This equality of production is, however, not owing to a like degree of saccharine or sugar bearing capacity in the two plants, but to the more successful extraction of the sugar they contain in the manufacture of the beet than the cane. Were the modes of treatment of equal skill and efficacy in both cases, beet sugar, there cannot be much doubt, would have to take a lower position in the category, notwithstanding the fiscal support accorded to it in the country of its growth. Without the premium on export to stimulate its manufacture, a sustaining power could hardly have been found for the large production in the part retained for home consumption. Beet sugar, until of late years, could not, except in the form of refined sugar, bear comparison with sugar from the cane. The raw beet sugar is from the disagreeable smell and taste of the molasses, unfit for consumption as human food. By skilful treatment, a nearly pure white grainy sugar is now produced without the refiner's aid, but no grocery sugar made of beet can without offence come near the cane muscavado or v.p. crystals. In chemical composition, beet sugar is considered to be identical with cane. Whether it is so in the use also is doubtful. It is supposed to be deficient in sweetening power. And yet raw beet is largely imported for our refiners, and is preferred, perhaps, to the low classes of raw cane for its better preparation, as it is known much less crystallisable sugar can be obtained from beet than from cane of a similar analysis. The consumer may, consequently, be somewhat inconvenienced in pocket, and there being no way of telling one sugar from the other over the shop counter, it would be only fair towards him if a label of distinction were introduced. Analytical figures show that, in moisture and ash, no difference to speak of exists between the kinds of highly refined sugar, whether beet or cane. But they also show the unrefined white beet sugar to be as pure, although to smell and taste it is foul with the "hogo" of the beet that clings to it. If chemistry cannot find out the difference of odour, neither can it of sweetness. This is, perhaps, a matter of taste only, and the common notion that beet is inferior to cane may be justified by fact. It is well known that all the first-class jam makers and manufacturers of British wines will not use sugar made from beet, however beautiful it may look, or however cheap it may be. And it is to the beet in the sugar of the shops, it is said, that is often owing in home-made preserves the disappointment of the cook's expectation of a good jelly. If the difference of sweetness should be 10 per cent. less in the beet, it is an indirect taxing of the cane to allow beet sugar to be sold as one and the same thing with cane sugar, and ought to be discontinued.

The crude materials possessed by the sugar maker in the cane are acknowledged to be superior to those he finds in the beet, or in any other of the plants from which supplies of sugar are obtained. The advantage claimed for the beet is that the pulp, after exhaustion of the sugary juice, furnishes the cultivator with a valuable food for cattle. And it is this contributive force in stock feeding that to the farmer forms perhaps the chief object in growing the sugar-beet. Unless meat production went along with sugar production, the latter alone would be barely profitable. But as regards the cane, there is—to say nothing of the tops and leaves, which would make good ensilage like the beet tops—a set-off to the spent pulp of the beet in the megass or refuse of the cane after crushing, that is quite equal in value to wood for fuel to the manufacturer. The megass, too, if it could be returned unburnt to the land, would supply the cultivator with the natural fertiliser for his plants. The produce of a crop of sugar-beets in Germany is not more than ten tons of washed and topped roots per acre, whilst in India the native farmers are said to get twelve or thirteen tons of cut canes per acre. In Jamaica the yield is supposed to be from seventeen to twenty tons, and in Demerara twenty-five to thirty tons per acre. In France, where the beet is cultivated less for the sugar it affords, and more for the advantage of the pulp to the farmer, much larger crops are grown than in Germany, from twenty to thirty tons per acre being a common yield. But the bigger beets have inferior saccharine matter, and the deficiency of richness is not compensated for by the greater quantity produced, as the adverse chemical salts and other bodies inimical to sugar crystallisation increase also, not only in proportion to the sugar, but even to the gross weight. In quality, the juice of the cane is both purer and richer than the juice of beets. Weight for weight, the former has almost double the amount of sugar that the latter possesses; and taken when the cane is fully matured, the juice is said to be almost a pure syrup, and more free from contamination with uncrystallisable forms of sugar than beet juice. By analysis, the ripe cane is shown to contain from 13 to 22 per cent., with a mean of 18 per cent., of sugar. The beet contains from 5 to 10 and 11 per cent. of sugar, with a mean of 7½ per cent. In Germany, where the roots are taxed on the weight without reference to excess in the relative amount of sugar in them, the proportion has, with high cultivation, risen to 13·75, and even a per-centage of 18 appears to have been reached; but this may be looked upon as a maximum of the laboratory difficult of attainment, and in practice not more than 13 per cent. of sugar should be reckoned upon as the average in good years. The cane is also a more favourable crop to cultivate than the beet, giving less trouble, requiring less labour, and suffering less from vicissitudes of the weather. The cane roots send up a succession of young shoots, or rattoons as they are called, for three and four or more years; whilst for the beet, an annual tilling and sowing of the land is necessary; and the rattoons, taking into account the shorter time of growth, may be considered to yield as abundantly as the plant canes. The great draw-back in cane cultivation is that seed time and harvest fall together, causing the pressure of work to be doubly heavy in the season.

Where the cane is seen to be apparently inferior to the beet is in the course of extracting the juice. The sugar-beet contains from 94 to 96 per cent. of juice, and all of it, with the exception of 5 or 6 per cent., can be extracted. From the cane, on the other hand, only 60 per cent. is obtained of the 88 to 90 per cent. of juice that it contains. The new and enlarged mills, with rollers of greater length and diameter, will procure a yield of from 65 to 70 per cent., but the common run of mills do not get more than 45 to 50 per cent. of the weight of the cane in juice. This resistance to a fuller surrender of the juice is sought to be overcome by using more powerful machinery on the same principle, and as much as 80 per cent. of juice is said to have been expressed in experimental trials. But that this extra yield should be secured in the crushing of a whole crop of canes is scarcely to be expected. And beyond a certain point the excessive power employed would not be paid for by the increased quantity of juice, or the quality of what is got. The juice drawn from the lighter and less complete crushing of the cane is known, by the experience of the old cattle mills, to be the best. That which comes away, under more forcible pressure, may have a greater density, but it is the objectionable salts, albumen, and fragmentary fibre of the cane which increase in it, and not the sugar. Besides pressure is practically inoperative to squeeze out of the crushed body of the cane the juice that it holds hygroscopically, or retains by absorption. And it is only the wealthy owners of estates who can bear the cost of these big mills. No inconsiderable portion of the sugar must, therefore, continue to be lost, and the full profit of the manufacture fail to be got, unless a change can be made in the mode of treatment, and some improved method, such as would extract the saccharine matter from the cane as effectually as is done in the beet, be adopted. In the beet-sugar manufacture, which began upon the plan used with the cane, the old mode of extracting the juice by pressure has in Germany, nearly, if not altogether, given way to the diffusion process, with its auxiliary methods for saving the sugar in the molasses. And in France, where roller and hydraulic presses are still generally employed for the convenience of the farmers, who require to have the compressed pulp returned to them, and get back from the best mills as much as 20 per cent. in weight of the beet roots supplied, that is from 5 to 6 per cent. of solid residue, holding 14 to 15 per cent. of juice diluted with 18 per cent. of water, many of the large factories have begun to substitute diffusion for pressure. That the diffusion process can be applied successfully to the cane has been also demonstrated. By its use at the Aska works in Ganjam, India, 87½ per cent. of the 90 per cent. of juice in the cane has been abstracted, and, according to a published return, an average yield of 83½ per cent. was obtained from the crops worked off in the three years ending in 1870. In Guadeloupe the almost absolute exhaustion of the cane juice was effected by it; and in Louisiana, by the competitive trials of pressure and diffusion made in 1874, a surplus was shown in favour of diffusion over mill of from 40 to 43 per cent., obtained at a cost of but 1·30 $ more per 1,000 lbs. of sugar and molasses. But whether diffusion is in ordinary practice the process most suited for economic use in cane-sugar making, and would be as fully applicable to the cane as other processes, remains still to be determined. In growth and structure the cane is dissimilar to the beet. The one has a long slender stalk above ground, formed of strong parallel fibres, and divided by knots every few inches apart. The other has a short stem distended under ground, made of vascular pulp, and with a long tap root. And as they differ in substance, the tendency of the sugar and water to pass through the walls of the closed cell until equalised by transference, which is the condition of diffusion, will vary in some degree. But the position of the sugar cells in the cane, the largest number being found about the softer parts in the middle, should make it easier to displace the sugar by diffusion than to expel it by pressure through the rind. Defective, however, as the ordinary machinery for extracting the cane juice confessedly is, this is not the only or chief difficulty in the way of an extended sugar production. A greater obstacle is perhaps the want of time and labour in harvest. The canes, of which the gross quantity is enormous when compared in bulk with other crops, have to be cut, carried, and converted into sugar within the short space of three or four months. In manufacturing beet sugar, on the contrary, the period of working can be extended over a longer time, and the roots kept for later use, or till germination begins in spring, by storing them in pits. And it were a thing much to be desired, if the means of relief could likewise be found for the cane-sugar maker.

