the milk protein which leads to shrinkage. The factors tending to hasten the shrinkage of ice cream are alternating high and low temperatures, long storage periods, high overrun, increased acidity in the mix, and high percentages of milk solids-not-fat.

Studies in the manufacture of cottage cheese by Ruehe, Tracy, and A. S. Ambrose indicated that a satisfactory product can be manufactured from pasteurized skim milk, using pure lactic acid cultures for ripening, with or without the addition of rennet or pepsin. Washing the curd and salting removed much of the lactic acid present and consequently much of the flavor, tending to cause a flat flavor or lack of flavor in the resulting product. Such cheese tended to spoil more rapidly than cheese having a higher acid content.

Control of market milk sold by a Michigan dairy, 1922-1925, L. H. COOLEGE (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 56-60).—An account is given of the use of methods for improving the bacterial counts and grade as determined by the pH score of raw milk delivered to a Michigan dairy from 1922 to 1924. The reduction in the bacterial count through pasteurization was materially increased at this plant by thoroughly sterilizing the cooler before use by running steam through the pipes.

Evidence indicates that the bacterial count of chocolate milk may be controlled by better sanitary measures.

[Experiments at the Arkansas Station with neutralizers and starters] (*Arkansas Sta. Bul.* 215 (1926), pp. 35, 36).—Analyses of several commercial neutralizing agents indicate that the bases of these substances are either one or more of the following ingredients: Calcium oxide, magnesium oxide, calcium hydrate, calcium carbonate, sodium carbonate, and sodium bicarbonate. Data on the solubility of the agents show that those neutralizers with a high percentage of calcium or magnesium in the form of a hydrate or oxide are more insoluble than those composed of calcium and sodium in the form of a carbonate or bicarbonate. Lime neutralizers have a tendency to cause a limey flavor, while soda neutralizers tend to produce soapy flavors. Lime neutralizers were much more efficient than soda neutralizers.

In studies of 9 different starter cultures with reference to their effect on the quality of the butter and the type of organisms which predominate in each, it was found that the addition of 5 to 20 per cent of a reliable starter culture to sour neutralized cream enhanced the flavor of the butter sufficiently to compensate for the extra labor and expense involved. All brands of starter cultures used gave equally good results, and there were only slight differences in the flavor of the butter produced. All the commercial starters studied contained practically the same types of lactic acid bacteria, but at certain times undesirable organisms such as yeasts, molds, and alkaline-producing bacteria were present as a result of contamination during manufacture.

A suggested bacteriological standard for ice cream, F. W. FABIAN (*Michigan Sta. Spec. Bul. 158 (1926), pp. 3-18*).—Based on bacteriological analyses of 1,110 samples of ice cream from 36 different ice cream plants located in 5 different cities of Michigan, in which samples the numbers of bacteria ranged from 1,000 to 300,000,000 per gram, the author suggests that the plate counts made by standard methods of ice cream should not be over 100,000 per gram. Evidence is presented to show that it is possible and practical for sanitary ice cream manufacturing plants to make ice cream conforming to such a standard. A legal requirement for pasteurization of the mix at 150° F. for 30 minutes in order to control pathogenic organisms is also recommended.

VETERINARY MEDICINE

[Animal disease investigations at the Delaware Station], C. C. PALMER and H. R. BAKER (*Delaware Sta. Bul. 147 (1926), pp. 8, 9*).—The work in animal pathology during the year is here briefly referred to.

The university herd, which contained 20 per cent reactors to the abortion test four years ago, is now composed entirely of nonreacting animals. This has been accomplished through rigid isolation at calving time to prevent the spread of the disease and the disposal of reacting animals as rapidly as possible. The breeders have shown considerable interest in the progress of the work and are now fostering a plan for the establishment of State-accredited abortion-free herds, the work to be carried on under State supervision.

In investigations of the vaccine treatment of roup, four cultures of secondary invaders in outbreaks of ocular roup were isolated and found to be strains of *Staphylococcus albus*, and in one case *Bacterium coli* was also present. In an experimental transmission a roup bird was placed with a normal bird in each of five cages, and it was observed that the heads of the birds would frequently be rubbed together while feeding, but their constant contact for eight weeks failed to result in transmission of the disease to any of the normal birds. The treatment of nine cases of ocular roup with boric acid resulted in their recovery, indicating that individual treatment in this manner may be highly efficient.

In a study of the bacteriophage in the control of fowl typhoid, negative results were obtained. *B. sanguinarium* soon lost its virulence when grown on artificial media.

Anti-abortion vaccines (*Arkansas Sta. Bul. 215 (1926), pp. 37, 38*).—In the course of a brief discussion of the subject, reference is made to work undertaken with a view to determining whether aggressins were produced by cultures of *Bacillus abortus* introduced into the peritoneal cavity of guinea pigs and to studying their antigenic efficacy.

It was found that the injection of 10 cc. of a suspension of virulent *B. abortus*, in density comparable to tube No. 3 of the McFarland nephelometer, into the peritoneal cavity of guinea pigs resulted in the death of the animals

in from 16 to 26 hours. Twelve cc. of purulent exudate were received from the peritoneal cavities of selected animals, which exudate contained numerous typical organisms and might be presupposed to contain aggressins if such are produced by *B. abortus*.

"The exudate was centrifuged and phenolized, and sealed in glass ampules. Guinea pigs injected with exudate and with a suspension of live cultures simultaneously presented at 2 and 4 weeks no more marked progression of the inoculation disease than guinea pigs receiving live cultures only. Guinea pigs inoculated with 2.0 cc. exudate showed no more advanced pathological changes than guinea pigs receiving 0.5 cc. exudate. Thus no aggressin action was observed, and it may be presumed that *B. abortus* does not produce aggressins, at least under the conditions outlined."

Anthrax prophylaxis (*Arkansas Sta. Bul.* 215 (1926), pp. 64, 65).—In five separate attempts to attenuate anthrax bacilli by cultivation on agar with high sodium chloride content, three were successful, but in the other two no reduction of virulence was noted. This indicates that the method of attenuation employed should not be expected to yield the desired results in all cases. It was found possible to secure cultures of graded virulence by continuing the attenuation process for four or five weeks, thus indicating that the loss of virulence of the anthrax bacillus is a more or less gradual process with the means here used and is analogous to what occurs during attenuation by cultivation above optimum temperatures. In field tests it was found that injections of up to 200,000,000 NaCl attenuated anthrax spores can be made into mules without inducing febrile disturbance when the animals are idle.

Foot-and-mouth disease, J. R. MOHLER (*U. S. Dept. Agr., Dept. Circ.* 400 (1926), pp. 83, figs. 12).—The first part of this account deals in detail with the California outbreak in 1924, and this is followed by an account of the Texas outbreaks in 1924 and 1925.

Inclusion bodies in foot-and-mouth disease [trans. title], K. TRAUTWEIN (*Arch. Wiss. u. Prakt. Tierheilk.*, 52 (1925), No. 6, pp. 475-482, pl. 1, figs. 2; *abs. in Trop. Vet. Bul.*, 14 (1926), No. 1, p. 29).—The author confirms the observations of Gins,¹ and Gins and Kraus² regarding the occurrence of inclusion bodies in specimens from foot-and-mouth disease lesions. He states that, whereas Gins showed that these could be detected from 2 to 4 days after infection in guinea pigs, he has been able to find them in still larger numbers up to 18 days after infection. The author considers them to be fragments of chromatin derived from leucocytes.

Immunization against foot-and-mouth disease [trans. title], H. VALLÉE, H. CARRÉ, and P. RINJARD (*Rev. Gén. Méd. Vét.*, 35 (1926), No. 411, pp. 129-134; *trans. in Vet. Rec.*, 6 (1926), No. 16, pp. 361, 362).—This is a report on the results of attempts at vaccination carried out with the authors' viruses O and A, separately and with the two virulent forms used together. The authors call attention to the fact that all essential researches on foot-and-mouth disease should be carried out on bovines.

Foot-and-mouth disease: Control by chemotherapy, G. K. WALKER and W. TAYLOR (*Punjab Dept. Agr., Vet. Bul.* 17 (1926), pp. 22; *abs. in Vet. Rec.*, 6 (1926), No. 29, pp. 611, 612, 613).—This is a report of experiments in which, after a period of incubation and during the thermal stage of foot-and-mouth disease, each animal received Lugol's solution of iodine intravenously, in doses of from 50 to 100 cc. The solution consisted of iodine 1 gm., potassium iodide

¹ H. A. Gins. *Centbl. Bakt.* [etc.], 1. Abt., Orig., 88 (1922), No. 4, pp. 265-269.

² H. A. Gins and C. Krause, *Ergeb. Allg. Path. Mensch. u. Tiere*, 20 (1924), pt. 2, pp. 805-912.

2 gm., and distilled water 300 cc. The results lead to the conclusion that cattle infected with foot-and-mouth disease can be cured in the febrile stage by the intravenous injection of Lugol's solution, and that such animals will not develop eruptive lesions if the treatment is adopted in time. It is pointed out that iodine is very rapidly eliminated from the system and the amount used is unlikely to have any harmful effect on flesh or milk.

Foot-and-mouth disease, S. N. VENDEL (*Vet. Rec.*, 6 (1926), No. 42, pp. 931-936, figs. 2).—This is an account of observations and studies conducted by the author in Denmark. The results of such as relate to the treatment of the disease by chemotherapy correspond closely with those of Walker and Taylor, above noted.

Avian tuberculosis can be transmitted to calves (*Illinois Sta. Rpt.* 1926, pp. 65, 66).—Studies by R. Graham and E. A. Tunncliff indicate that avian tuberculosis is transmitted to calves more slowly and with less regularity than to swine, but that calves are not immune to avian tuberculosis infection. Slight lesions resembling tuberculosis have been found in the mesentery lymph nodes of calves following contact with tuberculous fowls. On only one occasion, however, have the lesions proved virulent when injected into guinea pigs and chickens. The practical significance of avian tuberculosis to calves, as observed in exposure experiments, was confirmed by the results of injecting tuberculous lymph glands of cattle into healthy chickens and guinea pigs. Of 47 lymph glands injected, 6 failed to produce lesions in either chickens or guinea pigs, 29 of the 41 remaining proved to be of the mammalian type, 4 were distinctly of the avian type, and 8 were capable of producing gross lesions in chickens as well as in guinea pigs. The mild character of the gross lesions in the chickens was considered to suggest that they were caused by the intermediate or aberrant types of the mammalian bacilli. It is pointed out that the part played by strains deviating from the normal type may be an important consideration in the ultimate eradication of tuberculosis in animals and in keeping herds free from it.

The results of typing tests on 106 tuberculous sputa from man are considered. The examination of 6 tuberculous lymph glands of children revealed 1 aberrant mammalian strain which produced lesions closely resembling the avian type in fowls.

[Investigations of swine diseases at the Illinois Station] (*Illinois Sta. Rpt.* 1926, pp. 59-62).—A brief reference is made to the continuation of work on the resistance of pigs to hog cholera virus conducted by Roberts and Carroll (*E. S. R.*, 56, p. 275). Further studies by Graham and Tunncliff (*E. S. R.*, 56, p. 275) indicate that it is practical to immunize pigs from 1 month to 6 weeks old. When pigs are treated at this age, the amount of serum can be reduced to approximately 37.5 per cent of the amount that would be required after weaning.

Progress of investigations on swine abortion conducted by Graham and Tunncliff is also briefly reported upon. The porcine type of *Bacterium abortum* has been found in several herds in the State. This organism resembles the bovine type but grows more luxuriantly. It is pointed out that the organism may be present in the testicular tissue of young pigs 14 to 16 days after artificial exposure by feeding or intravenous injection. No gross lesions were observed in infected testes.

"*B. abortum* was found in the bulbo-urethral glands and seminal vesicles of an actively breeding boar 17 months after the feeding of the organism, suggesting that males with genito-urinary infection might play a part in the spread of the disease. The nongravid uterus and ovaries of sows may harbor

M. abortum for a period of 6 to 20 months following subcutaneous or intravaginal injection, or infection by feeding or by association with infected animals. . . . Pigs 10 to 12 weeks old injected subcutaneously with *B. abortum* vaccine gave a rather definite primary agglutination curve extending over a period of approximately 6 months, followed by a secondary curve of shorter duration lasting approximately 2 months. Uninoculated control pigs in the same pen showed comparable primary and secondary agglutination curves with comparable maximum reactions. The maximum agglutination titer of the inoculated pigs apparently precedes the agglutination reaction of the control pigs by about 90 days. Healthy pigs allowed to associate with vaccinated pigs, with living culture, may contract the disease. Pigs vaccinated 10 to 12 weeks old with *B. abortum* were not followed by an intra-uterine infection at the first farrowing approximately 9 months later, as was determined by direct cultures and by guinea pig inoculations of feti and fetal membranes. Of 35 control or uninoculated pigs of the same age that were exposed to the vaccinated pigs, 5 aborted, while none of the 24 pigs receiving the vaccine aborted."

Bacillary white diarrhea in fowl, L. D. BUSHNELL, W. R. HINSHAW, and L. F. PAYNE (*Kansas Sta. Tech. Bul.* 21 (1926), pp. 3-85, figs. 4).—This is a report of investigations extending over a period of five years, presented in connection with a review of the literature on the subject, a list of 65 references to which is included. Following a brief introduction, the historical review of the literature (pp. 7-29) is given in chronological order. The nature of *Salmonella pullorum*, next considered (pp. 29-32), includes a table which graphically illustrates the fermentation of various carbohydrates within a three weeks' period of incubation at 37° C. Under the heading of incidence of the disease (pp. 33-38), the disease in adult fowls and in chicks is considered. The symptoms and pathology of the disease (pp. 38-40) and the sources and modes of infection (pp. 40-49) are then dealt with. Under the latter heading the incubator as a source of infection is considered, a report of investigations of which by Hinshaw, Upp, and Moore has been noted (*E. S. R.*, 55, p. 374).

In considering the influence of the disease on fertility and hatchability (pp. 50-63), the authors present much data in 12 tables. It is shown that in many cases there is a marked reduction in fertility and hatchability between the eggs of reacting and nonreacting birds. With 19 infected hens 45.2 per cent of the 387 eggs were fertile, and 25.8 per cent hatched against 63.4 per cent fertile and 57.3 per cent hatched of 5,066 eggs from 164 noninfected hens. Individual hatching records of infected and noninfected birds, data showing the influence of age upon fertility and hatchability of reactors and nonreactors, the decrease in agglutinins in serum of a single fowl, and the influence of the male on fertility and hatchability are also shown. The average percentage of fertility is estimated for nonreactors at 90, for reactors 70; hatchability of fertile eggs for nonreactors 70, for reactors 58; livability of chicks from nonreactors 90, from reactors 50; infection in Kansas flocks 25; and of Kansas flocks infected 75. The losses to the hatcheryman and to purchasers of day-old chicks are also considered.

It is pointed out (pp. 66, 67) that sour milk may be of value as an intestinal antiseptic and to prevent chicks from becoming infected through the food, but that it has no influence on the course of the disease once it has become established.

The account concludes with an extended discussion of testing for the disease. With a view to developing some standard of procedure which will be universally used, the authors describe and report upon a comparison made of the Kansas test with some of the various tests suggested.

The results indicate the Kansas (K. S. A. C.) two-tube (1:20, and 1:80) test to be the most effective thus devised. No trouble was experienced with the "fat-like" phenomenon when less than 0.3 per cent phenol is used for a preservative.

The authors conclude from their study that for general testing a two-tube test of a low and high dilution will prove most efficient because it avoids prozone cases and determines the largest number of carriers. If a one-tube test is used it should be one using as low a dilution of serum as possible. They point out that the small unit value of an average bird will not warrant leaving it in a flock if it is a low reactor on the supposition that it is an immune bird or a carrier of another disease.

In a brief discussion of the collection and transfer of blood to a laboratory, the authors point out that it is probably best to test just before the breeding season in order not to throw the birds out of production. While a fatty serum may be corrected to some extent by withholding feed for 18 to 36 hours before bleeding, this will influence the egg production, and it is best to control this trouble by reducing the amount of phenol in the test fluid.

[Bacillary white diarrhea investigations at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 76, 77*).—Thirty flocks among the 334 flocks in 63 counties in the State that were given the serum agglutination test for bacillary white diarrhea were found free of the disease. Of all the blood samples tested from 49,056 chickens, 80.4 per cent gave negative and 17.2 per cent positive reactions. The making of the intradermal test was placed in the hands of 7 veterinarians, who tested 27,396 chickens, of which 15.2 per cent gave a positive reaction. In continuation of the studies on resistance by Roberts and Card (*E. S. R., 56, p. 275*), the mortality was found to be more than twice as high among chickens from random stock as it was among those produced from stock selected for resistance.

The therapeutic efficiency of avian diphtheria, roup, and bird pox vaccines and bacterins, N. J. PYLE (*Massachusetts Sta. Tech. Bul. 10 (1926), pp. 205-216, fig. 1*).—In the investigations here reported, the author found a filtrable virus to be the cause of all three types of the disease. Several organisms were isolated from the lesions of avian diphtheria, diphtheritic roup, and pox, but they proved to be of no causative significance although prominent secondary invaders. The commercial stock powdered pox viruses were found to vary markedly in their ability to produce disease. The need of a method of standardizing the virus and vaccine was indicated. One, two, and three injections of the powdered pox virus vaccines failed to produce an absolute protection against artificial infection with homologous and heterologous viruses. Infection by contact occurred in 50 per cent of all cases. A slight improvement in the general condition of diseased birds followed the administration of powdered pox virus vaccine as a remedial measure. One attack of either or both types of the disease conferred an immunity of at least 50 days' duration against both types. Autogenous bacterins, when administered in the early stages of the disease, caused a general improvement in the health of the birds. As avian diphtheria and pox advance in severity, the egg production of the hens increases. With the injections of these bacterins, the data at hand indicate that the egg production is increased.

AGRICULTURAL ENGINEERING

[Agricultural engineering studies at the Arkansas Station] (*Arkansas Sta. Bul. 215 (1926), pp. 27-29, figs. 2*).—Studies of the cost of rice irrigation indicate that the most important factor involved is the efficiency of the pump-

ing plant. There is a wide variation in the power required for pumping and in the flow of water, and a close relation between the power used and the capacity of the pump for satisfactory pumping.

Experiments on the preservation of fence posts (E. S. R., 55, p. 75) indicated that lime sulfur spray solution has little value as a wood preservative. Ten per cent of the posts so treated were unfit for further service, and the sapwood was decayed to a depth of 0.75 in. Inspection of steel posts after 4 years' service showed considerable rust on the painted specimens, while the galvanized posts were in good condition. Of 148 butt treated, open tank process, creosoted green oak posts, 22 per cent were unfit for service after 5 years.

Tests to determine a practical method of treatment of wood with water-soluble toxic salts showed that on the average slightly more salt was absorbed by cooking the specimens for two hours at 180° F. than by soaking over night in cold solution. Most of the absorption occurred in the first hour of heating. Steeping in cold solution for as long as 24 hours per inch of thickness did not cause sufficient penetration, only about half as much dry salt being retained as in the heating process.

[Agricultural engineering studies at the Illinois Station] (*Illinois Sta. Rpt. 1926, pp. 121-133, 136, 137, figs. 3*).—The progress results of a number of agricultural engineering studies at the station are briefly summarized (E. S. R., 56, p. 280) which include data on electrically driven equipment, farm septic tanks, methods of working large teams, plow draft, terracing, waste caused by inefficient threshing, the use of the combine for soy bean harvesting, and seed cleaning.

Some of the outstanding results obtained are that the 2-chamber septic tank is the best farm type. It was found that 7- and 8-horse teams will prove of practical size for plowing and other field work on many Illinois farms. Seven horses can be used to pull three 12-in. bottoms and 8 to pull three 14-in. bottoms with little if any more side draft than when 6 horses are used on two 14-in. bottoms. The larger team can apparently be driven quite as easily as 5 or 6 horses in tandem. Plow draft was found to vary under different rotations.

Blanket tests made in representative sections of the State showed threshing losses as high as 4.05 per cent for wheat and 10.28 per cent for oats. In 9 cases the adjustment of concaves reduced the loss and better feeding reduced the loss in 8 cases. An increase in cylinder speed, closing of wind boards, raising of tail boards, and other adjustments also gave results. The combine was found to give promise for soy bean harvesting, the loss of soy beans being much less than by any other method and the cost about one-third of that with the ordinary methods.

Surface water supply of St. Lawrence River basin, 1923 (*U. S. Geol. Survey, Water-Supply Paper 564 (1926), pp. IV+171, pls. 3*).—This report, prepared in cooperation with the States of Wisconsin, Ohio, New York, and Vermont, presents the results of measurements of flow made on streams in this basin during the year ended September 30, 1923.

Surface water supply of Hawaii, July 1, 1921, to June 30, 1922 (*U. S. Geol. Survey, Water-Supply Paper 555 (1926), pp. IV+177*).—This report, prepared in cooperation with the Territory of Hawaii, presents the results of measurements of the flow of certain streams and ditches in the Territory of Hawaii made during the year ended June 30, 1922.

Relations between quality of water and industrial development in the United States, W. D. COLLINS (*U. S. Geol. Survey, Water-Supply Paper 559 (1926), pp. IV+43, pls. 5, figs. 6*).—Data are presented on the subject indicating, in general, that the largest quantities of water used industrially come from

public supplies or from sources that yield water of the same quality as that of some of the large public supplies.

The flow of water through culverts, D. L. YARNELL, F. A. NAGLER, and S. M. WOODWARD (*Iowa Univ. Studies Engin. Bul. 1 (1926), pp. 128, pls. 23, figs. 26*).—Studies conducted in cooperation with the U. S. D. A. Bureau of Public Roads are reported, the purpose being to determine (1) the quantity of water which will flow through culverts or sluiceways under levees of different materials, sizes, and shapes under conditions of actual use, (2) what conditions tend to increase or decrease such quantity, and (3) what principles should be followed in design to secure the greatest discharging capacity for the least cost. The results of 1,480 experiments on pipe culverts made of concrete, vitrified clay, and corrugated metal of 12, 18, 24, and 30-in. sizes, and 1,821 tests on concrete box culverts of sizes varying from 2 sq. ft. cross section to 16 sq. ft. cross section are analyzed. The tests were made on culverts flowing partly full and full with both a free and submerged outlet, and various types of entrances were used.

The discharging capacity of a culvert was found to depend primarily upon its cross section and the difference in water levels at the two ends. To obtain the maximum discharge the culvert must be so laid as to insure the full cross section being filled by flowing water. If a culvert is so laid that both its upstream and downstream ends are completely submerged, the amount of water which it discharges will be proportional to the square root of the difference in water levels at the two ends. It was found that the exact grade at which the culvert is laid has no effect upon its maximum discharging capacity.

The tests of pipe culverts showed that the coefficient of roughness n in the Kutter formula for the concrete pipe ranges from 0.012 for the 12-in. size to 0.013 for the 30-inch size, for the vitrified clay pipe from 0.01 to 0.013, and for the corrugated metal pipe from 0.019 to 0.023.

On the basis of these studies the formulas derived for culverts 30.6 ft. long with straight end wall entrances were as follows:

Concrete pipe with beveled lip end upstream:

$$Q = 4.61 D^{2.18} H^{0.50}$$

Concrete pipe with square cornered entrance:

$$Q = 4.40 D^{2.09} H^{0.50}$$

Vitrified clay pipe with bell end upstream:

$$Q = 5.07 D^{2.05} H^{0.50}$$

Corrugated metal pipe:

$$Q = 3.10 D^{2.31} H^{0.50}$$

The general discharge formulas derived for pipe culverts with straight end wall entrance and of any size and length, when flowing full, were as follows:

Concrete pipe, beveled lip entrance:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1.1 + \frac{0.026L}{D^{1.2}}}}$$

Concrete pipe, square cornered entrance:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0.31 D^{0.5} + \frac{0.026L}{D^{1.2}}}}$$

Vitrified clay pipe, regular bell end upstream:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0.023 D^{1.9} + \frac{0.022 L}{D^{1.0}}}}$$

Corrugated metal pipe:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0.16 D^{0.6} + \frac{0.106 L}{D^{1.2}}}}$$

In these formulas, Q =discharge in cubic feet per second, A cross sectional area of pipe in square feet, D =diameter of pipe in feet, L =length of culvert in feet, H =head on pipe in feet or the difference in the water level at the two ends of the culvert, and g =acceleration of gravity.

The following general discharge equations were developed for concrete box culverts with straight end wall entrances when flowing full:

Box culverts with rounded lip entrances:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1.05 + \frac{0.0045 L}{R^{1.25}}}}$$

Box culverts with square cornered entrances:

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0.4 R^{0.3} + \frac{0.0045 L}{R^{1.25}}}}$$

in which the same symbols are used as in the pipe culvert formulas and the term R is the mean hydraulic radius of the culvert in feet.

Rectangular concrete box culverts were found to require more head to overcome friction than square concrete box culverts of the same area, and hence have a smaller carrying capacity provided the entrance losses are the same. The head lost in friction for culverts of the same area varied inversely with the hydraulic radius. However, the entrance losses on the rectangular culverts tested were less than those on the square culverts with the same area and type of entrance.

A detailed comparison and discussion is given of the results of the tests on different types of pipe and box culverts.

Public Roads, [November, 1926] (*U. S. Dept. Agr., Public Roads*, 7 (1926), No. 9, pp. 177-192+[2], figs. 11).—This number of this periodical contains the status of Federal-aid highway construction as of October 30, 1926, together with the following articles: Five Years of State Road Building and Its Results, by F. Page; An Unusual Construction Record, by C. F. Rogers; Modern Highway Traffic and the Planning of State Highway Systems, by J. G. McKay; The Use of Hiring Cars and Busses on Rural Highways, by H. R. Trumbower; and The Penetration of Wood Preservatives, by R. I. Rudolph.

Binder and knotter troubles, J. M. SMITH (*Alberta Univ., Col. Agr. Bul.* 10, 2. ed., rev. (1926), pp. 78, figs. 74).—This is the second revised edition of this bulletin (E. S. R., 54, p. 78).

Electric ploughing, R. B. MATTHEWS (*Engineering [London]*, 122 (1926), No. 3161, pp. 211-214, figs. 23).—A critical analysis of the important features of electric plowing is presented.

Dissipation of heat by cast-iron water radiators, F. E. GIESECKE (*Heating and Ventilating Mag.*, 23 (1926), No. 6, pp. 67-72, figs. 9).—Tests conducted at the engineering experiment station of the University of Texas are reported which indicate the fallacy in the use of comparatively small pipes and the superiority of 2-pipe over 1-pipe water heating systems.

Choosing a home electric lighting plant, F. E. FOGLE (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 40-44).—Factors to be considered in the selection of a home electric lighting plant are enumerated.

Septic tanks for farm sewage disposal, F. L. COOPER (*Colo. Agr. Col. Ext. [Bul.]*, 247-A (1926), pp. 16, figs. 8).—Practical information on the planning and construction of small sewage disposal systems for Colorado farms is presented.

RURAL ECONOMICS AND SOCIOLOGY

[Investigations in farm organization and management in agricultural economics at the Illinois Station, 1926] (*Illinois Sta. Rpt. 1926*, pp. 97-120, figs. 6).—The results obtained during the year in investigations in progress are summarized.

[*Cooperative farm management and farm accounting*, H. C. M. Case and M. L. Mosher].—The first year's records from 225 of the 239 farms in Livingston, McLean, Tazewell, and Woodford Counties in the cooperative farm bureau-farm management project are tabulated and discussed. These farmers lacked \$382 of making 5 per cent on their investment after paying all expenses but without making any allowance for the labor of the operators. The 25 most profitable farms had an average of \$2,320 left over to pay for the operators' labor and management after paying all expenses and allowing 5 per cent on the investment. The 25 least profitable farms lacked an average of \$2,404 of making 5 per cent on the investment and had nothing to show for the operators' labor and management. The most profitable farms had an average total expense of \$17.72 per acre and gross receipts of \$37.83 per acre, as compared with \$16.32 total expenses and \$14.80 gross receipts for the least profitable farms. Yields of corn and oats were from 20 to 30 per cent greater and of wheat slightly lower on the most profitable than the least profitable farms. The most profitable farms had \$4.80 per acre more invested in productive livestock, received \$18.14 per acre higher returns from livestock, \$43.19 greater returns for each \$100 worth of feed fed, and \$55.70 greater returns for each \$100 invested in livestock. The utility type of corn and Iowar, Iowa 103, and Iowa 105 strains of oats gave the best yields.

[*Farm earnings*, H. C. M. Case, R. R. Hudelson, P. E. Johnston, and K. H. Myers].—A table is given showing by sections of one or more counties the type of farming, the investment per acre, and the rate earned on the investment in 1924 and 1925. The figures are based on 650 farm records in 14 sections in 1924 and 1,100 records in 25 sections in 1925. After deducting a conservative sum for the value of the operator's own labor, the average earnings in all the sections studied on the average capital invested was 6.2 per cent in 1924 and 5 per cent in 1925. Based on a survey of 113 farms in McLean County, it is estimated that the average earnings of all farmers of the State for the 2 years were 2 per cent lower than the figures given above.

[*Cost of production*, H. C. M. Case, R. H. Wilcox, and H. A. Berg].—The cost accounting investigations in Champaign and Piatt and in Knox and Warren Counties were continued. The average costs of producing corn, oats, and winter wheat were 57 cts., 65 cts., and \$1.12 per bushel, respectively, in Champaign and Piatt Counties, and 47 cts., 39 cts., and \$1.13 per bushel, respectively, in Knox and Warren Counties, the yields being 51.7, 30.3, and 21.1 bu., respectively, in Champaign and Piatt Counties, and 60, 52.3, and 21.4 bu., respectively, in Knox and Warren Counties. Soy beans in Champaign and Piatt Counties yielded an average of 20.5 bu. per acre at an average cost of \$1.25 per bushel. The cost per 100 lbs. of pork produced was \$10.69 in Champaign and Piatt Counties, and \$9.34 in Knox and Warren Counties; per 100 lbs. of beef \$15.76 and \$17.30, respectively; per animal unit of maintaining milch cows \$102.81 and \$104.33, respectively; and for maintaining 100 hens, \$250.49 and \$356.43, respectively.

On the 16 farms in Champaign and Piatt Counties the costs of production per bushel varied from 45 to 81 cts. for corn; from 93 cts. to \$2.27 for wheat; from 47 to 79 cts. for oats; and from 99 cts. to \$2.34 for soy beans. The cost of producing 100 lbs. of pork varied from \$7.83 to \$22.34, and the cost of horse labor ranged from 9 to 23 $\frac{1}{3}$ cts. per hour.

[*Farm power costs*, R. C. Ross and R. I. Shaw].—The yearly use per farm and cost per hour of use of 2-plow tractors during 1925 were 300 hours and 79 cts., respectively, on 68 Champaign County farms, and 304 hours and 76 cts., respectively, on 28 Knox and Warren County farms. Three-plow tractors were used on an average of 237 hours at a cost per hour of \$1.39 on 33 Champaign County farms, and 374 hours at an average cost of \$1.13 on 24 Knox and Warren County farms. Horse labor on 16 Champaign and Piatt County farms averaged 793 hours per year at a cost of 14.6 cts. per hour. The percentage of different kinds of work done by 2-plow and 3-plow tractors for the different counties is shown.

[*Farm grain profits*, L. J. Norton].—The value of corn gradually increased from 1860 to 1917, but the increase has not continued since 1917. Production and prices of corn since 1900 indicate that a change of 1 per cent in production causes a change of 1.7 per cent in price in the opposite direction.

Years of high wheat prices were found to be poor years to store, as two poor harvests usually do not come in succession. It was also found that on an average it is not profitable to store for 12 months during years of low prices.

[*Different wheat areas of the State*, C. L. Stewart, L. J. Norton, O. L. Whalin, and L. F. Rickey].—A survey showed that the southern part of the State shipped soft wheat exclusively, that the northern part shipped chiefly hard wheat, while the central part shipped both hard and soft wheat and a considerable amount of mixed wheat.

A comparison of the prices of hard wheat at Chicago and soft wheat at St. Louis from 1914 to 1924 indicates that there was no premium on soft wheat at harvest, but that the price advanced until there was an average premium of 11 cts. per bushel in January.

Rural economics and sociology (*Arkansas Sta. Bul. 215 (1926)*, pp. 60-64).—Results of work in rural economics and sociology are given.

Farm incomes and the standard of living.—Records of a year's business on 903 farms were obtained. The size of the farm business measured in terms of the amount of work accomplished was found to be the most important factor in determining profits, as more efficient utilization of land, labor, and capital was possible on the larger size farm. The better paying farms had a larger acreage in cash crops and slightly higher yields than those that failed to make money.

Factors of practical farming.—The accounts kept in 1925 of about 100 farms were compiled. The average income above farm expenses, not including family and personal expenses or interest on mortgages, was \$759. Measuring the size of the farms on the basis of days of labor required, the larger farms made more than the smaller ones. Farms deriving from 15 to 50 per cent of their income from cotton made more than other farms, while those deriving more than 50 per cent from livestock, dairy, and poultry made less than other farms. Farms with yields higher than the average State yields and those with the higher gross receipts per worker made the most money.

Farming in the Big Bend country, W. J. SPILLMAN (*Washington Col. Sta. Pop. Bul. 135 (1926)*, pp. 4-72, figs. 11).—Information is given as to the soil, climate, and other natural factors; the results obtained at the experiment stations in the area with varieties of wheat, methods of tillage, etc.; the farm organization and practices of the most successful farmers; and the present and prospective economic conditions of the section. Systems of farming and methods of production are outlined with a view to increasing profits. The work was done in cooperation with the Bureau of Agricultural Economics, U. S. D. A.

Returns from the Arkansas radish crop in 1926, C. O. BRANNEN and J. A. DICKEY (*Arkansas Sta. Bul.* 214 (1926), pp. 4).—The sale value per acre and bushel and the itemized cost of producing and marketing radishes in 1926 are given. The net returns for labor, use of land, overhead, etc., were \$31.52 per acre and 25 cts. per bushel in the southwestern counties, and \$47.03 per acre and 72 cts. per bushel in the northeastern counties.

Woodlot taxation in Michigan, K. DRESSEL (*Michigan Sta. Quart. Bul.*, 9 (1926), No. 2, pp. 44-47).—Up to 1925, 50 woodlot owners in 22 counties had taken advantage of the woodlot tax act of 1917, permitting woodlot owners, in lieu of taxes on the existing valuation of the land, to pay taxes on a valuation of \$1 per acre and a 5 per cent cutting tax on the actual stumpage value of timber removed, except for the use of the owner or tenant. The reduction of tax valuations of lands listed under the act are summarized.

Crops and Markets, [December, 1926] (*U. S. Dept. Agr., Crops and Markets*, 6 (1926), Nos. 24, pp. 369-384; 25, pp. 385-400; 26, pp. 401-416; 27, pp. 417-440).—The usual weekly tabulations, notes, and summaries are given for the period November 29 to December 31 for livestock, meats, and wool, fruits and vegetables, dairy and poultry, grain, hay, feed, cotton, and foreign crops and markets. This series of weekly reports has been discontinued with the above numbers.

Cotton facts, compiled by A. B. SHEPPERSON, rev. by C. W. SHEPPERSON (*New York: Shepperson Pub. Co., 1925, 50. ed., rev. and enl., pp. 255, pl. 1, fig. 1*).—A revised edition of the work previously noted (*E. S. R.*, 45, p. 342). Statistics are included as to crops, receipts, stocks, exports, imports, visible supply, sales, consumption, and manufacturing output of cotton and cotton products.

Report on the grain trade of Canada . . . 1925, W. DOUGAN and E. A. URSELL (*Canada Bur. Statis., Rpt. Grain Trade Canada, 1925, pp. 215, figs. 5*).—This report succeeds an earlier one (*E. S. R.*, 54, p. 788).

Report on the marketing of pigs in England and Wales (*[Gt. Brit.] Min. Agr. and Fisheries, Econ. Ser. 12 (1926), pp. VI+103, pls. 22*).—A description is given of the methods employed and the services involved at each stage of the marketing of pigs in England and Wales. The market requirements and causes of price fluctuations are discussed. Progress in replacing the £57,000,000 worth of pig meat imported in 1925 was found to be practicable in two directions, viz, by filling the gap in the fresh-pork market caused by the embargo on imported carcasses and by supplying mild-cured Wiltshire side bacon and other cuts, of which about £23,500,000 worth were imported.

Greater uniformity and higher quality of supplies, breeding to meet market requirements, a body for coordinating the efforts of producers and distributors, cooperative marketing, uniform classification for price recording and improved dissemination of market information, and payment on the basis of quality are suggested as means of improving marketing conditions.

Report on the marketing of poultry in England and Wales (*[Gt. Brit.] Min. Agr. and Fisheries, Econ. Ser. 11 (1926), pp. VI+122, pls. 32, figs. 4*).—The results of a detailed investigation into the marketing of poultry in England and Wales are given. The methods employed and the services involved at each stage are reviewed, and comparison made with corresponding activities in other countries. Suggestions are made as to possible improvements which will enable home producers to meet the competition of other countries.

Expense factors in city distribution of perishables, C. E. ARTMAN (*U. S. Dept. Agr. Bul.* 1411 (1926), pp. 36, figs. 13).—This study is based on approximately 14,000 individual price records for 14 commodities collected from February, 1923, to May, 1924, from 50 retail stores in the New York metropolitan area. The purchasing habits of consumers, i. e., the prevailing size of the

individual retail sale; the special services involved in the delivery of goods and extension of credit; and the form of organization or management of the retail store were found to be the features of outstanding significance in determining the expense of distributing perishable foods to city customers.

The percentage of margins between mean wholesale and retail prices for the 14 commodities varied from 37 to 63, the weighted mean being 45. The value of the standard retail sale varied from 20.3 to 27.8 cts., averaging 25.3 cts., and the price spread per standard retail sale from 9.9 to 12.8 cts., averaging 11.3 cts. Differences in margins were found to be directly due to differences in size of the retail sale, and the practice of marking retail prices so as to obtain for different articles a fairly constant money spread per sale, regardless of the size, explains the differences in percentage margins. The jobbers' and retailers' portions of the price spreads of standard retail sale for unit stores varied from 1.6 to 3 cts., averaging 2.1 cts., and from 8.7 to 10.9 cts., averaging 9.7 cts., respectively. The price spread in chain stores was 43 per cent below that of typical unit stores and 31 per cent below that of unit cash-carry stores. In unit stores the spread in cash-carry stores was 9 per cent below that of cash-delivery stores and 23 per cent below that of credit-delivery stores, and that of cash-delivery stores was 16 per cent below that of credit-delivery stores. The weighted mean value of standard retail sales of 7 of the 14 commodities was 20.2 cts. for chain stores, 23.3 cts. for cash-carry stores, 24.9 cts. for cash-delivery stores, and 27 cts. for credit-delivery stores.

The analysis of the implications in commodity differences through which the theory of a constant price spread per retail sale was developed is presented.

Consumer habits and preferences in the purchase and consumption of meat, K. B. GARDNER and L. A. ADAMS (*U. S. Dept. Agr. Bul. 1443 (1926)*, pp. 64).—This bulletin is the third of the series on retail marketing of meat previously noted (*E. S. R.*, 56, p. 288). The aim of the study was to obtain information regarding the purchasing habits of housewives; their knowledge of grades, quality, and cuts of meat; their preferences for various kinds and cuts of meat; and the use of meat in the household. Housewives representing households totaling 20,744 persons in 16 representative cities of the United States were interviewed. Of the households represented, 2,912 were American white, 400 colored, and 1,154 foreigners. The replies to the several questions in the questionnaire used are tabulated and analyzed, and the results are summarized under consumption, purchasing, advertising, and consumer knowledge of meat quality and cuts. A copy of the questionnaire used is included.

Possibilities and limitations of cooperative marketing, F. L. THOMSEN and H. C. HENSLEY (*Missouri Sta. Circ. 150 (1926)*, pp. 4).—This circular briefly discusses the benefits to be derived from cooperative associations for marketing farm products.

Co-operative ideals and problems, A. ÖRNE, trans. by J. DOWNIE (*Manchester: Co-operative Union Ltd., 1926*, pp. [XIX+143, fig. 1]).—This book, translated from the Swedish, discusses some of the ideas and problems affecting the consumers' cooperative form of enterprise. Much of the material presented is drawn from the experiences of the Swedish Cooperative Union and the Swedish cooperative societies.

Price fixing by governments 424 B. C.—1926 A. D.: A selected bibliography, including some references on the principles of price fixing, and on price fixing by private organizations, compiled by M. G. LACY, A. M. HANNAY, and E. L. DAY (*U. S. Dept. Agr., Bur. Agr. Econ., Agr. Econ. Bibliog. 18 (1926)*, pp. [3]+149).—This is a selected bibliography in mimeographed form bringing that previously noted (*E. S. R.*, 49, p. 559) down to date and enlarging it by including agricultural products other than food products. Colonial, Federal,

and State statutes of the United States have been consulted, and the laws of approximately 60 foreign countries cited from official sources or the information supplied from secondary sources. Some references are included on the principles of price fixing and on price fixing by private organizations.

Needed readjustments in rural life: Proceedings of the Eighth National Country Life Conference (*Natl. Country Life Conf. Proc.*, 8 (1925), pp. VII+158, pl. 1).—Addresses and papers presented before the conference, held at Richmond, Va., in 1925, were *Needed Readjustments in Rural Life Today*, by K. L. Butterfield; *Public Welfare and Democracy*, by H. W. Odum; *The Farmer's Adjustments to the Commercial World*, by C. C. Taylor; *The Canadian Situation*, by J. B. Reynolds; *The Family and Private Ownership*, by E. V. O'Hara; and *Economic Effects of Belief in Transmigration*, by S. Higginbottom. Farmers' income, farmers' standards of living, and the adjustments that should be made by farmers' cooperative organizations, community organizers, educators, and religious workers formed the chief topics of the discussions at the conference.

AGRICULTURAL AND HOME ECONOMICS EDUCATION

A handbook of educational associations and foundations in the United States (*U. S. Bur. Ed. Bul.* 16 (1926), pp. III+32).—An alphabetical list with cross references of the association and foundations in the United States engaged in the promotion of education. It includes national associations and foundations, some important sectional associations, general State associations, and a few international organizations having offices in the United States.

The place of vocational agriculture in the present agricultural situation, C. H. LANE (*Fed. Bd. Vocat. Ed. Monog.* 3 (1926), pp. 14).—This monograph outlines some of the fundamentals of efficient farming which should be included in programs for systematic vocational education in agriculture.

The folk high schools of Denmark and the development of a farming community, H. BEGRUP, H. LUND, and P. MANNICHE (*London: Oxford Univ. Press, Humphrey Milford; Copenhagen: Arnold Busck*, 1926, pp. 168, pls. 2).—A brief description is given of the origin, development, purposes, and results of the folk high schools and the International People's College of Denmark.

The story of the women's institute movement in England and Wales and Scotland, J. W. ROBERTSON SCOTT (*Idbury, Kingham, Oxon: Village Press*, 1925, pp. XV+290, pls. 17, figs. 4).—A historical account is given of the introduction and growth of this movement, the object of which is "to improve the conditions of rural life and to provide opportunities for mutual help and intercourse."

Report of H. M. inspectors on the educational work of women's rural institutes (*London: Bd. Ed.*, 1926, pp. 22).—This report of the inspectors of the Board of Education deals with the history and organization of women's rural institutes in England and Wales and the educational work carried on under the various county education authorities in connection with such institutes.