Great interest is shown in discussions upon the beet-sugar bounties, which are an evil, regarded from the refiners' point of view, that is not unmixed with good to the people of this country, but indifference appears to be profound on the subject of cane sngar. And yet it is indisputable that we, with our tropical possessions, are as distinctly a cane-growing people, as on the Continent they are beet growers. We are concerned not so much with how they manage things in France and Germany, as with what we can do to double and treble the produce of our own sugar-fields. The consumption of sugar per head of the population of these islands has more than doubled in the last quarter of a century. And were it not for the largely increased supply of beet, the price also would have been very appreciably affected. The relief of their wants received from the cane by those who take sugar has been small in comparison to that given by the beet. On a decennial estimate, the cane contributes only an additional amount of 277,958 tons, against an increased yearly quantity of 987,994 tons furnished by the beet. The relative figures for the two periods are—cane sugar, 1872, 1,782,607 tons; 1882, 2,060,565 tons; beet sugar, 1872, 873,000, tons; 1882, 1,860,994 tons. The cane is thus seen to be no longer the most important factor in the sugar market; and the superiority of the beet in this respect is further shown by the crop of the following year, 1883, with its enormous yield of 2,146,534 tons of sugar. No wonder, then, if exaggerated ideas of its potentiality in the future should be conceived, and the beet be looked upon as king, going on ruling, and to rule the markets. The legitimate claim, however, of the cane to the first place in the market of this country will very generally be admitted. But its restoration can only be brought about by producing good and cheap sugar more abundantly. And how is this to be done? It is an important question, in endeavouring to deal with which it may be allowable to make one or two suggestions. To say we are not justified in trying experiments, and must let improvement wait upon success, is to wait behind. As a good field for action, therefore, take Jamaica. It is easy of access, and its natural advantages of soil, water, and climate enable it to compete with other sugar-growing countries. The island has, unfortunately, suffered a long period of decadency, since the time of emancipation, and of the Act of 1846, equalising the duties on free and slave-labour sugar. But the official returns show that there was no decrease in the value of the staple and other products during the ten years ending in 1880. And if the year 1881 was a bad year, from blight and other causes, the year 1882 was a "bumper," and the exports of sugar, regard being had to the increased size of the hogshead, were the largest of any year since 1847—signs that present a good augury for the future. There is evidence, too, that the black and coloured population, already numbering more than half a million, are becoming sensible of new wants, and feeling a desire even for luxuries. The continual extension of provision grounds must cease to be profitable, or to provide a lazy subsistence, and the Negro, if he would have the means for an enlarged expenditure, will be compelled to prosecute the cultivation of the old commercial products of the country that are in repute abroad. Labourers for sugar estates are said to be scarce in some districts, but are commonly to be hired at from 5s. 3d. to 8s. 9d. per week of five days, the people not caring, or being pushed by want, to turn out on Saturday. And hundreds of men have left the island for Colon, engaged to work on the Panama Canal for wages of ten cents per hour; a strong proof that employment is not plentiful, and of a willingness to seek it under the attraction of good pay. Much land is lying waste and unproductive in both public and private ownership. The area under cultivation, including pasture, is 554,162 acres, out of which the average acreage under cane for five years, ending 1881, was only 43,999 acres. Of that vacant cultivable land a part might be very well applied to the growth of canes, and by the introduction of the East India system of farming, turned to good account. In India the ryot, as the peasant farmer is called, has usually in his holding a small patch of sugar cane growing with his other crops. The produce he makes into goor, or raw concrete sugar, and sells to the refiner, who turns it into clean white sugar for consumption. And experience shows that the ryot, giving his immediate care and attention to the work, and aided by wife and children, does better and more economically than a factory or sugar works, dependent on hired labour, and having the supervision of an extended area, can manage to do. The ryot has his plough, bullocks, rude crushing mill, and boiling pans, and when in want of money can, on the security of his interest in the land, obtain advances from the native banker. The adoption in Jamaica of this system is, however, not advisable in its entirety, but only so much of it as relates to the culture of the land, which, by the consension of opinion in India, is best left in native hands. The negro is not so inferior in capacity to the ryot that he could not, if put in the way and helped in the beginning, farm his small holding as efficiently, and secure in a market for his canes, do it successfully. The small agriculturists in Jamaica, making their couple of casks of sugar yearly, of whom there were 5,615 in 1871, though reduced in number to 4,700 in 1880, witness to this. But their example in being sugar makers is to be followed rather in the avoidance. With the cropping of the canes the proper work of the agriculturist ceases. The extraction of the sugar in them requires skill of another kind, and separate machinery; a fact that seems naturally to indicate a division of labour between the planter and the sugar maker, as there is between the paddy grower and the rice miller. Supposing, then, an estate, with 300 acres of suitable land, to be laid out in plots of convenient size for cultivation by a family, say 5, 10, or 15 acres, and let to the occupants at a fair rent on a fixed settlement, either perpetual or subject to revision after a period of years, there would be on the average 30 families, and counting the usual five in a family, a population of 150 attached to the land; a number that should afford more than a sufficiency of labour for its proper cultivation, since from two to three labourers are enough to plant from 8 to 10 acres; and if it were made a firm stipulation of the tenancy that three-fourths of the holding should be kept in cane-bearing, the sugar-works would only have to provide a supply of labour, required concurrently with the machinery, to convert the canes into concrete sugar for refining. In these small holdings there might, at first, be little room for any but the commonest implements of husbandry, yet opportunity would come to introduce carrying and other labour-saving machinery in aid of the manual labour of the occupiers. Formerly land, mill, and people, made one machine, but the people have since become a part detached; and if a well ordered land and sugar company could be framed on these or similar lines, the moneyed man might reasonably hope to find profit in aiding the readjustment of the mechanism for its new work. The numerous little sugar estates that are in Jamaica, would naturally group around and co-operate with diffusion works placed conveniently near them. On some of these estates cattle mills are still in use; on others, where water or steam is the power employed, the ordinary roller presses are wanting in capacity. For these small properties to incur the expense of new or enlarged machinery, in order to obtain better results in sugar making, would be economically less to their advantage than to spend the money in improved and useful agricultural instruments. And to raise the per-centage of sugar in the juice would be more for the common good than if they were to increase the per-centage of juice expressed. A successful grower of canes might, by selling to the adjoining diffusion works, lay his account to reap all the farming profit, and by taking a prospective interest in the sugar made, participate in the profit of manufacture also.

As regards keeping the canes for later use, when cropped, there are two things to be noted; the great liability of the juice, as an aqueous solution of sugar, to ferment on exposure to the air, and the influence of heat to turn it sour. The tendency of all vegetables upon reaching maturity is to fade and spoil. Sound ripe canes, however, deteriorate but little if the skin is unbroken, and the sugar cells are not ruptured. The juice is produced separately in each joint, and the plant ripens from the bottom upwards. Cut canes have been known to keep for days without harm, and even with positive advantage, the ripening of the top joints continuing to form sugar. Fermentation is said only to take place in a solution of sugar and water when sufficiently dilute, with less than four parts water to one part sugar it takes place imperfectly, if at all. As, therefore, the proportion of 18 sugar to 90 juice is just 1 to 4, the natural drying up of the cut canes should help to preserve them. In these circumstances it might be possible, if there was available space, to stack and keep the upper part of the stalk, whilst using the lower part that has ripened, and thus to lengthen out the time for working in the sugar-house. The means employed to lower the temperature and prevent the heating of hay in the rick, would probably answer with the cane, and by facilitating evaporation accelerate the reduction of the water in the juice to a safe point. Were the experiment successful, and the practice of storing canes to come into use, sugar works would be able to maintain a permanent gang of skilled workmen, and to carry on operations with a smaller outlay for machinery. But the drier the canes became, the less amenable they would be to pressure, and for the liberation of the juice it might be needful to have recourse to a solvent like the water of diffusion or maceration.

These processes, maceration and diffusion, are the opposites of one another. Diffusion is applied to, and acts upon, the close cell of the plant; maceration on the open cell. And the advantage is with diffusion, which, applied to the beet, has surpassed maceration in success. By crushing the canes, the cell walls are burst open, and with the admission of the air to the juice, fermentation begins. The juice gets also mixed with bits of broken fibre, mucilage, and other parts of the substance of the cane, which are washed out with it in the act of maceration. Impurities are left behind, or not meddled with in the course of diffusion, as in slicing the canes a certain number only of the cells are cut open. The cells appear to act as clarifiers, the sugar passing through the cell wall, to change places with the water outside, whilst the albumen remains inert. The diffusion process, as improved by Julius Robert, dates from 1864-5, and was first applied to the cane at the Aska works, in the year 1866. From the reports of good success in the use of it by this company, its introduction into Louisiana followed in 1873. Twenty years before, in 1845, in Guadeloupe, attention had been directed to a plan of putting sliced canes, in baskets, into copper vessels with water. But nowhere in the British possessions, excepting at Aska, does there appear to have been any endeavour made to prove the capabilities of the system for working up our cane crops. In Louisiana, an apparatus used before for beet was brought over from Europe and set up; on trial, however, it was found to be unfitted for manipulating sugar cane, and two new and complete machines were constructed for use, on separate plantations. Upon one of them, where the common kettles, or open pans, used for making brown sugar, were employed, the diffusion juice failed to granulate so readily as the juice from the mill. On the other plantation, where an exact test was made between the mill, an ordinary three roller mill, and diffusion, a vacuum pan being in use, the result demonstrated a considerable gain by the diffusion process. Disagreements, however, arose between the parties concerned in the affair, which prevented further experiments from taking place. The next year, the two diffusion machines were removed and set up on another plantation, and canes were purchased for working. But the season was most unfavourable, the canes did not ripen well, the transport arrangements were bad, there was no pecuniary benefit, and thus the enterprise failed. The apparatus was worked two or three years after this by the people who bought it, but only on a small scale, and finally they took it down, and re-erected the mill. With more judicious management, it is very possible the process might have been made a success, as the gain in saccharine matter was great. At Aska, also, the working of the diffusion process was said not to have been continued, a sure sign it was no success. But so far is this from being the fact, that the process is still in successful practice, and has been, yearly for seventeen years. At the works they now cut up during the season, 1,000 tons of canes a week, and are so satisfied with the results, that they have ordered out a complete apparatus of the newest construction.