Source book for the economic geography of North America, C. C. COLBY (*Chicago: Univ. Chicago Press*, 1926, pp. XXII+549, pls. [6], figs. [89]).—A collection of source material on the economic geography of the United States, Canada, Mexico, and Alaska, prepared for use in a course on the economic geography of North America in the University of Chicago. The material is organized on a regional basis.

The botany of sugar cane [trans. title], E. MAMELI DE CALVINO (*Chaparra Agricola*, 1 (1924), Nos. 4, pp. 3-6, pls. 2; 5, pp. 20-23; 6, pp. 15-18; 7-8, pp. 13-17; 1 (1925), Nos. 9, pp. 13-16, pls. 2; 10, pp. 9-23, figs. 11; 11, pp. 4-17, figs. 20; 12, pp. 3-17, figs. 10; 2 (1925), No. 1-2, pp. 8-20, figs. 7).—The several sections (mainly descriptive) above indicated are intended to comprise, with a physiological portion to be published later, the basis of an introductory course for students not yet fully accustomed to the use of strictly scientific terms.

An animal feeding experiment, showing the effect of deficient diet on growth, G. SPENCER (*Austin: Tex. Univ., Div. Ext., Nutrition and Health Ed. Bur., [1925?], pp. 67, figs. 17*).—Directions and information are given for conducting a simple experiment with rats to demonstrate the relative growth-promoting value of milk as compared with candy, chili, coffee, and a bottled beverage. It is planned for use in high-school classes studying nutrition under a biology or home economics teacher, and in connection with health program work in the grades. An account is included of how the experiment can be used in connection with a health program in extension work.

Agricultural journalism, N. A. CRAWFORD and C. E. ROGERS (*New York: Alfred A. Knopf, 1926, pp. VII+300, pls. 5, figs. 3*).—This textbook applies the fundamental principles of journalistic writing to agricultural and other rural subject matter. It is arranged for use either as a basic text in an extended course, or as a manual in a brief course covering only the rudiments of agricultural writing. Each chapter is followed by questions and assignments.

FOODS—HUMAN NUTRITION

Nutritive value of Oriental foods, A. OHN (*Western Dietitian, 1 (1926), No. 6, pp. 23-25, 37, 38, figs. 3*).—This paper consists of a comparison of Oriental with Occidental food habits, with emphasis on some of the advantages of Oriental methods of food preparation and preservation. Data on the chemical composition and nutritive value of typical Oriental foods are tabulated, and a comparison is given of the distribution of foods in the middle-class Chinese diets of north China as reported by Adolph (E. S. R., 54, p. 591), with estimated values for south China. The latter show a slightly lower consumption of cereals and a higher consumption of fruits and vegetables, meats and fish, and fats and sugar.

Studies in Chinese economic botany, C. Y. SHIH (*Chinese Econ. Mo., 2 (1925), Nos. 9, pp. 24-29, figs. 4; 10, pp. 36-43, figs. 3; 11, pp. 23-36, figs. 3; 12, pp. 37-44; 13, pp. 30-44, fig. 1; 15, pp. 38-53, figs. 3*).—This is a compilation of information on methods of cultivating some of the common food plants of China and recipes for their use in the preparation of various food products. The materials include soy beans and other varieties of beans, peanuts, Chinese cabbage, rape, mustard, spinach, parsley, watercress, onions, leeks, garlic, peppers, various cucurbitaceous plants, roots and storage stems, fruits, nuts, and cereals. A summary of the Chinese, Latin, and English names of the different products discussed is appended.

Influence of granulation on chemical composition and baking quality of flour, J. H. SHOLLENBERGER and D. A. COLEMAN (*U. S. Dept. Agr. Bul. 1463 (1926), pp. 36*).—In this investigation of the optimum degree of fineness of flour particles from the standpoint of chemical composition and breadmaking qualities, three methods were used to obtain samples of flour of varying fineness. In the first, portions of coarse middlings and flours were ground on smooth rolls of a laboratory mill 1, 4, 10, and 20 times without sifting; in the second, middlings were ground in the same way to pass through 8xx, 12xx, 20xx, and 25xx silk cloth; and in the third, coarse middling stocks were sifted in sieves covered with 8xx, 10xx, 12xx, 16xx, 20xx, and 25xx silk bolting cloth. All of the samples thus obtained were subjected to the usual flour analyses, and special studies were made of the quality of the gluten in the excessively ground samples, the quantity and quality of the gluten in different sized flour particles, and the diastatic action of the flours.

The results obtained confirm those of previous investigations, such as that of Alsberg and Griffing (E. S. R., 55, p. 504), that excessive grinding affects

the chemical composition and baking quality of the flour unfavorably. It is noted, however, that under commercial conditions the grinding would probably never be excessive enough to bring about marked changes in the flour except in its fineness and whiteness. The most important chemical changes resulting from excessive grinding (methods 1 and 2) were a deterioration in the quality of the gluten and an increase in the diastatic action of the starch. In baking results the most marked effect was an increase in water absorption and deterioration in the color of the crumb. Of the samples obtained by the third method, the smallest sized particles were found to contain less protein and wet and dry gluten than the coarser particles, and the quality of the gluten was less good. With the soft red winter wheat the smallest sized particles had lower and with the hard wheat higher ash content. The smallest particles usually contained the least amount of gasoline-soluble pigment. The particles of intermediate size gave the best appearing loaf and those of the smallest size loaves of very inferior quality. It is noted, however, that satisfactory pie crust can be made from the very fine flour, suggesting the possibility of separating flour for the two purposes.

Numerous tables give the detailed results of the chemical and baking tests.

A study of the use of Missouri soft wheat flour in making light bread, E. M. DAVIS and J. A. CLINE (*Missouri Sta. Research Bul.* 87 (1926), pp. 5-47, figs. 45).—In this publication are given the details of the experimental work upon which were based the formulas and directions for making bread from Missouri soft wheat flour with the use of compressed yeast (E. S. R., 53, p. 58) and dried yeast (E. S. R., 55, p. 291), together with the results of a similar study of the use of liquid yeast.

Good results were obtained with the use of only a small amount of liquid yeast and the addition of potato water or buttermilk as the rest of the liquid. The best loaf of the series was obtained with potato as the gelatinized starch for the starter, as suggested in the previous study, and potato water as the liquid. Corn sirup did not give as good results as cane sugar. Excellent bread was obtained with apple and apple water with the liquid yeast. The bread thus made is said to have a fine silky texture, excellent volume, and to keep fresh longer than any of the other breads made from Missouri soft wheat flour.

A review of the literature on breadmaking with soft wheat flour, a short bibliography, and numerous photographs of the breads made by the different processes are included.

A bakery infection with *Monilia sitophila*, G. B. REED (*Abs. in Phytopathology*, 14 (1924), No. 7, p. 346).—It is claimed that bread produced from a small bakery in eastern Ontario when kept for four or five days developed a deep shell pink color throughout the loaf. The infection was due to *M. sitophila*.

The dietetic value of oatmeal proteins, G. A. HARTWELL (*Biochem. Jour.*, 20 (1926), No. 4, pp. 751-758, figs. 3).—On a ration prepared by heating 100 gm. of oatmeal, 2.88 gm. of salt mixture, and 14 gm. of butter with 500 cc. of water, as in the method previously described (E. S. R., 55, p. 411), rats grew well although not so rapidly as control animals on a mixed diet of kitchen scraps, bread, and milk. The ration proved less satisfactory for gestation and lactation. The litters were small, many of the young were below average weight at birth, and not all were raised. The growth of the young was also slower when the mothers received this ration than either raw or cooked oatmeal and water. This observation, together with the fact that better growth in the suckling young was secured when casein, gluten, gelatin, or egg albumin was added to the ration of the mother, is thought to indicate that oatmeal proteins are of good quality, but that the amount present in the ration was too low for the extra burden of lactation.

[Studies at the Illinois Station on milk composition and energy] (*Illinois Sta. Rpt. 1926, pp. 91, 92*).—From a study by O. R. Overman and F. P. Sanmann of the relation of the composition of milk to its energy value as determined on 212 samples of milk ranging in fat content from 2.68 to 7.59 per cent, formulas have been prepared for computing the heat of combustion of a quart of milk as follows: If the percentages of fat (A), protein (B), sugar (C), total solids (D), and specific gravity (E) are known, the formula is F (calories per quart of milk) = $52.78A + 16.41B + 37.87D + 46.91E - 2.75C - 57.70$. If the percentages of fat, protein, and sugar are known, the formula $F = 90.67A + 54.27B + 26.73C + 55.44$ should be used. If only the percentage of fat is known, the formula $F = 113.7334 (A + 2.4404)$ should be used. If only the percentage of fat is known and the metabolizable energy is wanted, the formula $F_M = 105.287 (A + 2.4185)$ should be used.

Acidophilus milk proves desirable beverage (*Illinois Sta. Rpt. 1926, pp. 95, 96*).—The method used by M. J. Prucha and J. M. Brannon in the preparation of acidophilus milk is as follows: Skim milk of good quality is pasteurized in a glass-lined vat at 175° F. for 30 minutes, cooled to 100° and allowed to stand for 3 or 4 hours, repasteurized under the same conditions, cooled to from 100 to 102°, and inoculated with a strong acidophilus culture, using at least 3 per cent of inoculum. When an acidity of from 0.5 to 0.6 per cent is reached the milk is cooled to about 60° and cream is added to make a fat content of about 1 per cent, together with from 5 to 10 per cent of a good lactic acid starter to improve the flavor. The milk is finally passed through a homogenizer and over a cooler.

Fruit jellies—the rôle of pectin, P. B. MYERS and G. L. BAKER (*Delaware Sta. Bul. 147 (1926), pp. 15-17*).—In this progress report on the study of fruit jellies (*E. S. R., 55, p. 385*), data are summarized on the properties of solutions of commercial grades of citrus and apple pectins of varying degrees of purity.

With increasing purity of the pectin there was an increase in the viscosity and the H-ion concentration of the pectin. The jelly strength at the H-ion concentration corresponding to the optimum point of jelly formation varied directly with the viscosity of the pectin solution regardless of its source, indicating that the jelly strength at the optimum point varies with the purity of the pectin.

It was found possible to remove a small percentage of impurities from the pectin by successive precipitations with alcohol, but beyond a certain point the ash remained fairly constant, indicating a possible combination of pectin with some of the impurity represented by the ash. Still more ash could be removed by treating the pectin with acid before precipitation with alcohol and by electrolyzing the solution, using diaphragms impermeable to the pectin. After electrolysis the H-ion concentrations of the various pectins were practically the same if at the same degree of purity.

It is noted in conclusion that when acid is added to a pectin solution the acid radicle does not combine with the pectin as stated in an earlier paper. "It has been definitely established that the acid radicle unites with metallic ion, either adsorbed by the colloidal pectin or actually in the pectin molecule, to form salts, while the hydrogen ion of the acid simply replaces the metallic ion."

The science of making sauerkraut, F. W. FABIAN (*Michigan Sta. Quart. Bul., 9 (1926), No. 2, pp. 50, 51*).—Simple directions are given for the home manufacture and preservation of sauerkraut. In the author's opinion the best means of securing the desirable flavor is by the use of a homemade starter prepared by adding to a shredded cabbage 2.5 per cent of its weight of common salt and allowing it to ferment at 80° F. for several days in a clean suitable container properly weighted. If at the end of this time the starter has the desired flavor it is added in small portions to a large batch of shredded cabbage as

the container is being filled, 1 gal. of the starter being sufficient for about 25 gal. of the cabbage. The same proportion of salt and the same temperature are used for the fermentation of the large batch as for the starter. If the starter does not acquire the desired flavor it should be thrown away and another prepared.

To prevent the growth of lactic acid-destroying organisms, the sauerkraut should be canned or sealed by pouring melted paraffin over the surface of the liquid.

Remedies being found for canned corn defects (*Illinois Sta. Rpt. 1926*, pp. 161, 162).—In an experiment by W. A. Huelsen a comparison of the brown discoloration due to tin sulfide and the black due to iron sulfide in high protein and low protein corn packed in cans with different weights of tin plate coating showed that the protein content is one of the factors largely responsible for the black discoloration. In cans having no tin coating the black discoloration was about 25 times as great with the high protein as with the low. With increasing weight of tin in the coating there was a decrease in the black discoloration, but in the high protein corn an increase in the brown.

Concerning commercial varieties of dextrin and their use in artificial diets for the biological analysis of foods [trans. title], L. RANDOIN and R. LECOQ (*Jour. Pharm. et Chim.*, 8. ser., 4 (1926), No. 7, pp. 289-294, figs. 2).—Attention is called to observed differences in the growth curves of rats on diets identical except for dextrin, which in one case was white and in the other a light brown. On supposedly adequate diets there was noted a loss in weight with the white dextrin and gain at the usual rate with the brown. The difference is attributed to difficulty in digesting the white dextrin, which more nearly approached starch in its properties. In the brown dextrin it was assumed that the starch had been more completely broken down, with increased digestibility. It is recommended that if dextrin is to be used in basal diets for nutrition experiments preference should be given to the light brown form.

Calcium balance with hydrochloric acid milk, R. G. FLOOD (*Amer. Jour. Diseases Children*, 32 (1926), No. 4, pp. 550-553).—Calcium metabolism experiments were conducted on normal and rachitic infants receiving first a sweet milk formula and then the same formula with the substitution of N/10 HCl for the water of the previous formula.

In the normal subjects there was no variation in the calcium retention with sweet or acidified milk, but in the rachitic subjects the retention was much lower on the sweet milk than on the acidified milk, the difference increasing with the severity of the rickets. This is thought to explain the favorable action of hydrochloric acid milk in the prevention and cure of rickets. The prophylactic action is attributed, first, to the low buffer content of the hydrochloric acid milk which enables the utilization of a higher percentage of fat and incidentally vitamin D and, second, to the high absorption of calcium on account of the change from insoluble to soluble salts.

Attention is also called to the fact that infants suffering from chronic infections are especially prone to rickets, and that such conditions are apt to be accompanied by a moderate hypochlohydria which is counteracted by the acidity of the hydrochloric acid milk.

The antirachitic vitamin (*Brit. Med. Jour.*, No. 3430 (1926), pp. 606, 607).—An editorial discussion based upon recent literature emphasizing the greater relative importance of sunlight than of diet in the prevention of rickets.

Contributions to tropical physiology, with special reference to the adaptation of the white man to the climate of North Queensland, E. S. SUNDSTROEM (*Calif. Univ. Pubs. Physiol.*, 6 (1926), pp. 216, figs. 26).—The extensive investigation reported in this monograph was conducted at Townsville,

North Queensland, situated 19° south on the coastal belt of the Australian Tropics and inhabited by a pure white race. The climate is thought to be fairly representative of wide expanses of tropical country. The average humidity is high (75 per cent) and the temperature range from 20 to 28° C. by dry bulb and 17 to 25° by wet bulb thermometer. The studies reported included analyses of the blood of 45 individuals for sugar, nonprotein nitrogen, phosphorus, and lipoid constituents; determinations of water regulation and acid base equilibrium in a few subjects; basal metabolism and dietary studies and urinary analyses; studies of the growth of children, growth of hair and nails, and growth of rats; measurements of cooling power; determinations of red and white blood corpuscles; and reaction times to stimuli.

The blood studies appeared to indicate that a tropical environment predisposes to a decrease in the blood sugar level, an increase in the level of nonprotein nitrogen primarily due to lack of water for proper excretion, a decrease with increasing time spent in the Tropics in the phosphorus and total fatty acids, an increase in fat, a somewhat wider range for cholesterol and the ratio lecithin to cholesterol, and a higher concentration of total solids. In general the changes were more noticeable in women than in men and in subjects born in the Tropics than those coming from cooler climates. The necessity of copious water drinking is thought to be indicated by the tendency to higher concentration of most of the blood constituents and the tendency to alkalosis.

Basal metabolism determinations with the Zuntz portable respiration apparatus were conducted on 8 male and 7 female subjects, 29 determinations being made in all, including 8 on the author on consecutive days. The minimum, maximum, and average basal metabolic rates were 25.5, 36.1, and 31 calories per square meter of body surface for the males and 22.1, 33.8, and 27.8 calories, respectively, for the females. Physically active individuals showed a relatively high basal metabolism. There were decided fluctuations from day to day, apparently due to variations in relative humidity.

The dietary studies were conducted for a week on a man, a woman, and a 9-year-old child weighing 66.6, 70.4, and 32.8 kg., respectively. The daily calorie intake was 3,044 for the man, 2,374 for the woman, and 2,078 for the girl. The water intake was 2,650, 1,730, and 1,760 cc. daily and the nitrogen balance -0.15, +0.56, and +1.28 gm., respectively. The balance of the phosphorus was positive and sulfur negative for all of the subjects.

Growth studies were made at monthly intervals for 6 months or more on 107 boarding school girls. Data are tabulated for the average height and weight and weight-height ratios from the ages of 8 to 17 years, inclusive. The data for 10 to 15 years are thought to be sufficiently reliable for statistical use. The rate of growth was found to be more rapid than for girls of the same stock in temperate climates, but no differences in the build as judged by the ratio of weight to height were observed. A seasonal rhythm in growth was demonstrated.

Growth standards: Height, chest-girth, and weight for private school boys, H. GRAY and F. FRALEY (*Amer. Jour. Diseases Children*, 32 (1926), No. 4, pp. 554, 555).—The data for ideal standards of height, chest, and weight for age and weight for height for boys in private boarding schools in the country and in country day schools (*E. S. R.*, 46, p. 563) have been extended to a total of 1,016 records by measurements from two schools. The new data confirm and smooth out the earlier tentative standards. The figures for stature and chest girth are higher than those reported by Baldwin for California gifted children,³ but represent a strikingly slender type in weight for height.

³ Anthropometric measurements, B. T. Baldwin. *In Genetic Studies of Genius*, I., L. M. Terman et al. [Stanford University]: Stanford Univ. Press, 1925, vol. 1, pp. 135-171.

Metabolism of undernourished children, I-III, C. C. WANG, M. FRANK, B. B. HAYS, and R. KERN (*Amer. Jour. Diseases Children*, 32 (1926), Nos. 1, pp. 63-71, fig. 1; 3, pp. 350-366, figs. 3).—An extensive investigation of undernourishment in children with a view to determining whether occasional failures to gain in nutrition classes are due to metabolic abnormalities has been undertaken at the Nelson Morris Memorial Institute for Medical Research of the Michael Reese Hospital, Chicago, under the auspices of the Elizabeth McCormick Memorial Fund. The first three phases of the investigation are reported in the papers noted below.

I. Gain in weight.—This report deals with 33 underweight children and 9 normal children from 4 to 13 years of age who remained in the hospital under constant supervision for periods varying from 2 weeks to 5 months. The children, most of whom came from Jewish, Polish, Irish, and Italian families, were selected for the most part from those failing to gain weight while attending nutrition classes. Twenty-two of them were more than 10 per cent and all more than 5 per cent below the Baldwin-Wood normal figures for age and height and nearly all were below normal height for age by the Woodbury standards. In general, the diet given at the hospital provided a caloric intake desirable for a child of the same age and normal height and weight and included plenty of fresh vegetables, fruit, and milk.

Four of the children, including 3 of normal weight, neither gained nor lost weight and 2 lost slightly during their stay at the hospital, but no child remaining longer than 2 weeks failed to gain. Eleven had reached normal weight and only 8 were more than 10 per cent below normal on discharge. Among the underweight children, those below 6 years of age showed the greatest gains, while in the normal children the 8-year-old group gained more rapidly than the 4- and 5-year group. The degree of underweight apparently had no effect upon the rate of gain. The most rapid gain was made by a 5-year-old girl who changed from 17.7 to 1.5 per cent underweight in 4 weeks, and the greatest total gain by a 10-year-old girl who gained more than 35 per cent of her weight on entry in 23 weeks.

In discussing the apparent causes of malnutrition among the subjects studied, racial emotional characteristics and poor home conditions leading to bad food habits were considered important factors. Slow eating resulting in inability to finish a meal in the usual time, apathy toward normal play and overexcitement when drawn into it, and poor dental hygiene are cited as individual variations from the normal.

II. Basal metabolism.—Basal metabolism determinations are reported for all but one of the subjects of the previous study. Benedict's cot chamber with universal respiration apparatus was used, the determinations being made in duplicate on 3 consecutive days. The values obtained were compared with the Benedict-Talbot standards for age, weight, and height, a 10 per cent decrease being made since all records in the present study were made with the children awake. All of the children came within the normal limits. The metabolism decreased with increasing underweight when computed on the basis of height and increased when computed on the basis of weight. The food intake showed a rather constant level of 1.7 times the caloric value of the basal metabolism.

III. Urinary nitrogen with special reference to creatinine.—This paper, which opens the discussion of the substance metabolism of the above subjects, deals with the urinary nitrogenous constituents, particularly creatinine, on

controlled diets. Nine boys and 17 girls served as subjects for the creatinine determinations and 14 boys and 17 girls for the total and ammonia nitrogen. The results obtained are summarized as follows:

"The creatinine coefficients of 26 normal and underweight children ranged from 5.5 to 9.5, with averages of 7.1, 7.4, 7.7, 7.9, and 7.5 for vigorous normal children, normal in weight, 5.1 to 10 per cent underweight, 10.1 to 15 per cent underweight, and more than 15 per cent underweight, respectively. These children showed no signs of diminished creatinine excretion up to 15 per cent below normal weight. Creatinine excretion remained very constant for the same child from time to time. Creatinine nitrogen increased with increasing body weight and likewise with age, although the latter factor may be secondary to the former. Creatine occurred in all children examined, and indications are that it varies according to protein intake. Total and ammonia nitrogen in the urine were approximately the same in all groups."

Goiter in children in New York City, F. COHEN (*Amer. Jour. Diseases Children*, 31 (1926), No. 5, pp. 676-692, figs. 3).—This paper includes the report of a survey of the extent of goiter among schoolgirls in New York City previously noted from a paper by Goldberger and Aldinger (*E. S. R.*, 54, p. 295), and of a similar survey covering the examination of 783 boys from the fifth grade through the first year of high school in Manhattan.

Of the boys, 94.6 per cent had normal thyroid glands, 4.9 per cent slight enlargements, and 0.5 per cent moderate enlargements. The highest incidence of enlargement was at the time of puberty, from the thirteenth to the fifteenth year. The rate of slight enlargement among the boys was about one-third and moderate enlargement one-fourth that among the girls. There were no cases of marked enlargement of the thyroid among the boys as compared with 0.4 per cent among the girls.

The author is of the opinion that the incidence of goiter in boys and men is an important index of the degree to which a definite region is goitrous. As thus judged, New York City is not an endemic center of goiter.

TEXTILES AND CLOTHING

Strength tests at any atmospheric conditions, P. E. MORRILL (*Textile World*, 70 (1926), No. 24, pp. 43, 44, figs. 3).—The results of tests made on cotton sheetings and Osnaburgs under varying relative humidity with constant dry bulb temperature, and vice versa, indicated that the tensile strengths of such materials can be computed fairly accurately at standard atmospheric conditions of 70° F. and 65 per cent relative humidity from the strengths observed at other temperatures and relative humidities. Procedure based on the tests is outlined.

Result of light-fastness tests (*Textile World*, 70 (1926), No. 24, pp. 115, 116).—Experiments by the U. S. Bureau of Standards cooperating with the American Association of Textile Chemists and Colorists have revealed that dyeings subjected to continuous vertical exposures facing north, under glass, have faded very differently from similar exposures facing toward the sun (south). Exposures made without glass faded on the average very much like exposures under glass, but with a slight increase in fading in some cases. A good many dyes darkened in light exposures instead of becoming paler, although on prolonged exposure they eventually became lighter. Basic dyes of various chemical classes and indigoid dyes on cotton faded more, relatively to other classes of dyes, on exposure to the northern sky than they did in the sun (southern) exposure. Exposures of the faster dyes have been carried out to 384 hours.

Odors in woolen goods, TEXTUS (*Textile World*, 70 (1926), No. 26, pp. 34, 35).—The causes for odors in woolen goods are described, and methods for detecting and correcting them are outlined.

Fur-dyeing and fur dyes in America, W. E. AUSTIN (*Indus. and Engin. Chem.*, 18 (1926), No. 12, pp. 1342, 1343).—A brief discussion of the development and present extent of the fur-dyeing industry in America, and of some of the difficulties in dyeing fur.

Quilts: Their story and how to make them, M. D. WEBSTER (*New York: Doubleday, Page & Co.*, 1926, pp. XVIII+178, pls. 81, figs. 16).—A history of patchwork quilts from ancient to modern times, including a chapter on the technique of quilt making. Many photographic illustrations, some in color, of fine examples of quilts of various types, an alphabetical list of quilt names, and a list of literature references are included. The volume is a reprint of an edition published in 1915.

A book of hand-woven coverlets, E. C. HALL (*Boston: Little, Brown & Co.*, 1925, pp. XIII+279, pls. 64).—The chief value of this volume, a reprint of one published in 1912, lies in the many photographic illustrations of early American hand-woven coverlets, enabling those inheriting such coverlets to identify them by name.

Clothing: Choice, care, cost, M. S. WOOLMAN (*Philadelphia and London: J. B. Lippincott Co.*, 1926, 3. ed., rev., pp. XIII+288, pl. 1, figs. 40).—In the revision of this volume, the first edition of which has been noted previously (E. S. R., 46, p. 95), considerable attention has been paid to the economics of the textile industries as affected by conditions during and following the war and the adjustment of clothing budgets to increased prices. The discussion of this phase of the subject will be found chiefly in the chapters on clothing problems of the day and intelligent shopping, and in five other chapters dealing with the manufacture, value, and uses of the leading textiles and accessories to the wardrobe.

Standard hosiery lengths, E. M. SCHENKE and C. W. SCHOFFSTALL (*U. S. Dept. Com., Bur. Standards Technol. Paper 324* (1926), pp. 667-680, figs. 12).—Standards are proposed for the length of ladies', men's, children's ribbed, children's sport, infants' ribbed, and infants' and children's socks from measurements on hosiery representing the product of 30 manufacturers.

Methods of investigating ventilation and its effects ([*Gt. Brit.*] *Med. Research Council, Spec. Rpt. Ser.*, No. 100 (1926), pp. 71, pls. 2, figs. 21).—This report, which continues the discussion of the principles of ventilation and use of the kata-thermometer by Hill and Campbell (E. S. R., 55, p. 589), is composed of four parts. Part 1, by H. M. Vernon and J. J. Manley, contains descriptions of two new instruments for the measurement of variations in the velocity and in the temperature of air currents; part 2, by H. M. Vernon, deals with the further calibration of the kata-thermometer; and part 3, by H. M. Vernon and T. Bedford, assisted by C. G. Warner, consists of a comparative study of the objective indications of the kata-thermometer and the actual sensation of comfort.

Part 4, by H. M. Vernon, should be of particular interest to readers of this section in that it deals with the influence of temperature, air velocity, and clothing on the rate of cooling of the human body. In this study the rate of cooling of the human body between 99.3 and 98.3° F. was determined after its temperature had been raised by step climbing. In the unclothed or very lightly clothed body an air current of 100 ft. per minute caused an extra cooling over that with still air, corresponding to a lowering of the air temperature by from 2 to 4°, while in the warmly clothed body it corresponded to a lowering of only 1°. It was calculated that the unclothed body would remain in

temperature equilibrium at an air temperature of 81 to 83°, while the warmly clad body would remain in equilibrium at 59 to 60°. It was concluded that to induce cooling of the overheated body of a person engaged in heavy work temperature reduction is of the greatest importance, followed by a reduction in the clothing, and least in importance an increase in air velocity.

MISCELLANEOUS

Thirty-eighth Annual Report [of Arkansas Station]; 1926, D. T. GRAY (*Arkansas Sta. Bul. 215 (1926), pp. 67, figs. 15*).—This contains the organization list, brief summaries of the chief lines of work of the station, and a financial statement for the fiscal year ended June 30, 1926. The experimental work reported not previously noted is for the most part abstracted elsewhere in this issue.

Annual report of the director for the fiscal year ending June 30, 1926, C. A. McCUE ET AL. (*Delaware Sta. Bul. 147 (1926), pp. 37*).—This contains the organization list; a report of the director including a financial statement for the fiscal year ended June 30, 1926, and departmental reports. The experimental work recorded not previously noted is for the most part abstracted elsewhere in this issue.

A year's progress in solving some farm problems of Illinois: Thirty-ninth Annual Report [of Illinois Station, 1926], compiled and edited by F. J. KEILHOLZ (*Illinois Sta. Rpt. 1926, pp. 184, figs. 31*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1926, and a summary compiled from reports of heads of departments and project leaders on the work during the year. The experimental work reported not previously noted is for the most part abstracted elsewhere in this issue.

Michigan Agricultural Experiment Station Quarterly Bulletin, [November, 1926], edited by R. S. SHAW and E. B. HILL (*Michigan Sta. Quart. Bul., 9 (1926), No. 2, pp. 33-78, figs. 2*).—In addition to articles abstracted elsewhere in this issue, this number contains the following: Machinery and Corn Borer Control, by H. H. Musselman; The Use of Electricity on Farms, by H. J. Gallagher; Sterility in Cattle Serious Problem, by E. T. Hallman; Spraying for Scab Control, by W. C. Dutton; and Profiles of Michigan Soils, by J. O. Veatch.

Publications available for free distribution (Idaho Sta. Circ. 41 (1926), pp. 4).—The available station and extension publications are listed.

NOTES

Georgia Station.—J. P. Nichols, jr., of Griffin, has been appointed to membership on the board of directors, effective January 5, succeeding Judge J. J. Flynt of Griffin, who has been actively associated with the board for many years.

Michigan College.—An increased interest in forest plantings is reported. Over 450,000 seedlings have been sent out by the forestry department for spring planting, as compared with 350,000 for the entire previous year. An estimated demand for over 600,000 seedlings is predicted.

Association of Southern Agricultural Workers.—The twenty-eighth annual convention of this association was held at Atlanta, Ga., February 2 to 4, 1927, with delegates from the agricultural colleges and experiment stations of the South and from the U. S. Department of Agriculture and a considerable number of representatives of commercial and transportation organizations interested in agriculture.

The president of the association, A. M. Soule, of Georgia, declared that more than \$2,000,000,000 now wasted annually in the South through mismanagement and misdirected energy on southern farms can be saved through cooperation and coordination of the activities of agriculture, commerce, and industry. Waste in American agriculture constitutes in the aggregate an economic loss of staggering proportions. It is one of the primary reasons for the current depression complained of by farmers and is deterrent to prosperity. He asserted that in comparison with the country as a whole, southern farms contain too much so-called cultivated land, they are materially under capitalized, and lack proper equipment of buildings, implements, and livestock. The exploiting tenant is also a detrimental factor, and Doctor Soule claimed that the South lost \$1,000,000,000 in 1926 farming operations through dependence on cotton in a one-crop program. He suggested that corn, cereals, potatoes, and other food crops should be grown in an effort to balance the agricultural program. Realization by industrial and commercial leaders of an as yet unassumed responsibility and duty to the farmers seems to be one of the most feasible solutions to the problem. The farmers are not appealing for charity, but they need and must have a better coordination of effort and procedure, a balancing up of privileges and opportunities.

A program for agricultural development with the idea of bringing about greatly needed improvement in farming conditions, as set forth in resolutions adopted, recommends the abandonment of agriculture on unproductive lands and intensive cultivation of productive lands for special purposes, adequate Federal and State appropriation for extension work, continuation of the Federal crop reporting service, particularly in regard to cotton, and formulation of a permanent merchant marine policy by the Government.

Advocacy of more diversified farming with drastic reduction of cotton acreage formed the basis of the report of the Cotton Production Council. It deplored the fact that the announced acreage reduction of cotton did not offer promise of betterment of conditions in the approaching season. Planting of more food and feed on more acres was urged, as well as the guarding of American cotton against deterioration. Giving detailed suggestions for control of insect pests, the council held that present methods of dusting have proved satisfactory and should be continued.

Different angles of the problems facing the farmers of the South, principally the economic waste involved in present day agricultural operations, were discussed during the sessions, particularly by the sections of agronomy, agricultural engineering, horticulture, agricultural economics and rural sociology, phytopathology, animal husbandry, dairy husbandry, and home economics, the Cotton States Entomologists, the Southern Plant Board, and a conference of extension agronomists. A review of the scope and results of agronomic investigations conducted with cotton since the World War at the southern experiment stations, presented in the agronomy section by H. M. Steece of the Office of Experiment Stations, showed several lines which can be developed further. Continuation of physiological studies on the cotton plant and of experiments on the effects of cultivation, nutrition, and other environmental factors on the technological qualities of cotton fiber seemed warranted. The movement toward fewer and better varieties should not stop. Further inquiries could be directed toward adjustment of the plant's fertilizer needs to the quality or character of the soils, the prevention of losses of fertilizers by leaching, and the microbiological activities in cotton soils. The soils and crops agronomists could unite in the allocation of the best cotton soils to approved types and varieties of cotton with judicious fertilizer usage and correct spacing, and they must provide suitable crops for lands released from cotton production. Cooperating with the agricultural engineer the agronomist might attack the problems of storage of seed cotton, cotton seed, and lint, and undertake research in ginning. Cultural and harvesting methods must be so modified or devised as to economize labor, reduce investment, and cut production costs.

The following officers were elected: President, H. W. Barre, of South Carolina; vice presidents, H. A. Morgan, of Tennessee, and W. Newell, of Florida; secretary, W. E. Hinds, of Louisiana; and additional members of the executive committee, J. R. Ricks, of Mississippi, J. N. Harper, of Georgia, and A. M. Soule.

First International Congress of Soil Science.—Additional information recently made available concerning this congress, which will be held in Washington, D. C., June 13 to 22, indicates that it will be an event of prime importance in the world of science and agriculture. The congress is the gradual growth of the cooperative efforts of soil experts in various parts of the world. Four meetings of a less definitely organized nature have occurred since 1909 in Budapest, Stockholm, Prague, and Rome. These pioneer conferences have led the way to the forthcoming more pretentious congress with its more comprehensive scope and systematically arranged program.

It is announced that about 100 delegates from 25 or more foreign countries will be in attendance. Papers already received indicate that nearly every phase of soil physics, chemistry, microbiology, mapping, fertility, and cultivation is to be discussed. The program also includes an address by President Coolidge on the afternoon of the opening day and on the evening of the second day a reception to the delegates and their wives by Secretaries Kellogg and Jardine and the foreign ambassadors in Washington. Immediately following the 10-day series of sessions, the delegates will leave on a special train for a month's tour across the country to the Pacific coast, returning part of the way through Canada.

Dr. A. G. McCall has been designated executive secretary of the congress and has been assigned space in the Main Building of the U. S. Department of Agriculture.

Association of Land-Grant Colleges and Universities.—The forty-first convention of this association is to be held in Chicago November 15 to 17, 1927.

EXPERIMENT STATION RECORD

VOL. 56

APRIL, 1927

No. 5

A significant development of the past few months has been the renewal of interest in the promotion of research. This renewal is indicated alike by numerous public utterances from men eminent in a variety of fields and by a number of specific attempts which have been made to facilitate its orderly organization and extension.

The immediate effect of the World War on research was one of stimulation. A host of new problems arose, pressing for immediate solution and for which the inadequacy of routine experience and empirical knowledge became speedily apparent. Under these circumstances there was a widespread turning to the findings of research, and the authoritative and convincing information thereupon made available created a general feeling of confidence and of appreciation. The agricultural production campaign and the food conservation program will be recalled as classic examples of governmental policies which could hardly have been intelligently undertaken or successfully conducted had they not been based on the experimental work of many years. As time went on, scientific men were more and more systematically mobilized for effective service, listened to as never before, and their value to the Nation universally acknowledged.

Unfortunately for the permanent upbuilding of research which these conditions seemed to forecast, much of the prevailing appreciation proved to have been more or less superficial. Because of the relatively brief period of American participation in the war, it was for the most part merely the accumulated findings of long-continued inquiries that were drawn upon with such satisfaction, and the struggle ended before full realization had come that the reservoir would need replenishing. The months following the signing of the armistice were in this regard, as in many others, a period of disillusionment. The emergency past, many of the agencies which had been most active and assiduous in meeting its requirements found themselves stranded in an environment distinctly less favorable than before the war.

Most of the difficulties, both institutional and individual, were financial in nature. With the rising cost of living, the expense of carrying on research had virtually doubled, yet scientific resources

had remained well-nigh stationary. Publicly supported research was confronted by the general demand for retrenchment and a reduction of expenditures, and this attitude, while seldom carried to the point of curtailing the appropriations customarily made to research institutions, none the less commonly operated in much the same way by merely continuing grants which were no longer adequate. Similarly, endowed institutions, including the large foundations and the universities, found themselves with greatly reduced purchasing power and with a more or less unresponsive public to which to make appeal.

This period of reaction and discouragement in turn has proved to be only temporary, and there are not wanting many indications that the trend is again toward more favorable conditions. In agriculture, for example, public funds have been gradually becoming available in increasing measure. Many appropriations, to be sure, have been granted to meet specific emergencies or restricted in their scope to narrow fields of inquiry rather than for the promotion of research which is fundamental and of wide application. At the same time, there have been noteworthy exceptions in a number of States, while the Federal Government by the passage of the Purnell Act in 1925 has provided a most notable endowment of the experiment stations by increasing the Federal contributions to each State to an amount aggregating in 1930 and thereafter \$90,000 per year.

In the field of pure science the outlook has been less promising. Hon. Herbert Hoover, Secretary of Commerce, reported in an address at the Philadelphia meetings of the American Association that "some months ago our leading scientists in reviewing the organizations of pure science of the country were discouraged to find that their activities had been actually diminished during the last decade, whereas if these laboratories are to furnish the increasing vital stream of discovery to our Nation, and our normal part to the world, they should have been greatly enlarged. Moreover, they discovered that the pressures of poverty in Europe were taking a worse toll of pure science abroad."

The causes for this retrogression in this country Secretary Hoover considered to be mainly the increased teaching demands upon university and college staffs and the alluring opportunities in industrial laboratories, but he expressed the belief that "these men of pure science are the most precious assets of our country and their diversion to teaching and applied science reduces the productivity which they could and should give to the Nation. It is no fault of their own but it is the fault of the Nation that it does not give to them and to the institutions where they labor a sufficient support."

As remedies for such a situation he advocated "more liberal appropriations to our national bureaus for pure science research instead

of the confinement as to-day of these undertakings for applied science work," more liberal support of pure science research in our State universities and other publicly supported institutions, increased support from business and industry, and more generous assistance from private benevolence. He predicted great material gains from such a course, but declared that it also embodied something beyond monetary returns. "Our Nation must recognize that its future is not merely a question of applying present-day science to the development of our industries, or to reducing the cost of living, or to eradicating disease and multiplying our harvests, or even to increasing the general diffusion of knowledge. We must add to knowledge, both for the intellectual and spiritual satisfaction that comes from widening the range of human understanding and for the direct practical utilization of these fundamental discoveries. If we would command the advance of our material and, to a considerable degree, of our spiritual life, we must maintain this earnest and organized search for truth."

The address of Secretary Hoover attracted much attention and comment, yet it was by no means an isolated appeal. In speaking a few weeks later at Yale University, under the auspices of the American Institute of Chemists, the Secretary of Agriculture contributed another noteworthy presentation of the matter. Secretary Jardine was discussing the indebtedness of modern agriculture to science, and he pointed out instance after instance of specific discoveries of untold value, declaring that "it is no exaggeration to say that through the research accomplishments of recent years the average farmer to-day knows more of the science on which his industry rests and brings it into constant application than the scientist knew 50 years ago."

Yet, as he went on to say, there remains much to be done. "The agricultural field is full of problems, a large proportion of which depend for their solution on the effectiveness with which underlying problems in pure science are dealt." Accordingly, he argued for a further development of the pure sciences. "American science," he maintained, "needs to concern itself more with fundamental research than it has done heretofore. No country in the world has made such progress in applied science, but our record in pure science is not so flattering." He recalled that since 1900, when the Nobel prizes in physics, chemistry, and medicine were inaugurated, but 4 of the 76 awards have gone to the United States. "On the basis of population, the Netherlands, Denmark, Sweden, and Switzerland received one to every million inhabitants, Germany one to every two and one-half million, Austria one to every three million, England one to every three and a quarter million, France one to every four million, the United States one to every twenty-nine million. This is the situa-

tion despite the fact that we have vastly more students in colleges and universities in proportion to the population than has any other country in the world."

In his opinion this difficulty is twofold: "We are not laying enough emphasis on pure science in proportion to our emphasis on the application of science, and we are not stimulating and training an adequate personnel in scientific research."

On the latter point, that of shortage of personnel, confirmation is given in a report on research in colleges and professional schools, presented at the recent Philadelphia meeting of the American Association. In this report Prof. Maynard M. Metcalf, of Johns Hopkins University, declares emphatically that "more recruits for research are needed. Every man engaged in research finds his studies opening vistas along many most interesting and important paths which he can not himself follow. Each piece of work entered upon opens up dozens of others. 'The harvests truly are plentiful but the laborers are few.' A much larger proportion of our abler college graduates should choose the life of research—a much larger proportion. Some men, of course, have to provide food and clothing for our bodies, and this army of common laborers needs executive leaders. But the problem of better adjustment of human lives to the realities in the midst of which we live demands not only, and not even chiefly, the proper application of truth as already grasped. It demands much more the search for further truth. Man needs more and better, more nourishing, truer food for his mind, and more grace and beauty to clothe his spirit. A much larger proportion of our abler college graduates might well devote their lives to the search for truth and beauty (two aspects of the same thing), to the search for sounder knowledge of the realities in the midst of which we live and to which we must relate ourselves."

Additional testimony to the need of stimulating pure research has appeared in numerous other recent addresses, and a significant feature is the fact that it has emanated in most cases from men actively engaged in the promotion of some branch of applied science. Among these is Dr. L. O. Howard, Chief of the Bureau of Entomology. Speaking before the staff of the Federal Department of Agriculture on the subject Fifty Years of Economic Entomology, Doctor Howard set forth instance after instance of the progress which has been made in combating specific injurious pests, but he emphasized the fact that underlying all progress in applied entomology was the basic work in pure research, and he urged that provision for its upbuilding should be made in keeping with its fundamental importance.

Likewise in a symposium arranged by the American Association at the Sesquicentennial Exposition on the Contribution of Science to

the Nation, the close relationships of applied science and pure science were pointed out by several of the participants. Among them was Dr. John M. Coulter, of the Boyce Thompson Institute for Plant Research, who, in discussing the progress and service of botany, stated that "there is one fact, however, that we should always emphasize. This progress has not been due to the study of practice, for the study of practice alone is sterile. It has been due to the fundamental research which has advanced our knowledge, and incidentally this knowledge has suggested new practice."

Doctor Coulter proceeded to take up the tendencies in modern botanical research, and mentioned as the first of these the choice of problems that underlie some important practice. "This tendency was stimulated by the Great War, for at that time botany was called upon to solve many important practical problems. This tendency is so strong at present that I do not believe it will ever subside, but it should be understood. There is no evidence that it is tending to diminish research whose whole purpose is exploration of the unknown, but our recent experience has shown us that many important practices suggest fundamental problems of pure research."

A second tendency among botanical workers which he noted was their increasing realization of the fact that botanical problems are very complex and must be attacked from several points of view. "For example, in former days, in plant morphology we described structures, with no knowledge of their functions. Plant physiologists, on the other hand, described functions, with no adequate knowledge of the structures involved. Ecologists often described responses, with no adequate knowledge of either structure or function. This is all changing, and around each bit of investigation there is developing a perspective of other points of view and other methods of attack."