(*To be continued.*)

MAORI LAW.

Consul Griffin, of Auckland, in a report on the history of New Zealand, says that the Maori or native population, according to the census of April, 1881, was 44,097, and it has not increased since then. The males numbered 24,368, and the females 19,729. The disproportion of sexes is cited as a proof that the race is not a productive one; in fact, the native races appear to be dying out all through the islands of the South Pacific Ocean, and in some they have disappeared altogether. When Captain Cook first visited New Zealand, he estimated the population of the Maories at 400,000. Captain Hobson, in 1840, fixed the number at 200,000; while Sir George Grey in 1849 thought they were fewer than 120,000. From these figures it will be seen that the race has steadily declined. The pure Maories are believed to be of Malayan origin, and there is a tradition that their ancestors landed in New Zealand in fourteen canoes from Hawaiki, probably the island of Savaii in the Samoan or Navigator's group. The natives of the South Pacific islands have little or no knowledge of the laws and principles of human life. They almost invariably build their residences in low, miserable, and unhealthy situations, and it is chiefly for this reason that consumption, scrofula, and rheumatism make fearful ravages among them. The Maori language is a peculiar one, and is wholly unlike any language in Europe. It consists of fourteen letters—*a*, *e*, *h*, *i*, *k*, *m*, *n*, *o*, *p*, *r*, *t*, *u*, *w*, *ng*. *A* is pronounced as in *fall* and *flat*, *e* as *a* in *acorn*, *n* as *na*, *t* as *ta*, *ng* as *nga*. The words are seldom composed of more than two or three syllables, and the accent is on the penultimate. Distinctions of gender are seldom recognised. Dr. Maunsell, who has devoted much study to the origin and construction of the Maori language, is of opinion that its forms of prepositions are more extensive than those of the Hebrew or English, or, indeed, any other ancient or modern language. The Maories are slow to adopt the habits and customs of the Europeans, but they endeavour to blend them with their own, with the result that the distinctive features of neither race are preserved. In the King country, a modified form of the ancient Maori laws of *tapu* and *muru* still exist. The law of *tapu* was everywhere acknowledged, and the word itself doubtless means sacred. According to the law of *tapu*, certain persons and things were always sacred. The bodies of chiefs and priests, and everything connected with their dignity and honour were held sacred, and the chiefs and priests had the power of imposing the *tapu* on others, and they had also the right to remove it. The first potato dug was tapued, the sticks on which the memorial records were kept are tapued, and the Maories even *tapu* their food. Certain chiefs are not allowed to touch food with their fingers, and unless fed by others, they have to eat like dogs Various methods are employed to remove the *tapu*, one of which consists of throwing leaves into the air, and jumping after them. The law is now generally admitted to be a religious observance established for government and political purposes. Rivers were tapued until the fishing was ended; and cultivations were tapued until the planting was done. If a drop of blood of a high chief fell on anything, it was tapued, that is it was unlawful to touch it. Consul Griffin says that it is extremely difficult to thoroughly understand many of the more important principles of that branch of Maori jurisprudence, the law of *muru*. This law is so broad and general in its application that no human being, whatever may be his rank or condition in life, is exempt from its benefits or penalties; but, in order to understand the practical working of the law, it must be borne in mind that the Maories are communists in theory and practice. They do not think it right for one person to own more property than another; in fact, property changes hands so often that a man cannot tell a week or a month beforehand who will be the owner of his canoe, blanket, or mat, or even the house in which he lives. The great principle is to keep property in circulation—the oftener it changes hands the better. A man's relatives have the first claim, and his friends and neighbours the next; no one, however, would presume to assert a claim to the property of another, except in accordance with the strictest principles of the law of *muru*, which alone can determine the right of ownership. Should a great misfortune overtake a man, such as the death of a favourite child, his relatives are allowed to dispossess him of all his goods, and, if need be, of the house in which he lives. He must pay a penalty for his misfortunes; but, strictly speaking, he does not regard the loss of his earthly possessions as a misfortune, but looks upon it as a great honour and a great blessing. He is considered to be favoured both by gods and men. If everything he possessed is taken from him, he is treated with the most profound respect, and becomes a man of great importance in the community in which he lives. If a man's wife or child should be burned to death, and the accident prove unavoidable, everything is taken from him, his goods, his food, clothing, spears, mats, boats, in fact all his earthly possessions, and in order to favour him still further, he is severely beaten with clubs, and usually left on the ground in a bruised and bleeding condition. It is, however, against the law of *muru* to kill him. He is duly warned of the process of the law, and a messenger is despatched to inform him of the approach of the law officers. He is expected to defend himself with a spear or club until overpowered, but it is against the law for him to strike the officers too hard. As soon as the first blood is drawn he must stop, but sometimes a very stubborn resistance is made, and the fight is carried on in earnest. Though the victim knows that he is doomed, he does not wish it otherwise, for to be victorious would be against the law of *muru*.

IMPROVEMENTS OF THE ROMAN CAMPAGNA.

Her Majesty's Vice-Consul at Rome says that the sanitary amelioration of the Campagna was determined upon and decreed by a law passed on the 11th December, 1878. It was ordered as a work of public utility that the marshes and ponds existing in the Campagna, should be drained, and in addition, the collecting of the springs and the regulating of the soil by means of a complete canal system of all the waters, comprising the under-ground waters. By virtue of a law recently passed, the work is to commence by improving, agriculturally, a zone of ground within a radius of about six miles from the centre of Rome. The total area of the Agro Romano is 525,316 acres; that included in the circle of six English miles is about the seventh part of this surface, or 77,647 acres, which are subdivided thus:—Town, 3,546 acres; rivers, 1,043; vineyards, gardens, parks, or villas, and intermingled roads and streams, 18,611. The remaining 54,447 acres are now used for pasture, wood, and quadrennial sowing, and to that surface is specially applied the agricultural amelioration which becomes obligatory on all the landowners. The Italian Government desire to attain their object without infringing on the rights of property, and they express their intention of leaving to proprietors a certain liberty in the choice of the works to be executed, and of the cultivation best adapted to the soil. The proprietors are invited to present a report in which should be indicated the agricultural improvements which they intend carrying out on their own account, and which should specify the quality and extent of the proposed cultivation of trees, plants, and herbs, and the roads and buildings for workmen and horses. A special agricultural commission will examine and modify these propositions, and will decide for those proprietors who have made no proposals which are the best improvements to adopt, and the estimated time and expense. In case the improvements are not effected, the Government will have the right of expropriating and at once occupying the land, with indemnity according to the general law on expropriation, and will have power to let the land on lease or to alienate it; and the obligation to execute the improvements will, in this case, devolve upon the tenant or purchaser, under pain of the devolution of the land. Those who construct any buildings in any part of the Campagna within or beyond the zone formed by the circle of six English miles, will enjoy exemption from taxation for ten years, and the increase of income which will be obtained by the agricultural improvements of the land comprised in the zone will be exempt from land tax for twenty years; and equal exemption will be conceded to the proprietors of the Campagna anywhere beyond the zone, if they execute at their own expense the agricultural improvements. Vice-Consul Franz says that "the future will show if these means are sufficient to execute the enterprise, which, in the opinion of the Government, has become a national obligation, to endeavour to deliver the capital from the tyranny which the *malaria* and the deserted country exert round Rome, and in changing the Agro Romano into a fertile and flourishing region."

MANUFACTURE OF GLASS BEADS.

The above manufacture includes turned massive beads, pressed, drawn, and blown descriptions. The first named kind was first manufactured in Venice, and about 200 years ago was introduced into the Fichtelgebirge district of Bavaria. At first the beads for rosaries were the principal articles made, and they are still produced in Bavaria, whence they are exported in quantities to Spain, Portugal, &c. The manufacture is, however, less important than formerly. As an illustration of the scale of production, it is remarked that a workman can make of some kinds of beads as many as 36,000 per day.

In contrast to the heavier Bavarian descriptions, come the Venetian productions. These are mostly beads for embroidery. The process of manufacture a curious one. The glass is drawn into thin tubes and then cut up. The beads are afterwards placed in heated drums, where the sharp corners are rounded off. After being rubbed in chalk and charcoal, they are strung together. In Bohemia a kind of bead for trimming is made in a similar manner.