A somewhat similar point of view is revealed in the paper of Dr. C. E. McClung, of the University of Pennsylvania, dealing with the contribution of biology and its applications. Doctor McClung believes that "one outstanding lesson in our progress so far is that the scientific method provides the best means for determining conditions of existence and of providing the means for meeting them. To the final end of such understanding all divisions of science contribute, and it is not well to emphasize the service of one above the others. To-day one makes the chief contributions; to-morrow another. Each supports and contributes to the rest."

This trend toward research in general is characteristic of the renewed interest in the matter, and may be significant of a reaction from a long period of narrow specialization with little regard for other fields, however closely related. Two recent manifestations of

this broader spirit may be mentioned. One of these is the establishment by the Union of American Biological Societies of *Biological Abstracts*, as a medium for assembling current findings in the entire field of biological research, thereby rendering more readily accessible to the botanist, for example, the discoveries of the zoologist or the worker in animal genetics. This is, of course, a very useful service, for while, as its editors state, "the necessity for specialization, probably to an increasing extent, is recognized, on the other hand it is becoming more and more apparent that highly specialized work is more likely to result in sound progress if undertaken with at least reasonable familiarity with contributory fields." The announced intention of this journal is to summarize all biological literature appearing since January 1, 1926, and it is of interest to note that the initial number, which was issued last December, brought together 1,878 abstracts, a rate of over 22,500 per year. The large reliance upon voluntary assistance for the abstracting of this tremendous quantity of material is another significant experiment for a publication of this size and scope, and if found feasible it will be a practical exemplification of the new spirit of cooperative effort of which there are so many indications.

A second manifestation of the growing belief in the conception of research as an entity finds expression in the attempts to train prospective workers in what may be called the general principles of the subject. The course of lectures on the nature and method of research which was offered to the Graduate School of the United States Department of Agriculture in 1924-25 will be recalled as an early attempt to provide formal instruction of this kind. One of the prime objects of that course, it was stated, was "to present certain principles relating to research which apply throughout the field of science, regardless of the particular subject, in history and bibliography as well as in chemistry and agronomy, the essential qualities of research, the motive which inspires it, the attitude of mind which controls it, and the qualifications in the individual which make for success."

The course was well attended, and while admittedly an experiment seemed to demonstrate quite conclusively the practicability of this sort of instruction, although no instances have been reported of its equivalent having been offered subsequently elsewhere. Of late there have appeared, however, a number of books with much the same purpose. Some of these have been intended primarily for workers in sociology or other specialized branches, but at least one has embraced the field as a whole. This book, entitled *How to Do Research Work*, has been written, it is announced, "primarily to provide the research worker with a method of procedure from the beginning to the end of a research undertaking."

As an indication of the scope of the book and of the author's treatment of the subject; it may be mentioned that this entire process is divided into 15 steps, of which 9 precede the actual collecting of the data and 5 deal with their subsequent utilization. Over half of the 139 pages which the book contains are devoted to a discussion of such preliminaries as surveying the field, developing a bibliography, formulating or defining the problem, determining the data required, and ascertaining their availability. While the author disclaims any belief that it is possible to "formulate any rigid theory of procedure which shall be correct regardless of actual conditions in practical fields of research," he has striven to "clarify the fundamentals of all research methods," hoping that even to those already familiar with research procedure the undertakings may offer suggestions for improved methods and new viewpoints. A more detailed summary of the book is presented elsewhere in this issue.

The revival of interest in research is a matter of considerable importance to every scientific worker whatever may be his specialization. While pure research may not directly repel the corn borer or improve orcharding practice or increase the yield of milk or corn, it may ultimately lead to results no less tangible and substantial. The increasing popular realization of these things is in itself encouraging, and it may be that the movement now apparently getting under way will result in further developments of broad potential significance.

RECENT WORK IN AGRICULTURAL SCIENCE

AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Lectures on certain aspects of biochemistry, H. H. DALE, J. C. DRUMMOND, L. J. HENDERSON, and A. V. HILL (*London: Univ. London Press, 1926, pp. VIII+313, pl. 1, figs. 20*).—This volume consists of a series of lectures given at the University of London during the summer term of 1925 as follows:

Lectures by H. H. Dale on The Chemical Control of Certain Bodily Functions, including The Control of the Circulation in the Capillary Blood Vessels, Active Principles of the Pituitary Body, and The Pancreas and Insulin; lectures by J. C. Drummond, on Modern Views on the Mechanisms of Biological Oxidations, Certain Aspects of the Rôle of Phosphates in the Cell, and The Vitamins; three lectures by L. J. Henderson on Blood and Circulation from the Standpoint of Physical Chemistry; and lectures by A. V. Hill on The Physical Environment of the Living Cell and Lactic Acid as the Keystone of Muscular Activity.

Colloid symposium monograph, [IV], edited by H. B. WEISER (*New York: Chem. Catalog Co., 1926, vol. 4, pp. 378, figs. 126*).—This volume contains the 24 papers which were presented at the Fourth National Symposium on Colloid Chemistry held at Cambridge, Mass., June 23–25, 1926. Of particular interest is the opening paper entitled A Survey of the Main Principles of Colloid Science, by J. W. McBain of the University of Bristol, England, the foreign guest of honor at the symposium. The third symposium has been noted previously (*E. S. R.*, 54, p. 802).

Practical agricultural chemistry.—Quantitative analysis, H. WIESSMANN (*Agrikulturchemisches Praktikum. Quantitative Analyse. Berlin: Paul Parey, 1926, pp. IX+329, figs. 95*).—This laboratory manual of quantitative agricultural chemistry requires no preliminary training in quantitative analysis, the general principles of which are discussed briefly in the opening sections on gravimetric and volumetric analysis, with special reference to fertilizers. These are followed by sections on the analysis of crops, manures, feeding stuffs, milk, and soils.

The use of collodion sacks in obtaining clear soil extracts for the determination of the water-soluble constituents, W. H. PIERRE and F. W. PARKER (*Soil Sci.*, 23 (1927), No. 1, pp. 13–32).—In this contribution from the Alabama Experiment Station, the advantages and disadvantages of different methods of obtaining clear soil extracts are discussed, and a detailed study is reported of the dialysis method with reference to the best technique for preparing the collodion sacks and the extracts, the time necessary for establishing equilibrium between the solution inside and outside the sacks, and the use of the method in determinations of the H-ion concentration, nitrate nitrogen, phosphorus, and calcium of soil extracts.

In the preparation of the sacks, Loeb's procedure (*E. S. R.*, 54, p. 108) was used, with slight modifications. It was found possible to make 20 sacks in an hour and to use the sacks several times.

The time required for equilibrium was found to depend upon the kind of ion and the kind and amount of shaking. For readily soluble ions such as

hydrogen, chlorine, and nitrate two hours of shaking of the flask in a drawer-type shaker or 18 hours standing with occasional shaking by hand were found to establish complete equilibrium. For more difficultly soluble ions such as phosphate, calcium, and potassium an arbitrary time of 18 hours of standing with hand shaking of the flasks once every hour during the day is recommended.

A comparison of the results obtained in H-ion concentration determinations of soil extracts prepared by the collodion sack method, of filtered soil extracts determined by the colorimetric method, and of soil suspensions determined by the electrometric method showed good agreement.

In the nitrogen determinations a comparison was made between soil extracts prepared by dialysis, modified suction filtering, and flocculation by the Harper method (E. S. R., 51, p. 111). The results showed good agreement except that the flocculation method gave poor checks. The use of flocculations was found to necessitate the making of a nitrate determination on the reagents, while the filtration method was open to the possibility of loss of nitrates through absorption. The collodion sack method eliminated both of these sources of error. Adsorption of color in the extracts by the carbon black "G Elf" was found not to affect the nitrate nitrogen content of the extract.

In the phosphorus and calcium determinations, the collodion sack method and the suction filter method gave extracts of practically the same concentration.

"It is evident from these studies that the collodion sack method is not only adaptable to the securing of extracts for determinations of H-ion concentration, of nitrates, and of water-soluble phosphorus and calcium, but also that it should be equally well adapted for use when any of the other water-soluble constituents of the soil are to be determined. Not only does it furnish large amounts of clear extract from which all water-soluble constituents can be determined by even the most exacting colorimetric methods, but also its use is simple."

The composition of mesquite gum; the isolation of *d*-galactose and *l*-arabinose, E. ANDERSON and L. SANDS (*Jour. Amer. Chem. Soc.*, 48 (1926), No. 12, pp. 3172-3177).—Further studies on the composition of mesquite gum (E. S. R., 55, p. 10) are reported. By successive hydrolysis with sulfuric acid in 4 per cent concentration at 80° C. and 3 per cent concentration in the autoclave or boiling water bath, *l*-arabinose was obtained to the extent of 50.7 per cent, *d*-galactose 18.7 per cent, and an aldehyde acid belonging to the glucuronic acid group 13 per cent of the gum. These products, together with the moisture, ash, and a small amount of nitrogenous material, accounted for nearly all of the gum.

Vitamins and other constituents of grape-fruit rind, S. G. WILLIMOTT and F. WOKES (*Biochem. Jour.*, 20 (1926), No. 6, pp. 1299-1305, figs. 3).—Data are reported on the composition of the rind of ripe West Indian grapefruit and on the content of vitamins A and B in the flavedo (outer rind) and rind oil.

The flavedo, which constitutes from 4 to 5 per cent of the total weight of the grapefruit, had a moisture content of from 70 to 75 per cent as determined by drying at 40° C. The H-ion concentration of both flavedo and albedo (inner rind) ranged from pH 4.3 to 4.6 and of the juice from pH 5.1 to 5.2. An extract of the fresh flavedo in 90 per cent alcohol gave the following results on analysis: pH 4.4, specific gravity at 15° 0.9497, total solids 5.74 per cent, reducing sugar 2.8 per cent, and total sugar after hydrolysis at 40° 3.6 per cent.

In the vitamin A experiments, which were conducted on only three rats, the Hopkins basal vitamin A-free diet was used, with vitamin D supplied by direct irradiation of the animals. The addition to the basal diet of 0.5 gm.

daily of finely minced fresh flavedo caused a resumption of growth at a slow rate for a short period. When growth had again ceased an equivalent quantity of 90 per cent alcoholic extract was fed, with a slight and temporary resumption of growth. It was concluded that the flavedo contains a small amount of A. The oil extracted from the fresh rind was found to contain only slight traces of A. The flavedo proved to be quite rich in vitamin B when tested by methods used in the previous study of the vitamin B content of lemon rind (E. S. R., 55, p. 593). An amount of 0.5 gm. daily brought about vigorous resumption of growth, but the 90 per cent alcohol extract did not have so pronounced an effect. This was thought to indicate that the alcohol had not completely extracted the vitamin B from the rind.

The flavedo was found to give a strong peroxidase reaction, which may possibly account for its small content of vitamin A.

Antineuritic vitamin [trans. title], B. C. P. JANSEN and W. F. DONATH (*Chem. Weekbl.*, 23 (1926), No. 16, pp. 201-203; *Eng. abs.*, p. 203).—In this study of the antineuritic vitamin content of rice bran, with attempts at its isolation, tropical singing birds (*Munia maja*) were used to test the potency of the various preparations as recommended in a previous paper (E. S. R., 44, p. 171).

The bran was extracted in portions of 100 to 250 kg. at an acidity giving a final H-ion concentration of the extract of about pH 4. Attempts at purification by precipitation with mercuric sulfate, phosphotungstic acid, etc., were unsuccessful, but on treatment with acid clay, a form of fuller's earth, about 80 per cent of the vitamin was adsorbed. The active material was set free with barium hydroxide and further purified with norit, which removed some of the impurities but did not precipitate the vitamin. From 3 to 4 gm. of a semi-crystalline residue was obtained as the final product from 100 kg. of bran. This substance did not reduce Fehling's solution even after hydrolysis, and contained from 10 to 11.5 per cent of nitrogen. About 0.05 mg. per day was sufficient to protect the birds against polyneuritis for from 15 to 20 days.

Effects of various agents on colour tests for vitamin A, S. G. WILLIMOTT, T. MOORE, and F. WOKES (*Biochem. Jour.*, 20 (1926), No. 6, pp. 1292-1298, fig. 1).—On further examination the Fearon pyrogallol test for vitamin A (E. S. R., 55, p. 712), at first thought to be specific for this vitamin (E. S. R., 56, p. 112), has been demonstrated to be unreliable. Cod-liver oil sulfonated by treatment with concentrated sulfuric acid was found to give positive results with the Fearon reagent but negative with all of the other color reagents proposed. Biological tests conducted with the sulfonated oil showed it to be devoid of vitamin A. Similarly, cod-liver oil after treatment with phosphorus pentoxide still gave the Fearon but not the other color tests. Cod-liver oil exposed to irradiation for varying lengths of time gave negative results with arsenic trichloride and antimony trichloride after irradiation for 1½ hours, but positive with the Fearon reagent after over 3½ hours. Arsenic trichloride and antimony trichloride gave parallel results at different stages of the destruction of vitamin A by irradiation. Of the two, the antimony trichloride test is recommended as the more suitable in that the color persists a little longer. In either case it is recommended that the readings be made not more than 30 seconds after mixing. Absolute dryness of the chloroform is considered essential.

A critical study of colour tests suggested for vitamin A, O. ROSENHEIM and T. A. WEBSTER (*Lancet* [London], 1926, II, No. 16, pp. 806, 807).—In this brief report of a comparison of the Rosenheim-Drummond arsenic trichloride (E. S. R., 55, p. 307) or the Carr and Price antimony trichloride test for vitamin A (E. S. R., 56, p. 10) with the Fearon pyrogallol test (E. S. R., 55, p.

712), evidence is presented along chemical and biological lines that the Fearon test is not related to vitamin A.

The unsaponifiable fractions of active oils gave the arsenic trichloride or antimony trichloride test with increased intensity but negative pyrogallol tests. The liver oils of birds and mammals also gave positive tests with antimony trichloride and negative with pyrogallol, while some body fats gave negative tests with antimony trichloride and positive with pyrogallol.

In the biological tests sardine oil was ineffective as a source of vitamin A in growth experiments on rats, although giving a pyrogallol test as pronounced as cod-liver oil. Pig-liver fat gave results with antimony trichloride, and feeding tests showed it to possess a high content of vitamin A but a negative test with the Fearon reagent.

Incidentally attention is called to the possibility of using the peroxide test in connection with other tests when judging the value of cod-liver oil as a source of vitamin A. An old sample of cod-liver oil reacting negatively to the arsenic trichloride and growth tests was found to give a strong peroxide reaction. The authors state in conclusion that it is surprising that the knowledge of the destructive action of both light and air on vitamin A has not led to the more extensive use of small brown glass bottles for the distribution of cod-liver oil.

The nature of Fearon's colour reaction and its non-specificity for vitamin A. O. ROSENHEIM and T. A. WEBSTER (*Biochem. Jour.*, 20 (1926), No. 6, pp. 1342-1345).—Essentially noted above.

The antirachitic vitamin D of cod-liver oil. S. G. WILLIMOTT and F. WOKES (*Pharm. Jour. and Pharm.* [London], 4. ser., 63 (1926), Nos. 3285, pp. 473-476; 3286, pp. 495-497, figs. 2; 3287, pp. 521-524, fig. 1).—This paper consists of a survey and critical discussion of the literature on the fat-soluble vitamins A and D, particularly as regards methods for their determination, with comments from the authors' experience.

In their opinion one of the most satisfactory sources of vitamin A uncontaminated by vitamin D is an acetone-ether extract of dried spinach which is said to contain from 200 to 300 times as much vitamin A as fresh spinach and to be practically devoid of vitamin D. Materials suggested as sources of vitamin D free from A are irradiated cholesterol and the vitamin D concentrate of cod-liver oil prepared by the method described by Zucker (*E. S. R.*, 49, p. 608). The various color tests for vitamin A are criticized on account of the fact that as yet they have been tested chiefly on cod-liver oil (a mixture of vitamins A and D), rather than on pure vitamin preparations, and because of the evanescence of the color. To overcome the latter difficulty, the authors recommend the use of stabilizing agents such as resorcinol. In considering tests for the quantitative determination of vitamin D, the McCollum line test is criticized as requiring considerable time, skill, and pathological experience for its successful application. The method employed by Luce (*E. S. R.*, 52, p. 277) is considered unsatisfactory on account of confusion between the growth-promoting and antirachitic values. "It appears to us that the only sound technique for estimating vitamin D is one based on definite pathological changes which have been proved experimentally to be due to absence of that vitamin only. These specific pathological changes must be ascertained by feeding rats on a diet deficient in vitamin D only, and containing the other three vitamins, A, B, and C." It is emphasized that in such a method attention should be paid to the Ca:P ratio of the diet, a suggested optimum for which is 1.4 to 1.6.

The possibility of using for the determination of vitamin D the absorption of calcium from the intestine as measured by the reaction of the intestine is

discussed at considerable length. A repetition of the work of Zucker and his associates (E. S. R., 49, p. 65) has been undertaken, preliminary results of which are thought to indicate that in rachitic animals the relations between the pH of the feces, the calcium balance, and the condition of the animal in regard to rickets are much more complicated than would appear from Zucker's work.

A bibliography of 94 titles is appended.

A rapid and reliable test for vitamin D, H. JEPHCOTT and A. L. BACHARACH (*Biochem. Jour.*, 20 (1926), No. 6, pp. 1351-1355, figs. 3).—The test described was suggested by the observation of Zucker and Matzner (E. S. R., 51, p. 464) that the H-ion concentration of the feces of rats on a rachitic diet is on the alkaline side of neutrality, but is rapidly changed to the acid side on the administration of antirachitic substances or by irradiation. The technique for the test is as follows:

Inbred white rats from 20 to 40 days old and weighing from 40 to 60 gm. are fed ad libitum on the Zucker diet 401 composed of patent flour 85, powdered egg albumin 10, calcium lactate 2.8, ferric citrate 0.2, and sodium chloride 2 per cent, with the addition of from 2 to 3 gm. of fresh spinach daily as a source of vitamins A and B. The cages used have false bottoms consisting of zinc screens of such a mesh as to allow passage of concentrated food but not of feces. The feces are collected daily, weighed, taken up in water to make a 2 per cent suspension, and after thorough shaking poured through loose wads of cotton into hydrogen electrodes of the rocking type for electrometric determinations of the H-ion concentration. The determinations are made every 3 or 4 days until the suspension is definitely alkaline, and then more frequently until two consecutive readings give a value of pH 7.3 or more. The material to be tested for vitamin D is then administered to the rats, and after 2 or 3 days daily determinations are made of the feces until two consecutive readings give a value of pH 6.7 or less. The quantity of antirachitic substance necessary to produce the change is considered an antirachitic unit.

It is stated that since the test was first adopted over 280 groups of 4 animals each have been tested, with the development of pH values above 7 in from 10 to 15 days and maintenance of this level as long as the rachitic diet was being fed. The administration of substances without antirachitic effect did not alter the pH values, but samples of cod-liver oil and irradiated cholesterol known to have definite calcifying properties brought about a prompt reduction in the pH of the feces, as did irradiation.

Although it is admitted that similar effects have been produced by the use of acid substances or by diminishing the calcium-phosphorus ratio of the diet, it is thought that this does not detract from the usefulness of the test for substances of known origin such as cod-liver oil extracts.

Determination of fat in malted milk, E. S. ROSE (*Amer. Jour. Pharm.*, 98 (1926), No. 11, pp. 595, 596).—Following the trial of various methods of determining fat in malted milk, the author recommends the following modification of the Werner-Schmid method:

A sample weighing from 0.5 to 1 gm. is emulsified with 5 cc. of hot water in a large test tube and then heated with 10 cc. of concentrated hydrochloric acid in a water bath for 5 minutes. After cooling, the mixture is shaken for 2 minutes with from 25 to 30 cc. of a mixture of U. S. P. benzoin 2 parts and washed ether 1 part. To avoid loss of liquid through the escape of vapor during shaking, the tube is fitted with a cork stopper containing a piece of glass tubing about 4 in. long bent at a right angle and attached to a short piece of rubber tubing. During the shaking the rubber tube is closed with the fingers except occasionally when the liquid is allowed to flow back into the test tube by releasing the pressure. After the shaking the rubber tube is removed, the

bent glass tube and stopper are washed with a few cubic centimeters of the extraction mixture, and the extract removed by blowing on a dry filter into a tared flask. The whole process is repeated twice, after which the benzine and ether are removed from the combined extracts by distillation, and the flask is dried to constant weight in an oven at 95 to 100° C.

Cider-making trials for the season 1924-25, O. GROVE (*Univ. Bristol, Agr. and Hort. Research Sta. Ann. Rpt., 1925, pp. 119-128*).—Washing of all apples to be used in cider making is recommended, and a simple contrivance for continuous washing and conducting the apples to the mill is described. The washing not only removes the dirt and débris, but automatically eliminates badly decayed apples which sink to the bottom of the vat, while the sound apples float.

The advantages and disadvantages of pasteurizing cider and inoculating it with a pure culture of yeast instead of allowing it to ferment naturally are discussed, and a new type of pasteurizing apparatus, consisting of a preheater and pasteurizer proper, is described. In this the cold juice entering and the warm juice leaving the pasteurizer pass through alternating coils, by means of which the pasteurized juice leaves the apparatus cold and the cold juice becomes partly heated before entering the pasteurizer, where very little steam is needed to maintain the required temperature of 70° C. (158° F.).

The principal advantages of pasteurization are considered to be the destruction of harmful organisms and a slowing down of the rate of fermentation after inoculation. Possible disadvantages are changes in the flavor of the juice resulting from the heating and the cost of the treatment. The only difference in flavor is said to be a slight lack of freshness which is difficult to detect. The cost of the process with the particular type of pasteurizer used is estimated to be very low.

Theory and practice in processing, C. O. BALL (*Canner, 64 (1927), No. 5, pp. 27-32, figs. 2*).—An attempt to interpret to the commercial canner the significance and application of the results obtained in studies of the heat resistance of bacteria and the rate of heat penetration in canned foods.

Pickle fermentation, F. W. TANNER (*Canning Age, 7 (1926), Nos. 2, pp. 121-123; 3, pp. 353-356*).—This is a discussion of the processes involved in the curing or fermentation of cucumber pickles under factory conditions, of the chemical changes taking place in normal fermentation and in the deterioration of brine pickles, and of improvements in the usual processes by means of which spoilage may be reduced. The suggestions include the use of desirable bacteria as starters, the proper care of empty tanks and barrels, and the preservation and control of the acidity of the brine.

On the refrigeration and preservation of fish.—The first report [trans. title], Z. OGURA and K. FUJIKAWA (*Chosen Fishery Expt. Sta. Bul. 1 (1925), pp. 8+3+162, pls. 3, figs. 12; Eng. abs., pp. 8*).—This report of an investigation of the practicability of brine freezing as a method of preserving fish includes a description of the freezing apparatus used and data on the factors affecting the speed of freezing of the fish and the length of time the fish remain frozen during transportation, on the comparative value of brine freezing and cracked ice and ice water preservation as determined by chemical analyses of the fish, on the extent of salt penetration during the freezing process, and on the physical changes taking place in the fish during freezing and thawing.

METEOROLOGY

The dependence of yield of crops in Prussia on precipitation and temperature [trans. title], E. LESS (*Landw. Jahrb., 64 (1926), No. 2, pp. 241-296, figs. 24*).—The relation of yield of wheat, rye, barley, oats, potatoes, clover,

alfalfa, and meadow hay to precipitation and temperature in different parts of Prussia during the 15 years 1899–1913 is dealt with in 3-year periods and with reference to seasonal variations. The studies indicate that under the usual climatic conditions prevailing in Prussia the yield of these crops is more obviously dependent upon precipitation than upon temperature during the growing season as well as preceding it. Incidentally, it was observed that variations in solar radiation did not appear to be of very great importance.

Rainfall interception by plants, J. PHILLIPS (*Nature* [London], 118 (1926), No. 2980, pp. 837, 838).—The work of Marloth, De Forest (E. S. R., 50, p. 315), and Horton (E. S. R., 42, p. 317) on this subject is briefly referred to. The author concludes from his own investigations that there is a decided interception loss due to plant cover, especially with fine rains.

A dew-graph areometer [trans. title], P. I. ANDRIANOV (*Nauch. Agron. Zhur. (Jour. Landw. Wiss.)*, 3 (1926), No. 10, pp. 661–663, figs. 3; *Eng. abs.*, p. 663).—A modification of the dew areometer previously noted (E. S. R., 54, p. 13) is described, and observations with it at the Meteorological Observatory of Moscow are reported. The maximum dew during May to July was recorded one hour after sunrise. This was maintained for one hour, then rapid evaporation took place.

Forecasting spring weather from phenological data, I. D. MARGARY (*Quart. Jour. Roy. Met. Soc. [London]*, 52 (1926), No. 220, p. 404).—This is a brief preliminary note on forecasts based on the Marsham phenological observations on seven selected plants during January–May, comparing the forecasts with actual results. It is stated that the forecast for the spring of 1926 merely suggested that it would be “rather mild and early,” which proved to be “somewhat of an understatement.” The phenological data are stated to point to a cold and late spring in 1927.

Climatological data for the United States by sections, [September–October, 1926] (*U. S. Dept. Agr., Weather Bur. Climat. Data*, 13 (1926), Nos. 9, pp. [196], pls. 4, figs. 2; 10, pp. [195], pls. 4, figs. 2).—These numbers contain brief summaries and detailed tabular statements of climatological data for each State for September and October, 1926.

Meteorological observations at the Massachusetts Agricultural Experiment Station, J. E. OSTRANDER and W. H. PARKIN (*Massachusetts Sta. Met. Buls.* 455–456 (1926), pp. 4 each).—The usual summaries are given of observations at Amherst, Mass., during November and December, 1926. The December number gives an annual summary, from which the following data are taken:

Mean pressure 29.981 in.; mean (hourly) temperature 45° F., highest 100° July 22, lowest –10° December 27; total precipitation 40.92 in., snowfall 76 in.; cloudiness 2,274 hours; bright sunshine 2,188 hours (49 per cent); prevailing direction of wind, west; total movement 49,840 miles, maximum daily 441 miles November 16; last frost in spring May 6, first in fall September 24; last snow April 27, first November 9.

SOILS—FERTILIZERS

Review of German literature on soil science and plant physiology in 1925 (*Soil Sci.*, 22 (1926), No. 3, pp. 213–219).—A list of 38 abstracts is presented.

Methods of practical application of research on soil physics, A. NOSTITZ (*Internatl. Rev. Sci. and Pract. Agr. [Rome]*, n. ser., 4 (1926), No. 1, pp. 38–42, figs. 3).—In a contribution from the Technical High School of Munich methods for the practical interpretation of the results of physical studies of soils are outlined.

The relation of light to soil moisture phenomena, L. B. LINFORD (*Soil Sci.*, 22 (1926), No. 3, pp. 233-252, figs. 6).—Studies conducted at the Utah Experiment Station showed that soils at the moisture content corresponding to the hygroscopic coefficient will continue to absorb large amounts of water when exposed to a saturated atmosphere in a dark constant temperature chamber. The amount that the soil will absorb is in excess of the moisture content at the wilting coefficient. The equilibrium point reached under any but isothermal conditions was found to be a function of the light intensity in the apparatus containing the soil. Laboratory light was sufficiently intense to cause serious differences in temperature between transparent and dark bodies.

A theoretical discussion of the problem is also presented.

Some observations upon the effect of the size of the container upon the capillary rise of water through soil columns, H. A. WADSWORTH and A. SMITH (*Soil Sci.*, 22 (1926), No. 3, pp. 199-211, figs. 2).—Studies conducted at the California Experiment Station are reported in which evidence was obtained that the extent of capillary rise through soil masses from a free water table is affected by the cross sectional area of the column under consideration. In general large columns showed a greater rise after a given time than did small columns.

The results are taken to indicate that the size of the container is of greatest importance in columns with a cross sectional area of less than 25 sq. in. Intensive soil moisture samples indicate that there is no uniform distribution of moisture throughout the length of the capillary columns.

A point or zone of maximum moisture content was found at an appreciable distance above the water table. Some evidence was obtained that in columns of small cross sectional areas the distance of this zone of maximum moisture content above the water level varies with the size of the column, being greater as the columns become larger. When the cross sectional areas of the columns became greater than about 16 sq. in. further increases in size did not affect the relative position of this zone of maximum moisture content.

Moisture samples taken at various points in the same horizontal plane within the column indicated a fairly uniform and consistent moisture content at all points. No experimental evidence was obtained to support the belief that the upward rise as indicated through the glassed face of a capillary column is not indicative of the rise within the whole soil mass.

Investigations into the resistance of sandy soils to wetting, R. ALBERT and M. KÖHN (*Internatl. Rev. Sci. and Pract. Agr.* [Rome], n. ser., 4 (1926), No. 2, pp. 312-318).—Studies conducted at the Soil Science Institute of the Eberswalde Forestry High School are briefly reported which indicate that the vegetable humus coverings of the grains of soil play, at least in many cases, a decisive part in the saturability of the soil concerned.

The relation between the electrokinetic behavior and the base exchange capacity of soil colloids, S. MATTSO (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 6, pp. 458-470, figs. 3).—Studies conducted by the U. S. D. A. Bureau of Soils showed the existence of a relationship between the electrokinetic behavior, the base exchange capacity, and the composition of soil colloids. The quantities of methylene blue required to neutralize the negative charge of different soil colloids corresponded closely to the total contents of exchangeable bases.

The charge on the soil colloids varied markedly according to the kind of exchangeable base present. When a given colloid was saturated with sodium, the charge was much higher than when saturated with calcium. When the exchangeable bases were replaced by the methylene blue cation, the colloids

became isoelectiric. The contents of exchangeable bases and the quantities of methylene blue required to neutralize the negative charge of the various soil colloids paralleled the $\frac{\text{SiO}_2}{\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3}$ ratios.

Base exchange in soil colloids and the availability of exchangeable calcium in different soils, F. W. PARKER and W. W. PATE (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 6, pp. 470-482).—Studies conducted at the Alabama Experiment Station are reported, the purpose of which was to determine (1) the exchangeable base content of the colloidal and noncolloidal soil constituents, (2) the relation between the chemical composition of soil colloids and their content of exchangeable base, (3) the influence of the nature of the exchangeable base on soil properties, and (4) the availability of exchangeable calcium in different soils.

It was found that all of the exchangeable base in a soil is in the colloidal material. It was possible to determine the colloid content in this soil by the ratio method, using base exchange data. There was a good correlation between the $\text{SiO}_2/\text{R}_2\text{O}_3$ ratio of soil colloids and their content of exchangeable base. Colloids having a high ratio were high in exchangeable base.

The nature of the exchangeable base was found to influence the heat of wetting and the absorption of water by the soil. Soils saturated with monovalent bases had a lower heat of wetting and, with the exception of sodium, absorbed less water than soils saturated with divalent bases. The exchangeable calcium in soils having a high H-ion concentration was found to have a low availability while that of calcium in nonacid soils was high.

The effect of the nature of the exchangeable bases upon the retention of anions by soils, C. H. SPURWAY (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 6, pp. 497-515, figs. 4).—Studies conducted at the Michigan Experiment Station are reported from which the conclusion is drawn that of the many soil factors influencing the fixation of anions, the kind and quantity of base, the ratio of base to base and of base to acid, and the degree of hydrolysis and ionization of both soil bases and soil acids are of great importance.

The influence of electrolytes on the absorption of hydrogen ions, B. AARNIO (*Internatl. Rev. Sci. and Pract. Agr.* [Rome], n. ser., 4 (1926), No. 1, pp. 31-37, figs. 4).—Studies are reported which showed that the electrolytes potassium chloride and calcium chloride can not expel H ions from clay. It was observed that the potassium chloride solution causes an increase in the acidity of the soil solution as compared with pure water solutions. This is attributed to the interchange of the potassium ions with aluminum ions and the consequent hydrolysis of the resulting aluminum compounds. It was also found that if the ions absorbed in a soil are to be determined, an acid must be used, because the H ions very strongly displace other ions.

The influence of electrolytes on different types of suspensions of clay, F. WIRYN (*Internatl. Rev. Sci. and Pract. Agr.* [Rome], n. ser., 4 (1926), No. 1, pp. 43-82).—A detailed report of a highly technical study of the influence of electrolytes on different types of clay suspensions is presented.

No conclusions are drawn beyond the fact that the results point to the very great importance of lime in agricultural practice, especially in districts in which the amount of rainfall exceeds the evaporation and from which a certain amount of electrolytes, including calcium, is removed from the upper level of the soil and carried into the lower levels. It was found that when the soil has a high lime content the carbonic acid present possesses almost the same properties as sulfuric acid. Consequently in these cases the carbonic acid set free from the roots of the plants can cause flocculation of the finest soil

particles and improve the physical qualities, provided no other factors have a retarding influence on the development of the plants. If, however, the lime content of the soil is not great then gypsum may become of considerable importance, since in comparatively small concentrations it can cause flocculation of the finest soil particles.

Reciprocal repression by calcic and magnesian additions in surface soil, W. H. MACINTIRE (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 6, pp. 482-497, figs. 4).—Studies conducted at the Tennessee Experiment Station are reported from which the conclusion is drawn that solutions of calcium or magnesium bicarbonates will not effect reciprocal interchange as measured by the loss of soluble salts, irrespective of the preponderance of either in soils; nor will potassium be replaced by neutral salts of either calcium or magnesium if an appreciable quantity of the bicarbonate of either is present. The results indicate that the presence of an added excess of either bicarbonate will result in a repression of the hydrolysis of the native content of the other bicarbonate.

The absorption of iron by soils, H. C. DOYNE and C. G. T. MORISON (*Soil Sci.*, 22 (1926), No. 3, pp. 163-173, figs. 2).—Studies conducted at the University of Oxford, England, are reported, the purpose of which was to show (1) the extent to which iron is removed from solution by various soils, and (2) the soil constituents which are concerned in the removal.

The absorption of iron by 18 air-dried soils in contact with a ferric chloride solution was determined. Of these soils there were three which showed complete removal of the iron from the solution used, and all these contained considerable quantities of calcium carbonate. The results showed, however, that although calcium carbonate is an appreciable and important factor in the absorption of iron other factors such as the gross amount and activity of clay and ferric oxide and organic matter contents also contribute.

The conclusion is drawn that the absorption of iron by the clay fraction of a soil can be attributed chiefly to the effect of exchangeable bases in producing colloidal ferric hydroxide from the solution of ferric chloride by neutralizing the acid formed by hydrolysis, and that this ferric hydroxide effects a mutual flocculation with the clay. It is considered probable that the ferric hydroxide gel in the sandy loam soils tested absorbs iron in the same manner as does the clay fraction. The results also indicate that organic matter apparently is a factor in the absorption of iron, partly because of the amount of exchangeable bases held.

The iron-absorbing powers of soils showed an increase as the weight of calcium carbonate was increased, so that as soon as any additional ferric hydroxide was formed it was immediately removed by the colloidal material in the soil. On increasing the quantities of added calcium carbonate the soil suspensions became more and more turbid up to the point where all the iron was absorbed, when a very complete and extraordinarily rapid flocculation took place. As the concentrations of iron in the solution diminished, the power of the soil to remove iron apparently decreased.

Soil survey of Lake County, Florida, A. E. TAYLOR ET AL. (*U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils*, 1923, pp. III+401-439, pls. 4, fig. 1, maps 2).—This survey, made in cooperation with the Florida Department of Agriculture, deals with the soils of an area of 649,600 acres lying in the Lake Region of central Florida. The county embraces three topographic divisions, namely, the rolling upland in the southern portion; the flatwoods in the extreme southern, southwestern, extreme eastern, and northeastern parts; and the undulating to gently rolling uplands in the remaining sections. The drainage of the flatwoods is poor, and that of the rolling and undulating to gently rolling uplands is good.

The poorly drained soils have dark colored surfaces, comparatively thick organic layers, and gray subsoils, whereas the well drained soils are featured by gray surfaces, comparatively thin organic layers, and yellowish gray, yellow, and brown subsoils. The soils vary in texture from loose sands to clay loams and peat, but types of fine sand texture predominate. Including swamp, water and grass, peaty muck, peat, and shell mounds, 20 soil types of 11 series are mapped, of which the Norfolk and Leon fine sands cover 23.7 and 14.8 per cent of the area, respectively.

A list of the common and scientific names of characteristic plants found in the county and of various soil types on which they are usually found is appended.

Soil survey of Bibb County, Georgia, S. W. PHILLIPS ET AL. (U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1922, pp. III+1083-1120, fig. 1, map 1).—This survey, made in cooperation with the Georgia State College of Agriculture, deals with the soils of an area of 160,000 acres lying in the Piedmont Plateau and the Coastal Plain in central Georgia. The topographic features include rolling to hilly uplands, terraces, and bottoms that are narrow in the Piedmont section. The uplands are well drained with the exception of some sinks in the southern part of the county, while the bottoms are subject to overflow.

The heavy red lands of the northern part and the light sandy soils of the southern part are the two distinct classes of soils in the county. Including meadow, 19 soil types of 15 series are mapped, of which the Norfolk and Wilkes sandy loams, the Congaree silty clay loam, the Cecil clay loam, and the Norfolk sand cover 15.7, 14.2, 13.5, 10.9, and 10.5 per cent of the area, respectively. Chemical analyses of some of the prevailing types are included.

Soil survey of Muscogee County, Georgia, S. W. PHILLIPS and A. T. SWEET (U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1922, pp. III+1121-1158, fig. 1, map 1).—This survey, made in cooperation with the Georgia State College of Agriculture, deals with the soils of an area of 142,720 acres lying in western Georgia, which is divided into two distinct parts by the fall line between the Piedmont Plateau and the Coastal Plain. The topography ranges from smooth and gently rolling to steep and broken. The county as a whole is well drained.

The soils of the county are prevailingly light in color, ranging from gray to red. They are dominantly low in organic matter. The Piedmont soils are of residual origin. Including meadow, 23 soil types of 16 series are mapped, of which Norfolk sand, Cecil sandy clay loam, Norfolk and Hoffman sandy loams, and meadow cover 19.5, 11.9, 10.9, 10.1, and 10.1 per cent of the area, respectively. Chemical analyses of some of the prevailing types are included.

Soil Survey of Mercer County, West Virginia, A. W. GOKE (U. S. Dept. Agr., Adv. Sheets Field Oper. Bur. Soils, 1923, pp. III+247-269, fig. 1, map 1).—This survey, made in cooperation with the West Virginia Geological Survey, deals with the soils of an area of 271,360 acres lying in the Appalachian Plateau in southern West Virginia. The topography is rough to gently rolling. The principal drainage system of the county consists of the Bluestone River and its tributaries.

The soils of the uplands are of residual origin, and those occupying the flood plains are alluvial deposits washed from the surrounding uplands. Including rough stony land, 15 soil types of 10 series are mapped, of which Dekalb silt loam, stony loam, and loam cover 44.5, 15.4, and 12.6 per cent of the area, respectively.

Why are serpentine and other magnesian soils infertile? A. GORDON and C. B. LIPMAN (Soil Sci., 22 (1926), No. 4, pp. 291-302).—In studies conducted at the University of California of 10 widely different serpentine soils

from different localities, it was found that all these soils were deficient in important available ions. The nitrate content was low even where the total nitrogen content was considerable, and most of the soils had a pH value generally of about 8.1. The ratio of magnesium to the total concentration of the soil extract was not necessarily high. A few of the soil extracts were deficient in phosphate and potassium.

The addition of nitrate improved the growth of barley in culture solutions in three of the soils. The lowering of the pH value also improved plant growth where necessary ions had been added. The addition of potassium improved root development, and the addition of phosphate increased plant growth. The addition of magnesia to solutions from one soil had no effect on plant growth.

There was a strong parallelism between the composition of serpentine soils and the vegetation found on them.

Some notes on Nelson soils and their treatment, T. RIGG (*Cawthron Inst., Nelson, N. Z., Dept. Chem. and Agr. Bul. 3, n. ser. (1926), pp. 8*).—Practical information on the fertility treatment of these soils is presented.

The absorption of fertilisers by Ceylon soils, A. W. R. JOACHIM (*Trop. Agr. [Ceylon], 66 (1926), No. 4-5, pp. 303-308*).—The absorptive power of Ceylon soils was found to vary with the nature, compactive power, porosity, and moisture content of the soil. The loss of added fertilizer was slightly greater in the drainage waters from moist soils than from air-dried soils and was also slightly greater from loosely packed soils than from those more firmly compressed.

The nitrates of sodium and potassium were least absorbed, while soluble superphosphate and the sulfates of potassium and ammonium were most absorbed. Potassium chloride was absorbed to a less extent than potassium sulfate. The amount of fertilizer absorbed by a soil increased with time, but by far the greater part was found to take place during the first two hours.

When the fertilizer was incorporated in the upper 3 in. of a 6-in. layer of soil the losses due to a rainfall of 2 in. during 2 hours were hardly appreciable. When a further rainfall of 1 in. occurred 24 hours later a very small proportion of the fertilizer was drained from the top 6 in. This was most marked in the case of the nitrates. The conclusion is drawn that there is less fertilizer leached from soils under the action of rainfall than is generally supposed.

Soils and fertilizers and the maintenance of soil fertility by the use of manures, green manures, and fertilizers in Ontario, S. WATERMAN and G. N. RUHNKE (*Ontario Dept. Agr. Bul. 322 (1926), pp. 54, figs. 12*).—This extensive discussion presents a large amount of practical information relating to soil management and the selection, purchase, and use of fertilizers and fertilizer materials.

Influence of manures and microorganisms on H-ion concentration in the soil, E. AGHNIDES (*Internatl. Rev. Sci. and Pract. Agr. [Rome], n. ser., 4 (1926), No. 2, pp. 294-306, figs. 3*).—Studies are reported which showed a striking parallelism of variation of the yields of kidney beans and of the pH values of soils under different manurial treatments. The numerical importance of the pH value also measured the bacterial activity of the soil. This was taken to indicate that the yield of a soil depends upon its richness in aerobic microorganisms. An influence of solar heat on the pH value of the soil by the agency of microorganisms was manifested, giving results practically identical with those which were obtained with artificial heating. Soils receiving no nitrogen became most acid.

While badly aerated soils showed a distinctly acid reaction, good soils, the aeration of which was completely destroyed for 48 hours under a tempera-

ture of 23° C. (73.4° F.), showed a perceptible decrease of acidity or even became alkaline. The results are taken to indicate that the reaction of the soil is subjected to the action in opposite directions of two forces of micro-organic origin. Under normal conditions the fertility of a soil is directly proportional to its aerobic bacterial activity and inversely proportional to its anaerobic bacterial activity.

A new process for determining pH values is briefly described.

The decomposition of green and organic manures under tropical conditions, A. W. R. JOACHIM (*Trop. Agr. [Ceylon]*, 66 (1926), No. 4-5, pp. 308-312).—In both laboratory and field experiments the maximum nitrification of green and stable manures took place in nearly every case in soils under tropical conditions at the end of the sixth week. It was found that the use of any green leafy material, such as wild sunflowers, will give as good results so far as nitrate formation is concerned as many of the leguminous green manures. Little nitrate formation was observed in the case of cattle manure. Rainfall was found to affect the nitrate content of the soils to some extent. As the mean rainfall increased the nitrate content of the soil diminished, and vice versa.

Investigations on the decomposition of peanut cake, castor cake, fish guano, crushed fish, and dried blood showed that the period of maximum nitrification for these organic materials varied from the eighth to the tenth week. Organic manures like castor cake and crushed fish, which contained comparatively low percentages of nitrogen, reached their maximum nitrification at about the eighth week. The maximum percentage of nitrogen nitrified was the highest for castor cake and crushed fish and the lowest for blood meal.

Nitrogen availability of green manures, F. LÖHNIS (*Soil Sci.*, 22 (1926), No. 4, pp. 253-290, figs. 2).—Field, greenhouse, and laboratory experiments on the efficiency of green manures, conducted by the U. S. D. A. Bureau of Plant Industry, are reported.

The nitrogen availability of green manures showed wide variations which were dependent upon the quality and quantity of the green substances used and on the character of the manured soils. Small amounts of young materials as a rule gave higher percentage returns than large quantities of old materials, with certain important exceptions. Cowpeas, for instance, proved of greater value with increasing age, while young cowpeas and young yellow lupines showed an exceptionally low nitrogen availability. Frozen cowpeas displayed the highest efficiency.

The average availability of green manure nitrogen was from 50 to 80 per cent if the green substances were added to the soil after they had been grown elsewhere. It is considered an open question whether the effect of green legumes turned under in place is really the result of the green manuring or whether it is due more to the influence of the growing legumes as such.

A general acceleration of the activities of soil organisms took place when green manures were incorporated in a soil not too deficient in humus, with the result that the nitrification of the green manure nitrogen was accompanied by an intensified mineralization of the humus nitrogen. Accordingly more nitrogen may be found in the first crop increases than has become available from the green manures. Occasionally on a rich soil more than 200 per cent of the nitrogen applied was returned within a few years. Nitrification tests made in the laboratory gave much lower figures than vegetation tests with the experimental soil, whereas concordant results were obtained by both methods for a soil of low humus content.

On the origin and nature of soil organic matter or soil "humus," II-IV (*Soil Sci.*, 22 (1926), Nos. 3, pp. 221-232; 4, pp. 323-333; 5, pp. 395-406, figs. 2).—Parts II-IV of this series (E. S. R., 56, p. 210) are presented.

II. *Method of determining humus in the soil*, S. A. Waksman.—A method for determining soil humus is outlined.

III. *The nature of the substances contributing to the formation of humus*, S. A. Waksman.—It was found that among the various ingredients of natural organic material, such as straw, the lignins are the most resistant to the action of fungi and bacteria, and that their accumulation in the soil accounts for a large part of the soil humus which is formed as a result of the decomposition of the straw. Since humus is usually considered as that part of the soil organic matter which is extracted by alkalis and precipitated by acids, the lignins added to the soil form one of the constituents of this humus. This is due to the fact that most of the fungi and bacteria which attack the natural organic substances added to the soil are unable to decompose lignins to any considerable extent. The lignins are thus allowed to accumulate in the soil in the absence of organisms which are capable of decomposing them.

IV. *The decomposition of the various ingredients of straw and of alfalfa meal by mixed and pure cultures of microorganisms*, S. A. Waksman and F. G. Tenney.—The removal of ether-soluble fractions from barley straw was found to hasten the decomposition of the straw somewhat, but the treatment was without influence upon the decomposition of alfalfa meal.

The removal of alcohol and water-soluble substances had little influence on the decomposition of the straw materials, but greatly reduced the rapidity of decomposition of alfalfa meal. The removal of the lignins from straw and alfalfa meal hastened the rapidity and increased the amount of decomposition of the residual materials. It was found that lignins are not decomposed in the soil, at least within the experimental period of from 32 to 35 days. If they are decomposed at all, the amount of decomposition is insignificant in comparison with that of the other constituents of natural organic matter. The lignin introduced into the soil was recovered practically quantitatively at the end of the incubation period as soil humus.

Carbon and nitrogen transformations in the decomposition of cellulose by filamentous fungi, H. HEUKELEKIAN and S. A. WAKSMAN (*Jour. Biol. Chem.*, 66 (1925), No. 1, pp. 323-342).—Studies conducted at the New Jersey Experiment Stations of the carbon and nitrogen transformations in the decomposition of cellulose by two typical soil fungi, a *Trichoderma* and a *Penicillium*, are reported.

It was found that cellulose is completely decomposed by these organisms, giving carbon dioxide as the only waste product. No intermediary products are left in the media. A considerable part of the carbon of the cellulose is reassimilated by these organisms and built into protoplasm. It was shown conclusively that the carbon evolved as carbon dioxide and that assimilated by the fungi account for nearly all of the carbon of the cellulose decomposed. The carbon and nitrogen assimilated by the organisms showed a definite relationship to one another. The organisms preferred ammonia to nitrate as a source of nitrogen. This was assimilated and transformed into microbial protoplasm. A direct correlation was thus found between the amount of cellulose decomposed and the amount of nitrogen transformed into an insoluble organic form.

Peat: A contribution towards a bibliography of the American literature through 1925, compiled by A. C. ATWOOD (*U. S. Dept. Agr., Library, Bibliog. Contrib.* 12 (1926), pp. [3]+95).—This comprehensive bibliography was compiled at the request of the American Peat Society.

New investigations on the utilization of stable manure nitrogen in cultivated soils [trans. title], C. BARTHEL (*Fortschr. Landw.*, 1 (1926), No. 2, pp. 37-41).—From studies conducted at Stockholm, the conclusion is drawn that the microbiological action of stable manure in cultivated soils is of an indirect nature. It was found that stable manure acts not so much through the microorganisms which it carries to the soil as through the ammonia nitrogen which is added and acted upon by the microorganisms already existing in the soil. The same result was accomplished by the addition of corresponding amounts of other available nitrogenous compounds.

It is further concluded that the physical action of stable manure, especially in certain soils, should not be underestimated, and that the manure should be carefully handled and composted in order to conserve a maximum amount of ammonia nitrogen.

The value of farmyard manure, C. A. MOOERS (*Tennessee Sta. Circ.* 6 (1926), pp. 2).—Popular information on the subject is given.

Studies on the use of raw rock phosphate as a supplement to rotted manure on the Fargo clay, H. L. WALSTER (*North Dakota Sta. Bul.* 198 (1926), pp. 15, figs. 5).—It is reported that raw rock phosphate applied at the rate of 1 ton per acre every 5 years as a supplement to rotted manure applied every 5 years at the rate of 10 tons per acre gave an average annual increase in the yield of wheat of 2 bu. per acre over that obtained from an application of the same amount of rotted manure. During 10 comparable years raw rock phosphate failed to increase the yield of sweet clover hay or of barley. During 9 comparable years it caused no significant increase in the yield of flaxseed, and during 6 comparable years it failed to increase the yield of ripe corn.

Under continuous culture no evidence was obtained that the addition of raw rock phosphate increased the yields of wheat, oats, or barley. The average corn yields were very slightly increased by the supplemental use of raw rock phosphate, which were, however, not sufficient to cover the costs involved.

How far does superphosphate penetrate soil? T. D. HALL and P. KAMERMAN (*Union So. Africa Dept. Agr. Jour.*, 12 (1926), No. 5, pp. 406-409).—Experiments conducted at Potchefstroom are briefly reported, from which the conclusion is drawn that in a brown loam soil there is no danger of loss of superphosphate by leaching below the reach of common crops.

The rôle of phosphorus in agriculture, E. VANSTONE (*Jour. Soc. Chem. Indus.*, 45 (1926), No. 13, pp. 78T-80T).—A review of studies by different investigators on the use of phosphoric acid as a fertilizer is briefly presented.

Influence of sulfur and gypsum on the solubility of potassium in soils and on the quantity of this element removed by certain plants, O. M. SHEDD (*Soil Sci.*, 22 (1926), No. 5, pp. 335-354).—Studies conducted at the Kentucky Experiment Station are reported which consisted mainly of solubility tests for potassium of 11 Kentucky soils of different types subjected to different treatments. Cropping tests with young wheat and buckwheat plants were also conducted on treated soils for a short time at the end of a 4-month period of digestion.

The results indicated that all soils showed increases in water-soluble potassium with the sulfur treatment, and that five out of seven showed gains even when calcium carbonate was added with sulfur. Only one soil produced more water-soluble potassium when treated with gypsum, although three soils treated with this material gave an increased amount of potassium in the ammonium nitrate digestion. An increased quantity of potassium was found in wheat grown in one soil after the gypsum treatment, and larger amounts of the same element were extracted by water and ammonium nitrate. This is taken to indicate that the gypsum may have liberated potassium in this soil.

The results on the other soils generally were not so good with gypsum as with sulfur.

No consistent correlation between the amounts of potassium extracted by the solvent and by the plant appeared except in a few instances. The results are taken to indicate that the plants obtained the potassium for their initial growth from that which was soluble rather than absorbed. Calcium carbonate generally had a beneficial effect on the oxidation of sulfur, but a depressive effect on the soluble potassium extracted by every solvent except 0.2 N nitric acid.

In the majority of treatments without calcium carbonate the amount of potassium soluble in ammonium nitrate solution was larger than the combined amount obtained by distilled water and 0.2 N nitric acid, whereas with this base present it was less. Moreover, with the same solvent and calcium carbonate treatment the potassium obtained was generally less than that extracted from the untreated soil. There was very little variation in the H-ion concentration in the different treatments of the same soil except when calcium carbonate was added.

Agricultural liming materials (*Md. Univ. [Quart.] No. 119 (1926), pp. 16*).—Guaranties and actual analyses of 105 samples of limes and limestones collected in Maryland from November 1, 1925, to November 1, 1926, are presented.

Report on inspection of commercial fertilizers, 1926, E. M. BAILEY (*Connecticut State Sta. Bul. 282 (1926), pp. 95+X*).—Guaranties and actual analyses of 789 samples of fertilizers and fertilizer materials collected for inspection in Connecticut during 1926 are presented, together with a statement of the provisions of the State fertilizer law and a list of brands registered in the State during the year. A brief review by E. H. Jenkins on The Effect of Chlorides upon the Burning Quality of Tobacco is appended.

Commercial fertilizers, C. H. JONES, G. F. ANDERSON, and E. F. BOYCE (*Vermont Sta. Bul. 258 (1926), pp. 20*).—Guaranties and actual analyses of about 300 samples of fertilizers and fertilizer materials, representing 146 brands which were collected for inspection in Vermont during 1926 are summarized, and the results are discussed.

1926 "year book" [of] **Commercial Fertilizer** (*Atlanta: Walter W. Brown Pub. Co., 1926, pp. 147, figs. 2*).—Information relating to the fertilizer industry, with special articles as to individual fertilizer materials, is given.

AGRICULTURAL BOTANY

Textbook of plant physiology, W. LEPESCHKIN (*Lehrbuch der Pflanzenphysiologie. Berlin: Julius Springer, 1925, pp. VI+297, figs. 141*).—This textbook, presenting plant physiology on a physicochemical basis, is in three parts, dealing, respectively, with metabolism, growth, and movement in plants.

The physiology of growth, C. H. FARR (*Iowa Acad. Sci. Proc., 31 (1924), pp. 175-182*).—A synthetic and somewhat critical review is presented of available facts and views regarding phases of growth in plants.

A note on the relation of rate of growth to structure in plants, L. S. PENROSE (*New Phytol., 24 (1925), No. 5, pp. 294-299, figs. 4*).—The author notes, approvingly, statements to the effect that the form of an organism is determined by its rate of growth in various directions, and that the ratio between rates of growth in various directions may sometimes be of a simple kind, as when growth results in the definable outline of a shell or the smooth curve of a leaf. It is the purpose of the present paper to amplify this idea in regard to one or two special cases of plant growth by showing how certain common forms

can be referred to relations between the growth rates of their parts and to the growth rate of the whole plant at different periods. While only the simpler possibilities are here discussed, the assumptions are considered to be in harmony with what other methods of investigation in related spheres have warranted.

Light and growth.—I, The effect of brief light exposure upon etiolated plants, J. H. PRIESTLEY (*New Phytol.*, 24 (1925), No. 5, pp. 271-283, pls. 4, fig. 1).—Experiments are described showing that etiolated plants of certain species are very sensitive to daily exposures to light of only a very short duration, marked morphological changes resulting. This fact clears up many apparent contradictions in the literature of etiolation, and eliminates any explanation of the morphological changes produced upon etiolated plants by light which is based upon the effects of photosynthetic products. The light action is supposed to be catalytic and to affect products of metabolism in the shoot, not the living metabolic machinery itself.

The isoelectric point for plant tissue and its importance in absorption and toxicity, W. J. ROBBINS (*Missouri Univ. Studies*, 1 (1926), No. 1, pp. 3-60, figs. 13).—"The influence of hydrogen-ion concentration on the absorption of basic and acid dyes indicates an isoelectric point of pH 6.0-6.4 for potato tuber tissue. . . . Elodea (*Anacharis canadensis gigantea*) responds in many ways as though it has an isoelectric point of pH 6.0-6.2."

The transpiration stream, H. H. DIXON (*London: Univ. London Press*, 1924, pp. 80, figs. 2).—In three lectures delivered before the University of London in January, 1924, the author endeavored to indicate the position of the cohesion theory of sap ascent, with a summary of adverse criticism offered since the publication of the author's work on transpiration and ascent of sap in plants (*E. S. R.*, 33, p. 127). The third of these lectures is claimed to have shown how, by an extension, this theory may, in addition to solving the old problem of the ascent of sap, be made to furnish a clue to the mechanism of the transport and the distribution of the organic substances in plants.

On the solutes exuded by root pressure from vines, J. H. PRIESTLEY and A. WORMALL (*New Phytol.*, 24 (1925), No. 1, pp. 24-38, fig. 1).—A distinction is suggested between plants typified by *Vitis* sp., in which the sap pressure is always upward from the root, with only one maximum, and those typified by *Acer* sp., in which the flow is downwards as well as upwards and in which flow and pressure fluctuate more and are more closely related to air temperature. It is suggested that in the *Acer* type, the result of the development of an exudation pressure by the root in the spring may be the irrigation of the cortex of the shoot by the sap, with a considerable increase of flow and pressure as a consequence of activity in the parenchymatous region of the shoot. It is thought that the chemical nature of the sap exuding from *Acer* may disagree with that from *Vitis*. Methods are described by which large quantities of vine sap were collected under sterile conditions, and the chemical results are summarized of the examination of this sap. The presence of several dibasic acids, with practical absence of any other type, is emphasized and discussed. The absence of all but a trace of organic nitrogen is noted. The presence of the enzymes diastase and peroxidase is briefly discussed.

Photosynthesis: The assimilation of carbon by green plants, W. STILES (*London and New York: Longmans, Green & Co.*, 1925, pp. VII+268, figs. 15).—The work previously noted (*E. S. R.*, 33, p. 821) presented a critical account of what were at the time recent results of study applied to carbon assimilation by plants. The present volume, though not a revision of the earlier one, is an attempt to present similarly a unified general view of the present state

of knowledge regarding photosynthesis. The bibliography, confined mainly to works cited in this text, contains 870 references, including most works of importance up to the autumn of 1924.

The first sugar of photosynthesis and the rôle of cane sugar in the plant, J. PARKIN (*New Phytol.*, 24 (1925), No. 1, pp. 57-64).—A somewhat controversial critical review is given, with comments, of the rôle of cane sugar in plants.

The rôle of cane sugar in the plant, R. E. CHAPMAN (*New Phytol.*, 24 (1925), No. 5, pp. 308, 309).—A short discussion of the paper by Parkin above noted.

The mechanism of carbohydrate splitting during anaerobic respiration in plant organs [trans. title], J. STOKLASA and J. BAREŠ (*Sborn. Českoslov. Akad. Zeměděl. (Ann. Czechoslovak Acad. Agr.)*, 1 (1926), No. 1, pp. 1-46, figs. 2; *Fr. and Ger. abs.*, pp. 42-44).—The present article presents results of studies carried out during 25 years on aerobic respiration in plants with references to related literature. The authors have not been able to confirm the view that alcohol is always formed from acetaldehyde. They hold that acetaldehyde may be formed as a secondary product in the process of oxidation of ethyl alcohol. All changes in the plant cell are processes involving reduction or oxidation.

The effect of artificial aeration of the soil on *Impatiens balsamina* L., C. HUNTER and E. M. RICH (*New Phytol.*, 24 (1925), No. 5, pp. 257-271, figs. 7).—*I. balsamina* showed the beneficial effects of soil aeration in immediate augmentation of growth rate, transpiration, and respiratory activity. It is suggested that these results are due to removal of carbon dioxide caused by root respiration and soil organism activities. Turgor pressure increase may also be a feature.

Growth of wheat roots in salt solutions containing essential ions, S. F. and H. M. TRELEASE (*Bot. Gaz.*, 80 (1925), No. 1, pp. 74-83, figs. 2).—A study is reported of root growth in young wheat seedlings supplied with solutions containing one or more of the salts potassium dihydrogen phosphate, calcium nitrate, and magnesium sulfate. Thirty-seven different solutions were tested, each having a total concentration of 0.06 gram-molecule per liter. Besides the 3 single-salt solutions, the series included 9 2-salt solutions and 25 3-salt solutions. No marked retardation of root elongation occurred unless the volume-molecular concentration of at least one of the three salts constituted less than about 15 per cent of the total volume-molecular concentration of the solution. The roots were not very sensitive to small differences in salt ratios, except when the partial concentration of calcium nitrate in the solution was below about 5 per cent of the total concentration. Root elongation in very young seedlings is considered as not too complex for experimentation aiming toward reliable results.

Theory of regeneration based on mass action, II, J. LOEB (*Jour. Gen. Physiol.*, 6 (1923), No. 2, pp. 207-214, figs. 2).—In Part II of this series (*E. S. R.*, 51, p. 731) the polarity in the regeneration of an isolated piece of stem of *Bryophyllum calycinum* is said to express itself by the characteristic facts, first, that regeneration occurs only at the extreme ends, and, second, that the character of the regenerated organs is different at the opposite ends, shoots being formed at the most apical nodes and roots at the extreme basal end of the piece. Quantitative proof is furnished that all the material available for shoot and root formation in an isolated leaf of *B. calycinum* flows to those notches where, through the influence of gravity or by a more abundant supply of water, growth is accelerated. As soon as acceleration of growth in these

notches commences, the growth of the shoots and roots in the other notches which may already have started ceases.

"It has been shown in a preceding paper that the regeneration of an isolated piece of stem may be, and frequently is in the beginning, not markedly polar, but that after some time the growth of all the roots except those at the base and of all the shoots except those at the apex is suppressed. This analogy with the behavior of regeneration in a leaf in which the growth in one set of notches is accelerated suggests that in an isolated stem a more rapid growth is favored at the extreme ends (probably by a block of the sap flow at the extreme ends), and that when this happens the total flow of ascending sap goes to the most apical buds and the total flow of the descending sap goes to the most basal roots. As soon as this occurs, the growth of the other roots and shoots is suppressed."

Theory of regeneration based on mass relation.—III, Further experiments on the cause of the polar character of regeneration, J. LOEB (*Jour. Gen. Physiol.*, 6 (1924), No. 4, pp. 463-477, figs. 8).—The term "mass relation" is adopted as preferable to the term "mass action" used in previous papers (see above).

"Small stems with one large leaf in the middle produce shoots and roots chiefly at the expense of material sent into the stem by the leaf. Since the sap of the leaf can cause the formation of roots and shoots in the same notch of the leaf it is difficult to assume that the polar character of the regeneration in the stem is due to a chemical difference in the ascending and descending sap sent by the leaf into the stem.

"When the ascending sap sent by a leaf into the stem is caused with the aid of gravity to reach those tissues of the stem from which roots are formed, an abundant root formation is produced by the ascending sap.

"These two observations in connection with a fact already published in a preceding paper [referred to above] support the idea that the polar character of regeneration in a stem of Bryophyllum is not due to any of the chemical differences between the ascending and descending sap but to a difference in the nature of the tissues or anlagen which are primarily reached by the ascending and descending sap."

Regeneration from a physico-chemical viewpoint, J. LOEB (*New York and London: McGraw-Hill Book Co.*, 1924, pp. IX+143, figs. 115).—The main basis of this short monograph has been furnished by the author's own work, papers reporting phases and results of which are noted above. The contents are arranged in two parts, the first correlating mutilation and regeneration on the basis of the mass relation, and the second attempting a similar treatment of the problem of the polar character of regeneration.

It is said to be the purpose of this volume to show that a simple mass relation can be used as a guide through the various phenomena of regeneration. Equal masses of isolated sister leaves produce, under like conditions of illumination, temperature, etc., approximately equal masses of shoots and roots in equal time. With this relation in view it is claimed to be possible to explain certain puzzling matters for which various explanations have been offered. Theoretical and practical considerations are presented.

Further studies of the germination of woody plants, L. H. PAMMEL and C. M. KING (*Iowa Acad. Sci. Proc.*, 31 (1924), pp. 157-167, figs. 11).—This is designated as Contribution No. 7 on the germination of woody plants (E. S. R., 52, p. 516). Trials are made with seeds of about 30 species, which are indicated.

On the anatomy of *Orobanche hederæ* Duby, and its attachment to the host. P. TATE (*New Phytol.*, 24 (1925), No. 5, pp. 284-293, figs. 3).—Seeds of *O. hederæ* do not germinate in the absence of the host plant. The results of its activity in connection with the host are discussed.

The "spruce budworm" biocoenose, I, II. I. W. BAILEY (*Bot. Gaz.*, 80 (1925), Nos. 1, pp. 93-101, pls. 3; 3, pp. 300-310, pls. 3, figs. 3).—In studying the more or less abnormal growth layers in the stems of conifers defoliated by the spruce bud worm, it is found difficult in many cases to determine which rings were formed during specific growing seasons. This is due to the omission of layers, particularly in the basal portions of the stem, and to the occurrence of structures resembling false rings.

A study of frost rings in various forest areas of eastern Canada, noted in Part I, is said to indicate that the injuries produced by certain frosts are widely distributed in the stems of such trees as fir balsam, alder, hazel, birch, willow, poplar, cherry, and mountain ash, these injuries affording a reliable means of cross correlating homologous growth layers in different trees, and therefore of accurately dating specific growth layers in fir balsams.

In Part II, structural abnormalities in *Abies balsamea*, two methods are outlined of overcoming difficulties noted in this and the preceding paper. It is shown that weakened and dying trees in coniferous forests defoliated by the bud worm are attacked by various insects and fungi, one of the commonest of these secondary parasites being *Pissodes dubius*. The areas of traumatic tissue induced by the feeding of this weevil are of considerable significance in stem analyses.

Pollen morphology as an index to plant relationship.—I, Morphology of pollen. M. A. POPE (*Bot. Gaz.*, 80 (1925), No. 1, pp. 63-73, pl. 1).—A study is reported of pollen morphology in numerous genera of about 80 families represented in the flora of Colorado, together with a small number of familiar exotic forms. It is found that while, in general, the shapes and sizes of grains in the various genera of a family correspond rather closely, some families show striking differences, which are particularized.

On the longevity of pollen. R. M. HOLMAN and F. BRUBAKER (*Calif. Univ. Pubs. Bot.*, 13 (1926), No. 10, pp. 179-204).—To find a pollen readily obtainable in quantity and capable of maintaining a high germination rate over a long period, the authors tested the pollen longevity of 50 angiosperm species stored at room temperature under varying humidity conditions. The behaviors of these pollens are reported, with comment. The mean dry air longevity was about 23 days, but this period could be tripled by providing favorable storage conditions. The maximum longevity was over 336 days for *Typha latifolia* pollen stored over fused calcium chloride. The relation between germinating power and ability to fertilize, the causes of differences in longevity of different pollens, and the practical application of methods of extending pollen longevity are briefly discussed.

GENETICS

Body and germ cells. J. W. HARMS (*Körper und Keimzellen. Berlin: Julius Springer, 1926, vols. 1, pp. X+516, figs. 202; 2, pp. [3]+517-1023, figs. 107*).—The two volumes of this book deal with the relations between the germ cells and the somatic tissue, with special reference to the origin of the somatic tissue from germinal tissue, the production of germ cells by the mature animal, and the physiological influence of the gonads.

A comparative study of the chondriome in animal and plant cells [trans. title], H. BOUYGUES (*Actes Soc. Linn. Bordeaux, 76 (1924), pp. 5-166, figs. 35*).—This is a detailed comparative study.

Cytological study of meiosis in anthers of *Oenothera muricata*, R. E. CLELAND (*Bot. Gaz.*, 82 (1926), No. 1, pp. 55-70, pls. 2).—This is a contribution from Goucher College, Baltimore, Md.

Studies in morphogenetics of animal pigmentation, I, II [trans. title], N. A. IL'IN (ILJIN) (*Trudy Lab. Ėksper. Biol. Moskov. Zooparka (Trans. Lab. Expt. Biol. Zoopark Moscow)*, 1 (1926), No. 1, pp. 96-106, 130-181, figs. 8; *Eng. abs.*, pp. 106, 177-181).—Two studies in this series are presented.

Morphogenetic analysis of the genetical constitution in albino guinea pigs.—The hereditary constitution of albino guinea pigs is compared with that of the Himalayan albino rabbit with reference to the effect of temperature in the production of pigmented hair on different parts of the body. The darkening of the nose, ears, and toes is more pronounced with age, but the removal of the hair tends to accelerate the darkening.

Investigations of the temperature influence on the Himalayan rabbit's pigmentation.—The so-called "reaction of Schultz" (E. S. R., 53, p. 526), which consists of the darkening of the hair on various parts of the body by means of temperature influences, is discussed. The threshold of irritation for the production of color in this reaction, which is the maximum temperature at which a minimum amount of pigment is produced, has been worked out for the various parts of the body of Himalayan rabbits in the Zoological Park of Moscow as follows: Side, back, and breast 1 to 2° C., nose 29 to 30° C., ears 25 to 27° C., upper eyelid 3° C. and higher, spots under the eyes 2 to 7° C. and higher, fore feet 14° C., hind feet 16° C., and tail 29° C.

The thresholds of irritation for the sides and back were found to be raised in Himalayan rabbits from 5 to 8 days of age and again with advanced age, and were found to differ in Himalayan rabbits of different origin.

Studies of the effect of diseases, irritators, and chemicals indicated that the threshold of irritation is dependent on the temperature of the normal tissue. With a rise in the tissue temperature the threshold falls, and vice versa.

The genetic formula of the individual evidently controls the degree of pigmentation which may be induced. A factor A', a third allelomorph in the albino series, is considered responsible for the Himalayan pattern by sensitizing the tissue so that it responds to the influence of temperature.

White as a dominant color in Merinos [trans. title], M. M. ZAVADOVSKIĪ (ZAWADOWSKY) (*Trudy Lab. Ėksper. Biol. Moskov. Zooparka (Trans. Lab. Expt. Biol. Zoopark Moscow)*, 1 (1926), No. 1, pp. 252-255, figs. 3; *Fr. abs.*, p. 255).—Studies of breeding records of Merino sheep indicated that white is dominant to black and brown.

Ruby eye in animals and its heredity, I, II [trans. title], N. A. IL'IN (ILJIN) (*Trudy Lab. Ėksper. Biol. Moskov. Zooparka (Trans. Lab. Expt. Biol. Zoopark Moscow)*, 1 (1926), No. 1, pp. 107-129; *Eng. abs.*, pp. 128, 129).—Two papers in this series are presented.

The ruby eye in the guinea pig.—The characteristics of the ruby-eyed condition as found in the guinea pig are briefly described. The results of experiments have indicated that the gene for ruby eye forms a third allelomorph in the series, with factors for dark eye and pink eye.

The ruby eye in mammals.—The occurrence of the ruby-eyed condition in the guinea pig, mouse, rat, cat, dog, and man is described, and as far as the evidence goes this condition can evidently be combined with most of the known characters.

A second gene producing golden plant color in maize, M. T. JENKINS (*Amer. Nat.*, 60 (1926), No. 670, pp. 484-488).—A second factor for golden plant color, golden 2 (g_2), which appeared in Reid Yellow Dent strains in cooperative

studies by the Iowa Experiment Station and the U. S. Department of Agriculture, was found to behave as a simple Mendelian recessive as did the original factor for golden plant color, reported by Emerson (E. S. R., 28, p. 231) and designated as golden 1 (g_1). The factor pairs for golden 1 and golden 2 exhibited a complementary action toward one another, but G_1g_1 and G_2g_2 did not seem to be linked.

Constricted ears of maize, H. J. SCONCE (*Jour. Heredity*, 17 (1926), No. 7, pp. 257-260, figs. 3).—The original constricted ear described, found by the author in a field of Johnson County White corn, was normal in size at the butt half while the tip half was constricted, apparently because of incomplete development of kernels on that end. The cob was normal.

Experiments of the author indicated that this constriction is heritable, and that constricted ears are quite susceptible to disease. Only the dwarfed kernels of the original ear showed a tendency to produce a deformed progeny, but during subsequent years all the kernels of the selfed constricted ears, whether normal or dwarfed, produced the constricted ears. The character can evidently be combined with pericarp color.

Nicotiana deformis n. sp. and the enzyme theory of heredity [trans. title], J. A. HONING (*Genetica [The Hague]*, 5 (1923), No. 5-6, pp. 455-476, pls. 2, figs. 5).—A further account is given of the stock previously reported as a new species, *N. deformis* (E. S. R., 40, p. 38), and of its divergent behavior when grown in Sumatra or the Netherlands. *N. deformis* suggests, in both foliage and floral anomalies, both the kroepoek and the mosaic disease.

Genetic studies in potatoes.—I, The inheritance of parti-color and suffused tuber color, F. A. KRANTZ (*Potato Assoc. Amer. Proc.*, 12 (1925), pp. 32-37).—Results obtained at the Minnesota Experiment Station on the breeding behavior of three potato varieties could not be explained by the suggestion of Collins (E. S. R., 52, p. 32) that an allelomorphous series of factors is involved in the tuber color, nor was the hypothesis of Kelly (E. S. R., 52, p. 32) applicable. The data were explained by adding a factor AA responsible for a suffused tuber color to Salaman's (E. S. R., 24, p. 632) hypothesis in which D is a basic factor necessary for the development of pigment and R a factor for red color. In the author's experiments D and R , when both were present, resulted in parti-color tubers. The following genetic constitution for tuber color was indicated: Triumph $DD Rr Aa$, Early Ohio $Dd Rr AA$, and Red McCormick $Dd Rr Aa$.

Fatuoid or false wild forms in Fulghum and other oat varieties, T. R. STANTON, F. A. COFFMAN, and G. A. WIEBE (*Jour. Heredity*, 17 (1926), Nos. 5, pp. 153-165, pl. 1, figs. 2; 6, pp. 212-226, figs. 5).—An account of aberrant fatuoid forms occurring in *Avena sativa*, varieties Aurora, Culberson, Sixty-Day, Swedish Select, Victory, Navarro (Ferguson Navarro), Ruakura, and Cornelian; *A. byzantina*, varieties Fulghum and Burt; and *A. nuda*, variety Naked (Hull-less), some of which have been studied genetically, is presented, and conclusions from the more important genetic investigations of these forms by others are reviewed.

The occurrence of these forms in cultivated varieties has not been unusual. On the basis of breeding behavior, four distinct genotypes, homozygous-fatuoid, heterozygous-fatuoid, homozygous-cultivated, and heterozygous-cultivated are recognized. While fatuoids occur frequently in Fulghum oats, observations and experiments of the authors suggest that there is little reason to fear their becoming a weed pest.

Apparently genetic variation exists between the aberrant forms found in varieties of *A. byzantina* and those in varieties of *A. sativa*. Fatuoids found in *A. sativa* varieties seem to differ from the cultivated form by a single factor,

while those so far studied in *A. byzantina* may differ by several factors. The data presented led the authors to believe that chromosome irregularity may offer a better explanation for occurrence of fatuoids than mutation or natural crossing. Fatuoids are discussed in relation to the origin of oats species.

Breeding wheat for high protein content, J. A. CLARK (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 648-661, figs. 5).—Marquis-Hard Federation crosses grown in Montana under environmental conditions favorable for high protein content and Hard Federation-Propo crosses in California under conditions usually producing wheat low in protein were studied in an attempt to determine the segregation and inheritance of crude protein content in hybrids. See also a previous note (E. S. R., 55, p. 127).

There seemed to be segregation for crude protein content in wheat hybrids similar to that for other quantitative characters, including yield. According to the data, inheritance of crude protein content is as complex as of yield, and environment is quite as important in determining the result in either case. The two characters are often but not always negatively associated. Kernel texture and awnedness of plants are also important factors affecting protein content. Some high crude protein F_2 strains were obtained from plant selections made in the F_2 on the basis of high crude protein content, but such selections were not always superior to others from an F_3 plant of lower protein content. Strains higher in crude protein content than the better parent were not obtained. These studies suggested that the total amount of crude protein per acre, however, may be increased through improvement in yield with maintenance of the crude protein content of the highest parent. To increase the crude protein content of the grain materially it seems necessary to select a high-protein parent, even at a sacrifice in yield.

Contribution to the genetics of wheat [trans. title], K. MEYER (*Jour. Landw.*, 73 (1925), No. 4, pp. 241-304).—Studies at the University of Göttingen were concerned with the inheritance of type of spike, awning, pubescence, glume color, and kernel color in four wheat hybrids.

Genetics of breed characteristics, D. C. WARREN (*Poultry Sci.*, 5 (1926), No. 5, pp. 209-212).—The behavior of various breed characteristics in crosses between Single-Comb White Leghorns and Jersey Black Giants is described, essentially as in previous reports (E. S. R., 53, p. 427; 54, p. 325).

Crossing between yak (*Phoephagus grunniens* L.) and zebu (*Bos indicus*) [trans. title], M. M. ZAVADOVSKIĪ (ZAWADOWSKY) (*Trudy Lab. Ėksper. Biol. Moskov. Zooparka* (Trans. Lab. Expt. Biol. Zoopark Moscow), 1 (1926), No. 1, pp. 245-251, figs. 6; Eng. abs., pp. 250, 251).—Brief results are given of the offspring produced by crossing a zebu bull with a yak cow in the Zoological Park at Moscow. Seven progeny were produced as the result of back-crossing the zebu bull to his cross-bred daughter. It is pointed out that the offspring are fertile, at least as far as females are concerned. The inheritance is alternative, and segregation is clearly observed in the pigmentation of the hair, the length of the hair, and the hump.

The dependence of male characteristics on gonads in *Lebistes reticulatus*, I, II [trans. title], L. ĪA. BLĪAKHER (L. J. BLACHER) (*Trudy Lab. Ėksper. Biol. Moskov. Zooparka* (Trans. Lab. Expt. Biol. Zoopark Moscow), 1 (1926), No. 1, pp. 81-95, pls. 2, figs. 9; Ger. abs., pp. 89-95).—The results of two studies are presented, preliminary accounts of which were noted (E. S. R., 56, p. 130).

The disappearance of male coloring correlated with an atrophy of the gonads.—Three additional fish have been added to this series, and histological examinations of the testicles have confirmed the atrophy of the germinal portion of the testicle with a marked development of the interstitial fibrous tissue.

A case of hermaphroditism in Lebistes.—A study of this case which has been described indicates that the male hormone in fish is predominant over the female hormone. From this it is further suggested that the sex hormone of the heterozygous sex is dominant over the hormone of the homozygous sex.

Cryptorchid testes and testicular hormone production, R. M. OSLUND (*Amer. Jour. Physiol.*, 77 (1926), No. 1, pp. 76-82, figs. 2).—Histological studies of natural cryptorchid testicles of man, dog, pig, and sheep at the University of Illinois showed that the seminiferous tubules contain cells which are actively growing and dividing. Not all of these cells were alike, and some resembled embryological spermatogonia. They form spermatogonia after the testicle is replaced in the abdominal cavity.

In discussing the production of hormones in the testes it is stated that the sex hormone is produced by the cryptorchid notwithstanding the absence of mature spermatogonia, spermatocytes, spermatids, and spermatozoa in the tubules. Whether hormone production is a product of the germinal epithelium or the interstitial cells could not be determined.

A study of the effects of testicular extract upon the pregnant guinea-pig and the fetus, F. E. EMERY (*Amer. Micros. Soc. Trans.*, 45 (1926), No. 1, pp. 44-53, figs. 6).—Weekly intraperitoneal injections into virgin and pregnant female guinea pigs at the Kansas Experiment Station with 5 cc. doses of testicular extract, prepared by mixing 1 gm. of desiccated pig testes with 10 cc. of salt solution, were found to produce local pain, watering of the eyes, occasionally coma, and frequently chronic peritonitis, with an emaciated condition accompanying long injection periods. Abortions were numerous in pregnant animals, as 25 per cent of the pregnancies terminated in abortion.

A histological examination of the gonads of the injected animals showed marked degenerative changes with atrophy of the Graafian follicles and cyst formation. The injections caused sterility in young females for as long a period as they were continued. The young born to injected pregnant females were normal, there being 39 females and 38 males among the offspring. The gonads of the males were normal, but the ovaries of the female young were somewhat shrunken with an overabundance of atresic follicles. Ovarian degeneration was not marked, and the formation of cysts was rare in control animals injected with ovarian extract or amniotic fluid.

Ligation of vasa efferentia in rats, R. M. OSLUND (*Amer. Jour. Physiol.*, 77 (1926), No. 1, pp. 83-90, figs. 2).—In studies at the University of Illinois, ligation of the vasa efferentia in rats caused an enlargement and hardening of the testes, due to the retention of spermatogenetic products. Within seven days the size and hardness decreased, due to the cessation of spermatogenesis, degeneration of the germinal epithelium, and absorption of the necrotic material. No signs of recovery were observed, even up to two months after ligation.

FIELD CROPS

The principles and practice of yield trials, F. L. ENGLEADOW and G. U. YULE (*Empire Cotton Growing Rev.*, 3 (1926), Nos. 2, pp. 112-146; 3, pp. 235-267, figs. 3).—Section 1 of this elementary exposition of the difficulties and principles involved in yield comparisons of crop varieties develops the general statistical principles. Section 2 deals with the agricultural significance of yield trial results, yield trial conditions and field conditions, observation plats and observations, the chessboard yield trial, the half-drill strip method described by Beaven (*E. S. R.*, 48, p. 333), size and arrangement of plats, and corrections for soil inequalities.

Some determinations of plat variability, C. K. McCLELLAND (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 9, pp. 819-823).—The yields of rows and half rows of corn and of $\frac{1}{10}$ -acre plats of oats at the Arkansas Experiment Station are tabulated to show the variability of land for experimental uses. In a study of the effect of size and shape of plat and distribution of corn rows (132 ft. long by 44 in. apart) on experimental error the results showed a gradual reduction of error with increase in size of plat and also a slightly lower error for long narrow plats than for short wide plats of equal area. Reduction of nearly 30 per cent was shown in going from $\frac{1}{30}$ to $\frac{1}{2}$ acre. By distributing the rows the error for $\frac{1}{30}$ acre was reduced from 8.6 to 3.55 per cent and for $\frac{1}{10}$ acre was reduced from 8.3 to about 2 per cent, showing a great advantage in such distribution.

The northern limits of agriculture [trans. title], IŪ. D. TSINZERLING (G. D. ZINSERLING) (*Trudy Prikl. Bot. i. Selekt. (Bul. Appl. Bot. and Plant Breeding)*, 15 (1925), No. 3, pp. 1-146, pls. 6, fig. 1; *Eng. abs.*, pp. 127-142).—This treatise discusses the factors determining the limits of northern agriculture, indicates the general and specific limits of field crop culture in Asia, Europe, Iceland, Greenland, and North America, and points out the prospects of agriculture at its northern limits. The discussion as summarized in English (pp. 127-142) is agronomic rather than economic.

The varietal diversity of the field crops in the Ukraine [trans. title], N. N. KULESHOV (*Trudy Prikl. Bot. i. Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 4, pp. 3-89, figs. 4; *Eng. abs.*, pp. 85-89).—The nomenclature of varieties of spring and winter wheat and of oats and their classification and geographical distribution are dealt with on the basis of district reports and analysis of samples from different parts of the Ukraine.

Report of the division of forage plants, [1923, 1924, and 1925], G. P. McROSTIE (*Canada Expt. Farms, Div. Forage Plants Rpts. 1923*, pp. 45, figs. 9; *1924-1925*, pp. 41, figs. 3).—Investigations (E. S. R., 50, p. 432) reported on for the years indicated include varietal trials with corn and corn hybrids, broom-corn, soy beans, mangels, swedes, fall turnips, field carrots, sugar beets, alfalfa, red clover, white clover, sweet clover, sunflowers, fleshy annual pasture crops (rape, cabbage, and kale), and annual hay crops; comparisons of grass-clover mixtures; breeding work with root crops, sunflowers, grasses, clovers, and alfalfa; and classification studies with mangel varieties according to root type and with corn varieties.

The influence of time of cutting on the quality of crops, A. C. ARNY (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 8, pp. 684-703).—Review of harvesting experiments indicated that the optimum time or period for cutting grain and forage crops depends on yield, quality, weather conditions at harvest, conveniences in relation to other work, and the maintenance of satisfactory stands of perennial crops. Climatic and soil variations influence results in different locations.

Harvesting crops grown primarily for grain or seed before approximate full maturity does not improve the quality of the product, although under cool humid conditions these crops may be harvested a week or more before maturity and under warm, dry conditions three to four days early without appreciable loss in yield or quality. Where cereal straw is to be fed, harvesting before maturity helps to prevent leaching of nutrients therefrom. The composition, digestibility, and palatability of forage crops can be directly controlled by cutting at the maturity stage, giving results desired. Annual grass crops should apparently develop the kernels to the soft dough stage to obtain the best balance between yield and quality of hay. It appears

desirable to cut soy beans for hay somewhere between the stages "seeds well formed" and "beans half grown." Ordinarily cutting alfalfa somewhere between tenth- and half-bloom as a regular practice seems to result in the best balance between yield and quality and also to maintain a vigorous stand. Leaving a growth from 6 to 8 in. high in the fall to hold winter snows appears important in maintaining alfalfa stands under severe winter conditions.

Injury from burning off old grass on established bluegrass pastures, L. F. GRABER (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 9, pp. 815-819, figs. 2).—Blue grass pasture at the Wisconsin Experiment Station burned March 9, 1925 (soil surface completely frozen) and May 11, 1925 (soil completely thawed) yielded 52.4 and 71.3 per cent, respectively, less dry old grass per acre April 21, 1926, than unburned plats and 34 and 34.3 per cent less weight of rhizomes and roots to a depth of 7 in. The burned areas, especially the earlier, became weed infested. So far as the amount of growth is concerned, burning has a very injurious effect upon blue grass pastures.

[**Registration of cereal varieties**] (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 10, pp. 920-948).—These pages embrace the following reports of subcommittees of the American Society of Agronomy: Registration of Standard Wheat Varieties, by J. A. Clark, H. H. Love, and E. F. Gaines; Registration of Improved Wheat Varieties, by J. A. Clark, H. H. Love, and J. H. Parker; Registration of Varieties and Strains of Oats, by T. R. Stanton, F. Griffiee, and W. C. Etheridge; and Registration of Barley Varieties, by H. V. Harlan, E. F. Gaines, and R. G. Wiggins.

[**Root crops experiments in Canada**], F. T. SHUTT (*Canada Expt. Farms, Div. Chem. Rpt. 1925*, pp. 46-51).—Further analytical data on sugar beets, mangels, turnips, and carrots supplement those noted earlier (*E. S. R.*, 53, p. 135).

Canadian-grown seed has produced sugar beets fully equal in sugar content and purity to those from imported seed of the most approved European varieties. Satisfactory evidence of the possibility of growing in many widely distant districts of the Dominion beets of excellent quality and eminently suitable for sugar production seems to have been presented.

Effect of color of seed, of scarification, and of dry heat on the germination of alfalfa seed and of some of its impurities, G. STEWART (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 9, pp. 743-760).—The effect of color on the agricultural value of alfalfa seed has been described in another contribution from the Utah Experiment Station (*E. S. R.*, 55, p. 735). Scarified seed gave a higher percentage germination than unscarified seed in the proportion of 132:100, but weak seedlings and moldy sprouts were more frequent in the scarified seed. Dry heat up to 85° C. (185° F.) applied for no longer than 4 hours increased the germination of alfalfa seed by causing most of the hard seed to germinate. Discolored alfalfa seeds were injured considerably at much lower temperatures than were bright, mature seed.