In making the blown, or so-called lamp beads, a bellows is employed, with which a paraffin or gas flame is brought to a blowpipe flame. In this process, as carried out in Venice and Thuringia, drawings are made on the glass balls or beads with pointed implements made of glass, and these designs are burnt in by the flame. The deadening process so extensively employed is both chemical and mechanical in its character. In the chemical operation, hydrofluoric acid is used, by means of which the surface of the glass is removed. There was formerly another process used in France which was a secret. A German workman, however, found it out by accident. This is the sand process, which is now used in Thuringia for the operation of deadening.

The manufacture of pressed beads is effected by pincers, of suitable form. The glass is heated on a moderate fire and brought into the mould. In this manner beads and buttons are produced in very effective styles, both plain and coloured. Of course the beads have to pass many times through the workman's hands before completion. To this branch belong the amulets, which are sent to the Gold Coast, and are used in various sizes according to the rank of the wearer. Originally these amulets were made of agate, but as this substance is eight or ten times dearer than glass, the latter material has been adopted.

The Central German Society of Industrial Art has lately been giving attention to this subject, on which a lecture was delivered by Herr Bettmann, of Frankfort, himself a manufacturer of the articles in question.

General Notes.

Coal in France.—The two coal-fields of the North of France yielded 10,051,461 metric tons or tonnes in 1883, as contrasted with 9,594,942 tons in 1882, or an increase of 4·7 in 1883 over 1882. Nearly the whole of this increase is due to the output in the Pas-de-Calais, which was 423,625 tons more in 1883 than in 1882.

Antwerp International Exhibition, 1885.—The Lords of the Committee of Council on Education have received, through her Majesty's Secretary of State for Foreign Affairs, a communication from the Belgian Minister at this Court, stating that the Executive Committee of the Antwerp Exhibition have decided to fix the 1st August, 1884, as the limit of time for receiving applications for admission to that Exhibition.

Industrial Statistics of Germany. — In June, 1882, the population of Germany amounted to 27,287,860, of which 11,712,485 may be regarded as the bread winners. The latter are divisible into the six classes following :—

	Men.	Women.
1. Agriculture, the rearing of animals, gardening, forestry, hunting, and fishing	3,462,268	1,230,080
2. Mines, works, and construction	3,065,218	585,408
3. Trade and commerce ..	766,127	145,579
4. Work for salaries and daily wages..........	160,640	118,283
5. The church, law, army, and liberal professions	526,549	60,661
6. Undeclared	352,431	353,064
	8,333,233	2,493,075

Among the 11,712,485 bread-winners, 1,788,679 engage in 1,916,035 subsidiary occupations, in addition to which, 399,244 of those returned as devoting themselves to household cares are also engaged in subsidiary occupations.

Briar-root Pipes.—The following note on the so-called briar-root pipes is from a report on the trade and commerce of Leghorn, quoted in the *Gardeners' Chronicle* :—An interesting industry has been started here within the last three years by a Frenchman from Carcasonne, for the export of material for the manufacture of wooden pipes. Similar works are also to be found at Sienna and Grosseto. Selected roots of the Heath (*Erica arborea*)—preference being given to the male variety—are collected on the hills of the Maremma, where the plant grows luxuriantly and attains a great size. When brought to the factory, the roots are cleared of earth, and any decayed parts are cut away. They are then shaped into blocks of various dimensions with a circular saw set in motion by a small steam-engine. Great dexterity is necessary at this stage in cutting the wood to the best advantage, and it is only after a long apprenticeship that a workman is thoroughly efficient. The blocks are then placed in a vat, and subjected to a gentle simmering for a space of twelve hours. During this process they acquire the rich yellowish-brown hue for which the best pipes are noted, and are then in a condition to receive the final turning and boring, but this is not done here. The rough blocks are packed in sacks containing 40 to 100 dozen each, and sent abroad, principally to France (St. Cloud), where they are finished into the famous G. B. D., or "Pipes de Bruyère," known to smokers in England under the name of "Briar-root pipes." The production of this article is considerable, four hands turning out about sixty sacks per month. Consignments are also made to England and Germany, but at present the demand is said to be rather slack.

Journal of the Society of Arts.

FRIDAY, JULY 25, 1884.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

MINERS' SAFETY LAMP.

The adjudicators for the prize of £500, offered by Mr. Ellis Lever for a new Safety Lamp, have now reported. They are Mr. Thomas Burt, M.P., nominated by the Central Board of the Miners' National Union; Prof. Grylls Adams, by the Council of the Royal Society; Sir Frederick Abel, by the Council of the Society of Arts; and Prof. Sylvanus Thompson, by Mr. Lever.

The following is the report:—

Ellis Lever Competition.

Report of Adjudicators.

The adjudicators had to examine 108 lamps; of these 4 were electric lamps, and 104 oil lamps, of which a few were designed to burn mineral oils.

With respect to the electric lamps, there was not one which fulfilled, or approached fulfilment of, the conditions of the award.

All the lamps which fulfilled the preliminary requirements were submitted to a series of experiments of progressively increasing severity. These experiments, based upon the experience gained by the Royal Commission, and by experiments instituted by other bodies in this country, were calculated to fulfil even exceptional conditions to which lamps may be exposed in actual practice. While there was a considerable number of lamps which behaved satisfactorily under the normal conditions existing in mine workings, the number was reduced to very few as the extreme tests were reached. Of these there is no one lamp that perfectly fulfils the whole of the conditions enumerated in No. 2, and the adjudicators are consequently unable to make the award to any one of the lamps submitted.

Among the best there are two which the adjudicators regard as deserving of special mention, viz., the Marsaut lamp, with three gauzes, which most nearly fulfilled the conditions; and the lamp of Mr. William Morgan, of Pontypridd, South Wales, which presents several good features of marked originality.

Thos. Burt.
F. A. Abel.
W. Grylls Adams.
Silvanus P. Thompson.

The following are the the conditions of the prize, which were announced in March, 1883:—

1. The five hundred pounds to be invested in the names of three trustees, one of whom shall be Mr. Thomas Burt, M.P., the other two to be chosen by the Central Board of the Miners' National Union.

2. The lamp to be a perfectly self-contained electric lamp, or other lamp, which the working miners can conveniently carry from place to place in the mine, which will continue to give a useful amount of light for not less than twelve hours, and which will not cause an explosion of gas under any circumstances at all likely to represent conditions which may occur in actual practice.

3. The efficiency of the lamps put in for competition, to be submitted to five gentlemen, composed as follows:—Three scientists to be named hereafter, one to be selected by Mr. Lever, one by the Council of the Royal Society, and one by the Council of the Society of Arts, one person representing the Mining Engineers, chosen by themselves, and one person representing the workmen, chosen by the Central Board of the Miners' National Union.

4. The adjudicators to meet in London after the allowed time for sending lamps for competition has elapsed.

5. The prize will not be awarded to any lamp now in use.

6. Not drawings or specifications, but lamps in a condition fit to be tested, must be sent for examination by the adjudicators.

7. The lamps must be sent to No. 2, Victoria-street, Westminster, London. No lamp to be sent in before the 1st of December, or none later than the 31st of December, 1883.

8. If a lamp meeting the requirements herein stated has not then been invented, the five hundred pounds to revert back to Mr. Ellis Lever.

Proceedings of the Society.

CANTOR LECTURES.

ALLOYS USED FOR COINAGE.

By W. Chandler Roberts, F.R.S.

Chemist of the Royal Mint; Professor of Metallurgy, Royal School of Mines.

Lecture II.—Delivered March 24th, 1884.

The meaning of the word alloy, in mint language, is different from that ordinarily accepted in scientific phraseology, as it is applied to the base metal added to a more precious one, and not to the mass, which may be either molten or solidified, of the mixed metals. This use of the word has been fostered by the way in which it has, from time to time, been employed in ordinances that have regulated the composition of the coin, and in the indentures made between the Sovereign and the Master of the Mint. It has also been perpetuated by the first schedule of the Coinage Act 1870, the legislative enactment which guides the currency at the present time. The earliest of these ordinances extant, that given by King Edward I. to Gregorie Rokesley, prescribes, that a pound of silver money shall contain "11 ounces, 2 easterlings (dwts.), and 1 farthing of silver, and the other 17 pence 3 farthings to be 'lay,'* that is, 'alloy.'" Biringuccio used the word with perfect accuracy in the 16th century. "I have told you," he says,† speaking of the gold alloys, "that an alloy only signifies an intimate association (*damicabile amicitia*) of one metal and another." The author of an interesting little work, entitled "A Touchstone for Gold and Silver Wares,"‡ usually employs the word in the Mint sense, as when he says, "Silver having too little alloy would be too soft, so too much alloy would make it brittle like brass;" but Cramer,§ a later writer, is scientifically accurate in calling a mixture of gold with silver a "white alloy." With regard to the derivation of the word, it may be sufficient to point out that the old French *alei* was retained in the Norman as *alai* or *allai*, whence our word allay. Through the erroneous fancy that the French *aloi* was equivalent to *à loi* (to law) the word, meaning originally simple "combination union," came to be used specially of the mixing baser metal with gold and silver in coin, so as to bring it to the recognised standard, and hence of the standard itself.‖ The French word comes from *alleium* or *alaium*, the original being probably *ad-ligo* (alligo), to bind to. Used in the Mint sense, the relation of the word "lay" or "allay" to the Teutonic *linderen*, to lessen, as pointed out by Sir John Pettus¶ is suggestive, as it is in the sense of a precious metal "lessened" in value, that "alloy" is retained in the Mint at the present day; but I may be permitted to repeat that this is an inaccurate use of the word, and that a sovereign should be viewed as a coined disc of an alloy of gold and copper, the union of the two metals constituting the alloy. The word sterling, again, deserves a brief notice, and I will only quote Stow,* as his explanation, adopted by later writers, is probably the correct one. He says, "but the money of England was called of the workers thereof, and so the Easterling pence took their name of the Easterlings, which did first make this money in England in the reign of Henry II., and thus I set it down according to my reading in Antiquitie of money matters, omitting the imaginations of late writers, of whom some have said Easterling money to take that name of a starre stamped on the border or ring of the penie: other some, of a bird called a stare or starling stamped on the circumference, and others (more unlikely) of being coined at Stiruelin or Starling, a towne in Scotland." Lowndes adopts this "Easterling" view of the origin of the word sterling,† and supports it by reference to a very old treatise "entered at large in the Red-book of the Exchequer, in the time of King Edward III," and he considers that the words "sterling" and "standard" are synonymous. Similar arguments are adduced at great length, with abundant references to authorities, in Hearne's "Curious Discourses."‡ The word sterling was, however, probably used to distinguish a definite alloy of silver and copper from certain other alloys containing less of the precious metal.

Throughout these lectures the words "standard fineness," indicates the amount of "fine" or pure metal present in any given alloy, and the degree of fineness will be expressed decimally, pure gold or pure silver being considered to be 1,000.

The reasons for the use of alloys, in preference to pure metals, are somewhat complex. In early states of civilisation coins are generally made of more or less pure metal, but a nation does not advance far in its history before the very important fact is recognised that alloys are more durable than pure metals, and that their substitution for pure gold or silver affords

a notable source of revenue. In cases where the coinage is in any degree international, the adoption of a low standard by one nation has to be followed by its neighbouring nations, in order to prevent loss, and to facilitate commerce by avoiding the necessity for tedious calculations as to the rate at which coins may circulate in the respective countries. It is still possible, though not to the same extent, to make profits in the way indicated by Sir John Pettus, who, writing in the 17th century, observes, "it is good for a traveller to be skilful in different alloys, whereby, as a friend of mine told me, that he carried out £100 with him, and by his art of exchange in countries where alloys differed, he bore his charge of travel, and brought his stock home again."* A well-known modern instance of such a system is presented by the action of the first Europeans trading with Japan in virtue of the Treaty of 1858, who, availing themselves of the fact that the gold coins of that country were current at considerably less than their true value in silver, bought the gold kobangs then in circulation for about one-third of their actual value, and realised large profits.

The actual melting of the precious and base metal is effected in small furnaces with natural draught, and the crucibles employed are usually made of a mixture of graphite and fireclay. The capacity of the crucibles is very varied; those used in this country for melting gold hold about 1,200 ounces, and the crucibles for melting silver 4,000 ounces. Gaseous fuel is sometimes, though rarely, employed in mints, and I only know of one mint in which metal is melted on the open bed of a reverberatory furnace, and then of course the alloy to be formed is only bronze. The use of such furnaces would present some advantages, but as a considerable amount of metal would be, temporarily at least, hidden in the more or less leaky furnace bed, it becomes absolutely necessary to employ crucibles for melting the precious metals.

With regard to the choice of the base metal to be added to the precious, many conditions have to be taken into consideration. The resulting alloy must be of good colour, must be ductile, and must not exhibit any traces of brittleness. In the case of gold, silver forms a very ductile alloy, but then, as we have seen, it sensibly lowers the colour of the gold. Copper, on the other hand, heightens the tint, and has the advantage of yielding a durable as well as ductile alloy. A triple alloy of gold, silver, and copper may be made of delicate tints, but a triple alloy is difficult to assay, and it is undesirable to complicate the accounts of a mint by the use of two precious metals and a base one in the same alloy, therefore a single base metal, copper, is now almost universally used.

It has long been known that the union of two or more metals produces a result which often differs more in physical properties from either of its constituents than they do from each other. Copper and tin, for instance, alloyed in definite proportions, yield alloys of a wide range of properties, and there is hardly any fact more remarkable in the whole range of metallurgy than the enormous influence exerted on a large mass of metal by a small quantity of another metal or metalloid.

From the Mint point of view, the properties which it is most desirable to secure are—1. Ductility; 2. Durability; 3. Uniformity of composition.

In addition to these, the alloy is expected to be sonorous, that is, the coin struck from it must have the true "ring;" and, finally, it must possess exactly the degree of viscosity which will enable it to flow, under pressure, into all the fine lines of an engraved die, while at the same time the metal must have sufficient rigidity to retain its impression when submitted to rough usage. This question of the flow of metals has been beautifully worked out by M. Tresca,* who has shown that when metals and alloys are submitted to compression, they so closely resemble fluids in their behaviour, that the shape they will assume can be deduced by calculation. In coining a disc of metal, the engraved work of the die forms a series of channels designed to facilitate the flow of the metal of which the coin or medal consists, and to guide it in the required directions. In the compression of a "blank" between dies, the portions not to be brought into relief by the action of the press are reduced in thickness for the benefit of the neighbouring raised portions, the metal literally flowing from the level parts to the reliefs.

I once heard Mr. Ruskin say in a lecture:—"You stamp the effigy of a cow on a pat of butter, why don't you stamp the bee on the honey?" Simply because one is much more viscous than the other, and will not retain a shape given to it; and from the coining point of view this is precisely true of lead, which

* Fleta Minor, Appendix, word, "Money."

* Paper read before the Society of Mechanical Engineers of Paris; translated, *Journal of Franklin Inst*, Philadelphia, 1878, vol. lxxvi., pp. 263-326.

rapidly becomes defaced by only a moderate amount of wear, and in a less degree of pure gold. It is absolutely necessary to add some other metal which will form a more or less rigid alloy.

With regard to the sonorous property of the alloys used for coining, if two rods, one of pure silver, and the other of the alloy of silver and copper, known as standard silver, be hung close together, one will ring loudly when struck, while the other gives a comparatively indistinct sound. The best indication, however, of the total difference between the molecular grouping of a pure metal and an alloy, is afforded by their electrical behaviour.

It will, I trust, be evident that the base metal added to gold or silver may be regarded from two distinct points of view; either as a useful constituent of the coin, which enables it to resist wear and hinders the obliteration of its impression, or, if coins containing base metal are made current at more than their intrinsic value, as a source of gain to the rulers of a country. With regard to the actual standards of fineness which have, from time to time, been employed, it may be pointed out that, in the numismatic history of the world, endless combinations of precious and base metal have been represented. Pure gold and silver have been used, either singly, or alloyed with each other, or alloyed with copper, the latter metal, in turn, being sometimes employed with only infinitesimal additions of precious metal.

The alloys actually used for coinage at the present time are not numerous, and it may be well to begin the consideration of such as are specially important by tracing the steps which led to their adoption.

In the case of both the gold and silver currency of this country, the adjustment of the relative proportions of the precious and the base metals was undoubtedly guided by the particular systems of weights used. To take the silver coinage first, the fineness of alloys of this metal has from very early times been computed by divisions of the troy pound, which weight is still retained in weiging gold and silver. The Commissioners appointed in 1868 to inquire into the conditions of the Exchequer standards, state that "the troy pound is said to have been derived from the Roman weight of 5759·2 grains, the 125th part of the large Alexandrian talent, this weight, like the troy pound, having been divided by the Romans into twelve ounces;" and they add, "the troy weight is universally allowed to have been in general use from the time of King Edward I. The most ancient system of weights in this kingdom was that of the moneyer's pound, or the money pound of the Anglo-Saxons, which continued in use for some centuries after the Conquest, being then known as the Tower pound, or sometimes the goldsmith's pound. It contained twelve ounces of 450 grains each, or 5,400 grains, and this weight of silver was a pound sterling. The Tower pound was abolished in 1527 by a statute of King Henry VIII, which first established troy weight as the only legal weight for gold and silver. . . . From that time to the present our system of coinage has been based on the troy weight."* The computation of the standard fineness of alloys of gold is based on the singular "carat" system of weights, the origin of which is popularly believed to have been derived from the weight of an oriental plant-seed. Mr. H. J. Chaney, who is entrusted with the duties of the office of Warden of Standards, informs me that "its history is not easily traced, but that the origin of the carat is doubtless Grecian. The *ceratium* was a small Greek weight."† It is uncertain whether the use of the carat came to us through the Arabian alchemists, or through the Roman mints, and the exhaustive inquiries of Vasquez Queipo do not throw much light upon the point; but with regard to the supposed derivation of the weight from the seed or bean, Mr. Chaney thinks "it is more probable that the Greek *Keration*, and the Arab *Kyrat* were applied to the beans or seeds by the native merchants, who made them serve provisionally as weights.