Staker's results (*E. S. R.*, 53, p. 135) were confirmed in that dodder, Russian thistle, and Atriplex tumbleweed were practically eliminated by heating to 85° for 4 hours. The germination of green foxtail (*Setaria viridis*), redroot pigweed (*Amaranthus retroflexus*), and hare's ear mustard (*Conringia orientalis*) was not affected much by heating to 90°.

The castor bean in central Asia [trans. title], G. M. POPOVA (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 4, pp. 145-240, pl. 1, figs. 12; *Eng. abs.*, pp. 227-240).—From investigations on *Ricinus* spp. over a wide range of material, the author gives a detailed account of the origin, classification, and specific characters of the castor bean, traces the development of the plant and shows its response to temperature, and describes its

distribution and cultivation practices in central Asia. The English summary (pp. 227-240) shows that considerable attention was paid to the characteristics and distribution of *R. persicus*, breeding work, and the oil contents of different sorts.

Experiments with corn on dry land at the Huntley Branch Station, A. E. SEAMANS (*Montana Sta. Bul. 194 (1926), pp. 43, figs. 20*).—Investigations with corn, made cooperatively with the U. S. Department of Agriculture (E. S. R., 56, p. 133) during the period 1913-1924, comprised continuous cropping v. rotation, tillage experiments, varietal trials, and hogging down tests. Data were also recorded on precipitation, evaporation, temperature, and wind velocity.

Corn yields were practically equal on spring and on fall plowing. Fall subsoiling to a depth of 14 in. did not increase the yields of grain and stover over those on ordinary fall plowing enough to justify the extra labor. Spring-listed corn has averaged higher in grain yield than corn on spring-plowed or surface-planted land, whereas stover yields were about equal. More grain and stover were produced by corn on summer-fallowed land than with any other method tested, but the advantage over spring listing was not enough to warrant the practice. Where corn followed small grains or flax in rotations, yields after spring wheat were somewhat heavier than after other crops. Manure depressed corn yields in some cases, while in others slight increases were recorded.

Disked corn land was preferred to plowed corn land for small grains and flax. On disked land small grains and flax averaged about midway between yields from continuous cropping and from alternate cropping and summer fallowing, although barley on disked corn land produced better than on summer fallow. The average yield of shelled corn (pounds per acre) was only slightly less than the average oats yield and exceeded that of any other cereal except winter wheat. Rotations including corn produced more total grain and a higher average acre yield of grain than rotations without corn. Northwestern Dent, Payne White Dent, Minnesota No. 23, Falconer, and Dakota White Flint could be depended upon to mature corn before frost practically every year. Several other sorts seemed desirable for silage, although not entirely dependable for grain production.

Experiments since 1915 indicate that hogging down corn is an economical means of harvesting. One acre of Northwestern Dent, yielding 16.8 bu., has supported 6.5 hogs (about 90 lbs. initial weight) for 23 days, with an average daily gain of 1.31 lbs. per animal.

Soil moisture determinations in connection with these experiments showed that in general each crop exhausted before harvest every year the soil moisture available to it, regardless of the moisture content of the soil in the spring. The average percentage of spring soil moisture varied somewhat for the crops and cultural methods used. Corn left more moisture in the soil after the removal of the crop than did wheat, oats, or flax. Wheat and oats were about equally efficient, and reduced the soil moisture content to the lowest percentage of any of the crops sampled. The average depletion by flax was about midway between that of small grains and corn.

Growing corn on irrigated land, D. HANSEN (*Montana Sta. Bul. 193 (1926), pp. 16, figs. 2*).—Production methods for corn on irrigated land are set forth on the basis of experimental results at the Huntley Substation (E. S. R., 55, p. 132; 56, p. 133) and observations elsewhere in the Yellowstone Valley. The choice of varieties for grain and silage, seed selection and preservation, cultural practices, and ways of harvesting and using the crop are discussed briefly.

Varietal trials showed that under conditions at Huntley best results are had with the semident and early dent corns such as Northwestern Dent and Payne

White Dent, these sorts being most desirable for both grain and silage. The types of corn that can be raised in Montana are best used for silage, forage or bundle feeding, or for harvesting with hogs and sheep. In crop rotation experiments corn thrived and gave uniformly high yields after alfalfa. Grains on disked corn land yielded nearly equal to grains after beets or potatoes.

With corn yields at about 60 bu. per acre the average returns over a 10-year period in hogging down experiments were at the rate of 720 lbs. of pork per acre on corn alone and 783 lbs. on corn and rape. In 1925 on a 3-acre cornfield yielding about 40 bu. per acre hogging down produced pork at the rate of 481 lbs. per acre.

Corn: Relation of protein content to specific gravity, F. T. SHUTT (*Canada Expt. Farms, Div. Chem. Rpt. 1925, pp. 34, 35*).—Specific gravity of kernels of corn did not appear to be directly related to their protein content, although within a strain and its progeny there was a distinct trend towards high gravity being associated with high protein. It appeared that specific gravity can not be relied on for the selection of kernels as to protein content, high or low, and that the protein content of the parent has not determined that of the progeny.

An improved method of delinting cotton seed with sulphuric acid, C. D. SHERBAKOFF (*Tennessee Sta. Circ. 3 (1926), pp. 2*).—The author found that cotton seed could be delinted by the application of 1 part by volume of concentrated commercial sulfuric acid to 17 of seed, saving about 60 per cent of acid as compared with the original method. Delinting can also be accomplished with acid diluted 1 part to 5 of water for 60 parts by volume of cotton seed, seed being delinted in about 5 days. Procedure is outlined.

Fertilizer experiments with cotton, C. B. WILLIAMS, S. K. JACKSON, and H. B. MANN (*North Carolina Sta. Bul. 250 (1926), pp. 18*).—Fertilizer experiments with cotton carried on in North Carolina on Cecil sandy loam in the Piedmont and on Norfolk fine sandy loam in the Coastal Plain dealt with the effects of different proportions of nutrients on yield and maturity and rates of application. Sources of nitrogen were compared on these soils and on Cecil clay loam.

As measured by the average percentage of total crop open at first picking, increases in the phosphorus in the formula made for earliness, in nitrogen caused little or no change, and in potassium caused reduction in earliness on both soils. In most of the field experiments applications of commercial fertilizer increased the percentage of cotton open at the first picking as compared with unfertilized cotton. Fertilized or not, more cotton was open at the first picking on sandy or sandy loam soils in the Coastal Plain than on clay or clay loam soils in the Piedmont. Increasing the quantity of fertilizer per acre had a rather marked effect upon maturity. About 300 lbs. (7-3-2.5) per acre had the maximum effect on Cecil sandy loam, with a decrease after 900 lbs. per acre.

Fertilizer formulas are indicated for certain soil types of the Coastal Plain and Piedmont sections. For average soil types in the Coastal Plain a safe analysis is about 8-5-3 used at the rates of from 600 to 800 lbs. per acre. The percentage of nitrogen at planting should be reduced to about half if as much as 100 to 150 lbs. of sodium nitrate or ammonium sulfate is used as a side dressing after chopping. A 10-4-2 formula at similar rates seems to be the best general fertilizer for the more important soils of the Piedmont. The most economical applications of 7-3-2.5 formula were 800 lbs. per acre on the Coastal Plain and 200 lbs. in the Piedmont, although the greatest net returns in both cases were from 1,000 lbs. Data cited show that fertilizer mixtures

suites to particular soils will often produce increases over the same amount of an unadapted fertilizer sufficient to pay for the entire application of the better suited mixtures.

Trials of nitrogen carriers showed that, as compared with sodium nitrate, dried blood and cottonseed meal each possessed less relative efficiency when used on Norfolk sandy loam in the Coastal Plain than when used on the Cecil sandy and clay loams in the Piedmont, and they averaged only about four-fifths as effective as sodium nitrate and ammonium sulfate. The efficiency of ammonium sulfate ranged from four-fifths to nine-tenths of that of sodium nitrate.

In a study of the value of inorganic and organic nitrogen applied to cotton on Piedmont soils by different methods with normal amounts of phosphoric acid and potash, sodium nitrate divided into two equal applications gave larger increased yields of seed cotton than did blood as the nitrogen source, either when the blood was all applied with the phosphoric acid and potash carriers at planting or when half went in at planting and the other half as a side dressing just after chopping. With the Coastal Plain soil, decidedly best returns were had from applying half the nitrogen in the form of blood with all the phosphoric acid and potash at planting and applying the other half as sodium nitrate.

Annotated bibliography on the storage of cottonseed and of seed cotton, H. M. STEECE (*U. S. Dept. Agr., Ext. Serv., Off. Coop. Ext. Work, 1926, pp. 13*).—This mimeographed bibliography presents in summary form the results of official and other investigations concerned with the storage of cottonseed and seed cotton, and calls attention to bulletins and articles giving general information on the problem.

Fulghum oat the best variety for spring seeding, C. A. MOOERS (*Tennessee Sta. Circ. 4 (1926), p. 1, fig. 1*).—Fulghum oats is indicated as superior for spring seeding in Tennessee. It outyielded Burt by about 33 per cent at the station and surpassed Burt at Columbia.

Certified Irish potato seed, J. A. McCLINTOCK (*Tennessee Sta. Circ. 7 (1927), pp. 2*).—Certified potato seed averaged 183 bu. per acre during 3 years compared to 102 bu. from uncertified commercial stock. Plants from uncertified seed showed 25 per cent of degeneration diseases, while those from certified seed had less than 2 per cent.

Influence of early and late planting and sprouting on the yield and dry matter content of potatoes, F. T. SHUTT (*Canada Expt. Farms, Div. Chem. Rpt. 1925, pp. 42-44*).—Results in the fifth year of this inquiry (*E. S. R., 53, p. 137*) did not seem to warrant definite conclusions.

Fertilizer formulae for potatoes, F. T. SHUTT (*Canada Expt. Farms, Div. Chem. Rpt. 1925, pp. 11, 12*).—In experiments during several years in the Maritime Provinces, formulas involving sodium nitrate and ammonium sulfate in equivalent amounts for nitrogen, superphosphate for phosphoric acid, and potassium chloride for potash were applied at acre rates of 1,000, 1,500, and 2,000 lbs. to potatoes in a 3-year rotation of potatoes, grain, and hay.

Practically all of the 30 treatments used gave profitable returns. The data indicated that good returns may be expected from such mixtures as 3:8:6, 3:6:6, 4:8:6, 4:8:8, or 4:8:10, depending on the character and fertility of the soil. An acre dressing of 1,200 to 1,500 lbs. of any of the formulas mentioned would probably suffice under average conditions of soil and season for a maximum yield.

Studies on inoculated soybeans.—I, The importance of determining the number and size of soybean nodules for evaluating relative efficiencies of

two or more cultures, L. W. ERDMAN (*Jour. Amer. Soc. Agron.*, 18 (1926), No. 9, pp. 799-804).—Nodules collected from Manchu, Dunfield, Peking, and Midwest soy beans at the Iowa Experiment Station were grouped as small, medium, and large; were washed, dried, counted, and weighed, and then were pulverized and analyzed for total nitrogen. The relation between the average amount of nitrogen in each nodule for the three groups for all four varieties was very similar to the average weights of the small, medium, and large nodules. A suggested classification of inoculated soy bean plants is presented for differentiating degrees or intensities of nodulation. The relative efficiency of two or more cultures for the inoculation of soy beans apparently can be accurately determined only after the number and different sizes of nodules have been ascertained.

A study of the sugar-beet position, A. BRIDGES and R. N. DIXEY (*Jour. Roy. Agr. Soc. England*, 86 (1925), pp. 59-89).—The history and development of the sugar beet industry in the United States and elsewhere are outlined, with discussion of its probable expansion in England and Wales and of some factors affecting its future development.

Determinative key to the principal sugar cane varieties in Java in 1925 [trans. title], C. A. BACKER (*Arch. Suikerindus. Nederland. Indië, Meded. Proefsta. Java-Suikerindus.*, 1926, No. 17, pp. 471-512, figs. 29).—Sugar cane varieties most widely grown in Java in 1925 are described and listed, and typical buds are illustrated.

Growing sweet clover, G. F. H. BUCKLEY (*Alberta Univ., Col. Agr. Bul.* 2, rev. (1926), pp. 26, figs. 6).—A revision of a publication noted (E. S. R., 52, p. 736).

Effect of chlorine in tobacco, F. B. CARPENTER and A. H. ALLEN (*Amer. Fert.*, 65 (1926), No. 7, pp. 21-24).—Popular brands of cigars were found to contain higher percentages of chlorine than generally supposed, especially in the better grades, whereas the average chlorine content of pipe tobaccos examined was much lower than for the cigars or for cigarettes. Where the chloride was a source of potash in the fertilizer, the chlorine content of leaf tobacco obtained from growers was higher than when the sulfate was used, and the burn was inferior.

The analyses and data from other sources appeared to indicate that while excessive amounts of chlorine are not desirable, a relatively large percentage does not necessarily produce a bad burn. Chlorine may injure the burning quality, but tobacco seldom contains enough to do serious harm. There seemed to be no evidence to support the popular notion that small amounts of chlorine in fertilizers will injure the quality of the tobacco grown, and the existing prejudice against fractional percentages of this element is not held justified. The variation in chlorine content of tobacco grown in different localities would appear due in part, at least, to variation in the amount present in the soil.

Protein survey of 1926 Minnesota wheat crop, R. C. SHERWOOD (*Minn. Dept. Agr. Bul.* 52 (1926), pp. 16, figs. 3).—Samples were collected in the principal wheat area of Minnesota and were examined at the State Testing Mill as in 1925 (E. S. R., 54, p. 536). Hard red spring wheat (1,838 samples) ranged from 8.56 to 17.95 per cent of crude protein, averaging 12.74 per cent. Winter wheat (180 samples) averaged 11.58 per cent, and durum wheat (63 samples) 12.45 per cent.

Hybrid selections of Marquis and Kota: A comparative study with regard to disease resistance, yield, and baking quality, L. R. WALDRON (*North Dakota Sta. Bul.* 200 (1926), pp. 64, figs. 11).—A detailed account is

given of extensive comparative studies made with the spring wheat varieties Marquis and Kota and two of their hybrid (Marquis×Kota No. 5) offsprings, Ceres and No. 1656, during efforts to obtain improved wheat varieties. Marquis and Kota appeared to differ in at least 17 physical and chemical characters. For certain characters two or more factor pairs seemed to be concerned.

During the period 1923–1926 for 85 comparisons at different stations, No. 1656 was found to rust (stem rust) 6.2 per cent less than the rust resistant Kota, and for 63 comparisons Ceres showed 1.8 per cent more rust than Kota. No. 1656 appeared to stand in a definite transgressive position in regard to rust resistance. Certain reselections from No. 1656 on the basis of rust resistance showed a lessened average amount of rust carried than check plantings of No. 1656.

Marquis wheat is slightly earlier than Kota, and No. 1656 and Ceres are both significantly earlier than Marquis. Selections from No. 1656 indicate that at least two pure breeding transgressive segregates for earliness exist in that wheat. Two such segregates seemed to necessitate the assumption that Kota and Marquis are separated by at least four pairs of allelomorphous factors. Both Ceres and No. 1656 are intermediate between the parents in strength of straw and differ significantly in height, No. 1656 being the taller and approaching Kota.

The Kota pure line (No. 5) was hardly significantly higher yielding than bulk Kota. In numerous trials during 1923, 1924, and 1925 Ceres outyielded Marquis and Kota 3.8 and 3.6 bu., or 14.2 and 14.9 per cent, respectively. When yields were grouped (4 classes) according to presence or absence of rust and lodging Ceres outyielded Marquis significantly in all except the group where lodging was severe and rust not severe, and outyielded Kota significantly in all groups. The data indicated that Ceres is a transgressive segregate as to yield, a position apparently resulting from an additive effect of high yielding factors from each parent. No. 1656 generally showed less yielding capacity than Ceres, except when rust was certainly the limiting factor. The lessened yield capacity of No. 1656 seemed in part due to its weaker straw and in particular to low yielding forms contained. Individual selections were obtained that yielded higher and lower than the bulk No. 1656.

The averages for 22 comparative milling and baking trials showed the respective weights per bushel for Marquis, Kota, and Ceres to be 58.4, 60.6, and 60.6 lbs., crude protein 12.1, 12.84, and 12.84 per cent, flour yield 71.61, 75.41, and 74.2 per cent, loaf volume 2,153, 2,304, and 2,247 cc., loaf color 91.8, 92.6, and 93.2 per cent, loaf texture 93.1, 93.1, and 93.6 per cent, flour absorption 58.9, 60.1, and 60 per cent, loaf weight 487, 488, and 490 gm., and ash 0.57, 0.571, and 0.53 per cent. In 15 comparative trials No. 1656 about equaled Kota in weight per bushel; was intermediate between the parents in crude protein content and loaf volume, higher in flour yield, loaf color, and texture, and equal in loaf weight; about equal to Marquis in flour absorption; and lower than either in percentage of ash. The relative flour yield of No. 1656 seemed to indicate the presence of at least two pairs of factors for flour yield distinguishing Marquis and Kota. As a group, selections from Ceres and No. 1656 exhibited markedly less variability in protein content than a miscellaneous group of varieties and hybrid selections. Comparing selections of Ceres and No. 1656, No. 1656 has a significantly higher protein content and a nonsignificant lower loaf volume. The variability of No. 1656 is significantly greater in both cases.

The greater heterozygosity of No. 1656 in relation to Ceres was demonstrated by comparing the variability for 14 characters in 23 cases. The data showing the possibility of securing transgressive segregates with respect to earliness,

yield, disease resistance, and quality of product indicated that marked advances are possible in wheat breeding if proper parental material is made available.

Zonal distribution of species and varieties of wheats in the valley of the river Aragva (Caucasus) [trans. title], M. I. PRIKHOD'KO (PRIHODKO) (*Trudy Prikl. Bot. i Selekt. (Bul. Appl. Bot. and Plant-Breeding)*, 16 (1926), No. 4, pp. 135-144; *Eng. abs.*, p. 144).—The distribution of species and varieties of Triticum according to altitude is shown for the locality indicated.

West Indian yams, R. O. WILLIAMS (*Trinidad and Tobago Dept. Agr. Bul.*, 21 (1925), No. 1, pp. 1-26, pls. 4, fig. 1).—Varieties of yams cultivated in Trinidad and Tobago are described, with information on cultural and field practices, comparative yields, and production costs.

Agricultural seed, A. S. LUTMAN (*Vermont Sta. Bul.* 259 (1926), pp. 14).—The tables presented show the guaranty, purity, germination, and weed seed and other crop seed contents for 279 samples of agricultural seed obtained from dealers in Vermont during April, 1926.

Tests on the poisoning of weed seeds [trans. title], G. SAMPIETRO (*Gior. Risc.*, 15 (1925), No. 11, pp. 168-175).—When seeds of Onsen rice, *Panicum* spp., and *Cyperus* spp. were immersed for 3 days in solutions of different chemicals, the germinability of the seeds of *Panicum* was in no case destroyed and that of *Cyperus* seeds was stimulated. Rice and also *Panicum* behaved similarly when the solutions remained for 25 days in contact with the seeds during germination, while only single *Cyperus* seeds germinated in each of the KCN and $K_4Fe(CN)_6$ solutions. The vegetation was normal with solutions of $FeSO_4$ and Na_2CO_3 and mediocre with $CuSO_4$ and $KMnO_4$; that of rice was rachitic with $K_4Fe(CN)_6$ and $KClO_3$ and for *Panicum* with $K_4Fe(CN)_6$, $KClO_3$, $KMnO_4$, $CaOCl_2$, and KCN. Rice made no growth with KCN, $K_2Cr_2O_7$, lysoform, and $CaOCl_2$ and *Panicum* none with lysoform and $K_2Cr_2O_7$. The reason for the inferior stature of *Panicum* vegetation as compared to that of rice seemed because of its lesser reserve matter.

Eradication of the wild onion, C. A. MOOERS (*Tennessee Sta. Circ.* 5 (1926), pp. 2, fig. 1).—Methods are outlined for the eradication of wild onions in fields, old sod land, lawns, and fence rows.

HORTICULTURE

Types and varieties of celery, P. WORK (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 333-337).—A brief discussion of methods of technique employed at Cornell University in a systematic study of celery varieties. Among the most useful characters for distinguishing varieties were the number of leaves, length of petiole, height, weight, and circumference of the plants, pithiness, suckers, ease in blanching, color of foliage, and cross section of stalks. The six varieties found of greatest importance in the United States were the Golden Self and Easy Blanching, Old and New Vilmorin strains, Golden Plume strain, and Giant Pascal.

Physical and chemical changes in celery during storage, L. W. CORBETT and H. C. THOMPSON (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 346-353).—Marked changes were noted from week to week during the storage period in the pectic compounds of the middle lamella of Golden Self Blanching celery stalks. Pectic acid and pectin gradually increased at the expense of the less soluble calcium pectate and pectose. Changes were less rapid in plants grown on plats receiving phosphorus and potash in addition to nitrogen than in those from the nitrogen plats. Breaking and cutting tests made at weekly intervals

showed a well-marked decrease in resistance during the first 7 to 10 days of storage, followed by a slow rate of change until the approach of decay. Analyses showed a decline in reducing and total sugars in the leaves and an increase in the stalks during the storage period. At the same time soluble nitrogen increased in both stalks and leaves. The insoluble nitrogen content of the leaves decreased during the entire storage period, while in the outer stalks the decrease ceased after the first month until the onset of decay, which naturally influenced the chemical composition of all parts of the plants. The increase in insoluble nitrogen in the inside stalks from harvest until the end of storage is believed due to translocation from the leaves and outside stalks, a phenomenon which must have been accompanied by the conversion of insoluble into soluble forms.

Horticultural groups of cucurbits, E. F. CASTETTER (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 338-340).—Pointing out the distinguishing characteristics of the three important species of cucurbits, namely, *Cucurbita pepo*, *C. maxima*, and *C. moschata*, the author classifies 67 varieties studied on the grounds of the Iowa State College into various subgroups under the three main species.

Preliminary notes on tip-burn of lettuce, R. A. MCGINTY and R. C. THOMPSON (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 341-346).—A chemical analysis at the Colorado Experiment Station of healthy lettuce plants and of those in which tipburn was induced by copious watering showed that the percentage of the different sugars was significantly higher in the healthy plants. Furthermore, determinations upon the two lots showed, almost without exception, that healthy plants were higher in the percentage of dry weight. No differences were noted in the pentosan content of the two lots. Since the plants were grown in a single greenhouse, it is concluded that temperature and humidity had no bearing on the development of tipburn, but that abundant soil moisture was the determining factor. The suggestion that excessive transpiration is the cause of tipburn was refuted by the fact that healthy plants placed under bell jars in which the humidity was unusually high soon developed tipburn injury.

Physiology of reproduction in horticultural plants.—I, Reproduction and metabolic efficiency in the tomato, A. E. MURNEK (*Missouri Sta. Research Bul.* 90 (1926), pp. 19, figs. 4).—A report upon a study of the growth and metabolism, as indicated by chemical determinations, of Bonny Best tomato plants grown under similar nutrient conditions, but divided into three lots as follows: (1) Normal, pollinated and allowed to carry fruits, (2) pollinated but defruited before the fruit reached 1 cm. in diameter, and (3) deflorated before anthesis.

The normal plants made less height growth and, as expressed by the dry weight of leaves, only one-half the total amount of foliage of the other two groups. The defruited plants absorbed the greatest quantities of soil nutrients and synthesized the largest amounts of organic substances. The deflorated plants resembled the defruited in general appearance, but were approximately 10 per cent lower in total fresh and dry weights of the various parts.

Flower buds and fruits were low in ash and crude fiber, but comparatively high in phosphorus, nitrogen, starch, and hemicellulose. In the normal plants approximately 50 per cent of the total phosphorus and nitrogen, 71 per cent of the sugar, and 83 per cent of the starch were concentrated in the fruits. Hence it was apparent that the reproductive organs, particularly the developing fruits, received the greatest stimulus from gametic union. It is pointed out that when a maximum number of embryos and their accessory tissues are permitted to develop, the inevitable result is a retardation or destruction

of further vegetative development, attaining in extreme circumstances the complete death of the plant. The large growth made by the defruited plants is explicable only in the light of the supposition that stimulation in metabolic activity from fertilization extends beyond the immediate region of the floral organs.

The effect of acid phosphate and muriate of potash on the vegetative growth of tomato plants, J. R. HEPLER (*Amer. Soc. Hort. Sci. Proc.*, 21 (1924), pp. 362-365).—To determine whether the earlier ripening noted on acid phosphate plats at the New Hampshire Experiment Station (E. S. R., 49, p. 234) was associated with vegetative growth, data were taken upon early growth, total growth, number of flower clusters, and the yield of ripe fruits of Bonny Best tomatoes subjected to differential fertilizer treatments. On July 17 the increased growth on plats receiving 1,000, 500, and 1,520 lbs. of acid phosphate in addition to the basic treatment of 20 tons of manure per acre amounted to 152, 113, and 155 per cent above the control plat. At the same time the use of 20 tons of additional manure yielded only 7 per cent increase, and where muriate of potash was used alone, or with acid phosphate, there was a 14 per cent decrease and a 19 per cent gain, respectively. On July 31 the 1,000, 500, and 1,520 lb. acid phosphate plats carried 138, 103, and 142 per cent more flower clusters than did the check plats, and up to September 17 yielded 346.3, 229.3, and 332.7 per cent more ripe fruits than did the checks. Growth data taken August 7 showed much smaller increases on the phosphate plats, indicating that increased growth due to acid phosphate was largely early growth.

Tomato production, P. WORK (*New York: Orange Judd Pub. Co.; London: Kegan Paul, Trench, Trübner & Co., 1926, pp. 127, pls. 13, figs. 3*).—A concise discussion of tomato growing based upon experimental results and practical experiences.

Pollination and fruiting habit of the watermelon, J. T. ROSA (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 331-333).—Following a brief discussion of the flowering habit in the watermelon, the author reports that observations upon a large number of varieties growing at the University Farm, Davis, and at Modesto, Calif., showed two distinct groups, namely, those bearing purely staminate and pistillate flowers and those bearing hermaphroditic blooms in place of the purely pistillate ones. The hermaphroditic flowers generally contained three well-developed stamens yielding an abundance of pollen indistinguishable from that of staminate blossoms. However, when bagged prior to anthesis these hermaphroditic blooms failed to set fruit unless hand pollinated, due, in the author's belief, to the sticking of the pollen grains to the anthers following dehiscence. Emasculated and pistillate blooms of several varieties failed to develop fruits when protected from insect visitation, indicating little tendency toward parthenocarp in the watermelon.

New fruits produced at the University of Minnesota Fruit Breeding Farm, W. H. ALDERMAN (*Minnesota Sta. Bul.* 230 (1926), pp. 47, figs. 34).—Following a brief discussion of the history and development of fruit breeding at the station, descriptions are offered of the more important seedlings, tree and bush fruits, and ornamentals which have resulted from these activities.

A record system for fruit breeding work, A. N. WILCOX (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 269-271).—A brief discussion of methods employed at the Minnesota Experiment Station in labeling pollinated blossoms and keeping records upon the resulting seedlings.

Tests show how to remove spray residue, H. HARTMAN and R. H. ROBINSON (*Better Fruit*, 21 (1927), No. 7, pp. 5, 6, 16).—Of a considerable number of compounds tested at the Oregon Experiment Station as possible media for removing

spray residues from apples and pears, hydrochloric acid used at concentrations ranging between 0.25 and 2 per cent was found most effective and satisfactory. Among advantages cited are cheapness, effectiveness at low temperatures, nonoxidizing properties, volatility, easy removal from fruit, and noninjurious qualities.

Removal of arsenate of lead from sprayed fruit, W. P. HEADDEN (*Colorado Sta. Press Bul. 63 (1926), pp. 4*).—Finding that hand and machine wiping machines such as exist are not satisfactory for removing arsenical residues from apples, a bath was devised, made up of 4 lbs. each of soda ash (Na_2CO_3) and common salt (NaCl) dissolved in 12.5 gal. of water. When maintained at a temperature of 100° F., this was found highly effective, provided the solution was gently agitated. Not less than 5 nor more than 10 minutes were required, following which the apples were rinsed with fresh water. The resulting fruits not only satisfied the necessary requirements, but were attractive in appearance.

Pollination studies with certain New York State apple varieties, L. H. MACDANIELS (*Amer. Soc. Hort. Sci. Proc., 22 (1925), pp. 87-96*).—Records taken in the spring of 1925 at Cornell University upon the set of fruit on McIntosh, Cortland, and Baldwin apple trees inclosed in mosquito-net tents containing a hive of bees showed McIntosh to be practically self-sterile, Cortland sterile, and Baldwin self-fertile. The introduction of foreign pollen showed McIntosh \times Rhode Island to be intersterile and McIntosh \times Cortland interfertile. Counts of seeds in the resulting fruits showed sharp reductions below those of control trees exposed to open pollination. Germination studies with pollen of the experimental and other trees showed 24, 9, 13, 83, 89, and 12 per cent of average germination, respectively, for McIntosh, Baldwin, Rhode Island, Golden Delicious, Delicious, and Arkansas. Cortland pollen germinated as high as 75 per cent. A large portion of imperfect pollen grains was found in those varieties with low pollen germination. The author suggests that the several varieties may have different optimum temperatures for pollen tube growth and hence varieties probably vary in their effectiveness as pollinizers in accordance with the weather.

First 20 years of a variety apple orchard; apple cion selection, M. B. CUMMINGS and E. W. JENKINS (*Vermont Sta. Bul. 255 (1926), pp. 32, pls. 4, figs. 2*).—A further report (*E. S. R., 45, p. 835*) upon variety and miscellaneous studies conducted in the station apple orchard, planted in 1905. Grass-mulch treatment, utilized from the sixteenth to twenty-first years was not equal, even when supplemented with fertilizer applications, to tillage. Light annual pruning of diseased and crowding limbs sufficed to keep the trees in good condition during the later years. A cylinder of galvanized wire cloth, 12 strands to the inch, proved successful, when pressed several inches into the soil, in protecting the trees from mice and from borers. Records taken on 27 varieties during the 20 years showed but little difference in the total production of annual and alternate year producers. Of standard varieties, Yellow Bellflower was the most productive, closely followed by Fameuse, Red Astrachan, and Shiawasse. Yellow Transparent, a filler variety, was the most productive of all. Within varietal limits, trunk diameter, head diameter, and the height of the tree were correlated with productivity.

A second report upon the study of the relative value of 268 apple scions derived in part from high and in part from low yielding parent trees failed to show any significant results attributable to parentage.

Investigations in cool storage, C. E. BAKER (*Ind. Hort. Soc. Trans., 1925, pp. 58-71*).—Studies by the Indiana Experiment Station in an air-cooled storage cellar showed that natural air cooling is not sufficient to keep Grimes and

Jonathan apples from rapid ripening. The addition of ice during September and October reduced temperatures from 12 to 18° F. below that of a comparable uniced chamber, and the fruit in the iced chamber kept considerably longer. However, as the temperature of the iced compartment averaged approximately 56° during September, whereas the ideal temperature for apples is 31 to 32°, the author considers icing to be impractical from the commercial viewpoint. In concluding, the author points out the necessity of careful ventilation and the advisability of introducing fruit into the storage cellar in the early morning. The use of shredded oiled papers as a medium for preventing scald in Grimes and York Imperial is discussed.

Use of leaf characters in identification of plum varieties, W. H. ALDERMAN and J. S. SHOEMAKER (*Amer. Soc. Hort. Sci. Proc.*, 22 (1925), pp. 264-269).—A careful study of the leaves located about midway the length of strong-growing shoots showed varietal distinctions sufficiently clear to be used in the identification of plums. A key for identifying Minnesota plums is presented.

Two years' results on the effect of nitrate of soda on the yield of strawberries, S. W. WENTWORTH (*Amer. Soc. Hort. Sci. Proc.*, 21 (1924), pp. 358-362).—Due to soil heterogeneity and other causes, fluctuating results were obtained in 1923 from the use of different sized and timed applications of nitrate of soda upon Senator Dunlap strawberries growing at the New Hampshire Experiment Station. However, in the case of Premier plants set in the spring of 1923 as an intercrop in a young apple orchard which had been fertilized with 10 tons of manure per acre in 1922 for sweet corn, differential nitrate treatments gave marked results. Plants receiving 300 lbs. of nitrate of soda per acre on September 1 and those receiving 100 lbs. July 31, August 18, and May 26 of the succeeding year yielded 18.4 ± 5.3 and 16.8 ± 8 per cent less fruit than control plants, whose yield was estimated on the basis of performance of neighboring checks. Leaf area measurements showed those of the nitrated plants to be 20 per cent larger than those of the check plants. However, the leaves of nitrated plants showed a much greater tendency to wilt, a fact which is suggested as a possible cause of the crop decrease on the nitrated areas.

The capsules, seeds, and seedlings of the orange day lily, A. B. STOUT (*Jour. Heredity*, 17 (1926), No. 7, pp. 243-249, figs. 4).—Failure to secure seeds from self- and interpollinations of various stocks of *Hemerocallis fulva* led to the suggestion that *fulva* lilies are simply vegetative propagations from a single original seedling and hence constitute a clon. Of over 7,000 flowers of the *fulva* clon crossed with pollen of other *Hemerocallis* species, only 23 yielded mature capsules, containing 70 seeds, of which only 11 germinated. Records of success with *fulva* as a pollen parent are also very scanty. As both pollen and pistils appear perfect in the *fulva* lily, the author believes that sterility in this group involves incompatibilities in fertilization and may, perhaps, be overcome at some time by the discovery of a truly compatible form.

A handbook of flowering trees and shrubs for gardeners, R. C. NOTCUTT, edited by W. R. DYKES (*London: Martin Hopkinson & Co.*, 1926, pp. VII+246, pls. 24).—Brief descriptive and cultural notes are given on a large number of flowering trees and shrubs.

FORESTRY

Studies in tolerance of New England forest trees.—V, Relation of the moisture content of the soil to the sensitiveness of the chloroplast to light, G. P. BURNS (*Vermont Sta. Bul.* 257 (1926), pp. 16, figs. 8).—In this fifth contribution to the general subject (*E. S. R.*, 50, p. 343), the author reports that a

current assumption that the amount of light required for photosynthesis increases as the soil moisture content decreases was not borne out in laboratory studies with young conifers, the tops of which were enclosed in sealed jars containing a known amount of carbon dioxide and the roots in pots of soil the moisture content of which was subject to change. Constant light was furnished by four Nela Trutint lamps placed about the tree. Under constant light and decreasing soil moisture, there actually occurred an increase in photosynthetic activity as the moisture content reached a critical point. In Scotch pines this increase took place at about an 8 per cent moisture content. There was no apparent indication that photosynthetic activity decreased as the soil moisture content was lowered.

The author points out that the data obtained in the studies tend to show a certain independence of light and soil moisture so long as neither become a limiting factor. In fact a decrease in moisture content of the soil did not affect photosynthetic activity until after the tree began to perish from a lack of water.

The growth of the oak in relation to the weight of the acorn [trans. title], G. [R.] EITINGEN (*Forstwiss. Centbl.*, 48 (1926), No. 24, pp. 849-863, figs. 3).—Measurements taken upon 165 5-year-old oak trees resulting from acorns which previous to planting were assorted into three grades, the average weights of which were 2.2, 4.7, and 7.2 gm., showed average values for height in centimeters of 44.1 ± 0.9 , 68.4 ± 1.2 , and 82.5 ± 1.3 , respectively. Measurements taken three years later on other trees of the same lot, but derived from acorns averaging 2.2, 5, and 8 gm. in weight, showed average height values of 109.1 ± 0.3 , 136.7 ± 0.3 , and 143.5 ± 0.4 cm., respectively, indicating that the differences due to the size of the acorns tended to diminish as the trees increased in age.

The larger oaks not only exceeded the smaller ones in height, but also in diameter of the trunk and in the number of young shoots. At the age of 5 years oaks derived from small, medium, and large acorns averaged 7.4 ± 0.2 , 10.1 ± 0.2 , and 11.4 ± 0.2 mm. in diameter at the base, and at 8 years 11 ± 0.3 , 12.6 ± 0.3 , and 14.1 ± 0.4 mm., respectively. The average weights of the above-ground portion of 5-year-old trees without leaves were 8.8 ± 0.4 , 23.3 ± 1.2 , and 33.1 ± 1.3 gm. for small, medium, and large trees, respectively. The weights of the air-dried leaves of 5-year-old trees were 5.2 ± 0.2 , 7.1 ± 0.3 , and 8 ± 0.3 . The number of leaves were 73.2 ± 3.7 , 96.5 ± 5.4 , and 99.5 ± 4.2 .

Although it is expected that the stimulating effect of large acorns would gradually reach 0 in open plantings, the author points out that in dense stands this original superiority would give the young oak a decided advantage and lead to the ultimate suppression of the small trees resulting from small acorns.

The identification of furniture woods, A. KOEHLER (*U. S. Dept. Agr., Misc. Circ. 66* (1926), pp. 76, pls. 30, figs. 4).—Devoted principally to the structure, coloration, figuration, and uses of the woods commonly used in furniture manufacture, this paper discusses in a general way the selection of wood for furniture making, the amounts and kinds used, the structure of woods, methods of cutting, figures in wood, veneers, rules for nomenclature, the effect of atmospheric changes on furniture, etc. A key for the identification of woods used for the exposed parts of furniture is included.

DISEASES OF PLANTS

Plant pathology on an anatomical-physiological basis [trans. title], H. M. QUANJER (*Angew. Bot.*, 6 (1924), No. 2, pp. 225-232).—Chiefly this note compares contributions by about 22 authors, with reference also to related accounts by himself (*E. S. R.*, 52, p. 746; 53, p. 244).

Wisconsin studies upon the relation of soil temperature to plant disease, L. R. JONES, J. JOHNSON, and J. G. DICKSON (*Wisconsin Sta. Research Bul.* 71 (1926), pp. 144, figs. 59).—A summary is given of contributions of the Wisconsin Station on the relation of soil temperature to plant diseases, most of the work having been carried on at the Plant Pathology Laboratory of the station between 1916 and 1926. The data have been brought together in order that there may be given a unity of conception and method of the work on the effect of temperature on host plants and parasites and of development of diseases.

Data and perspectives of biological researches on parasitic fungi, 1850 to 1925 [trans. title], A. N. BUKHGEĬM (BUCHHEIM) (*Nauch. Agron. Zhur. (Jour. Landw. Wiss.)*, 2 (1925), No. 9, pp. 560–565; *Ger. abs.*, p. 565).—The author reports regarding progress in the field of experimental biology of parasitic fungi during 1850–1925, emphasizing their specialization and change (extension) as regards host range. It is emphasized that the resistance of plants to certain parasites is influenced in very high degree by conditions in the external medium.

Mycology [India], W. McRAE (*India Bd. Sci. Advice Ann. Rpt.* 1922–23, pp. 31–35).—Accounts are given in brief detail of conditions and work regarding economic plant diseases in several places or divisions throughout India.

Longevity of cultures of fusaria, W. E. MANEVAL (*Phytopathology*, 14 (1924), No. 9, pp. 408–410).—Stock cultures of *Fusarium conglutinans*, *F. niveum*, *F. oxysporum*, *F. vasinfectum*, *F. discolor*, *F. gibbosum*, *F. coeruleum*, *F. solani*, *F. trichotecioioides*, and *F. discolor sulphureum* in plugged test tubes were placed in an ice box in the spring of 1916, where they remained until March, 1924, when cultures were made of them and all but *F. coeruleum* and *F. discolor sulphureum* grew. After having been preserved for approximately 8 years, most of the time at a temperature near 10° C., 8 out of the 10 species grew more or less readily, indicating for field control the necessity of long periods of rotation for the eradication of these species, even where there is no new growth.

The effect of hydrogen-ion concentration on the extracellular pectinase of Fusarium cromyophthoron, C. P. SIDERIS (*Phytopathology*, 14 (1924), No. 11, pp. 481–489).—Tests were made of the effect of the pectinase of *F. cromyophthoron* contained in the filtrate from liquid media of different H-ion concentrations and growth periods on the maceration of onion disks and on the hydrolysis of pure pectin. The amount of pectinase, as measured by its action, secreted in the different cultures was found to vary with the age of the culture and the H-ion concentration of the medium. The age of the culture influenced the permeability or impermeability of the cells of the fungus to pectinase. The H and OH ions likewise influenced the rate of pectinase excretion.

The viability of uredospores, W. E. MANEVAL (*Phytopathology*, 14 (1924), No. 9, pp. 403–407).—Experiments of the author with uredospores of *Uromyces striatus*, *Puccinia sorghi*, *P. coronata*, *P. menthae americana*, and *U. caryophyllinus* and cited work of other investigators are said to indicate that these species and also *P. helianthi* and *Cronartium ribicola* retain their viability for at least six months at rather cool temperatures and with moderate humidity. It is considered probable that under certain conditions these and other species of rusts retain their ability to infect their host plants after a winter rest period. It is believed that such rusts as those of corn, alfalfa, and oats may overwinter in the uredo stage, be disseminated, and become established in the spring.

Measuring water flow interference in certain gall and vascular diseases, I. E. MELHUS, J. H. MUNCIE, and W. T. H. Ho (*Phytopathology*, 14 (1924), No. 12, pp. 580-584, fig. 1).—A form of apparatus designed to measure the interference of water flow through vascular tissues is described. By means of this device it was found that the vascular distortion caused by crown gall (*Bacterium tumefaciens*) in the trees studied induces sufficient interference to reduce the rate of water flow 30 per cent. The wilting incident to field infection of cabbage with *Fusarium conglutinans* was found to be due to a partial or complete stoppage of the ducts in the vascular system. Alfalfa wilt also results from a vascular plugging.

Fungi causing rots of fruits and bulbs [trans. title], J. TRZEBIŃSKI (*Pam. Państw. Inst. Nauk. Gosp. Wiejsk. Puławach (Mém. Inst. Natl. Polon. Écon. Rurale Puławy)*, 4 (1923), A, No. 4, pp. 1-49, figs. 4; *Fr. abs.*, pp. 44-49).—*Penicillium glaucum* (*P. crustaceum*) is made prominent among several organisms discussed as noted in connection with rotting diseases of fruits and of bulbs.

The alternate hosts of crown rust, *Puccinia coronata* Corda, S. M. DIETZ (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 10, pp. 953-970, figs. 4).—Thirteen species and one variety of *Rhamnus*, indigenous to the United States, and three species native to Europe were investigated as possible alternate hosts of crown rust. Normal infection was secured in at least one trial when teliospores from *Avena sativa* were transferred to *R. californica tomentella*, *R. caroliniana*, *R. cathartica*, *R. ilicifolia*, *R. lanceolata*, *R. pachyphylla*, *R. pinetorum*, *R. rubra*, and *R. smithii*. The following species were found also susceptible, and it is claimed that they may function as alternate hosts of the *Avenae* form of *P. coronata*: *R. alnifolia*, *R. californica*, *R. crocea*, *R. dahurica*, and *R. tinctoria*. *R. frangula*, *R. nevadensis*, and *R. purshiana* showed marked resistance to the physiologic form on oats.

Normal infection was secured by inoculation with teliospores from *Calamagrostis canadensis* on *R. alnifolia*, *R. californica*, *R. crocea*, *R. lanceolata*, and *R. smithii*. It was found that *R. californica tomentella*, *R. cathartica*, *R. pinetorum*, and *R. rubra* may function as alternate hosts of this physiologic form. The other eight species showed marked resistance.

Teliospores from *Festuca elatior* caused normal infection on *R. alnifolia*, *R. californica*, *R. cathartica*, and *R. lanceolata*. Only a few aecia were produced on *R. californica tomentella*, *R. caroliniana*, *R. crocea*, *R. rubra*, and *R. smithii*. Twelve trials on the remaining seven species showed that *R. ilicifolia* produced pycnia and *R. pachyphylla* developed flecks only. Teliospores from *Notholous lanatus* produced pycnia on *R. lanceolata*.

Ceanothus americanus, *Lepargyrea argentea*, and *Zizyphus lycioides* did not respond as alternate hosts of the crown rust. *Berchemia scandens* was infected with teliospores from oats. *L. canadensis* produced aecia when exposed to infection with teliospores from *Calamagrostis purpurascens*.

The different *Rhamnus* species, functioning as alternate hosts, are said to alter the physiologic response of specialized forms.

The author states that during nine years in Iowa aecial infection appeared on *R. cathartica* and *R. lanceolata* previous to the development of uredinia on oats, and these two species of *Rhamnus* are considered to have been instrumental in starting local and general epidemics in Iowa within the past two years.

Studies on the operation of phytopathological pickling fluids [trans. title], H. LUNDEGÅRDH (*Biol. Zentbl.*, 44 (1924), No. 9, pp. 465-487, figs. 9).—The finding regarded as the most significant resulting from this investigation

is that the physiological action of the Cu and Hg ions, absorbed by the seed used, show periodical alterations with increase of quantity.

The behavior of fungicides [trans. title], H. LUNDEGÅRDH (*Nord. Jordbrugsforsk.*, 1925, No. 5, pp. 209-223, figs. 6).—Absorptivity by seeds of fungicides and results are shown graphically with discussion, relating partly to the work above noted.

Seed treatments [trans. title], W. LANG (*Angew. Bot.*, 6 (1924), No. 2, pp. 335, 336).—This is a reply to the report of Gabel previously noted (E. S. R., 52, p. 49).

Streak disease of Gramineae in Mauritius [trans. title], E. F. S. SHEPHERD (*Rev. Agr. Maurice*, No. 22 (1925), pp. 540-542).—The author's attention was directed by G. Orian in April, 1925, to the presence in Mauritius of a mottling or striping sugar cane disease supposedly unknown previously on that island, and thought to be identical with streak disease as reported for portions of South Africa by Storey (E. S. R., 53, pp. 47, 546; 54, pp. 246, 250, 251) and by the present author (E. S. R., 54, p. 250), who now states as the results of experimentation herein briefly noted that the streak disease is propagated at last in the planting material.

Physiological specialization of *Ustilago hordei*, J. A. FARIS (*Phytopathology*, 14 (1924), No. 12, pp. 537-557, fig. 1).—In a previous paper (E. S. R., 55, p. 544) the author showed the effect of certain environmental conditions on the infection of barleys by *U. hordei*. In the progress of his investigations evidence of biological specialization was observed, and subsequent studies have shown definitely the existence of five biological forms of the fungus, with some indications of other forms.

Additional experiments on environmental relations showed that dehulling barley seed tended to increase infection, and it also reduced the stand. The character of the soil proved important in securing infection. High infections were secured over a wide range of soil moisture.

The author concludes that his studies show that the factors limiting infection may be environmental or biological, and that they may be exerted on the parasite or the host or on the relation between the two.

Physiologic specialization in *Puccinia graminis avenae* Erikss. and Henn., D. L. BAILEY (*Minnesota Sta. Tech. Bul.* 35 (1925), pp. 33, pls. 5).—Extensive collections of stem rust of oats were made and cultivated in the greenhouse, the reaction of a large number of varieties of oats to the cultures was determined, and physiological forms of rust were isolated and their reaction to differential hosts studied. Five physiological forms of *P. graminis avenae* were recognized, and in addition to differences in parasitism morphological differences were found. In addition to their infection capabilities of oats the grass-host range of the different forms is reported upon. Of the five forms recognized, one was of Swedish origin not yet found in North America; the second form was represented by cultures, one from Sweden and one from South Africa, neither of which is found in this country; while forms 1, 2, and 5 are said to be widely distributed throughout the United States and Canada.

Field tests of a large number of oat varieties were made at Indian Head, Saskatchewan, and at Brandon and Winnipeg, Manitoba. The uniform susceptibility of all the varieties, except White Tartar and Richland, is said to indicate the possible presence in these localities of forms 1, 2, and 5, and the definite absence of forms 3 and 4. Infection of the variety Victory, which is susceptible to all five physiological forms, is said to proceed in a manner similar to that of wheat varieties susceptible to *P. graminis tritici*. The resistance of Richland is thought to be not entirely dependent on morphological

characters. The mode of infection is said to be much the same as in a susceptible variety, except that pronounced local killing of the infected tissue seems to limit the development of the fungus.

Oat loose smut, *Ustilago avenae*: Biological researches, with particular reference to questions of infection and susceptibility [trans. title], A. ARLAND (*Bot. Arch.*, 7 (1924), No. 1-2, pp. 70-111, figs. 10).—The material employed in the present study was obtained from *Avena sativa* and *A. nuda* in August, 1924. The conditions, methods, and data are systematically presented, with about 90 references to related literature.

Some diseases of wheat crops and their treatments, W. J. SPAFFORD (*So. Aust. Dept. Agr. Bul.* 190 (1925), pp. 16).—Wheat diseases, here listed, with brief discussion also of protective measures, include stinking smut (*Tilletia tritici*), loose smut (*Ustilago tritici*), flag smut (*Urocystis tritici*), take-all (*Ophiobolus graminis*), foot rots (*Helminthosporium* spp. and *Wojnowicia graminis*), red rust (*Puccinia graminis*), and wheat mildew (*Erysiphe graminis*).

Varietal susceptibility of wheat to *Tilletia laevis*, G. M. REED (*Phytopathology*, 14 (1924), No. 10, pp. 437-450).—A report is given of studies begun in 1913 on the resistance of varieties of winter wheat to infection by *T. laevis*. The more common winter wheats grown in Missouri were tested, and all proved to be susceptible to bunt. In some early experiments wide variation was noted in the degree of susceptibility, and this was thought to be correlated with the dates of seeding, the early sowings being less affected. Experiments were conducted to determine the relation of temperature and moisture conditions to the incidence of disease, but it was found impossible to correlate the results with any definite temperature or soil condition. The author believes that soil moisture, soil temperature, and possibly other soil conditions are interdependent factors which determine the occurrence of bunt in wheat.

From the varying reactions observed in different years it is concluded that experiments to determine the resistance of plants to particular diseases should be repeated over a series of years under a wide range of conditions before conclusions are drawn.

Methods of eradicating the common barberry, N. F. THOMPSON and W. W. ROBBINS (*U. S. Dept. Agr. Bul.* 1451 (1926), pp. 46, pls. 13, fig. 1).—Detailed accounts are given of studies on barberry eradication by digging and by the use of chemicals, the practical results having been noted previously (*E. S. R.*, 49, p. 146; 52, p. 546).

Digging was not found to be altogether satisfactory, and cutting and grazing did not destroy the plants.

Experiments were conducted with 37 different chemicals, including inorganic salts, acids and acid formers, gas-forming substances, and oils and other organic substances. In the use of solutions the best results followed the application of the chemical as a drench about the base of the plant, whereas with dry substances, such as salt, the best results were obtained by piling them around the base.

The authors state that, all factors considered, common salt proved the most satisfactory chemical for killing the common barberry. Kerosene and sodium arsenite in solution ranked second and third, respectively, in efficiency. Sodium arsenite, although very effective, is not recommended for general use because of the danger to livestock.

The influence of soil temperature and soil moisture on the development of yellows in cabbage seedlings, E. C. TIMS (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 10, pp. 971-992, figs. 11).—In continuation of previous studies of the yellows disease of cabbage caused by *Fusarium conglutinans* (*E. S. R.*, 54, p.

846), the author gives the results of his investigations on the influence of soil temperature and soil moisture on the development of the disease in resistant and susceptible strains of cabbage seedlings.

It was found that young seedlings of Wisconsin All Seasons and commercial All Seasons strains were almost equally susceptible to yellows up to the age of 20 days. A high percentage of plants of the most resistant varieties became diseased when placed under conditions of low soil moisture and relatively high soil temperature. Cabbage plants of both resistant and susceptible strains grown in healthy soil at from 12 to 16° C. before transplantation to diseased soil at a higher temperature (27°) proved to be more susceptible to yellows than plants grown at from 25 to 28°. Air temperature was found to affect yellows development independently of soil temperature. At a soil temperature of 27° the disease developed most rapidly in the 25° chamber and slightly more slowly in the 19 and 14.5° chambers, but the final percentage of disease was about equal in the three. At a soil temperature of 21° the disease developed most rapidly in the 25° room and less rapidly in the 19° room, and the disease was very slight in the 14.5° room. Commercial Hollander plants were grown in diseased soil at a soil temperature of 21° and at air temperatures of 14 and 28°. Yellows developed much more rapidly, a larger percentage of plants was diseased, and a much greater number of plants were killed at an air temperature of 28° than at 14°.

A study of field conditions for two years, supplemented by a limited amount of greenhouse investigation, is said to have shown that the quantity of rainfall apparently affects the amount of disease independently of soil temperature relations.

Diseases of maize and notes on a parasitic maize weed in Kenya, J. McDONALD (*Kenya Colony Dept. Agr. Bul. 4* [1925?], pp. [1]+6, pl. 1).—The outline presented of maize diseases includes ear rot (*Gibberella saubinetii*), head smut (*Ustilago reiliana*), leaf blight (*Helminthosporium turcicum*), and rust (*Puccinia sorghi*). The parasitic weed *Striga hermonthica* is said to occur only in Kenya in the Nyanza Province, where it has been reported on maize, sugar cane, and sorghum.

Control of cucumber mosaic by eradication of wild host plants, S. P. DOOLITTLE and M. N. WALKER (*U. S. Dept. Agr. Bul. 1461* (1926), pp. 15, pls. 3).—In extension of previous reports (*E. S. R.*, 54, p. 346; 56, p. 49) the authors give the results of five years' field experiments on the control of mosaic of cucumbers by the eradication of the wild host plants on which it overwinters.

The authors state that when the experiments were begun it was known that mosaic was carried in the seed of the wild cucumber, *Micrampelis* (*Echinocystis*) *lobata*, and as the work progressed it was found that the disease overwintered in the roots of milkweed (*Asclepias syriaca*), pokeweed (*Phytolacca decandra*), ground cherry (*Physalis heterophylla* and *P. subglabrata*), and catnip (*Nepeta cataria*). Some of these hosts are said to occur in all the cucumber-growing regions of the Eastern and Central States. Mosaic was found to be transmitted from the wild cucumber to the cultivated cucurbits by the striped beetle, *Diabrotica vittata*, and to a lesser degree by the 12-spotted beetle, *D. 12-punctata*. The melon aphid, *Aphis gossypii*, is said to act as the chief agency of dissemination from the other wild host plants.

Experiments which were carried on in Illinois and Wisconsin included groups of from 8 to 17 fields where mosaic had been prevalent in previous years. In view of the results obtained, it is believed that cucumber mosaic can be controlled by the eradication of wild hosts, if the work is done with care and continued throughout the season.

Studies on disease resistance in the onion, J. C. WALKER (*Natl. Acad. Sci. Proc.*, 11 (1925), No. 3, pp. 183-189, fig. 1).—The studies here summarized contribute to the general subject of disease resistance in plants, the causes of which resistance appear from recent investigations cited to be widely varied and relatively complex when compared with certain cases or forms of resistance or immunity in animals.

Horticultural varieties of onion (*Allium cepa*) are grouped with respect to pigment dissolved in the cell sap into white (pigment negligible), yellow (flavone derivatives present in outer epidermis), and red (epidermal anthocyan, flavone derivatives also present). Diseases dealt with were smudge (*Colletotrichum circinans*), neck rot (*Botrytis allii* and *Botrytis* sp.), and black mold (*Aspergillus niger*), all of these organisms passing part of their life cycle as saprophytes on dead organic material on or in the soil, but infecting the living fleshy storage tissues of the scales in the the mature bulb and causing gradual decay during storage. Resistance of both yellow and red onion varieties to smudge becomes evident before harvest. No consistent evidence of varietal resistance to black mold has been noted. As regards neck rot, the white varieties always led in susceptibility. The present work, as here detailed, dealt largely with the correlation between coloration and susceptibility to the diseases mentioned.

From the results shown it is concluded that the resistance of colored bulbs to smudge and neck rot is due to a certain substance, readily soluble in the sap of the outer scales of such varieties and toxic to certain disease organisms. In experimentation, the substance becomes functional by dissolving into the infection drop and inactivating the fungus before penetration can take place. The nature of this inactivating substance, its origin, and associations are discussed. The possibility that the coloring substance itself is actually the agent toxic to the organism is not easily tested to a positive conclusion. The toxic substance may be a soluble derivative of quercetin, probably a glucoside not easily isolated in its original form by ordinary chemical methods.

Botrytis neck rots of onions, J. C. WALKER (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 10, pp. 893-928, figs. 6).—In a previous publication the author described neck rots of onions caused by *Botrytis* spp. and suggested some means of control (E. S. R., 53, p. 351). In the present contribution three species of *Botrytis*, *B. allii*, *B. byssoidea*, and *B. squamosa*, are described as causing related but distinct neck-rot diseases.

The author confirmed the claim of Munn (E. S. R., 38, p. 450) that colored varieties are less subject to attack than are white varieties. When infection once occurs, however, decay is said to proceed with equal rapidity in both types. It is said that the disease may be controlled in a large measure by the use of colored varieties. Artificial curing of the bulbs after harvesting so as to desiccate rapidly the neck tissues is also effective in checking the disease.

Fusaria causing bulb rot of onions, G. K. K. LINK and A. A. BAILEY (*Jour. Agr. Research [U. S.]*, 33 (1926), No. 10, pp. 929-952, figs. 8).—Descriptions are given of bulb rot of onions caused by several species of *Fusarium*, the characteristics of the disease being essentially the same as those described by Walker and Tims (E. S. R., 52, p. 348).

The authors claim that a bulb rot of onions caused by *Fusarium* spp. occurs widely in the field and after harvest both in transit and in storage. Red, yellow, and white varieties were equally susceptible, and decay was readily produced when bulbs were inoculated in wounds. The species which cause onion bulb rot are considered to be specialized pathogenes attacking only species

of *Allium*. In this paper descriptions are given of *F. zonatum* form 2, *F. cepae*, and *F. zonatum* form 1. *F. bulbigenum* was not found to be consistently pathogenic, and *F. moniliforme* is reported to be pathogenic at times.

Controlling onion smut with Kalimat, P. J. ANDERSON (*Phytopathology*, 14 (1924), No. 12, pp. 569-574).—Previous investigations reported by the author showed that under certain soil conditions formaldehyde, used for the control of onion smut (*Urocystis cepulæ*), caused considerable loss through reduced stand (E. S. R., 54, p. 545). Later tests were made in which formaldehyde and Kalimat were compared. As a result of two years' experiments, it is claimed that Kalimat controlled onion smut as well as formaldehyde, and it was safer to use in concentrated solutions or in very dry soils. A somewhat better stand was also secured, which may have been due to the more complete destruction of the soil organisms and not to stimulated germination. The present cost of Kalimat is considered rather high for its extensive use.

Potato diseases, G. B. SANFORD (*Alberta Univ., Col. Agr. Bul.* 5 (1924), pp. 34, figs. 22).—The several main divisions of this bulletin as indicated deal in varying detail with fungus diseases, bacterial diseases, insect injury, injury caused by factors of environment, degeneration diseases of obscure causation, the seed plat and disease control, certified seed, methods for seed treatment and sprays, and general recommendations.

Methods of studying the degeneration diseases of potato, D. ATANASOFF (*Phytopathology*, 14 (1924), No. 11, pp. 521-533).—The author outlines methods of investigation and offers suggestions which are designed to simplify and aid in studies of the virus diseases of the potato plant.

Standardizing of degeneration diseases of potato, H. M. QUANJER (*Phytopathology*, 14 (1924), No. 11, pp. 518-520).—The desirability of standardizing the symptoms of various degeneration diseases of potatoes is pointed out, and attention is called to the overlapping of symptoms of forms of mosaic and other diseases on different varieties of potatoes.

Three serious cane diseases not yet reported from the British West Indies, S. F. ASHBY (*West Indian Agr. Conf., Kingston, Proc.*, 9 (1924), pp. 84-89).—Attention is called to the significance of three cane diseases, Fiji or leaf gall disease, leaf stripe or *Sclerospora* disease, and gumming or Cobb's disease. Only the last named has been found, it is stated, in the West Indies, this having been detected in Porto Rico in 1920 and to be known to have spread considerably since that time.

Mosaic disease of sugar-cane, C. G. HANSFORD (*West Indian Agr. Conf., Kingston, Proc.*, 9 (1924), pp. 76-82).—Sugar cane mosaic is said to have been first noted in Java about 1890, but to have been regarded as simply an undesirable variation. It became serious in Porto Rico in 1917-1921, in Jamaica since 1920, and in Cuba since 1921. A list of known hosts is given. The disease is spread by planting diseased material and by transmission from diseased to healthy plants. Losses range from 30 up to 50 per cent. The relation of this disease to canes differing in susceptibility is discussed.

Java gum disease of sugar cane identical to leaf scald of Australia, D. S. NORTH and H. A. LEE (*Phytopathology*, 14 (1924), No. 12, p. 537).—The authors claim the identity of the leaf scald of sugar cane in Australia with the gum disease of Java described by Wilbrink (E. S. R., 45, p. 146). On account of the possible confusion with the gum disease described by Cobb (E. S. R., 7, p. 513), the authors suggest the retention of the Australian name. This disease, which is considered one of the most destructive diseases of the sugar cane, is known to occur only in Australia, Fiji, Java, and the Philippines.

Histology and cytology of sugar cane matizado [trans. title], M. T. COOK (*Rev. Agr. Puerto Rico*, 15 (1925), No. 6, pp. 291-293).—The conclusion to this brief account asserts agreement with the findings reported by Kunkel (E. S. R., 51, p. 449) regarding the presence of intracellular bodies in mosaic plants, although no claim is made as to the actual agency of these bodies in mosaic causation.

The use of sulphur as a fungicide and fertilizer for sweet potatoes, J. F. ADAMS (*Phytopathology*, 14 (1924), No. 9, pp. 411-423, figs. 4).—Two seasons' experiments covering a considerable number of individual tests with inoculated sulfur applied alone to soils or in connection with fertilizers are said to indicate that inoculated sulfur is valuable in the control of certain soil diseases of sweet potatoes, and that it also acts as a fertilizer.

Practical control of scurf was secured, and pox and black rot were reduced in the field, as well as the development of these diseases in storage. The yields were also increased where sulfur was used.

Evidence was secured that indicated a relation between soil reaction and disease control and increased yields. With a decrease in the pH exponent and an increase in the H-ion concentration the prevalence of disease diminished and yields increased.

Under the conditions of the experiments, an application of 300 lbs. of inoculated sulfur per acre was the maximum quantity required for practical disease control and increased yields.

Tobacco leaf diseases [Porto Rico] [trans. title], M. T. COOK (*Rev. Agr. Puerto Rico*, 15 (1925), No. 6, p. 282).—*Cercospora nicotianae*, only, is briefly discussed.

Tobacco mosaic in Southern Rhodesia, F. EYLES (*Rhodesia Agr. Jour.*, 23 (1926), No. 3, pp. 248-252).—The presence of tobacco mosaic in Southern Rhodesia is regarded as certain, and in some years severe crop damage is thought to be attributable to this disorder. It is assumed that the causal agent of tobacco mosaic may overwinter, or may originate, in some Rhodesian weed or weeds. Information and discussion, as herein presented, refer also to other diseases of widespread occurrence and undetermined causation, often referred to as virus diseases.

Bacterial soft-rot of tomato, S. A. WINGARD (*Phytopathology*, 14 (1924), No. 10, pp. 451-459, figs. 3).—A study was made of a bacterial soft rot of tomato fruits that is reported to have been of considerable importance in Virginia.

The disease was found to be caused by *Bacillus aroideae* (E. S. R., 16, p. 270). The organism is said to be a wound parasite, and green tomatoes are more susceptible to injury than ripe ones. All varieties tested were about equally affected. Losses due to this disease were appreciably reduced by spraying with soap-Bordeaux mixture.

A study of *Bacillus aroideae*, the cause of a soft rot of tomato, and *B. carotovorus*, A. B. MASSEY (*Phytopathology*, 14 (1924), No. 10, pp. 460-477, figs. 3).—Comparative studies of *B. aroideae* (E. S. R., 16, p. 270) and *B. carotovorus* (E. S. R., 13, p. 362) are said to indicate that these species are distinct although closely related.

Cellular interaction between host and parasite, C. H. FARR (*Phytopathology*, 14 (1924), No. 12, pp. 575-579, figs. 12).—A method is described for the direct observation of the growth reaction of hosts and parasites. By this method the author observed the reaction of *Fusarium lycopersici* toward the roots of several varieties of tomato susceptible and resistant to wilt.

Pathologic histology of apple blotch, E. F. GUBA (*Phytopathology*, 14 (1924), No. 12, pp. 558-568, pls. 2, figs. 5).—The gross histology of tissues of twigs, fruit, and leaves infected by *Phyllosticta solitaria* is described. On account of failure of the author's efforts to obtain artificial infection, some points in the pathological histology of the disease remain to be determined. Three forms of the blotch on the fruit are recognized, fringed, blistered, and pitted types of the disease.

Experiments in control of cankers of pear blight, L. H. DAY (*Phytopathology*, 14 (1924), No. 10, pp. 478-480, fig. 1).—Scarifying canker areas so that all bark is removed from the cankers and for some distance on sound wood and treating the scarred area with a solution of corrosive sublimate and cyanide of mercury in water and glycerine is said to have arrested all cankers so treated. The author states that all epidermal bark must be removed as the fungicide will not penetrate the waxy covering of the bark. If the bark is pared too deeply the cambium may be killed by the treatment.

Experiments with fertilizers and cultivation for the control of bacterial spot of peach, H. W. ANDERSON (*Ill. State Hort. Soc. Trans.*, 59 (1925), pp. 258-266).—Results, as detailed with discussion, of an experiment carried out near Ozark, Ill., to test the theory that nitrate fertilizers will control peach bacterial spot (shot hole), led to no definite recommendation. Nitrating, though not dependable to check disease, is considered important in lessening the harmful effect of bacterial spot by adding more leaf surface and by holding the leaves during a longer period.

Control of bacterial spot of peach with sodium silicofluoride, H. W. ANDERSON (*Ill. State Hort. Soc. Trans.*, 59 (1925), pp. 266-271).—As a result of laboratory and field experiments it is stated that peach bacterial spot or shot hole (*Bacterium pruni*), the most serious disease in Illinois commercial peach orchards, was controlled almost perfectly during the summer of 1925 by sodium silicofluoride. Though no injury resulted from the application of sodium silicofluoride at concentrations of 1 to 4 lbs. in 50 gal. of water, it is believed that this spray should not be recommended until after another season's trial. This substance is very cheap and plentiful. No injury followed its use as a dust with or without sulfur, even when the trees were sprayed with water following the application. However, owing to high winds and the lack of "fluffiness," the dust did not remain on the foliage and did not successfully control the disease.

Sodium silicofluoride is not only a germicide but also a fungicide and a contact and stomach insecticide.

The manner of infection of peach twigs by the brown rot fungus, G. W. FANT (*Phytopathology*, 14 (1924), No. 9, pp. 427-429).—Inoculation experiments with *Sclerotinia cinerea*, one series made in April and May and the other in midsummer, are said to show that the unwounded peach twig, whether newly formed or of the previous year's growth, is apparently resistant to infections through the epidermis. When twig blighting occurs it is largely confined to infections which enter through blighted blossoms, through attached mummies, or through various sorts of wounds which may appear upon the surface of the peach twig.

Cranberry disease investigations on the Pacific coast, H. F. BAIN (*U. S. Dept. Agr. Bul.* 1434 (1926), pp. 29).—The results are given of four years' study of diseases of cranberries in the Pacific Northwest. Six diseases of the plant and several of the berries in the field are described, and means are suggested for their control. Most of the diseases which occur in the field are said to be of minor importance, the diseases of the fruit in storage being the most de-

structive. Hard rot of the berries, caused by *Sclerotinia oxycocci*, is said to sometimes cause local losses in the field.

Of the storage rots, end rots, caused by *Fusicoccum putrefaciens*, was found to be the most important.

A series of spraying experiments followed by storage tests demonstrated that two applications of Bordeaux mixture, the first just before the blossom stage and the second immediately following blossoming, will control the development of storage rots satisfactorily. Dusting with a lime-copper mixture, in less extensive experiments, failed to give as consistently good control of storage rots as spraying. Cold storage at an average temperature of from 32 to 34° F. failed to prevent the development of rots, particularly over a period of several months.

Diseases of strawberries on the market, D. H. ROSE (*U. S. Dept. Agr., Dept. Circ. 402 (1926)*, pp. 8, fig. 1).—The results are given of the study of data furnished by certificates of the food products inspection service of the Bureau of Agricultural Economics covering 5,370 carloads of strawberries examined at terminal markets during the 7-year period ended December 31, 1925. These inspections are said to have covered 5.5 per cent of the total carload movement of strawberries for the 7-year period. Nearly one-third of the inspected cars showed no rot. The average percentage of rot in all carloads inspected was 5.8, while in those which showed rot the percentage was 8.4. Rot caused by the fungus *Rhizopus* was said to have caused approximately 58 per cent of all the disease found.

Some remarks on questions raised by the Panama disease of bananas, C. G. HANSFORD (*West Indian Agr. Conf., Kingston, Proc., 9 (1924)*, pp. 41-51).—A brief account is given of the Panama disease of bananas since its alleged discovery in Jamaica in 1912. Apparently this disease has here, as in large banana areas of Central America, tended to drive, more or less gradually, banana cultivation continually further inland and into the hills. A number of strains of *Fusarium* isolated from different sources and found to be culturally and morphologically identical with *F. cubense* have shown great differences as regards behavior on inoculation into healthy bananas, when compared with the *F. cubense* isolated from bananas showing the typical Panama disease.

The disease is spread by the planting of suckers bearing incipient stages of the disease, by banana trash, by wind-borne spores, and by the transportation of diseased soil. Attempts at control are discussed.

Researches on Panama disease, S. F. ASHBY (*West Indian Agr. Conf., Kingston, Proc., 9 (1924)*, pp. 51-53).—Immunity of bananas to the Panama disease does not exist; but some varieties show resistance, and forms are being tested along with those of known susceptibility, as Giant Fig with Gros Michel.

“This method of soil inoculation, therefore, promises to serve as a rapid means of testing the relative resistance of varieties, a highly susceptible kind being planted as a control.”

Red ring disease of the coconut, S. F. ASHBY (*West Indian Agr. Conf., Kingston, Proc., 9 (1924)*, pp. 164-172).—“This is a fatal parasitic infectious disease recently recognized as of wide distribution in the West Indian region but known for nearly 20 years under the name of root disease in Trinidad and Tobago. It is present in Honduras, British Honduras, Panama, Venezuela, British Guiana, Trinidad and Tobago, Grenada, and St. Vincent, but has not yet been definitely reported from the Greater Antilles. The evidence sug-

gests spread by means of seed nuts so that it may have been introduced already from Central America into one or more of the Greater Antilles."

Black rot or koleroga of coffee and its control, S. V. VENKATARAYAN (*Mysore Agr. Calendar, 1926, pp. 37, 40, 41, pls. 2*).—The most serious fungus disease of coffee in Mysore on estates of comparatively high elevation is koleroga (black rot), due to *Corticium koleroga*. This disease appears following the heavy rains of the southwest monsoon about the middle of June, spreading from plant to plant until the end of the season, attacking first leaves and twigs, and later berries. The name is due to the mass of black rotting leaves and berries suspended by the mycelial web. Sunshine hinders the development of the fungus. The spores are wind distributed. Several wild hosts grow in or around the coffee estates. Losses vary with rainfall and with lack of sanitation.

The only control method adopted usually on most estates is hand removal of the infected material. Spraying with Bordeaux mixture is effective. The strength found sufficient is that of 2.5 lbs. each of copper sulphate and quicklime to 12 gal. of water. The adhesive ingredient is made up either with resin and soda or casein and lime. The cost of spraying is not heavy if water is readily available. Attempts are being made to secure a reliable dust fungicide.

Fungoid diseases of coffee in Kenya Colony, J. McDONALD (*Kenya Colony Dept. Agr. Bul. 3 [1925?], pp. 17*).—Coffee diseases occurring in Kenya are outlined as those of leaf, berry, stem, and root, as nursery diseases, and as physiological diseases. The two preparations found most effective there are Bordeaux mixture at 2-2-40 and carbide mixture (in which the lime is replaced by calcium carbide).

Die-back of limes (*Citrus medica* var. *acida*), E. A. WALTERS (*West Indian Agr. Conf., Kingston, Proc., 9 (1924), pp. 232-234*).—Lime die-back, somewhat common in St. Lucia during recent years, is briefly described. An effort made during 1923 to determine the cause of this trouble shows an almost constant bad soil condition, which is described. A remarkable recovery of trees so affected has been found to result from deeper digging, large applications of humus, and spraying and pruning. It appears that lime trees tend to wilt daily during the prevalence of certain soil and atmospheric conditions which are described. Seedling bed lime plants, and in less degree established trees, appear to be unfavorably affected by the presence of *Casuarina* spp. used as a windbreak. This may be due to a limitation of water supply.

Withertip and blossom blight of limes, S. F. ASHBY (*West Indian Agr. Conf., Kingston, Proc., 9 (1924), pp. 172-176*).—Lime withertip and blossom blight (due to a fungus regarded in Florida as a strain of *Colletotrichum gloeosporioides* but said to have been described by Clausen (E. S. R., 28, p. 749) as *Gloeosporium limetticolum*), present for many years in Florida, Cuba, and probably Porto Rico and said to have been recently reported from the Philippines, became prominent about 1917 in Trinidad (and soon after in British Guiana), but was not known elsewhere in the Lesser Antilles until 1922. A reduction of about 40 per cent in the main crop of 1923 is attributed largely to this disease, which is here described. Tests in Florida have shown that the disease can be controlled measurably by timely spraying of the trees with Bordeaux oil emulsion, or in less degree with lime sulfur. The means regarded as really effective is replacement of susceptible trees with highly resistant or immune varieties, a number of which are now available.

Black rot disease of tea, W. S. SHAW (*Trop. Agr. [Ceylon]*, 65 (1925), No. 6, pp. 339-343).—Tea black rot, said to be due to *Corticium invisum* and *C. theae* and to have been first observed in Java in 1907 and in Ceylon (where now also coffee and cacao are attacked) in 1916, is discussed as to its causal fungi, symptoms, dissemination, and treatment.

A disease on *Amarantus* caused by *Choanephora cucurbitarum*, B. T. PALM and S. C. J. JOCHEMS (*Phytopathology*, 14 (1924), No. 11, pp. 490-494, pl. 1).—The authors describe a disease of *A. blitum* in Sumatra, the causative agent of the disease being *C. cucurbitarum*. *A. spinosus* was also attacked, as well as a number of other species of plants.

The *Phytophthora* disease of lilac, H. L. G. DE BRUYN (*Phytopathology*, 14 (1924), No. 11, pp. 503-517, figs. 6).—A description is given of a disease of cultivated lilac due to attacks of *P. syringae*. Leaves, buds, and stems are subject to attack, but the infection is usually brought about only under special conditions. The disease is said to be of economic importance only where lilacs are grown for forcing during the winter months. The usual method of attack is through the leaves to the stem and buds. Picking infected leaves before the fungus has grown down through the petioles is recommended as a means of control.

***Tylenchus dipsaci* on narcissus**, C. E. SCOTT (*Phytopathology*, 14 (1924), No. 11, pp. 495-502, pl. 1, figs. 3).—The occurrence of *T. dipsaci* on narcissus bulbs in the bulb-growing area of California is reported. The author states that characteristic thickened spots occur in the leaves, and that these serve to identify the disease in the field. Of control measures tested, treatments of bulbs in hot water at 110° F. for three hours is said to be the most promising method.

Endothia parasitica, H. M. QUANJER (*Phytopathology*, 14 (1924), No. 11, p. 535).—The reported presence of chestnut canker in Belgium (E. S. R., 56, p. 55) has been investigated by Marchal and Van Hove. The conclusion was reached that the case cited must have been an isolated one, as no trace was found of the disease and it is thought not to have been present in Europe in the fall of 1924.

ECONOMIC ZOOLOGY—ENTOMOLOGY

Proceedings of the International Congress for the Study of Bird Protection, edited by J. MORBACH (*Congrès International pour l'Étude et la Protection des Oiseaux, Luxembourg, 1925. Compt.-Rendu. Luxembourg: P. Worré-Mertens, 1925, pp. 280, pls. 5, figs. 5*).—The proceedings of this congress are reported.

Experiments in the economic control of the western crow (*Corvus brachyrhynchos hesperis*), L. L. GARDNER (*Auk*, 43 (1926), No. 4, pp. 447-461).—Injury by this crow to almonds and apricots, grown extensively in the Goodnoe Hills, Klickitat Co., Wash., and to considerable acreages of watermelons led to the work by the U. S. D. A. Bureau of Biological Survey here reported.

Damage commenced about the last of July among the apricots and continued through the almond season, or to early in November, by which time practically the entire crop would be destroyed. In a 20-acre almond orchard containing about 1,500 trees some 30,000 crows were observed to congregate. Efforts of the farmers, which included shooting, use of scarecrows, and belling and stringing the trees, had proved unavailing, and poisoning experiments were conducted by the author. Poisoned meat baits proved ineffectual, as the crows' predilection for almonds was too great. The use of poisoned almonds, when properly conducted, proved successful in protecting the crops. While the actual

number of crows poisoned was extremely small, not exceeding 1 per cent of the flock, many orchards were rendered immune from damage, and large melon patches were protected by the same means. Large and choice water-melons, which are the chief agricultural product of the area, were afforded complete immunity from the crows by the use of poisoned melons.

Effects of wheat treated with copper carbonate upon the common house mouse (*Mus musculus*), W. W. MACKIE and F. N. BRIGGS (*Phytopathology*, 16 (1926), No. 9, pp. 629-632, figs. 2).—In experiments at the California Experiment Station it was found that copper carbonate causes no apparent injury to mice when consumed by them on wheat as ordinarily treated to control bunt. When untreated wheat is available, mice will avoid wheat treated with copper carbonate. So far as the effect upon mice is concerned, copper carbonate is a repellent and not a poison.

Host-parasite specificity among human protozoa, R. W. HEGNER (*Sci. Prog. [London]*, 21 (1926), No. 82, pp. 249-259).—It is pointed out that a rather rigid host-parasite specificity exists among human protozoa; certain species are not known to occur in any other host, and others in only one or several animal reservoirs. Species that pass part of their life cycle in an insect host are usually restricted to one principal species or to several species belonging to one genus.

The physics of spray liquids, IV, V, R. M. WOODMAN (*Jour. Pomol. and Hort. Sci.*, 4 (1925), Nos. 3-4, pp. 184-195; 5 (1925), No. 1, pp. 43-49).—In the fourth paper of the series (*E. S. R.*, 53, p. 556), entitled *The Creaming Capacity of Emulsions—Paraffin Solutions*, it is shown, as Pickering demonstrated¹ that so-called emulsions tend to cream to give a clear aqueous underlayer and a cream containing approximately the mathematical limit (74 per cent) of disperse phase. It is argued that this cream is the only true emulsion, and that under ideal conditions it would contain the mathematical limit of disperse phase. Mixtures of this cream or emulsion with excess continuous phase are termed emulsion mixtures.

“The difference between the stability, and the stability to creaming, of an emulsion mixture is pointed out; in the first case lack of stability should be judged to mean the ‘cracking’ of an emulsion into separate layers of disperse and continuous phases; in the second case (which is often confused with true stability) lack of stability results in creaming to the true emulsion (cracking into disperse phase in mass usually taking place after formation of this cream). The creaming effect is probably one of the chief causes of failure of emulsion mixtures in spraying. The use of wide vessels as containers and the employment of dilute emulsion mixtures accentuate this defect. Equalization of densities of the disperse and continuous phases of an emulsion mixture by adding a substance of greater specific gravity than water, completely miscible with the disperse phase and showing limited miscibility with the continuous phase, gives very stable or lasting emulsion mixtures in the case of paraffin oil. In some cases actual solution of relatively large amounts of oil is obtained. The easiest methods of preparation of these solutions are discussed, and the probable use of the solutions as foliage sprays indicated.”

In Part V, *Paraffin—Cresols—Soap Solutions: The Detergent Action of Soaps*, it is shown that paraffin oil is soluble in cresols-soap solutions to a much greater extent than in soap solutions. The addition of cresols to paraffin oil emulsions in soap media stabilizes the emulsion mixtures to creaming in many cases. Solutions of paraffin oil at all concentrations up to 20 per cent can be made by the aid of soap and cresols.

¹ *Jour. Chem. Soc. [London]*, 91 (1907), pt. 2, pp. 2001-2021.

Cresol, saponified, as a larvicide. C. STRICKLAND and D. N. ROY (*Jour. Roy. Army Med. Corps*, 47 (1926), No. 3, pp. 188-195).—Experiments conducted are presented in detail, and Notes on the Cresols, by A. D. Stewart (pp. 193-195), are included.

Fifty-sixth annual report of the Entomological Society of Ontario, 1925 (*Ent. Soc. Ontario, Ann. Rpt.*, 56 (1925), pp. 111).—This report of the proceedings of the annual meeting of the Ontario Entomological Society held at Ottawa in November, 1925, includes the following papers: Report of Insects for the Year 1925, by C. B. Hutchings, A. Cosens, and H. F. Hudson (pp. 7-12); Insects of the Season in Ontario, by L. Caesar and W. A. Ross (pp. 13-17); Notes on the Control of the Grape Berry Moth, by W. A. Ross (pp. 17-19); The Rose Scale in British Columbia, by W. Downes (pp. 19-22); The Oriental Peach Moth in Canada, by A. Gibson (pp. 22-24); Derris as an Insecticide, by A. Kelsall, J. P. Spittall, R. P. Gorham, and G. P. Walker (pp. 24-40); Miscellaneous Notes on Lubricating Oil Sprays with Special Reference to Their Use for Pear Psylla Control, by W. A. Ross (pp. 40-44); The Distribution of Insects and the Significance of Extralimital Data, by E. P. Felt (pp. 44-47); Observations in Quebec in 1925, by G. Maheux (pp. 48-50); Insect Pests Imported on Miscellaneous Plant Products, by R. A. Sheppard (pp. 50-54); Some Insects and Entomologists, by W. E. Britton (pp. 55-63); Controlling the Brown Tail Moth in Nova Scotia, by F. C. Gilliatt (pp. 63-67); The Gypsy Moth Situation in Quebec, by L. S. McLaine and S. H. Short (pp. 67-69); The Birch Leaf Skeletonizer, *Bucculatrix canadensisella* Chamb., by C. B. Hutchings (pp. 69-71); A Preliminary Announcement on the Outbreak of the European Pine Shoot Moth, by L. S. McLaine (pp. 71, 72); Mortality of the European Corn Borer (*Pyrausta nubilalis* Hubn.) Adults and Larvae, by L. Caesar (pp. 72-75); The Spread and Degree of Infestation of the European Corn Borer in 1925, by W. N. Keenan (pp. 75-77); Recent Developments in the Introduction of Parasites of the European Corn Borer in Ontario, by A. B. Baird (p. 78); Egg Studies of the Clover Leaf Curculio, *Sitones hispidulus* Fab., by H. F. Hudson (p. 79); The Striped Cucumber Beetle, *Diabrotica vittata* Fab., by J. Marshall (pp. 80-83); Garden Insects of 1925 in Montreal District, by L. Daviault (pp. 83-85); Parasites of White Grubs in Southern Quebec—A Progress Report, by C. E. Petch and G. H. Hammond (pp. 85-91); Notes on the Life History of the Clover Root Borer, *Hylastinus obscurus*, by H. F. Hudson (pp. 92, 93); and The Entomological Record, 1925, by N. Criddle, C. H. Curran, and H. L. Viereck (pp. 94-107).

The discovery in September, 1925, of the oriental peach moth (*Laspeyresia molesta* Busck) in the peach belt of the Niagara district, Ontario, led to a survey which showed that, if not generally distributed throughout the whole belt, it at least occurs in patches from Hamilton to the Niagara River, and has doubtless been present for several years. Infestation by the European pine shoot moth (*Evotria buoliana*) has been found at six points in Ontario and in Victoria, B. C.

Notes on miscellaneous insects in 1924. B. A. R. GATER (*Malayan Agr. Jour.*, 13 (1925), No. 6, pp. 160-167).—This account includes a tabulated list of parasites reared during the year.

Notes on tree and shrub insects in southeastern Pennsylvania. A. B. WELLS (*Ent. News*, 37 (1926), No. 8, pp. 254-258).—This is a collection of miscellaneous notes.

[**Pests of the coconut palm in the islands of the southern Pacific**], H. W. SIMMONDS (*Fiji Dept. Agr. Bul.* 16 (1925), pp. 7-26, pls. 3, figs. 3).—The more important insects and other pests attacking the coconut palm in the islands of the southern Pacific are considered.

Pineapple insects and some related pests, J. F. ILLINGWORTH (*Hawaii. Pineapple Cannery Sta. Bul.* 9 (1926), pp. 64, figs. 44).—In this bulletin the author has brought together accounts of the insects which attack the pineapple and data relating to each where found, hosts, injury, distribution, and control.

An annotated bibliography of 179 titles is included.

[Insect enemies of mahogany (*Swietenia mahagoni* and *S. macrophylla*) cultivated in Java], L. G. E. KALSHOVEN (*Dept. Landb., Nijv. en Handel [Dutch East Indies], Meded. Inst. Plantenziekten*, No. 69 (1926), pp. 27-72, 111-121, pls. 8; *Eng. abs.*, pp. 111-121).—The insects of mahogany in Java here considered include the mahogany shoot borer (*Hypsipyla robusta* Moore), shot-hole borers of twigs and seedlings (*Xyleborus morigerus* Bldf. and *X. morstatti* Hag.), the red branch borer (*Zeuzera coffæ*), and several of lesser importance.

A further contribution to our knowledge of the bionomics and control of the migratory locust, *Schistocerca gregaria* Forsk. (peregrina Oliv.), in the Sudan, H. B. JOHNSTON (*Wellcome Trop. Research Labs., Ent. Sect. Bul.* 22 (1926), pp. 14, pl. 1).—This account furnishes information on *S. gregaria* in the Sudan additional to that supplied by King (*E. S. R.*, 47, p. 552).

The locust fungus, *Empusa grylli*, and its effects on its host, S. H. SKAIFE (*So. African Jour. Sci.*, 22 (1925), pp. 298-308, pl. 1).—Following an historical account, the author discusses climatic conditions, the transmission of the disease, experiments with conidia, the species attacked, development of the fungus, the resting spores, artificial utilization of the disease, and other diseases of the locust. The author finds evidence that there are strains of the fungus which are much more virulent than others, and that it might be found possible to isolate the extremely virulent strains or perhaps even to increase the virulence.