It has been necessary to offer the foregoing explanations, because the expression of the varying standards of fineness, either in the "carat and grain" system or in the "ounces, pennyweights, and grains" of the troy system, is somewhat obscure to those who are not familiar with their use; and although the decimal system will be adopted for the purposes of this lecture, it will be difficult to avoid references to the older methods of computation.

In 1790, Mirabeau, in an elaborate memoir submitted to the National Assembly in France,‡ urged that the decimal system should be applied to the coinage, and, as will be shown subsequently, his views were adopted in 1794.

---

* Third Report of Commissioners. Parliamentary Paper, c. 30, p. iii., 1870.

† Quoted by Mr. Chaney, in a letter to me, from "Lucae Paeti de Mensuris et Ponderibus," Venetiis, 1573, p. 88.

‡ "Collection complette des Travaux de M. Mirabeau l'ainé à l'Assemblée Nationale," Paris, 1792.

The use of this system spread rapidly over the Continent, but the computation of the fineness of gold alloys by the system of carats and grains survived in the English Mint until 1882, when the decimal system was introduced.*

With these remarks we may proceed to the consideration of the alloys used for coinage in early times.

It may be convenient to begin the history of the alloys used for coinage with the employment of the natural alloy of gold and silver, to which the ancients gave the name of electrum, native gold being always associated with silver, which is sometimes present in sufficient quantity to sensibly lower the colour of the more precious metal, and to cause the gold tint to disappear almost entirely when it exceeds one-third part of the mass.

Dr. Schliemann describes† three pale yellow rod-like bars, each 4·33 inches long, provided with fifty to sixty equi-distant horizontal incisions, at right angles to the length of the rods, which probably indicated their value, and facilitated their sub-division into definite portions. Dr. Schliemann kindly permitted me to analyse a small portion of one of these rods. which was found to contain 651 parts of gold, and 334 parts of silver in 1000 parts, and small quantities of copper and lead.

In a dissertation on the Homeric talent, Dr. F. Hultsch states that it weighed 16.8 grammes, or a little above ½ oz. troy, and was the prototype of the oldest gold stater, coined in the beginning of the 7th century B.C., at Phocea, and other cities of Asia Minor.‡ I have already referred to the coined nuggets of electrum which may have been adopted for purposes of currency long before the use of coined money; but, as M. Lenormant points out,§ in the series of coins of the kings of Lydia, gold and electrum were coined simultaneously, as distinct metals, having distinct monetary values.

The numerous analyses made by Dr. Rauch‖ and others have placed at our disposal much accurate information as to the standard fineness of the alloys used for coinage in Greek and Roman times. M. Lenormant,¶ who devotes a considerable portion of his elaborate work to the consideration of this subject, observes "that in the Hellenic world the coins of gold and silver were remarkably pure, the gold coins sometimes contained only three parts of silver in the 1,000, which represented the highest degree of purity attainable by the method of refining then in use.* In the coins of Darius a little base metal was intentionally introduced, but its amount did not exceed 30 parts in the 1,000, and, speaking generally, the Grecian silver coins contained considerably less base metal than coins issued in modern times. The standard of the tetradrachms of Athens, at the best period, varied from 983 to 986, while those of the second series fell only as low as 966, and these contained 2 parts of gold in the 1,000, as well as the 32 parts of copper. A series of Greek coins struck in Italy and Sicily in the 6th century before the Christian era, vary in fineness from 910 to 980. At the end of the coinage at Tarentium, the standard was sensibly lowered, for a didrachma assayed by Dr. Rauch was found to have only the fineness 880, but M. Lenormant observes that, in the entire series of Asiatic coins before the conquests of Alexander, there is no essential change in the standard of silver, which is uniformly high, although instances are met with of coins of as low a standard as 709. With regard to Roman money, I will only quote Lenormant's statement that the gold of the Republic was always pure, and that Imperial gold coins, until the time of Vespasian, were of excellent quality, although their standard was slightly reduced, that is, from pure gold to standard 991. After the time of this emperor, the standard appears to fallen to 938, and subsequently, about the time of Septimus Severus, it fell much lower. In the year 265 A.D. the gold coins were struck in a base alloy, containing—

827·3	of copper.
159·4	„ silver.
13·3	„ gold.
1000·0	

The silver of the Republic was always excellent, varying, according to Darcet, from 993 to 995, but under Imperial rule its debasement appears to have been rapidly effected, especially from the time of Nero until the 3rd century, when the silver became mere *billon*, containing—

820	of copper.
160	„ lead and tin.
20	„ silver.
1000

‖ Zeitschrift für Numismatik. Band 1, p. 36, 1873.

¶ Op. cit. t. 1, p. 187, *et seq.*

* This was the cementation process described by Geber in the 8th century, of which a full account is given b Biringuccio, original edition, p.72 (1540).

From the time of Diocletian, when the coinage of silver was resumed, it was of excellent quality. A series of Roman coins of the first three centuries, found at Baden Baden in 1828, was analysed by Dr. Walchner of Carlsruhe, whose results may be briefly stated as follows. A coin of Heliogabalus proved to be the lowest standard (505), while one of Antoninus Pius, which contained 913 parts of silver, was the highest, coins of Commodus, Domitian, Hadrian, and Trajan varying from standard 797 to 890.* It may be added that there was a coin of the Triumvir Antoninus† (B.C. 31) which had almost the same composition as British silver coin, as it contained—

925	of silver.
71	,, copper.
2	,, lead.
1	,, gold.
999	

Time will not permit me to trace the varying changes in the fineness of coins issued in the barbaric times which followed the overthrow of the Roman Empire. Judging from their appearance, the coins present endless variations of standard. In view, however, of the special interest connected with the early British series, I may point out that Mr. John Evans‡ has clearly traced the design they bear to the stater of Philip of Macedon, who struck the coin in question of gold of a high degree of purity. In view of this lecture, I have assayed an early British gold coin, believed to have been struck at a period ranging from 50 to 60 B.C.§ Its design well exhibits the characteristic evidences of its descent, and it proved to contain—

403·5	of gold.
400·2	,, silver.
196·3	,, copper (by difference).
1000·0	

The next historical point is presented by the early Saxon sceattæ, a single specimen of which, assayed by me, proved to contain 558 of silver, 12 of gold.

I have also assayed a silver coin of Burgred King of Mercia, 852-874, A.D., which proved to be of so low a standard as 331·6; and one of Ethelred (978-1016 A.D.), which contained 918·1 of silver, and a little gold, while a coin of Canute (1016 to 1035 A.D.) was of standard 931. Two coins of King Edward the Confessor, one of them kindly given me by Mr. John Evans, for the purpose of assay, proved to be of standard 943·2, and 940·4, both coins containing, in addition to the silver, nearly 2 parts of gold in 1000.

With these slender links, I must pass to the series of coins which began with the Norman conquest, observing, however, that a further connection between the Roman, mediæval, and modern series is maintained by at least two coins, which were so widely circulated, that they may almost claim to have afforded an international currency. These coins are the "bezant" of Constantinople, and the "florin" of Florence, which we know to have been of nearly pure gold.

"The gold bezants of the Greek Empire, and the gold coins struck during the 9th and 10th centuries by Arabic princes, in Sicily, were probably used, more or less, in mercantile transactions all over Europe, and are found occasionally in this country, but they had no legal currency here, and were probably accepted merely as bullion. In the middle of the 13th century, however, a native gold coinage was almost simultaneously adopted by the European nations. The first gold florin was issued by the Republic of Florence, in 1252. Louis IX. introduced gold coins into France, and the Emperor Frederick II. into his kingdom of Naples, and at the same time the same innovation took place in England."*

In the accompanying diagram (p. 841), the dates of issue, and the standards of fineness of the gold and silver coins of this country have been taken as co-ordinates, the points being mainly plotted from the tables given by Ruding.† Taking the gold coinages first, it will be seen that the line begins at the year 1257, the 41st year of King Henry III., who made a penny of the finest gold, which weighed two sterlings. This, as Ruding points out, is remarkable as the first coinage of gold in the kingdom, and it is extraordinary that it took place at the height of the king's distress for want of money. The next step of importance was taken in 1343, when King Edward III. coined, or projected a coinage of the standard 994·8 [23 carats, $3\frac{1}{2}$ grains, and $\frac{1}{2}$ grain of alloy], which was referred to by later writers as the "old sterling" or "right standard" of

* Quoted by Dr. Percy, "Metallurgy of Gold and Silver," part i, p. 169, 1880.