The banana thrips rust, A. A. GIRAULT (*Queensland Agr. Jour.*, 23 (1925), No. 6, pp. 471-517, figs. 2).—The author reports at length upon the biology and control of *Anaphothrips signipennis* (Bag.) in the Gympie district. This thrips, originally described from Ceylon in 1914, occurs on the north coast of Queensland and feeds upon the pseudostem and fruit of bananas. The effect of this feeding upon the fruit is a powdery blotching of the skin which, as it increases and ages, turns leathery and becomes more or less cracked—a condition known as banana rust. The insect is present through the seasons, never ceases to reproduce, and all stages occur at one time. Each generation develops in about 34 days, so that in continuity about 10 generations occur during a calendar year, though actually there are less. Treatment, which should not commence until late in the season, consists of regular powderings of the fruit with a bulb blower, using 50 per cent of pyrethrum powder to 50 per cent wood ashes, bulk measurement. Four or more treatments should be made at intervals of not more than 8 or 9 days. Meanwhile all tip fruits should be removed and destroyed. If a spray is desired, Blackleaf 40 in a strong soap solution should be used at double or single strength.

The life history of *Tectocoris lineola* F. and its connection with internal boll rots in Queensland, E. BALLARD and F. G. HOLDAWAY (*Bul. Ent. Research*, 16 (1926), No. 4, pp. 329-346, pls. 3, figs. 4).—The authors give a general account of the life history, bionomics, and distribution of *T. lineola*, together with a description of the adult and some remarks on the influence of weather conditions on mating. Several natural enemies are referred to. The connection between *T. lineola* and boll rot incidence is established. A table illustrates the comparative effect of boll rots and bollworm damage during the season 1924-25 on the Cotton Research Farm at Biloela. The effect of bug punctures

on cotton seed and its infection with *Fusarium moniliforme* are briefly discussed.

The hibiscus mealy bug (*Phenacoccus hirsutus* Green) in Egypt in 1925 with notes on the introduction of *Cryptolaemus monstrouzeri* Muls., W. J. HALL (*Egypt Min. Agr., Tech. and Sci. Serv. Bul. 70 (1926), pp. [3]+15, pls. 5*).—*P. hirsutus*, which has proved a very troublesome pest in Egypt although not of major economic importance, since 1920 has spread from Cairo to nearly all of Egypt in spite of legislation regulating the transport of infected plants and plant produce. Earlier accounts by the author have been noted (E. S. R., 47, pp. 657, 851; 48, p. 552).

Notes on the control of mealybugs, L. R. GARDNER (*Jour. Ent. and Zool., 18 (1926), No. 3, pp. 57, 58*).—A brief discussion.

Miscellaneous observations on a cranberry scale, *Targionia dearnessi* (Ckll.) (Homop.: Coccidae), D. S. LACROIX (*Ent. News, 37 (1926), No. 8, pp. 249-251*).—In this contribution from the Massachusetts Experiment Station, the author records the infestation of the cranberry at Sandwich, Mass., by *T. dearnessi*. It infested the Early Black, Howe, and Chipman varieties with no apparent preference for any one of the three kinds, and it appeared to be fully as abundant on bogs subjected to regular flowages as on dry bogs. It was also found on bearberry around the edges of cranberry bogs. Notes are presented on its life history, and parasitism by two species of Hymenoptera, *Coccidencyrtus ensifer* (How.) and *Signiphora* sp. (probably new) is recorded.

The San Jose scale in Wisconsin, E. L. CHAMBERS (*Wis. Dept. Agr. Bul. 73 (1926), pp. 8, figs. 3*).—A brief practical account.

The peach borer and the paradichlorobenzene treatment, W. W. MAGILL and A. J. OLNEY (*Ky. Agr. Col. Ext. Circ. 159 (1923), pp. 4, figs. 2; rev. ed. (1926), pp. 6, fig. 1*).—In this brief practical account the authors refer to experiments in 1 and 2-year-old peach orchards in Kentucky and adjoining States which indicate that paradichlorobenzene may be used without injury to the trees. It is stated that a majority of reliable commercial growers in Kentucky are using $\frac{1}{2}$ oz. on 1-year-old trees and $\frac{3}{8}$ oz. on 2-year-old trees, and have reported complete control of the borer with no injury to several thousand trees tested. As a protection against possible injury to the youngest trees, it is considered advisable to remove the mounds after three weeks, replacing them with fresh earth. Spring treatment with this material has not given satisfactory borer control in Kentucky. In order that paradichlorobenzene may volatilize or make sufficient fumes to kill the borer, the soil temperature should be above 60° F. It is stated that late fall treatment seldom gives satisfactory control.

The damage caused by the sugar cane moth borer in Guadeloupe, C. H. B. WILLIAMS (*Sta. Agron. Guadeloupe, Tech. Bul. 4 (1926), [Eng. ed.], pp. 28, fig. 1*).—This is a preliminary report on an investigation undertaken to determine the importance of the sugar cane borer in connection with the sugar industry of Guadeloupe. The data obtained indicate that a large percentage of the canes is attacked. The percentage of juice extracted and its sucrose content and purity were lowered, but the glucose content of the juice rose as the number of borer holes per stalk increased.

Studies on the spruce budworm (*Cacoecia fumiferana* Clem.) (*Canada Dept. Agr. Bul. 37, n. ser. (1924), pp. 91, pls. 25, figs. 6*).—This work consists of two parts (1) A General Account of the Outbreaks, Injury, and Associated Insects, by J. M. Swaine and F. C. Craighead (pp. 3-27), and (2) General Bionomics and Possibilities of Prevention and Control, by F. C. Craighead

(pp. 28-88), which includes a chapter on the Abnormalities of Ring Growth and Cell Structure, by I. W. Bailey (pp. 58-61).

The effects of changes on hydrogen-ion concentrations on culicine mosquito larvae, N. F. PATERSON (*So. African Jour. Sci.*, 22 (1925), pp. 311-317).—The author's study shows that the concentrations most favorable for mosquito development are those giving a reaction similar to that of the water inhabited by the larvae.

"In this case the culicine larvae used in the experiments preferred water having a pH concentration of 7.8, and, although several other concentrations have allowed of the development of adult mosquitoes, it is remarkable that in solutions with pH values of 7.8 or 7.6 the larvae have survived for a greater number of days and more have developed into imagines than in other solutions. The other concentrations must, therefore, have exerted some toxic effect on the mosquito larvae, resulting either in their early death or in inhibition of development. From this it may be inferred that any change in pH concentration of the aquatic breeding place of the mosquito will have some effect on its contained larval mosquitoes.

"Finally, it may be noted that superphosphates and lime are apparently potent larvicides and may be used without injury to water for domestic or irrigation purposes. Copper sulfate and common salt are likewise good destroying agents, but are only efficacious in rather concentrated solutions, and such solutions, especially of copper sulfate, would be highly dangerous. Consequently, as deduced from the results of these preliminary laboratory experiments, the two substances lime and superphosphate are preferable, and, as each is relatively harmless and inexpensive, they may prove a convenient means of aiding in the control of mosquito-borne diseases."

Tabanus rubidus Wied., T. striatus Fab., and Stomoxys calcitrans L. [trans. title], O. NIESCHULZ (*Dept. Landb., Nijv. en Handel [Dutch East Indies], Veeartsenijk. Meded.*, No. 55 (1926), pp. 25, pl. 1).—A report of studies of these dipterans, which are the more important flies attacking cattle in the Dutch East Indies.

Honey plants of North America (north of Mexico), J. H. LOVELL (*Medina, Ohio: A. I. Root Co.*, 1926, pp. III+408, pl. 1, figs. [128]).—Part 1 of this work deals with nectar, its secretion, protection, and distribution (pp. 1-35); part 2 with flowers valuable only for pollen (pp. 37-52); part 3 with honey plants of America north of Mexico (pp. 53-245); and part 4 with the honey floras of the different States and the best locations for beekeeping (pp. 247-397).

Report of the Dominion apiarist for the year 1925, C. B. GOODERHAM (*Canada Expt. Farms, Bee Div. Rpt. 1925*, pp. 16, figs. 5).—This is a brief report of the work of the division during the year, including an account of honey production at Ottawa and the out-apiary at Britannia Heights, bees and pollination, queen breeding, Carniolan v. Italian bees, the age of queen in relation to brood production, wintering 1924-25, etc.

Forty-sixth annual report of the Beekeepers' Association of the Province of Ontario, 1925 (*Ontario Dept. Agr., Beekeepers' Assoc. Ann. Rpt.*, 46 (1925), pp. 111).—The papers presented at the annual meeting of this association, held at Toronto in December, 1925, include the following: My System of Manipulating Colonies during the Active Season (pp. 15-36); Package Bees, by T. Shield (pp. 36-47); Diagnosing American and European Foulbrood and Sacbrood in the Apiary, by A. P. Sturtevant (pp. 47-57); Further Experiments in Sterilizing American Foulbrood Combs, by G. L. Jarvis (pp. 57-63); Light Honey Crop Report (pp. 64, 65); The Use of Honey in Food Preparation, by J. Roddick (pp. 67-71); Methods of Spread of American Foulbrood, Methods of Eradica-

tion, by A. P. Sturtevant (pp. 72-75); My System of Preparing Bees for Winter, and Method of Wintering (75-85); Spraying and Dusting Fruit Trees in Full Bloom, by R. B. Wilson (pp. 85-89); Address by E. R. Root (pp. 89-94); and Some Important Beekeeping Problems in New York State, by R. B. Wilson (pp. 95-111).

Bee-keeping in Victoria, F. R. BEUHNE (*Melbourne: Victoria Dept. Agr., 1925, rev. and enl. ed., pp. 170, figs. 82*).—A handy guide to beekeeping under Victoria conditions.

A first contribution on the Ichneumonidae of Japan [trans. title], T. UCHIDA (*Jour. Col. Agr., Hokkaido Imp. Univ., 18 (1926), No. 2, pp. 43-173, pls. 5, figs. 19*).—In this synopsis of the Ichneumonidae of Japan the author lists 241 forms, of which 90 species and 12 varieties are described as new to science, and 7 genera are erected. A list is given of 39 species new to Japan. A bibliography of 65 references to the literature and an index are included.

Some preliminary notes on tea termites, F. P. JEPSON (*Trop. Agr. [Ceylon], 67 (1926), No. 2, pp. 67-79, pls. 5*).—An account of termites associated with the tea bush, particularly *Calotermes militaris*, *C. dilatatus*, and *C. greeni*, and their control.

The intestinal flagellates of the termite *Cryptotermes hermsi* Kirby, H. KIRBY, JR. (*Calif. Univ. Pubs. Zool., 29 (1926), No. 4, pp. 103-120, pls. 2, figs. 4*).—Four flagellates are described as new, and the genus *Paradevescovina* is erected.

Progress report on red spider control, M. A. YOTHERS (*Idaho State Hort. Assoc. Proc., 24 (1924), pp. 111-116*).—In the author's experiments sulfur dust and the sulfur sprays gave but negligible results in killing the spiders and none whatever in killing the eggs. Lime sulfur at the rates of 1 to 100 and 1 to 50 killed 44 and 52 per cent of the spiders, respectively, but no eggs were destroyed. The Alhambra orchard spray killed 56 per cent of the spiders and 38 per cent of the eggs. Engine oil emulsion was superior to all other materials tested during the season. Used at strengths of from 0.25 to 1 and 2 per cent it killed from 95 to 100 per cent of the spiders and from 61 to 100 per cent of the eggs.

ANIMAL PRODUCTION

Physiological ontogeny: A, Chicken embryos, VIII, IX, H. A. MURRAY, JR. (*Jour. Gen. Physiol., 9 (1926), No. 5, pp. 603-619, 621-624, pls. 2, figs. 9*).—Two papers continuing this series (*E. S. R., 55, p. 860*) are noted.

VIII. Accelerations of integration and differentiation during the embryonic period (pp. 603-619).—It is shown that the shape of the curve for percentage growth rate is approximated only by the curve for the surface-weight ratio, when the surface is considered as proportional to the two-thirds power of the weight.

The more rapid changes in form occur when the growth rate is rapid, and this was shown to be the case with the form of the embryonic heart. The available data indicate that changes in the chemical form occur after the tenth day of incubation. The percentages of ash and total solids in the whole embryo change mostly during the third quarter and of fat mostly during the fourth quarter of the incubation period. The curve for the percentage of dried solids is intermediate between the ash and fat curves. It thus appears that internal integration and chemical differentiation are more or less synchronous, and that the percentage of dried solids may be taken as an index for both. The water-solids ratio also theoretically represents as significant a function as any.

Data available indicate a general relation between the katabolic rate and the chemical constitution. That the katabolic rate and the latent period are associated with the differentiation of chemical form was indicated from the work with embryos and also with tissue cultures.

IX. *The iodine reaction for the quantitative determination of glutathione in the tissues as a function of age* (pp. 621-624).—Analyses of chick embryos at various stages of incubation for the presence of the sulphydryl groups, according to the method of Tunncliffe (E. S. R., 54, p. 9), showed that the percentage of these compounds decreased with age, especially during the third quarter of the incubation period.

Organ weights of normal rabbits, [II], W. H. BROWN, L. PEARCE, and C. M. VAN ALLEN (*Jour. Expt. Med.*, 43 (1926), No. 6, pp. 733-741).—The maximum, minimum, median, and mean weights of various organs of 295 male rabbits are reported, as well as similar data for 350 male rabbits which were given in the first study of this series,² and the combined data for the two groups. The standard deviation, the probable error, and the coefficient of variability for the weights of each organ are also given.

Studies on the chemical composition of beef blood, I, II, C. S. ROBINSON, C. F. HUFFMAN, ET AL. (*Jour. Biol. Chem.*, 67 (1926), No. 1, pp. 245-255, 257-266, figs. 4).—Two papers are given.

I. *The concentrations of certain constituents in normal beef plasma* (pp. 245-255).—In studying the variations in the composition of the blood of normal cattle at the Michigan Experiment Station, 122 samples from approximately 40 animals over one year of age were analyzed for inorganic phosphorus, chlorine, carbon dioxide, and calcium, with some determinations of potassium and magnesium. Various methods of making the calcium determinations were compared.

The average number of milligrams of the different minerals per 100 cc. of blood from mature animals was as follows: Inorganic phosphorus 5.87, chlorine 329, calcium 11.0, carbon dioxide 59.2, potassium 27.3, and magnesium 2.16. The feeding of cod-liver oil and bone meal increased the content of inorganic phosphorus and calcium in the blood of 4 animals, but the values were still within the normal range.

II. *The composition of the blood of dams and calves immediately after calving* (pp. 257-266).—The content of inorganic phosphorus, chlorine, carbon dioxide, and calcium in the blood of 13 cows and their calves was determined on various days during the week following parturition. The determinations were generally within the range for normal cattle, but the inorganic phosphorus in the blood of cows was approximately 0.64 millimols lower than that for the blood of their calves at birth. The content of this element increased during the first week after birth in the blood of both cows and calves.

The chlorine content of the cows' blood was high at calving but dropped steadily during the observation period. Calves' blood showed a low chlorine content after birth but rose slightly and then dropped.

The carbon dioxide content of the blood of both cows and calves was low at parturition, and the values for the mothers were lower than for their calves throughout the first week.

The calcium content of the blood of cows was lower than that of the calves at birth, but increased during the following week, while the calcium in the calves' blood decreased.

Testicular degeneration in albino rats fed a purified food ration, K. E. MASON (*Jour. Expt. Zool.*, 45 (1926), No. 1, pp. 159-229, figs. 14).—A complete account of the investigation of which a preliminary report was noted (E. S. R., 54, p. 527).

Dietary factors influencing calcium assimilation.—VI, The antirachitic properties of hays as related to climatic conditions with some observations on the effect of irradiation with ultra-violet light, H. STEENBOCK, E. B. HART, C. A. ELVEHJEM, S. W. F. KLETZIEN, and B. M. RIISING (*Jour. Biol. Chem.*, 66 (1925), No. 2, pp. 425-440, pl. 1).—In continuing this series (E. S. R., 53, p. 379), the antirachitic properties of three lots of clover hay cured by different methods were tested in experiments with rats, milking goats, and growing chickens. The three types of hay used were (1) dried in the dark on the floor of an attic with a fan, (2) dried in diffused light in the laboratory and then exposed to the weather and sunlight for 14 days, and (3) allowed to lie in the field exposed to sun, dew, and rain for 14 days.

In the experiments with rats, finely ground samples of the hay were fed at levels of 1 and 5 per cent in a rickets-producing ration. All the lots fed the three different kinds of hays at the 1 per cent level developed rickets, but controls receiving similar amounts of the same hay which had been irradiated for 30 minutes by the rays of a Cooper-Hewitt quartz mercury vapor lamp proved to be normal. At the 5 per cent level the hay irradiated with ultra-violet rays and the sample cured in diffused light and exposed to the weather completely prevented rickets, while that cured in the sun, dew, and rain was partially protective. The sample cured in the attic was inefficient.

The hay cured in the sun, dew, and rain was fed in experiments with three goats. Negative calcium balances were observed when the goats received this hay, but the use of samples of the same hay which had been irradiated for 1 hour changed the calcium balances to positive. In the case of two goats which received hay cut in 0.5- to 1-in. lengths before irradiation it required 3 weeks' feeding to produce positive calcium balances, but when the hay was finely ground before irradiation the negative calcium balances were changed to positive in the second week of such feeding. Direct irradiation for 20 minutes daily of two of the goats receiving the weathered hay brought about positive calcium balances which were larger than those produced when the hay was irradiated.

The experiments with chickens were carried out by adding ether extracts of the three different hays in amounts equivalent to 1 gm. of hay per gram of grain and mineral mixture fed. All lots, including the control lot, showed evidence of leg weakness in 5 weeks. Ash analyses of the tibias indicated uniformly that the ether extracts did not improve the antirachitic properties of the basal ration.

From the results of these experiments it is concluded that the antirachitic properties of hay are increased by a certain amount of exposure to the sunlight, but that too much exposure inactivates this property. Chickens and lactating goats appeared to require far more of the antirachitic substance than rats.

Dietary factors influencing calcium assimilation.—VII, The influence of sunlight upon calcium equilibrium in milking cows, E. B. HART, H. STEENBOCK, C. A. ELVEHJEM, H. SCOTT, and G. C. HUMPHREY (*Jour. Biol. Chem.*, 67 (1926), No. 2, pp. 371-383).—In continuing this series of studies (see above) an attempt was made to simulate summer pasture conditions, especially in respect to exposure to sunlight and the consumption of green feeds.

During the first half of the experiment, January 1 to May 4, 6 cows were kept continuously indoors, and during the following 6 weeks calcium balances

were determined on 3 of the cows, which had freshened in March and were yielding from 45 to 60 lbs. of milk daily. During the last 3 weeks of the balance period the animals were placed in outdoor stalls when the weather permitted, thus receiving a maximum exposure to the sunlight. The average daily ration consisted of approximately 30 lbs. of corn silage and 40 lbs. of lawn clippings, with 1 lb. of a grain mixture for each 3 lbs. of milk produced.

The results showed that the calcium balances were all negative during the indoor feeding period, ranging in general from 100 to 200 gm. of calcium oxide per week. Negative balances prevailed with the exposure to sunlight, but the amount was reduced by 50 to 70 gm. of calcium oxide per week for the different animals.

Because of the unexpected inability of the sunlight to promote more favorable calcium balances the cows were put in an outdoor paddock during the day for the entire summer, during which time the ration consisted of timothy hay, corn silage, grain, and marl. All animals showed a marked decrease in milk production during the summer, which was so great in the case of one cow that she was replaced by another individual which freshened in August. Calcium balances were again determined on these animals for a 28-day period beginning September 14, during which time the cows were moved to the outdoor stalls in suitable weather.

The results showed that the 2 cows which had been continued on the entire experiment were in slight negative calcium balance during the first 2 weeks and in positive calcium balance during the remaining 2 weeks. The cow which freshened in August was in negative calcium balance, amounting to 333 gm. of calcium oxide for the 4 weeks.

The combined results of both experiments showed that it was only possible to maintain a positive calcium balance with normal sunlight and the ration fed when milk production fell below 25 to 30 lbs. per day. It is concluded that summer sunlight is relatively weak in its antirachitic properties as compared with the radiations of a quartz mercury vapor lamp. The advantage of supplying larger amounts of lime to the cows is somewhat questionable.

Potassium in animal nutrition.—III, Influence of potassium on total excretion of sodium, chlorine, calcium, and phosphorus, H. G. MILLER (*Jour. Biol. Chem.*, 67 (1926), No. 1, pp. 71-77).—In continuing this series at the Oregon Experiment Station (E. S. R., 49, p. 568), the effect on the excretion of minerals resulting from supplementing the ration of 2 male rats with a definite amount of potassium acetate, potassium citrate, or potassium chloride was determined. The data, which are presented in tabular form, show that increases in the intake of potassium caused an immediate rise in the excretion of sodium and chlorine, but later that the excretion of these elements was only slightly greater than on the basal ration. In some periods there was a small increase in the excretion of calcium and phosphorus during the high potassium periods.

These studies indicate that the potassium likely to be consumed on normal rations by animals is not a probable cause of an increased excretion of minerals.

The effect of thyroid feeding on the oestrous cycle of the guinea pig and mouse, G. R. CAMERON and A. B. P. AMIES (*Aust. Jour. Expt. Biol. and Med. Sci.*, 3 (1926), No. 1, pp. 37-43, pls. 2, fig. 1).—The results of experiments dealing with the effect of doses of dried thyroid equal to 0.0025 to 0.01 per cent of the body weight on the oestrous cycle of guinea pigs and mice are reported.

Eight parous female guinea pigs and ten virgin female mice were fed the dried thyroid, while four parous and six virgin female guinea pigs and five

virgin female mice served as controls. The guinea pig experiments lasted over a period of 64 to 113 days and the mice experiments for 240 days.

The oestrous cycle of the guinea pigs as determined by vaginal smears averaged 16.5 days with an average duration of oestrus of 1.73 days for the parous females, 15.7 days with an average duration of oestrus of 1.6 days for virgin females, and 16.1 days with an average duration of oestrus of 4.7 days for the females receiving the thyroid. In the control mice the cycle averaged 6.7 days with an average duration of oestrus of 2.4 days, while in the experimental animals the cycle was increased to 12.9 days and the duration of oestrus to 4.2 days. There was a rapid return to normal with the cessation of the thyroid feeding. Thus thyroid feeding in the mouse increased both the duration of oestrus and the length of the cycle, but there was no marked change in the length of the cycle in the guinea pig.

Commercial feeding stuffs, J. L. HILLS, C. H. JONES, G. F. ANDERSON, and E. F. BOYCE (*Vermont Sta. Bul. 254 (1926), pp. 56*).—A report listing the brands meeting their guaranties, and the analysis and deficiencies of brands not fulfilling their guaranties (E. S. R., 54, p. 560), from official samples taken during the months of December, 1925, and April, 1926, with discussion.

[Report of the] **National Live Stock and Meat Board, [1925-26], R. C. POLLOCK** (*Natl. Livestock and Meat Bd. Rpt., 3 (1926), pp. 89, figs. 64*).—The third annual report of the National Livestock and Meat Board (E. S. R., 54, p. 264) contains brief results of research activities dealing with the cooperative studies of the quality and palatability of meat, meat for blood regeneration, the iron content of meat, meat for the rearing of young, meat grading and branding, and the national study of the retail meat trade.

Studies on the refrigeration of meat.—I, Investigations into the refrigeration of beef, G. A. COOK, E. F. J. LOVE, J. R. VICKERY, and W. J. YOUNG (*Aust. Jour. Expt. Biol. and Med. Sci., 3 (1926), No. 1, pp. 15-31, pls. 3, fig. 1*).—This paper reports the results of an investigation of the possibility of freezing beef in such a manner that no changes occur which are not reversed on thawing. This work was conducted by the committee for the freezing of beef of the Australian National Research Council.

Various temperatures of freezing and thawing were employed, and the latent periods therefore varied. The results of 23 experiments showed that with meat from the same source the amount of drip steadily increased as the duration of the latent period of freezing increased, but there was little uniformity between the different samples in this respect. The calculated loss of nitrogen usually paralleled the amount of drip. The only experiment in which no drip occurred was when the meat was frozen almost instantaneously with liquid air at -193° C. The amount of drip was materially reduced by increasing the period of thawing. The drip was slightly reduced in 3 of 4 experiments by storing the thawed meat for 7 days at 1° . Further experiments showed that increases in the length of the storage period up to 10 or 11 days at 1° between killing and freezing reduced the amount of drip. There was only a slight increase in the autolysis, even after 20 days' storage.

Study of the histological structure of the samples showed that those frozen with liquid air were practically normal, but that as the length of the freezing period increased the formation of ice crystals was apparent, first within and then between the fibers, accompanied by deterioration and distortion of the tissues.

The curves of autolysis, as determined by the percentage of total nitrogen not precipitated by 10 per cent of tannic acid, were markedly different for frozen and fresh meat. The frozen meat had a lower initial percentage of

soluble nitrogen, but the percentage increased much more rapidly than in fresh meat and considerably exceeded it after 4 days.

The age of the animal killed for beef was found to affect the amount of drip and the amount of distortion when frozen and thawed under uniform conditions. Both the amounts of drip and distortion were least in the youngest animals.

Mutton showed much less ice formation and distortion after freezing than beef when both were frozen under similar conditions.

The development and maintenance of pigs during the suckling period [trans. title], J. SCHMIDT, E. LAUPRECHT, and H. VOGEL (*Züchtungskunde*, 1 (1926), No. 5, pp. 242-256, figs. 4).—The rate of growth and feed requirements were studied at the University of Göttingen from the records on 6 groups of pigs of different breeding obtained from various sources as follows: 45 litters of White Edelschwein at Ruhlsdorf, 48 litters of Improved Landschwein at Ruhlsdorf, 27 litters of Improved Landschwein at Friedland, 8 litters of Hanovarian-Brunswick Landschwein at Derneburg-Binder, 6 crossbred litters of Berkshire boars × Improved Landschwein sows at Friedland, and 10 crossbred litters of Yorkshire boars × Hanovarian-Brunswick Landschwein sows at Binder.

The weights of the pigs at birth varied with the different groups, depending more especially on the mature weights of the breeds. Male pigs were somewhat heavier in nearly all groups than females. The weights and gains of the pigs at 4 weeks when supplemental feeding was started and at weaning time are given, together with the percentage gains during these intervals.

In the first 4 weeks the different groups increased from approximately 290 to 360 per cent in live weight, and during the first 8 weeks from 660 to 890 per cent. A classification into 2 groups according to the birth weights showed that the pigs with the heavier birth weights made greater total gains to weaning, but the lighter pigs made considerably larger percentage increases over their birth weights. The same condition occurred in the comparison of the sexes.

The sex ratio in 248 litters was 100.7 males to 100 females. The proportion of males was slightly less in litters of more than 12 pigs. Birth weights were found to be affected by litter size. In 163 litters of Improved Landschwein the birth weights of individuals in litters of 9 or more averaged 1.23 kg. (2.7 lbs.) as compared with 1.37 kg. in litters of 8 or less.

The amounts of sow's milk and feed consumed and the gains made per week are tabulated for the Improved Landschwein and the crossbred Berkshire-Landschwein, including the feed necessary to produce a unit of gain up to weaning time. These results show that the crossbred pigs utilized their feed somewhat more economically than the purebreds.

The litter size of Improved Landschwein [trans. title], H. A. BARTRAM (*Züchtungskunde*, 1 (1926), No. 5, pp. 256-269, figs. 3).—The average sizes of successive litters of sows from the first to the twelfth have been tabulated from herd book records, together with calculations of the standard deviation and probable errors of the mean and standard deviation. The average litter sizes for the first to the twelfth litters consecutively were $8.888 \pm .071$, $9.804 \pm .088$, $10.498 \pm .115$, $11.015 \pm .134$, $11.054 \pm .161$, $11.436 \pm .202$, $11.510 \pm .250$, $11.290 \pm .316$, $10.618 \pm .355$, $11.744 \pm .511$, $10.552 \pm .487$, and $11.667 \pm .938$.

These results, as well as other tabulations for the sows having litters in all groups, show that the sixth and seventh litters were generally the largest. The variability in litter size appeared to increase with age.

[Poultry investigations at the Dominion experimental farms], F. C. ELFORD (*Canada Expt. Farms, Poultry Div. Rpt. 1925, pp. 67, figs. 19*).—This is the usual report of the Dominion poultry husbandman (*E. S. R., 54, p. 667*), giving the results of investigations in progress.

Duration and change of fertility.—In continuing the study of the length of time hens produced fertile eggs after removing the male, Barred Rock females were first mated with a Barred Rock male and later with a White Leghorn male. The results showed that the effect of the Leghorn mating was apparent in the case of one fowl on the fourth day after mating, but the effects of the Barred Rock mating did not cease in one hen until after the twelfth day.

Vigor and breeding power of registered hens.—Data are presented showing that high producing birds may lay eggs that are fertile, hatch well, and produce vigorous chicks.

Crossbreeding.—In crossing experiments with Barred Plymouth Rock ♂ × Single Comb White Leghorn ♀, Single Comb White Leghorn ♂ × White Wyandotte ♀ and Barred Plymouth Rock ♀, and Rhode Island Red ♂ × Single Comb White Leghorn ♀, it has been found that the eggs laid by the birds of the F₁ generation were brown in all cases, indicating that brown egg-color was dominant over white. In this experiment the relation of external characteristics of the chicks to sex has also been noted. In the cross of Rhode Island Red males with Single Comb White Leghorn females all the female chicks were spotted with black and 80 per cent of the males were white. In the cross of the Barred Plymouth Rock male with the Rhode Island Red female, or the Single Comb White Leghorn male with the Rhode Island Red female, there were no indications of sex differences at hatching.

The effects of feeding bone meal upon fertility, hatchability, and viability.—Twenty pens containing 236 hens in all were used for comparing the fertility, hatchability, and viability of chicks produced when 5 per cent of bone meal was added to a standard ration. The results showed that of the eggs produced by the birds receiving no bone meal 82.1 per cent were fertile, 64.9 per cent of which hatched. The eggs from those receiving bone meal were 83.6 fertile, of which 61.1 per cent hatched. The chick mortalities to 3 weeks of age were 24.9 and 27.1 per cent, respectively.

Starvation period for chicks.—Very indefinite results were obtained in an experiment in which chicks given their first feed at the time of removing from the incubator were compared with other lots receiving their first meal 24, 36, and 48 hours later.

Vitamin feeds and rations for brooder-chicks.—Fourteen lots of 50 chicks each were selected for comparing the effect of various feeds during the first 3 weeks of growth. The basal ration, consisting of a commercial scratch-grain mixture and a mash of equal parts of shorts, middlings, corn meal, and oat flour with one-half part of meat meal and 0.5 per cent of salt, fed with grit, green feed, and milk and water, gave better results than the rations from which the oat flour was omitted or to which corn meal and middlings or semi-solid buttermilk were added, or in which meat meal was given in place of the milk. The addition of refined cod-liver oil to the basal ration produced the best percentage increase in weight of all lots, followed in order as far as the gains were concerned by the rations containing Larro and Fleischmann's yeast, the basal ration, and Fleischmann's yeast and crude cod-liver oil. The amount of mortality ranked in inverse order to the gains. Mortality was 18 per cent in one lot receiving pork liver in place of the meat meal in the mash. The combined 2 years' results of similar experiments are tabulated.

Methods of feeding brooder-chicks.—A comparison of the advisability of leaving dry-mash hoppers open at all times as compared with making them available six times a day for brooder-chicks is reported. The results showed that those having access to the mash at all times made the largest gains, but the highest mortality also occurred among such chicks. A lot receiving crude cod-liver oil made the poorest gains of all lots.

The effect of sunlight upon growing chicks.—Nine lots of chicks were selected for studying the effect of exposure to sunlight and supplementing the ration with crude and refined cod-liver oil. The birds not being exposed to sunlight were in pens having the windows covered with heavy brown paper and light was supplied by electricity. The results showed that the highest mortality occurred in the pens having no sunlight, while the mortality was lowest in those having direct access to sunlight. The former group, however, made the greatest percentage gains in weight.

Buttermilk v. no buttermilk for growing chicks.—During a 9 weeks' test chicks receiving both buttermilk and water as drink made average increases in weight of 142 per cent over those receiving no milk, and the mortality was more than twice as heavy in the latter group.

Vitamin feeds and rations for rearing.—The value of various supplements to a basal ration for rearing was studied with seven pens of 3-weeks-old chicks during a 10 weeks' test. During the first 7 weeks the highest percentage gains were made by those receiving raw liver, followed in order by those receiving Larro yeast and crude cod-liver oil. The highest mortality occurred in the check lot, and the next highest mortality was in the pen receiving raw liver. The raw liver pen was superior during the entire experiment from the standpoint of gains. The results of 2 years' work feeding these supplements are tabulated.

Feed costs in brooding and rearing chicks to ten weeks of age.—Estimates of the cost of brooding and rearing Barred Rock and White Leghorn chicks indicated that the feed costs were similar for both breeds, but since the Barred Rocks made more rapid gains the cost per unit of gain was less.

The effects of feeding cod-liver oil upon the weight and texture of eggshell.—In an experiment in which one lot of birds received 4 cc. of cod-liver oil daily, no appreciable effect was noted in increasing either the gross egg weight or the weight of the shell.

The effects of a commercial stimulant and of bone meal on spring egg production.—During a 55-day test of a commercial stimulant known as "Egg Maker" and bone meal, fed as supplements to a basal ration, the birds receiving the "Egg Maker," both with and without bone meal, produced 3.46 more eggs per bird than those receiving the standard ration without the supplement. In the following 53-day period there was a difference of 0.9 per cent between these two lots in egg production. The birds receiving bone meal produced 0.39 more eggs per bird during the feeding period than those receiving no bone meal, and the decrease during the succeeding 53-day period without bone meal was 4.4 less than occurred in the birds in the check lot.

Feeding experiments for winter egg production.—In a 6 months' test 15 pens of White Leghorn pullets were selected for comparing semisolid buttermilk with fresh buttermilk when fed with and without mash, home-mixed mash with commercial mash, various green feeds with Epsom salts, and crude and refined cod-liver oil with Fleischmann's and Larro yeast for their effect on the production and hatching qualities of the eggs. The birds receiving the fresh buttermilk without mash produced eggs at the lowest cost per dozen in that test, being followed in order by those receiving fresh buttermilk and mash, semisolid buttermilk without mash, and semisolid buttermilk with mash.

The heaviest mortality occurred in the first group. In the comparison of green feeds the best egg production and largest profits occurred in the lot receiving the clover leaves, but the best hatching results occurred in the lot receiving the Epsom salts. Higher production occurred with the commercial mash, but the additional cost made the home-mixed mash more profitable. Studies of the vitamin feeds for egg production showed that the control pen produced eggs at the lowest cost per dozen, while the cod-liver oil somewhat increased the hatching results.

Egg-storage experiments.—A study of the "Guaranise" process for storing eggs showed that processed eggs after 6 months' storage were markedly superior to the unprocessed eggs. It is concluded from 3 years' experiments that this method of processing eggs is to be recommended. Better results in storing eggs in an ordinary cellar were also obtained with those which had been treated according to this process.

Duck-feeding experiments.—A study of the rate of growth of ducklings of four breeds, Pekins, Rouens, White Muscovies, and colored Muscovies is reported. The Pekins made the most rapid and most economical gains per unit of feed consumed, and consequently the largest profit over feed costs.

A comparison of different forms of milk in a ration for growing chickens, L. E. CARD (*Poultry Sci.*, 5 (1926), No. 4, pp. 199-202, fig. 1).—Sour skim milk, buttermilk, condensed buttermilk (fed as paste), and dried buttermilk (25 per cent of the mash) were fed as supplements to a basal ration to 4 different lots of 200 Barred Plymouth Rock chicks each at the Illinois Experiment Station. The cockerels were separated at 10 weeks of age, and the pullets were fed to 22 weeks.

There were significant differences between the average weights of the individual groups at certain times, but at the conclusion of the experiment the maximum difference between groups was only 2.3 per cent of the live weight, which is insignificant. The lot receiving dried buttermilk made slightly more regular growth than the others, and variations in the milk consumption were not so great as with the liquid milk products. The mortality was high in all lots, due largely to an outbreak of bacillary white diarrhea. It is concluded that the nutritive values of these milk products are similar.

Standard breeds and varieties of chickens.—I, American, Asiatic, English, and Mediterranean classes, M. A. JULL (*U. S. Dept. Agr., Farmers' Bul.* 1506 (1926), pp. II+37, figs. 33).—This bulletin supersedes Farmers' Bulletins 898 (E. S. R., 38, p. 373); 1052 (E. S. R., 41, p. 676); and 1347 (E. S. R., 50, p. 72).

A case of the normal development of geese twins within one egg [trans. title], J. KRÍŽENECKÝ (*Züchtungskunde*, 1 (1926), No. 5, pp. 233-241, figs. 3).—The author describes a case of a male and a female embryo which developed to near maturity in one double-yolked goose egg. The twins died from a lack of oxygen.

DAIRY FARMING—DAIRYING

The energy requirements of dairy cows.—II, Is net energy or metabolizable energy the more useful index for practical purposes? E. B. MEIGS (*Jour. Dairy Sci.*, 8 (1925), No. 6, pp. 523-536).—In continuing this series (E. S. R., 54, p. 66) the author discusses primarily net energy and metabolizable energy as a means of measuring the energy requirements of dairy cows. It is pointed out that the net energy value of food is that fraction of its metabolizable energy which an animal may use for maintenance or fattening and is subject to variation due to differences in the external temperature and the muscular

activity of the animal. It is therefore considered that net energy values obtained in the calorimeter would probably be more or less inapplicable to practical conditions, while total digestible nutrients and probably metabolizable energy are better and more constant measures of the relative values of feeds under practical conditions.

Energy requirements of dairy cows.—A reply to articles by E. B. Meigs and H. T. Converse, E. B. FORBES (*Jour. Dairy Sci.*, 9 (1926), No. 4, pp. 373-378).—A criticism of papers previously noted by Meigs and Converse (E. S. R., 54, p. 66), and by Meigs (noted above).

Investigations of the tethering of dairy cows on vetch and oats [trans. title], W. P. USTJANZEFF, I. I. GRIGORENKO, and N. S. PEREKREST (*Milchw. Forsch.* 3 (1926), No. 1, pp. 97-116).—Two lots of four cows each were selected for studying the influence of tethering on milk production. Both lots were stall-fed during the first and third periods of the experiment, but during the second period one lot was tethered on vetch, while the other lot received green vetch and oats in the stable. The test showed that during the period of feeding the green feeds the tethered lot increased their production an average of 25 per cent, while the stable-fed lot increased their production 12 per cent. Both groups also increased in live weight when receiving green feed, which was particularly pronounced in the tethered lot. The Reichert-Meissl and the iodine numbers of the butter showed only slight variations during the period of tethering as compared with dry feeding, but the time required for reduction to occur in the methylene blue test in the milk was somewhat shortened in certain cases. Such a condition was not observed during the stall feeding of the green plants. From the standpoint of the economical utilization of feed, stall feeding appeared to be slightly superior.

Silage feeding experiments, A. W. OLDERSHAW (*Jour. Roy. Agr. Soc. England*, 86 (1925), pp. 112-128).—The results of two experiments are reported in which the milk production of lots of cows fed on rations containing mangels was compared with the milk production of other cows receiving rations containing similar amounts of starch equivalent and protein, but in which the succulent roughage was derived mainly from silage. Milk production was slightly better with the root rations in both experiments, but was practically equal for the cows which ate the silage readily. Certain individual cows would not eat the silage.

Investigations with the fermentation of beet tops and their feeding value for milch cows [trans. title], W. P. USTJANZEFF and I. I. GRIGORENKO (*Milchw. Forsch.*, 3 (1926), No. 1, pp. 83-96).—In a test of the feeding value of beet top silage, 3 cows were fed during the first and third periods on a ration of hay, chopped wheat, and linseed oil cake. In the second period beet top silage replaced the chopped wheat on an equivalent starch value basis. Calculations of the normal milk production during period 2 from the production on the basal ration during periods 1 and 3 showed that there was a decrease of from 2.7 to 10.7 per cent in the production of the individual animals when beet top silage was fed.

Determinations of the digestibility of the beet top silage in two experiments with two wethers each showed wide variations in the results. Linseed oil cake and hay were fed in addition to the silage in one of the digestion experiments, while hay was the only additional feed in the other. Inaccuracy in the estimation of the digestibility of the hay or linseed oil cake may account for the variations in the results, but it is also mentioned that the tests were made with beet tops from different parts of the silo. The estimated starch value on

the basis of these experiments was lower than that given by Kellner and from that used in the calculations for the experiments with the dairy cows.

The influence of gluten feed on the milk production of cows.—A feeding experiment with 20 cows [trans. title], H. BÜNGER and H. LAMPRECHT (*Milchw. Forsch.*, 3 (1926), No. 1, pp. 69–82, fig. 1).—In studying the value of gluten feed for milk production, 2 lots of 10 cows each were fed during three periods of approximately 4 weeks' duration. One lot was fed throughout and the other lot during the first and third periods on an average daily ration of 2.5 kg. of clover hay, 3 kg. of oat straw, 3 kg. of barley straw, 6 kg. of vetch silage, 15 kg. of fodder beets, and 3 kg. of a grain mixture composed of equal parts of coconut cake, ground beans, and vetch seed. Two-thirds of the grain mixture was replaced by an equal amount of gluten feed in the second period for the one lot.

The data on milk and fat production are recorded for 21 days in the first period and for the last 21 and 19 days, respectively, of the second and third periods. The group receiving the basal ration throughout produced an average of 7.55, 7.02, and 6.80 kg. of milk per head daily in the first, second, and third periods, respectively. The substitution of gluten feed for two-thirds of the grain mixture tended to increase the production of the second group, as the average for the three periods were 8.14, 8.18, and 7.55 kg., respectively, per head daily. The fat percentage of the milk showed only small variations, and the amount of fat was, therefore, in general, proportional to the amount of milk. The same conclusions for milk and fat production followed when the normal production on the basal ration was estimated for the second period by interpolation, based on the production during the first and third periods. No abnormal flavors were detected in the milk as a result of the gluten feeding.

The efficiency of cacao meal with the fat removed for the feeding of milch cows.—A feeding experiment with 24 animals [trans. title], H. BÜNGER and H. LAMPRECHT (*Milchw. Forsch.*, 3 (1926), No. 1, pp. 3–20, figs. 2).—In testing the palatability of cacao meal and comparing it with coconut meal for milk production, 4 lots of 6 animals each were fed on a basal ration of hay, oat straw, and a grain mixture of ground oats, barley, wheat, and peas during a 23-day feeding period. In the following 29 days the basal ration was supplemented with 0.87 or 0.78 kg. of cacao meal or coconut meal in four different lots. During the following 25 days the basal ration was again fed. In general the cacao meal was relatively unpalatable, due to its fine powdery form and the presence of a fish meal flavor.

The results of milk production after eliminating the first 6 or 7 days after the rations were changed showed that both groups of cows receiving the cacao meal produced materially less milk than when on the basal ration, while the coconut meal stimulated milk production. Both the supplements increased the fat content of the milk, but the increase was considerably greater with cacao meal. The flavor of both the butter and the milk were unfavorably influenced by this feed. The possible effect of 2.68 per cent of theobromine in the cacao meal is discussed from the standpoint of palatability of the meal and the flavor of the milk and butter.

Contribution to the vitamin A content of butter under the influence of common feeds [trans. title], A. SCHEUNERT (*Milchw. Forsch.*, 3 (1926), No. 1, pp. 117–121, figs. 3).—Using rats, the author has compared the amounts of vitamin A in butter from cows receiving rations containing fodder beets with other grains, corn silage with similar grains, and pasture only. In making the tests, vitamin A-deficient rations were supplemented with 0.1, 0.25, and 0.5 gm. of butterfat from the different sources. The results show that the

butter from the cows receiving beets was lowest in its vitamin A content, as 0.5 gm. daily was not sufficient to allow normal growth in the rat after 53 days. The butter from the pasture-fed cows was the richest source of vitamin A, as normal growth was maintained with 0.25 gm. of butter, while 0.5 gm. of butter from the silage-fed cows was necessary for normal growth.

Relative rates of secretion of various milk constituents, W. L. GAINES (*Jour. Dairy Sci.*, 8 (1925), No. 6, pp. 486-496, figs. 3).—From a statistical study of the chemical analyses of weekly milk samples from 543 individual cows of several breeds published in Minnesota Experiment Station Bulletin 140 (E. S. R., 31, p. 670), the rates of secretion of fat and protein appear to be intimately related, the correlation coefficient being 0.812 ± 0.010 . The relation between fat and protein was found to follow a straight line in various species having fat percentages running as low as 0.36 per cent (ass) and as high as 22.46 per cent (reindeer). High negative correlations between the water and fat and water and protein are shown to indicate that these constituents are largely independent. Statistical constants and regression equations are also presented.

Milk production with special reference to some typical secretion anomalies and their practical importance [trans. title], G. KOESTLER, W. LEHMANN, W. LÖRTSCHER, and E. ELSER (*Landw. Jahrb. Schweiz*, 40 (1926), No. 3, pp. 287-440).—The first part of this publication gives a brief review of the physiological factors related to the production of normal milk and colostrum. The second part gives the results of studies of the quantity and quality of the milk produced by the different quarters of cows' udders under normal conditions, and studies of the various physicochemical and bacteriological properties of abnormal milk drawn from the different quarters of the udder and at different stages during milking.

Udder cocci (mammococcus) [trans. title], C. GORINI (*Milchw. Forsch.*, 3 (1926), No. 2-3, pp. 178-183).—Studies of the morphological and physiological characteristics of more than 50 strains of cocci, isolated from aseptically drawn milk, have indicated that much variability exists in these types, which allows them to be differentiated into different groups and intermediate groups.

The effect of these organisms on the milk is uncertain. They may cause abnormal fermentation or in severe cases mastitis, but when the amounts present are small there is no apparent effect.

The biology of *Bacterium casei* ϵ (v. Freudenreich) and *Mycoderma thöni* [trans. title], W. A. LOTT (*Milchw. Forsch.*, 3 (1926), No. 2-3, pp. 272-284).—The results of this study have shown that these two organisms make much better growth, especially in whey, when the two are present together, indicating a symbiotic relation. Certain differences in their physiological characteristics are pointed out.

Critical and experimental studies of pasteurization of milk, H. BRAND (*Kritische und Experimentelle Studien zur Pasteurisierung der Milch. Thesis, Eidg. Tech. Hochsch., Zurich, 1925, pp. 91, figs. 6*).—The first part of this publication deals with the purpose of pasteurization, the resulting changes in the milk, and methods and regulations for pasteurization in force in Europe and America. The second portion of the work deals with the efficiency of pasteurization for destroying bacteria and prolonging the keeping qualities of cow's and human milk. The results of these studies showed that pasteurization at 63° C. (145.4° F.) for 30 minutes killed all the pathogenic organisms but did not materially affect the keeping qualities. The findings were similar when human milk was pasteurized.

Investigation of current relations in agitator flash pasteurizers and their influence on the death of organisms [trans. title], K. RICHTER and H. M. WENDT (*Milchw. Forsch.*, 3 (1926), No. 2-3, pp. 200-208, figs. 6).—The amount of direct flow through two types of flash pasteurizers was determined by first sending skim milk and then whole milk through the pasteurizers. The length of time that different portions remained in the container was estimated from the fat content of the milk coming out.

The results showed that in one type of pasteurizer, which was cylindrical in shape, portions of the milk passed through in a few seconds, while other portions remained for as long as 4 minutes. The top of the other type of pasteurizer was larger in diameter than the bottom. The maximum and minimum time required for milk to go through this type was 70 and 15 seconds, respectively. In the latter type the destruction of *Bacillus coli* was very complete.

Contribution from the testing offices for dairy equipment in the Prussian Institute for Investigation and Research in Dairying at Kiel [trans. title], [K.] RICHTER ET AL. (*Milchw. Forsch.*, 3 (1926), No. 2-3, pp. 185-199, figs. 4).—An apparatus for holding milk at a uniform temperature and at the same time allowing a slow flow through it was tested as to its efficiency. It was found that milk heated to pasteurizing temperature lost some heat during its passage through the apparatus, and though the average time was 30 minutes, certain of the milk passed through considerably quicker while other portions of the milk were held for longer periods. The efficiency of the pasteurization, as judged by the numbers of organisms killed, was only 44.24 per cent in one test.

Keeping quality of sweet cream butter as affected by temperature of pasteurization of the cream, W. WHITE and G. R. CAMPBELL (*Jour. Dairy Sci.*, 8 (1925), No. 6, pp. 497-499).—The results of studies at the Bureau of Dairying, U. S. D. A., of the effect of various pasteurization temperatures from 145 to 165° F. for from 25 to 30 minutes on the keeping qualities of sweet cream butter stored at 0° for from 7.5 to 9 months indicated that the keeping qualities of such butter were not influenced by the pasteurization temperature.

Some factors concerning the "partial neutralization" of cream for buttermaking, B. A. STIRITZ and H. A. REUHE (*Jour. Dairy Sci.*, 8 (1925), No. 6, pp. 459-485).—This is a more complete account of work previously noted from the Illinois Experiment Station (*E. S. R.*, 52, p. 479). The work deals with the comparative effects of slaked lime, Lehigh lime, soda ash, and sodium bicarbonate as to the time required for neutralization, the reduction of acidity during pasteurization, the time required for churning, the completeness of churning, and the quality of the butter produced.

The effect of homogenization, condensation, and variations in the fat content of a milk upon the keeping quality of its milk powder, G. E. HOLM, G. R. GREENBANK, and E. F. DEYSHER (*Jour. Dairy Sci.*, 8 (1925), No. 6, pp. 515-522, figs. 3).—The keeping quality of milk powdered by the spray process and sealed in tin cans was compared at the Bureau of Dairying, U. S. D. A., when made from milk varying in fat content and which had been differently treated during manufacture. The results showed that precondensation and homogenization tended to improve the keeping qualities, but larger amounts of fat were not as favorable as smaller amounts. The ability to withstand oxygen absorption was directly measured as an indication of the keeping quality in part of the experiments.

VETERINARY MEDICINE

The spermatogenesis of domestic mammals, III, K. MASUI (*Jour. Col. Agr., Imp. Univ. Tokyo*, 8 (1923), No. 2, pp. 207-252, pls. 7, fig. 1).—This third paper (E. S. R., 43, p. 670) deals with the spermatogenesis of the mouse and of the rabbit. A list of 61 references to the literature is included.

A hitherto undescribed anomaly in blood groups, R. OTTENBERG and A. JOHNSON (*Jour. Immunol.*, 12 (1926), No. 1, pp. 35-44).—This is a report upon an anomaly in the blood of a professional donor, which contained an abnormal agglutinin and behaved practically like the blood of a foreign species of animal.

The sensitization of pigeons to foreign proteins, J. E. GAHRINGER (*Jour. Immunol.*, 12 (1926), No. 6, pp. 477-488).—The author demonstrated by the use of dog's serum that the pigeon is readily sensitized to a foreign protein.

"When the most favorable sensitizing and critical doses are used, a demonstrable induced sensitiveness occurs on the fourth day, increases rapidly to the tenth day, and reaches a maximum by the twentieth day. It then decreases gradually, to disappear between the sixtieth and seventieth days. When single or multiple shock reactions are induced in the pigeon, each and every reaction is followed by a definite period of insensitiveness. The primary change in blood coagulability during anaphylactic shock is an increase in coagulability, to which a decrease in coagulability is always secondary."

Prophylactic and therapeutic possibilities of the Twort-d'Herelle's bacteriophage, L. ARNOLD and E. WEISS (*Jour. Lab. and Clin. Med.*, 12 (1926), No. 1, pp. 20-31).—The authors' investigations here reported have led to the conclusion that the lysed, soluble bacterial proteins in the bacteriophage are antigenic and confer an early active immunity. Bacteriophage, free of antigenic bacterial proteins, prevents death when injected in the rabbit after a lethal dose of bacteria has been given. A list of 25 references to the literature is included.

A method for the preliminary identification of the common tissue-invading anaerobes, J. P. SCOTT (*Cornell Vet.*, 16 (1926), No. 1, pp. 55-58).—This is a contribution from the Kansas Experiment Station in which a simplified technique is described by means of which a preliminary identification of tissue-invading anaerobes may be made. Differentiation is based upon the type of growth made in six different media, including the brain-liver and liver agar used in isolation. Six media are described by the type of growth in which a preliminary identification of *Clostridium chauvoei*, *C. edematis*, *C. sporogenes*, *C. welchii*, and *C. novyi* can be made.

Bacterial variation: Serological characters of parent and sub-strains within the para B-suipestifer group, P. R. EDWARDS and L. F. RETTGER (*Jour. Immunol.*, 12 (1926), No. 5, pp. 377-392).—The authors conclude that there are two antigens present in the Salmonella group, one of which is specific to types within the group. The other relates the type with the group, and it is due to this that marked cross reactions between the different types occur.

"The two types of bacilli may be separated by plating stock cultures. When maintained under ordinary laboratory conditions the two types tend to resume the characters of the parent strains. The time required for this change to take place varies from a few days to several months. When subjected to unfavorable conditions strains may temporarily lose the ability to absorb agglutinins to which they have previously given rise. Strains may for a time lose their ability to agglutinate with group antisera. It appears that the two antigens present in the para B-suipestifer group are rather complex, and may at times be strain specific rather than type specific or group specific."

An experimental study of tick paralysis in Australia, I. C. ROSS (*Parasitology*, 18 (1926), No. 4, pp. 410-429, figs. 2).—In this contribution from the veterinary science department of the University of Sydney the author reports that tick paralysis occurs in man and in the dog and other domesticated animals on the east coast of Australia. As far as is known, the disease in Australia is conveyed only by the mature female of *Ixodes holocyclus*. There is said to be some evidence that immunity to the disease may be acquired after recovery from previous attacks.

Immunological studies in tuberculosis, III, IV, S. A. PETROFF and F. W. STEWART (*Jour. Immunol.*, 10 (1925), No. 4, pp. 677-717, figs. 40; 12 (1926), No. 2, pp. 97-121).—This is a continuation of the studies previously noted (E. S. R., 50, p. 80; 53, p. 583).

In Part III an account is given of an attempt to repeat with animals sensitized by dead tubercle bacilli the various allergic phenomena which in the past have been observed only in animals previously infected with living tubercle bacilli. In studying these allergic reactions two types of controls were used, one of tuberculous and the other of perfectly healthy animals. While much more work must be done before definite conclusions can be drawn, the authors find that animals sensitized with dead tubercle bacilli give an allergic reaction which in its essentials does not vary from that observed in infected animals, and that the severity of the reaction depends upon the degree of hypersensitiveness.

In the fourth paper of the series, five series of experiments with guinea pigs sensitized with dead tubercle bacilli are reported, in which tuberculin hypersensitiveness was induced with dead tubercle bacilli. During the allergic state inoculations of living tubercle bacilli were made, with the use of approximately the same number of normal control animals. The sensitized animals outlived the controls an average of 46 days, and the amount of macroscopic disease at autopsy in the former was much less extensive than in the latter, confirming the belief that dead tubercle bacilli can induce some degree of protection. In a small series, guinea pigs were sensitized with Dreyer's defatted tubercle bacilli. Only a mild skin hypersensitiveness was produced, and that not uniformly. No appreciable resistance could be observed in these animals.

Researches concerning avian tuberculosis in cattle; occurrence of avian as well as bovine tubercle bacilli in the same cow, N. PLUM (*Cornell Vet.*, 16 (1926), No. 4, pp. 250-255).—This is a contribution from the Veterinary Serum Laboratory at Copenhagen, Denmark, in which work with avian tuberculosis in cattle is briefly considered.

Tuberculous abortion disease in cattle, N. PLUM (*Cornell Vet.*, 16 (1926), No. 4, pp. 237-249).—This is a contribution from the Veterinary Serum Laboratory at Copenhagen, Denmark. The discussion includes a detailed report of six cases. In examination of a series of 834 consecutive fetal membranes, tuberculous abortion was found in 1.79 per cent.

The value of placental examination for the diagnosis of infectious abortion of cattle, W. A. HAGAN (*Cornell Vet.*, 16 (1926), No. 4, pp. 274-279, figs. 2).—It is pointed out that gross lesions of characteristic appearance are produced in the placenta through the action of *Brucella abortus* (Bang). These represent the only gross lesions due to this organism which may be recognized positively in the bovine species. The lesions are located in the chorion and are particularly characteristic in the portions of this membrane which lie between the cotyledons. The lesions may be widespread or may occur only in a circumscribed area. When abortion is due to *B. abortus*, it is believed that these lesions are always present and may be recognized in the majority of cases. In the present instance, a correct diagnosis was made in 29 cases in a series of 32 abortions.

A study of the value of whole milk and milk sediment for the isolation of *Bacterium abortus* Bang, C. P. FITCH and R. E. LUBBEHUSEN (*Cornell Vet.*, 16 (1926), No. 1, pp. 46-54).—This is a report of investigations conducted at the Minnesota Experiment Station. In summarizing the work, the authors point out that milk used for injection should be representative of a composite sample of an entire milking, and that both whole milk and milk sediment are of value in the isolation of *B. abortus* but neither should be used to the exclusion of the other. *B. abortus* was isolated from whole milk in 29.7 per cent and from milk sediment in 43.2 per cent of the samples showing evidence of infection. If either method is used, the injection of milk sediment is to be preferred as being most efficient.

Some recent advances in the protection of cattle and other animals against disease.—VIII, Haemorrhagic septicaemia in cattle in India, S. C. J. BENNETT (*Agr. Jour India*, 21 (1926), No. 5, pp. 351-356).—A brief discussion of the present knowledge of this disease including its prevention and control.

The blood and urine of the cow in milk fever.—A second report, C. E. HAYDEN (*Cornell Vet.*, 15 (1925), No. 4, pp. 399-404).—The author finds that there is hyperglycemia and glycosuria in milk fever, the hyperglycemia commencing to decrease with udder inflation and accompanying treatment. The hyperglycemia may be a reflex of the extreme nervous reaction evident before treatment. Nonprotein nitrogen and urea are both above normal. The average increase indicates a slight renal impairment. Uric acid in the blood is not increased in the same proportion as it is in eclampsia, and while there is a very slight increase it is not enough to indicate renal disturbance.

Pyocyanus bacillosis and mastitis due to *Ps. aeruginosa*, E. M. PICKENS, M. F. WELSH, and L. J. POELMA (*Cornell Vet.*, 16 (1926), No. 3, pp. 186-202).—The authors find in work at the Maryland Experiment Station that under proper conditions *Pseudomonas aeruginosa* seems to be capable of producing mastitis in cattle. A case of infection with *P. aeruginosa* in a calf here described is believed to be identical with the so-called "pyocyanus bacillosis" of Poels. It is pointed out that when cultivated upon artificial media this organism may lose its pathogenicity for experimental animals within a few weeks. Autogenic bacterins were found to be of questionable value in the treatment of mastitis in cattle due to *P. aeruginosa*. The blood of cattle suffering, or having recently suffered, from infection from *P. aeruginosa* may agglutinate homologous antigens in dilutions as high as 1:1,000. The blood of cattle not suffering, or not having recently suffered, from infection with the organism may agglutinate homologous antigens in dilutions as high as 1:50.

The account includes a list of 34 references to the literature.

Studies in dog-distemper, G. W. DUNKIN and P. P. LAIDLAW (*Jour. Compar. Path. and Ther.*, 39 (1926), No. 3, pp. 201-230, figs. 4).—The several parts of these studies deal with (1) dog distemper in the ferret (pp. 201-212), (2) experimental distemper in the dog (pp. 213-221), and (3) the nature of the virus (pp. 222-230).

It is concluded that the causative organism of this disease is a filtrable virus since (1) dog distemper can be transmitted from dog to dog, from ferret to ferret, or from ferret to dog by material in which no bacteria can be demonstrated and which yields no growth of organisms in ordinary culture media; (2) the infecting agent can be passed through bacterial filters of standard type and of proven quality; and (3) the infecting agent can not be cultivated in any straightforward manner so far employed.

The more important bacterial and protozoal diseases of poultry, J. P. RICE (In *National Veterinary Medical Association of Great Britain and Ireland, Annual Congress at Dublin, 1926. London, 1926, pp. 57-109*).—The bacterial

and protozoal diseases of poultry of importance in the British Isles here considered by the author include bacillary white diarrhea (pp. 57-73), coccidiosis (pp. 73-79), roup (pp. 79-90), tuberculosis (pp. 90-95), fowl typhoid (pp. 95-100), infectious entero-hepatitis (pp. 100-102), fowl cholera (pp. 102-104), and fowl plague (pp. 105, 106). The paper is said to be a summary of existing knowledge, and many of the statements are based upon the author's own work. The data are presented in connection with a list of 115 references to the literature.

The inheritance of resistance to bacillary white diarrhea, E. ROBERTS and L. E. CABD (*Poultry Sci.*, 6 (1926), No. 1, pp. 18-23).—This contribution from the Illinois Experiment Station reports on the status of investigations under way, accounts of which have been previously noted (E. S. R., 54, p. 380).

The results as here presented led the authors to consider the following conclusions justified: "Great variation exists among chickens with respect to their resistance to infection with *S[almonella] pullora*. The occurrence of resistant chicks is such as to indicate a natural resistance that is hereditary. Chicks from certain hens are much more resistant to infection than are the chicks from other hens, when the measure of resistance is the percentage of chicks that survive an inoculation, at approximately 24 hours of age, with a pure culture of *S. pullora*. The occurrence of resistance is sufficiently consistent among chicks from certain hens and flocks to suggest that it may be possible to establish a strain of fowls that will be highly resistant to infection with *S. pullora*."

Rickets in chicks.—I, Variations in the antirachitic potency of different brands of cod liver oil, G. F. HEUSER and L. C. NORRIS (*Poultry Sci.*, 6 (1926), No. 1, pp. 9-17, figs. 2).—The authors find that different brands of cod-liver oil vary significantly in antirachitic potency when this factor is measured by means of chicks. "Growth is some measure of the antirachitic factor of cod-liver oil, as the presence of rickets finally retards growth. In these experiments the cod-liver oils of American origin gave results superior to those of Norwegian origin. With plenty of calcium and phosphorus in the ration, it seems probable that the amount of cod-liver oil required to protect against rickets will depend upon both the antirachitic potency of the oil used and the amount of this factor stored in the body of the chick at the time of hatching."

The injection of argyrol for the treatment of sinusitis in turkeys, E. E. TYZZEE (*Cornell Vet.*, 16 (1926), No. 3, pp. 221-224).—In experiments conducted in the course of investigations of this condition of the turkey, it was found that when 1 cc. of fresh 15 per cent argyrol was injected into the distended antrum of an affected bird the swelling disappeared from the cheek and the corresponding nostril was dry within a period of several days. Of 13 other turkeys from a flock treated in this manner 9 recovered after a single injection, while 3 others responded to a second injection and a third injection was necessary for the recovery of the last of the 13.

This procedure is said to be very simple, requiring a minimum of time and effort. Where possible it is best, though perhaps not necessary, to empty the antrum by gentle pressure. Then with a hypodermic syringe inject 1 to 2 cc. of fresh 15 per cent argyrol into the cavity of the antrum, care being taken not to injure the eye nor to inject into tissues. The cheek should be punctured in front of and well below the eye in order to avoid the tear duct, which extends superficially over the upper portion of the antrum.

AGRICULTURAL ENGINEERING

Surface water supply of the United States, 1922.—Part 12, North Pacific Slope Drainage Basins, B, C (*U. S. Geol. Survey, Water-Supply Papers 553* (1926), pp. VI+295, pls. 2; 554, pp. V+186, pls. 2).—These papers present the results of measurements of flow made on streams in the following basins

during the year ended September 30, 1922: B, Snake River Basin (in cooperation with the States of Idaho, Oregon, Nevada, and Washington); C, Lower Columbia River Basin and Pacific Slope Drainage Basins in Oregon (in cooperation with the States of Oregon and Washington).

Developing new land under irrigation, R. P. BEAN (*Washington Col. Sta. Pop. Bul. 136 (1926), pp. 5-23, figs. 10*).—Practical information is given.

Graphic representation of the Kopecky soil classification scheme for technical purposes, E. G. DOEBELL (*Internatl. Rev. Sci. and Pract. Agr. [Rome], n. ser., 4 (1926), No. 2, pp. 307-311, figs. 3*).—A graphical representation of the Kopecky soil classification scheme is presented for the purpose of establishing distances between drains in soils. This soil classification scheme is brought into a system of sectors of a circle. The circumference of the circle is divided into 80 parts for the percentage content of the soil fraction with a diameter of less than 0.01 mm. On the radius the proportion of fraction II is drawn to contents of 40 per cent. The sectors so formed represent the types of soil. The direct reading, which corresponds to the distance between drains suitable to the mechanical composition of the soil as determined by analysis, can be taken from the graph with the compasses or any other aid. Curves are also given for the determination of distance between drains in layers of soil of varying permeability.

Durability of rammed earth walls, T. A. H. MILLER (*Agr. Engin., 7 (1926), No. 11, pp. 374, 375, figs. 9*).—In a contribution from the U. S. D. A. Bureau of Public Roads data are briefly presented to show the durability of rammed earth walls in building construction over long periods of years.

Strength tests of threaded pipe joints, J. G. DENT (*Agr. Engin., 7 (1926), No. 11, pp. 373, 374*).—Tests conducted at the University of Minnesota on the tensile strength of threaded pipe joints are briefly reported. The tests covered joints with engagements of 1, 2, and 3 threads as well as joints turned up tight and engaging approximately 7 threads. It was found that some pipe is defective in that it seems to be made up of at least two concentric layers with only a comparatively weak bond between them. In such cases the outer layer, when cut nearly or entirely through in the process of threading, slides off the underlying layers when the joint is subjected to tension.

Strength of lap soldered joints, J. G. DENT (*Agr. Engin., 7 (1926), No. 10, pp. 351, 352*).—In tests conducted at the University of Minnesota on the effect of different fluxes and solders on the strength of lap soldered joints a lap of $\frac{1}{8}$ in. was used in all cases. Both surfaces to be united were tinned, but instead of running the soldering copper over the upper sheet the heat for sweating was applied by running the copper along the joint on top of the lower sheet and against the edge of the upper sheet. It was found that the strength of soldered joints increased regularly with the proportion of lead in the solder until the 50-50 mixture was reached, after which it fell off rather sharply. The 50-50 mixture of solder not only exceeded all other proportions in strength but as prepared in the laboratory showed a strength materially higher than commercial solder of the same nominal composition. Block tin was inferior to 50-50 commercial solder for joining copper. Black sheet steel was found to be very easily soldered if properly cleaned and produced a joint of fair strength. In this case 50-50 commercial solder was materially stronger than block tin. When the galvanizing was not thoroughly removed from galvanized steel before soldering the limiting element in the strength of the joint was found to be the adhesion between the steel and the zinc, and failure occurred by the solder pulling the zinc coating from the steel.

Public Roads, [December, 1926] (*U. S. Dept. Agr., Public Roads, 7 (1926), No. 10, pp. 193-208+[2], figs. 14*).—This number of this periodical contains the status of Federal-aid highway construction as of November 30, 1926, together with the following articles: Time Losses in Concrete Road Construction, by A. P. Anderson; Tests of Concrete Curing Methods, by J. T. Pauls; and Researches on Bituminous Paving Mixtures, by W. J. Emmons.

Yoking oxen to the plough: A new system, W. S. H. CLEGHORNE (*Union So. Africa Dept. Agr., Sci. Bul. 53 (1926), pp. 14, figs. 12*).—Experiments conducted at the Potchefstroom Experiment Station are reported, the purpose of which was to develop methods and yokes for the yoking of oxen to prevent side draft in single and gang plows.

The results showed that the formula $Di=6+(n+1)W$ can be used for calculating the proper width of yokes between skeys for different types of plows. In this formula Di is the width of yoke between skeys, n is the number of plow bottoms, and W is the width of cut of each plow bottom.

The use of the dynamometer in soil cultivation studies and implement trials, B. A. KEEN (*Jour. Roy. Agr. Soc. England, 86 (1925), pp. 30-43, figs. 3*).—An account is given of studies conducted at the Rothamsted Experimental Station on the use of the dynamometer in studying the factors involved in the draft of implements in soil cultivation.

The conclusion is drawn that if careful attention is given to adjustments in the dynamometer the variations in drawbar pull obtained on the chart can be definitely ascribed to variations in the soil resistance. Variations in hitch and set of the implement were found to have no measurable effect on the drawbar pull unless the depth of working was affected. Tests on adjustment of depth alone showed that over the normal range the drawbar pull was proportional to the depth. The slope of the land was found to have no effect on the drawbar pull for gradients up to 1 in 40. The effect of speed was also slight. An increase of from 2.5 to 4 miles per hour caused only a 7 per cent increase in drawbar pull. It is considered unlikely that the cost of the extra fuel needed to sustain this 7 per cent increase would be more than a small fraction of the saving.

In order to express this work a power factor was used which is defined as the product of drawbar pull and the time in seconds required to plow 1 ft. length of furrow. In many cases this factor was found more sensitive than drawbar pull alone. It is closely related to fuel consumption and can therefore be used when the costs of various operations are being compared.

The studies of the degree of uniformity of soil resistance on different fields showed that visual inspection is quite unreliable as an indication of uniformity.

The changes in drawbar pull across the field were found to reflect corresponding changes in the physical properties of the soil. Since the latter have an effect on the growth of plants, a relationship was found between drawbar pull and plant growth, especially in its early stages. For instance, the number of plants of winter wheat that survived the winter was greatest on those soils having the lowest drawbar pull, and the same relationship held for percentage of tillered plants. As growth proceeded the closeness of the relationship fell off, until at harvest there was no significant relation.

Rural electrification from an economic and engineering standpoint, L. S. WING (*Agr. Engin., 7 (1926), No. 10, pp. 345, 346, figs. 2*).—This is an abstract of a paper presented before the annual meeting of the American Society of Agricultural Engineers at Lake Tahoe, Calif., in June, 1926.

Data are presented which indicate that the distribution of electric energy to rural customers over the long transmission and distribution lines necessary can not be done at reasonable cost unless the cost is spread over a larger

amount of energy than is represented by ordinary family use for lighting and small household appliances, even though these be somewhat greater for the farm than for the city family. In other words, the supplying of electric energy to farm consumers at an economical rate is contingent on the development of the equivalent of an industrial load which might perhaps be designated as an agricultural load in its proper sense.

Electrically heated chick brooders, G. W. KABLE (*Agr. Engin.*, 7 (1926), No. 11, pp. 376-378, figs. 11).—This is an abstract of a paper presented at the twentieth annual meeting of the American Society of Agricultural Engineers at Lake Tahoe, Calif., June, 1926, giving the results of tests conducted by the Oregon Experiment Station to determine the characteristics and merits of electric brooders, commercial and otherwise, now in use, the merits of various ways of providing heat and ventilation, and the possibilities of improving on present practice.

For the laboratory work a special floor with a glass panel in the center was built at a height convenient for observations from above and below. Horizontal distribution of temperature was studied by thermometers placed in wire racks at a standard chick height of 2.5 in., and vertical temperature ranges by thermometers arranged in racks with steps 1 in. apart. Air movements were observed by noting the behavior of smoke under and around the hovers, and an anemometer was used for measuring air velocities. The brooders tested were classified as to methods of heating as (1) direct radiation, nonglowing, (2) direct radiation, glowing, (3) direct-indirect, and (4) indirect.

In a brooder with a rather steep gable roof it was found that a large volume of smoke, released under the hover spread out at the level of the lowest heating wire, apparently was dispersed by radiation and reflection from the sheet iron lining of the top, and for the most part came out under the edge of the hover with only a small amount emerging from the vents. When slitted canvas curtains, reaching nearly to the floor, were attached to the edge of the brooder a much larger proportion of the smoke passed out at the vents. When 2-in. vent tubes extending downward through the holes in the top to within $4\frac{3}{8}$ in. of the floor were inserted, the smoke rose to the top of the brooder filling it down to the level of the bottom of the vent tubes. Smoke liberated under the hover of a flat-roof brooder spread out and more of it escaped through the vent than was the case with the gable roof construction. Smoke placed directly under a heating coil was spread out by the radiated heat, and when placed between the coils the movement was sidewise and out under the edge of the hover.

In a brooder differing from the above only in having the heating coils supported by hollowed out wooden strips, the air movement was exactly similar. In a conical shaped brooder with an inner heated area 35 in. in diameter and an outer unheated zone 55 in. in diameter surrounding the inner part, smoke placed between the inner and outer curtain had a slightly greater tendency to pass inward under the inner curtain and out of the vent than to escape through the outer curtain.

Tests with an octagonal pyramid brooder with an inner top joining the outer one 8 in. from the edge showed that when the top vent was closed and a special ventilating tube was installed the direction of movement was upward through the center tube and outward under the curtain, but the velocity of movement was extremely sluggish. When a similar tube of slightly different proportions was used with a 540-watt radiant heating element inside it, there was slightly more circulation upward through the heated tube than through the unheated tube used in the previous tests.

Tests of the effect of curtains and vent tubes on power consumption and ventilation showed that when the curtains were removed from the gable-roof type of brooder the cross ventilation beneath the hover was greatly improved,

with a corresponding loss in heat. With chicks under the hovers and curtains on both machines, the power consumption was greater for the brooder having vent tubes, indicating that the rate of air change and its attendant heat loss were greater than where tubes extending down inside the hover were not used.

In tests to determine the effect on vertical heat distribution of raising the brooder, it was found that with no change in the thermostat setting the temperature was lowered at all observation points from 0.25 to 5 in. above the floor. However, there seemed to be no simple or consistent relation between the amount of elevation and the temperature changes. The outstanding effect was a relatively greater excess of temperature at the 0.25-in. level as compared with other strata in the zone of observation.

Tests of the uniformity of temperature control by the thermostatic arrangement on the various brooders showed at chick height a range in temperature variation from 3.5° down to an amount too small for observation.

The results as a whole indicate that none of the brooders tested had less than 39 changes of air per hour, ranging to as high as 204. The cross ventilation under the curtains of most brooders is estimated to exceed that measured at the vents. Slatted floors covered with burlap do not affect the ventilation but do reduce the sweating. Sweating occurs less in warm weather, and there is less trouble of this kind under hovers heated with coal and oil stoves and electric hovers of the radiant heater type. It is concluded that sweating is not controlled so much by ventilation as by the temperature of the floors and the lower part of the chick's body. In the actual brooding tests of several electrically heated brooders operating in comparison with a coal-burning hover, the growth of chicks was practically identical but the mortality was higher with the electric brooders.

Artificial drying of crops in the stack, J. HENDRICK (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 36 (1924), pp. 141-160).—The results of a series of investigations conducted at the University of Aberdeen in Scotland on the artificial curing of hay and grain crops in the stack by blowing a blast of air through them are reported. The procedure was based on the heating of grain crops in the stack and subsequent cooling and drying under an air blast.

The results are taken to indicate that much is yet to be learned before crops can be dried with certainty and economy by means of an artificial air blast. It is necessary to know more of the conditions under which heating takes place in stacks. It was found, for instance, that damp oats did not heat much in stacks and such heating as did take place was very uneven. It was also found that stacks must be built so that the air will pass fairly freely through all parts. As the pressure is greatest in the bottom of the stack, this will normally be the part through which the least air passes. It is therefore necessary to arrange the stack around a conical boss or in some other way to provide the thinnest layer of material in the lower part of the stack.

Another difficulty found in carrying out the process, especially in a rainy climate or in rainy weather, is that the undried material absorbs rain readily, and it is therefore difficult to dry the head of the stack in unsettled weather. Where possible, therefore, the stacks should be dried under cover.

Poultry houses and equipment, N. R. MEHRHOF (*Fla. Univ. Agr. Ext. Bul.* 45 (1926), pp. 20, figs. 17).—Practical information on the planning and construction of poultry houses and equipment to meet Florida farm conditions is presented, together with working drawings and bills of materials.

Protection of buildings and farm property from lightning, R. N. COVERT (*U. S. Dept. Agr., Farmers' Bul.* 1512 (1926), pp. II+33, figs. 25).—This is a revision of and supersedes Farmers' Bulletin 842 (*E. S. R.*, 38, p. 15) and gives practical information on how to protect buildings from lightning.

Water and sewerage systems for Florida rural homes, F. ROGERS (*Fla. Univ. Agr. Ext. Bul.* 46 (1926), pp. 20, figs. 11).—Practical information on the planning and construction of water supply and sewage disposal systems for Florida rural homes is presented, together with working drawings of different types of systems.

RURAL ECONOMICS AND SOCIOLOGY

Studies in Vermont dairy farming.—II, Enosburg, Franklin Co., area, P. K. HOOKER (*Vermont Sta. Bul.* 256 (1926), pp. 45, pls. 4, figs. 12).—This is the second of the series previously noted (*E. S. R.*, 54, p. 882) and is based on records of farm business from June 1, 1922, to May 31, 1923, secured from 114 out of a total of 154 farms in the town of Enosburg, Franklin County. The object of the study is to analyze in their relation to profits (1) the factors entering into the cost of making dairy products, and (2) the methods of disposing of the product.

The receipts from the net cattle sales and increase cattle inventory and from the milk products sold amounted to 7.1 and 67.6 per cent, respectively, of the total farm receipts. Detailed discussions with tables and graphs are made of the effects on profits of land values, total capital invested, capital invested in cows, number of cows per farm, acreage per farm and per cow, housing costs, quality of sires and cows, length of the lactation period, amount of grain fed, labor costs, use of milking machines, winter and summer dairying, and different methods of disposing of products. Net earnings on land values from \$11 to \$20 per acre were greater than on lower or higher valued land. A higher profit per cow was made on medium-sized farms having \$10,000 to \$16,000 invested in the business, and the net earnings increased steadily as the percentage of capital invested in cows increased. Farms with 20 to 30 cows and those with 126 to 150 acres of crop land and open pasture showed the highest profits per cow. Farms averaging 4 acres of crop land and open pasture per cow showed 177 lbs. of butterfat and \$4 profit per cow, as compared with 171 lbs. and —\$8 and 161 lbs. and —\$12 for farms averaging 6 and 9 acres, respectively.

Housing cost varied from 74 cts. to \$11.73 per cow, the highest profit per cow being made from those housed at a cost of from \$2 to \$2.99. Seventy-five purebred and grade herds showed a loss of \$1 per cow as compared with a loss of \$12 per cow in 39 herds of mixed lots and "scrubs." The 11 herds headed by purebred sires for at least 15 years showed \$1.36 profit per cow as compared with a loss of \$4.84 per cow for all farms. Profits increased rapidly as the rate of production increased up to \$9 per cow in the 175–200-lb. butterfat group, after which the profits were nearly constant, except for the 275 lbs.-and-over group, which returned \$33 per cow. Cows yielding 200 lbs. and over of butterfat on from 750 to 1,250 lbs. of grain gave the highest profit. Profits per cow increased steadily from —\$23, where less than 25 per cent of the product sales were in the winter, to \$8 per cow where 45 per cent and over of the sales were in the winter. Sale of cream resulted in but \$1 greater loss per cow than sale of milk, but shifting from one to the other was \$6 per cow less profitable.

The wide difference in the correlation coefficient between profit per cow and price received per pound of fat (0.3070 ± 0.0573) and that between profit per cow and cost per pound of fat (-0.9328 ± 0.0082) indicates that the reduction of cost offers better opportunity for increasing profits than does an attempt to secure higher prices.

Judging creamery efficiency, B. A. HOLT and W. B. COMBS (*Minnesota Sta. Bul.* 231 (1926), pp. 22, figs. 6).—This bulletin analyzes some of the factors of

efficiency in the operation of creameries and presents a method for judging the efficiency of individual creameries. The analysis is based upon the data of Black and Guthrie previously noted (*E. S. R.*, 53, p. 489), revised to fit 1925 conditions.

The price paid for butterfat was found to be the best test of creamery efficiency. Curves are presented showing the effect on the price paid for butterfat of varying the price of butter, the creamery margins, and the overrun. Tables are given showing the effect on overrun of underreading the butterfat test and underweighing cream. The largest single factor affecting creamery costs per pound of butter is volume of business or output. Tables and curves are presented showing by different outputs the average cost per 1,000 lbs. of butter in 88 Minnesota creameries in 1925 of equipment, building and site, labor and management, supplies and miscellaneous expenses, and total cost. The computation of these costs for an individual creamery is illustrated. Indexes of costs of constructing creamery buildings of various types as compared with 1925 are given by 5-year periods from 1900 to 1925, and the method of making adjustments in computations necessitated by changes in construction costs, wages and salaries, prices of equipment and supplies, etc., are explained. The probable reasons for high costs in each class of costs are summarized.

Cost of producing crops in North Dakota, R. E. WILLARD (*North Dakota Sta. Bul.* 199 (1926), pp. 32, fig. 1).—The various items of costs, costs per acre, and costs per unit of yield for wheat, flax, rye, oats, barley, potatoes, millet, alfalfa, sweet clover, and corn for grain, fodder, silage, and hogging down are presented for the State as a whole and for the four geographical sections—the Red River Valley, central, northwestern, and southwestern divisions. The greater part of the records covered the years 1921 to 1923, inclusive. Those for wheat for the State covered 1919 to 1925, and those for flax and rye, 1921 to 1925. The method of calculating costs is the same as that used in Bulletin 165 previously noted (*E. S. R.*, 48, p. 490). The cost per acre of producing crops decreased about 60 per cent from 1920 to 1925, due to lowering of the price levels of commodities used by farmers, land rent, value of farmers' labor, and increased efficiency of the farmers.

Cost of filling silos, P. E. McNALL and W. A. HARTMAN (*Wisconsin Sta. Bul.* 386 (1926), pp. 12).—Data from 282 farms in 1921 to 1923, inclusive, show the cost of filling silos averaged \$2.06 per ton, varying from \$2.39 for silos of 50 to 70-ton capacity to \$1.89 for those having a capacity of over 111 tons. The difference in cost consisted of 5 cts. for man labor, 3 cts. for horse labor, 11 cts. for use of silo, 22 cts. for use of equipment, and 9 cts. for interest. The cost per ton for engine and cutter varied from 37 cts. for the smaller silos to 33 cts. for the larger silos when the engine and cutter were hired, and from 43 to 24 cts. when owned, indicating that hiring was cheaper for silos of less than 100 tons capacity.

Agricultural credit in Jugoslavia, M. K. DJORDJEVIĆ (*Belgrade Econ. Rev.*, 1 (1926), No. 1-2, pp. 3-6).—A brief description of the organization and operation of the Agricultural Credit Management, district treasuries for agricultural credit, and local agricultural treasuries under the Agricultural Credit Law of June 12, 1925.

Services in cotton marketing, A. B. Cox (*U. S. Dept. Agr. Bul.* 1445 (1926), pp. 40, figs. 9).—The delivery of cotton from the farm to the mill necessitates the services of preparation, standardization, classing, assembling and distributing, warehousing, inspection and regulatory work, financing, and furnishing information, the payment for which services constitutes the spread between what the grower receives and what the spinner pays. The functions of the several services, the present practices, and the assistance given by and the regulations of the Federal and State Governments and private agencies are discussed.

Business set-up of a cooperative marketing association, C. L. CHRISTENSEN (*U. S. Dept. Agr., Dept. Circ. 403 (1926), pp. 14*).—A brief general discussion is given of the problems involved in the development of a cooperative marketing organization. The type of organization; membership relations, including marketing contracts; financing, including problems of fixed capital and of marketing and production credit; management; and selling program are considered.

A students' list of works on co-operation (*London: Horace Plunkett Found., 1926, pp. 20*).—This is a list of 227 works on cooperation recommended by the Horace Plunkett Foundation. It is divided into works on (1) theory, organization, etc., of agricultural cooperation; (2) industrial cooperation (productive and distributive); (3) cooperation in specific countries; (4) cooperation in marketing of agricultural produce; (5) cooperative credit; and (6) rural economics, general economics, land, country life, and labor.

International yearbook of agricultural legislation (*Internatl. Inst. Agr. [Rome], Internatl. Yearbook Agr. Leg., 14 (1924), pp. XLIV+1191; 15 (1925), pp. XXXV+1104*).—These volumes continue the series previously noted (*E. S. R., 51, p. 794*) and give for the respective years the text for the various countries and a summary for the world of the current legislation regarding agricultural and commercial statistics; trade in agricultural products, including machinery, fertilizers, and livestock; financial laws and customs legislation as affecting agriculture; plant production and industries; animal production and industries; agricultural organization and training; plant diseases and pests noxious to agriculture; agricultural cooperation, insurance, and credit; rural property and land settlement; relations between capital and labor in agriculture; and rural hygiene and the policing of country districts.

[Summary of agricultural legislation, 1924] (*Cent. Landowners' Assoc. [London] [Pub.] 6 (1925), pp. 31*).—A brief summary is given of the principal legislation enacted by Parliament during 1924 affecting agricultural interests in England and Wales. The rules and orders of the Minister of Agriculture and Fisheries under the Agricultural Wages (Regulation) Act of 1924 are included.

The tariff on wool, M. A. SMITH (*New York: Macmillan Co., 1926, pp. XXII+350, pls. 4, figs. 20*).—The Institute of Economics has undertaken, as part of an analysis of the system of customs duties of the United States, a series of special investigations on the relation of the tariff to particular lines of production. This study on wool is the second of the series dealing with agricultural commodities, the first of which was previously noted (*E. S. R., 51, p. 690*). Part 1 of this study describes the growth and extent of the sheep industry in the United States and in competing countries; part 2 gives a brief history of the wool duties in the United States; and part 3 discusses the elements of the wool tariff problem, the proposed bases for a wool duty, the effects of a duty on wool upon sheep husbandry and the cost of woollen goods, and the questions of public policy involved.

The study indicates that if the present duty (31 cts. per scoured pound) is maintained the domestic production will probably increase slowly for several years, that if a much higher duty is imposed the output will probably not increase to any marked extent because of the increased costs of production and the fall in the price of mutton and lamb, and that if the present duties are abolished there will probably result an immediate decrease of 10 or 15 per cent in the domestic production. The general conclusion is reached that when a comprehensive readjustment of the tariff rates in the United States is made, wool should be placed upon the free list.

Appendixes contain a study of wool prices and the tariff from 1860 to 1924; index numbers of the monthly wholesale prices by groups of commodities and the yearly wholesale prices from 1910 to 1925 and monthly prices from

1921 to 1925 of woolen goods; a review of the production, marketing, and use of carpet wools; and an inquiry as to the best method of calculating costs in cases of joint production, such as wool and mutton. A bibliography is included.

The cattle industry and the tariff, L. R. EDMINSTER (*New York: Macmillan Co., 1926, pp. XV+331, figs. 9*).—This is the third of the series of special investigations of the Institute of Economics noted above. The study is limited to the duties on cattle and beef. The nature, development, and present status of the domestic industry are discussed. The competitive situation is described with a view to showing how far the industry is dependent on protective duties. The efficacy and public expediency of duties on cattle and beef are considered.