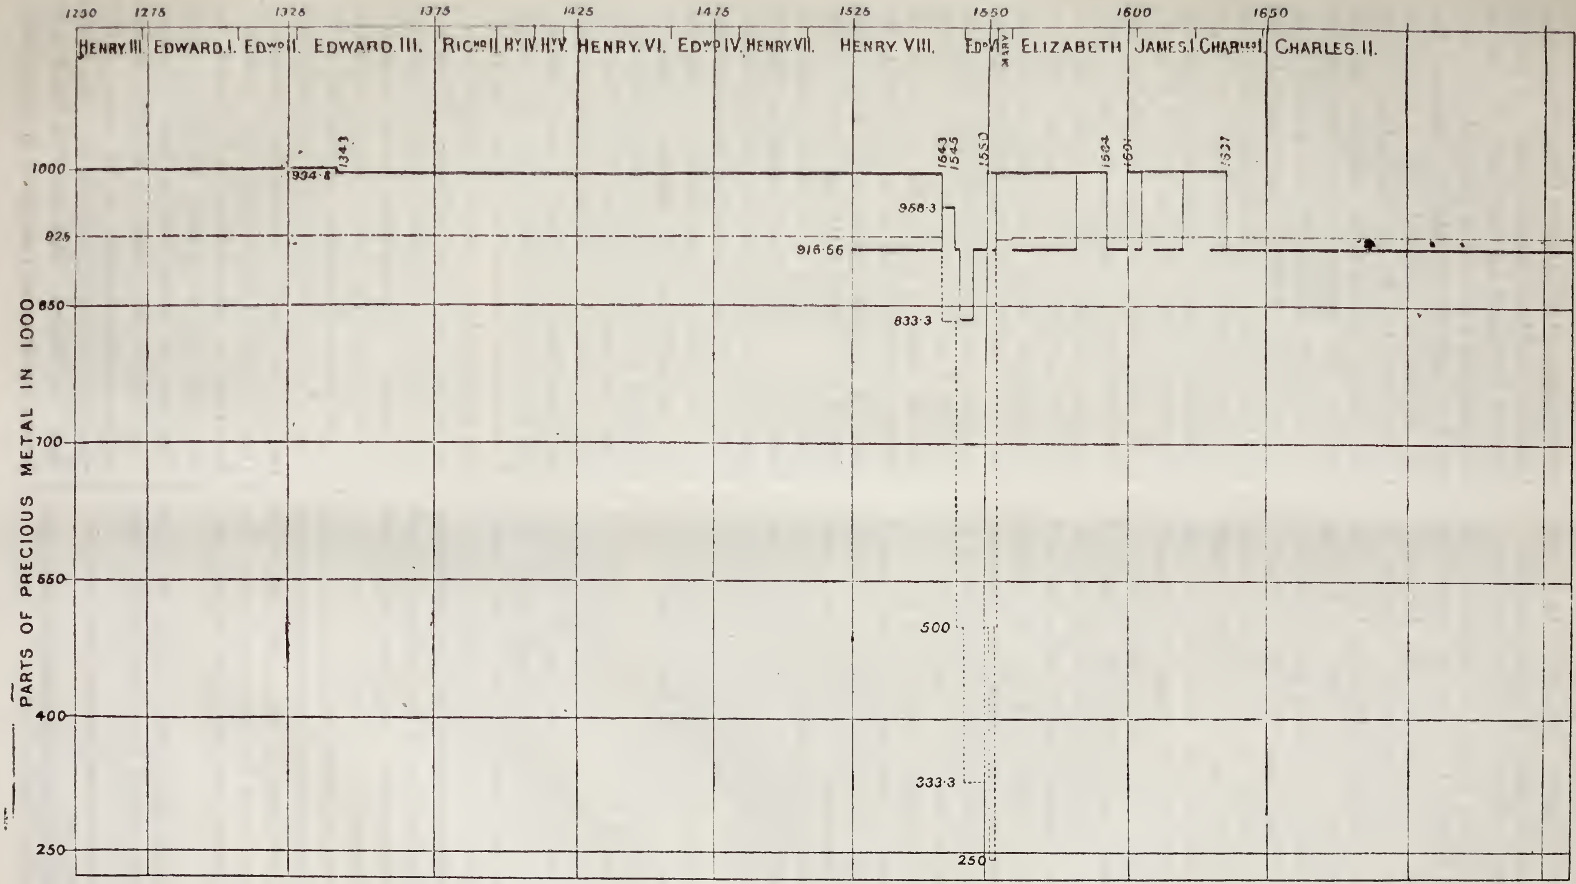
§ This coin is similar in design to that figured Plate C, No. 8 of the above work.

* "The Gold Coins of England," by R. L. Kenyon, p. 14., 1884.

† "Annals of the Coinage," vol. i., p. 10.



The gold coinages are represented by a thick line, thus:— ————. The silver by a dotted one ············. Changes of standard are indicated by a thin continuous line in the case of gold, and by a thin dotted line in the case of silver. The scale is doubled at the critical period between the years 1525-50. There has been no change in the standard of gold since the year 1660, or in the standard of silver since the reign of Queen Elizabeth.

England, and Lowndes, quoting the Red-book of the Exchequer, says, that the ½ grain of alloy might be either of silver or copper.* Although these were not, as Stow considered, "the first coining of gold in England," the coins of Edward III. were of remarkable beauty, and it was asserted that they were struck from gold prepared by occult aid, by the well-known alchemist, Raymond Lully, who had a laboratory in the Tower of London. There are, however, chronological difficulties in the way of this explanation of the origin of the precious metal. As the diagram shows, no further change was made in the standard fineness of the gold coin until the year 1526, when King Henry VIII. reduced the standard to 916·66 [22 carats], the professed object of the reduction being to prevent the exportation of the coin to Flanders. The further debasement of the standard, which was effected in 1543-4, was preceded by a kind of scientific research, as the King ordered the Officers of the Mint to prepare, whenever they should be so directed by the Privy Council, alloys to the value of one pound in weight, of such fineness as should be devised by the said Council, in order that the general nature of alloys, similar to those used in foreign realms, might the sooner come to his Majesty's knowledge. The standard 916·66 [or 22 carats fine] (which is the standard of the alloy used at the present day for the gold coinage of this country) was again issued in 1544. By a subsequent indenture, dated 1545, the gold was brought down to 833·4 [20 carats fine.]

King Edward VI. improved the fineness of the gold currency in 1549, and in 1552 an indenture was made authorising the coinage of gold both of the old standards 994·8, and of the standard 916·6̇. Queen Mary issued coins of fineness 994·8 [23 carats 3½ grs.] Queen Elizabeth struck coins of both standards. As the diagram shows, the coinage of gold of the "old standard" 994·8 was abandoned in the 12th year of King Charles I., and since that time the standard 916·6̇ [22 carats fine], has alone been issued. Coins made of the old standard previously to that period continued to be current until the year 1732, when they were withdrawn from circulation by proclamation.†

The vicissitudes through which the silver coinage has passed have been greater than those that have affected gold. I have selected a few examples of coins issued before the Roman Conquest, and have assayed them. A coin of Burgred contained only 302 parts of silver in the thousand, while one of Ethelred was 918·4, and was probably intended to represent the old standard of England, 925. A coin of Canute proved to be of standard 931, which was clearly intended to represent the old standard. Two separate coins of King Edward the Confessor, assayed by me, proved to be 941, which is "better" than standard; but Mr. John Evans, who kindly gave me one of the coins, considers that this slight superiority to standard is due to the fact of copper having been removed from the surfaces of the coins by the operation of cleaning to which they had been submitted. Anglo-Saxon and Anglo-Norman coins are believed to have been of the "old standard," 925, and a coin of William the Conqueror which I assayed, proved to be 922·8. In England, this old standard appears to have remained unchanged until the 34th year of King Henry VIII., when, as the diagram shows, a great fall took place. It will be seen that a still more rapid fall in the standard fineness ensued in the rest of the reign of King Henry VIII, and in the reign of Edward VI. It fell to its lowest point in the fourth year of the latter monarch, when the pound of silver contained only three ounces of fine silver, and nine ounces of base metal, that is, the standard, expressed decimally, was only 250. Strangely enough, this base coinage was projected with a view to secure by the transaction the sum of £160,000, to be devoted to the restoration of the standard generally. Half this sum appears to have been actually obtained. As a step to the withdrawal of the base money, it was almost universally decried, that is, the coin which had been current at rates far above its intrinsic value, was officially reduced to a value nearly corresponding with its standard of fineness. Dreadful distress was caused to the people, and the saddest pictures are drawn of the financial condition of England at the time. In 1552, the standard was restored to nearly its original richness, as coins containing 11 oz., 1 dwt. of pure metal, and 19 dwts. of base metal, or standard 921, were issued, and this alloy was maintained by Queen Mary. The diagram shows how far Queen Elizabeth contributed to the restoration and maintenance of the standard fineness of the coin. A proclamation, dated September 27, 1560, stated that "her Majesty, who, since she came to the throne, never gained anything by the coinage,

* "Lowndes, Essay for the Amendment of the Silver Coin," p. 18. London: 1695.

† Lord Liverpool's letter to the King, p. 32. Edition published by the Bank of England, 1880.

nor yet ever coined any manner of base monies, for this realm, had begun a coinage of fine money in the Tower of London." Notwithstanding the Queen's efforts to restore the coinage in England, the coins circulated in Ireland were deplorably low, as the pound only contained 2 ozs., 18 dwts. of fine silver, and 9 ozs., 2 dwts. of copper (that is the standard was only 250). Well might that shrewd economist, William Stafford,* remind her Majesty that, "though gold and silver be the mettals comonly wherin the coyne is stryken to be the tokens for exchange of things between man and man, yet it is the wares necessary for man's use, that are exchanged in deede under the outward name of the coyne;" or, in other words, by diminishing the value of coin, its purchasing power is diminished.

The restoration of the standard of the silver, begun in the reign of King Edward VI., was, however, completed by Queen Elizabeth, and it has not been since debased.

Before leaving this part of the subject, it may be well to offer a few remarks on the debasement of coinage generally. The famous antiquary, Sir Robert Cotton, in a well-known speech made before the Privy Council in the reign of Charles II., observes, "what renown is left to Edward I. in amending the standard, both in purity and weight, ... must strike as a blemish upon princes that do the contrary. When Henry VIII. had gained us much of power and glory abroad, and of love and obedience at home, as ever any, he suffered shipwrack of all upon this rock." And he elsewhere points out "that every man will rate his commodity in sale, not according to the accompt of pence or pounds, but to the weight of pure silver contained in the current money."

With reference to the apparent motives for the debasement of the currency, Lord Liverpool observes that "these motives were, first, a desire of augmenting the royal revenue, and, second, principles of mistaken policy," supported by "an idea that they should thereby prevent the coin from being exported," and he adds, "but this idea has been fully exploded since the principles of commerce and foreign exchanges have been well understood." † It may be pointed out that the exact standard fineness of the alloy used is a matter of but small importance, and that a coin poor in precious metal is not really "debased," if it is not made current at a rate below its intrinsic value.

* "A Brief Conceipt of English Policie," p. 29. London, 1581.

† Op. cit., p. 123.

One other method of debasing the coinage remains to be noticed, which was, so far as I know, confined to Roman times. It consists in the issue of pieces of copper, iron, lead, or tin, plated with a thin layer of silver, or more rarely gold. The workmanship of such coins exhibited much skill and care, and they appear to have been issued simultaneously with coins of full value, often with a view to defray the cost of the coinage of the good pieces. An elaborate literature has been devoted to them, which has been well condensed by M. Lenormant.*

The issue of coins of base metal by King James II., for use in Ireland, can hardly be called a depreciation of the standard, as in many cases they contained no silver at all, but were made from old guns, bells, kitchen utensils, "and the refuse of metals molten down together, and valued, by the workmen in the Mint, at no more that three or four pence the pound weight; but when coined into sixpenny, shilling, or half-crown pieces, and made current by arbitrary power, it passed at the rate of five pounds sterling the pound weight, or eleven thousand two hundred pounds the ton, when at the real value, namely, fourpence the pound weight, the compound metal was not worth more than thirty-seven pounds, six and eightpence the ton."†

I have thus attempted to trace the history of the gold alloy of standard fineness $916\cdot\dot{6}$, and the silver one of 925, the alloys used in this country for the gold and silver currency, and as the gold represents a large proportion of the coinage of the world, it may fairly claim to be the most important gold alloy in existence. England is not the only country in which it is retained; the explanation of its existence in other countries is found in the fact that standard $916\cdot\dot{6}$ is the metric equivalent of 22 carat gold, and, as the carat system has been in use from early times, it is natural that many nations should have originally adopted the convenient proportion presented by $\frac{22}{24}$, or $\frac{11}{12}$, which this alloy represents, and it has, accordingly, held its own in British India, Russia, the Turkish Empire, Portugal, Persia, and with a slight variation in Brazil.

As it will not be possible to examine the history of the alloys at length, attention must

* Op. cit., t. i., p. 221, *et seq.*

† King's state of the Protestants in Ireland, quoted in an essay on Irish coins by James Simon, F.R.S., p. 62, Dublin, 1749.

be limited to the more important ones, of which the alloy containing 900 parts of gold in the 1,000 parts demands special notice.

The coins in circulation in France from the beginning of the 17th to the end of the 18th century varied in fineness from 900 to 982; for instance, the louis d'or of King Louis XIII. were 22 carats fine, the ecus d'or of Louis XIV. were 23 carats, while the lys d'or of the same monarch were 23 carats and one-fourth of a grain.*

When, however, the decimal system of weights and measures was fairly established, coins were issued in conformity with it. The law of the 28th Thermidor, An. III. (1796), fixed the franc as the monetary unit, and enacted that the standard fineness of the silver coins should be 900, the weights as well as the fineness of the coins being strictly in accordance with the decimal system, although round numbers were not secured in the respective weights of the coin. Eight years later, the law of the 7th Germinal, An. XI. (28th March, 1803), prescribed the coinage of gold pieces of 20 francs, the standard of which was also 900. A subsequent law, the result of the recommendations of a committee appointed by the French Senate, directed, on the 25th of May, 1864, that pieces of 50 and 20 centimes should be of standard 835; and on the 14th of July, 1866, the standard of fineness of pieces of one and two francs was also reduced to 835.† By the Monetary Convention of the 23rd December, 1865, concluded between France, Belgium, Italy, and Switzerland, the standards of fineness above described were adhered to. Several other countries, notably Roumania, Servia, Greece, Scandinavia, and most of republics of South America, have partially adopted the same monetary system. In Germany, in virtue of the laws of the 4th of December, 1871, and the 9th of July, 1873, the standard fineness of both gold and silver has been fixed at 900. In the United States of America the use of the alloy 900 fine has been confirmed, for both gold and silver, by the Coinage Act of the 12th of February, 1873. It will be evident, from the foregoing remarks, that the two really important alloys used for coinage of gold have respectively the standard fineness 916·6 and 900, while for silver coins the standard 900 is now more widely used than any other, England alone employing 925, which still maintains the connection with Saxon coins.

In concluding this portion of the subject, it will be sufficient to examine briefly a few other standards of fineness, which either may be actually struck at the present time, or the circulation of which is permitted by the legal enactments of certain countries.* First, as regards gold, the richest gold alloy which survives to the present day would appear to be the gold ducat of the Austro-Hungarian Empire, which, in accordance with the laws of the 24th December, 1867, and the 9th of March, 1870, contain no less than 986 parts of fine gold in 1,000. The issue of gold ducats of fineness 983 is permitted in the Netherlands, by laws of 26th November, 1847, and 6th June, 1875. The poorest gold alloy in circulation appears to be that employed for certain Egyptian coins, the standard of which is only 875, and the same standard is also used for gold coins in Mexico, and in the Philippine Islands.

In the case of silver, the variations are greater. Since 1868, Austro-Hungary has issued kreutzers which contain, respectively, 400 and 500 parts of fine silver in 1,000. The 10 öre piece of Norway also contained only 400 parts of fine silver. The standard of the silver coins of Brazil is 917; the silver coins of British India are 916·6. In Russia, the roubles are of standard 868, while that of the Turkish piastre is 830. In the Netherlands the standard 945 for pieces of ½ to 2½ florins, which is the richest alloy of silver actually in circulation, is employed; and the standard 720 is employed for the currency of Java, because it is the most homogenous of all the silver-copper alloys.†

The alloys to which reference has hitherto been made, have been simple ones of two metals. In the case of gold coins, the second metal contemplated by law was copper, but silver was, in many cases, used, either to the exclusion of copper, or in conjunction with it. The Australian gold coins first issued contained a considerable proportion of silver, as their colour showed, but in all the examples given the use of triple alloys has rather been the result of accident than of design. It will now be necessary to con-

* Much information of interest relative to the standard fineness of coins of the 17th and 18th centuries will be found in the "Traité des Monnaies d'or et d'argent, examinées sur les rapports du poids, du titre, et de la valeur réelle," par P. F. Bonneville. Paris, 1806.

sider triple or complex alloys at some length. In early times, when complex ores were treated by metallurgists who may have possessed considerable skill, without knowing how to insulate each of the metals present in the ore, singular admixtures have been obtained as the result of the operation. A very experienced copper smelter, Mr. Tyrell, of Swansea, has shown * that it is only necessary to smelt copper pyrites with a small addition of an ore which contains tin, in order to obtain bronze of the composition frequently met with in ancient implements or weapons. Numerous instances of the involuntary use of complex alloys for coinage might be given, but the best example is probably presented by the coins of the early Britons, which were of copper alloyed with 20 to 25 per cent. of zinc and 5 to 11 per cent. of silver, together with small quantities of gold, lead, and tin. Mr. John Evans has pointed out that the Saxon stycas range through a wide field of alloys, and may in some cases have been formed by melting together the coins discovered in "hoards" of Roman coins with, of course, very variable results.† In the case of gold, such triple alloys have been used but seldom. A modern instance in which their use was suggested is presented by the triple alloys of gold, copper, and zinc, prepared in 1873, by M. Péligot.‡ He showed that an alloy containing 58·1 per cent. of gold, 36·1 of copper, and 5·8 of zinc is of good colour, can be readily worked, and possesses the advantage of being decimal as to weight. Péligot also suggested the use of three alloys of silver, copper, and zinc, containing respectively 5, 10, and 7·2 per cent. of zinc, and 90, 80, and 83·5 per cent. of silver, the rest being, in each case, copper; and he also described three simple alloys of silver and zinc, containing respectively 5, 10, and 20 per cent. of zinc.§ I have prepared several of the alloys, and entirely confirm his observations respecting them. The alloy of standard 900, used in France, when melted with 78 grammes of zinc per kilogramme, yields an alloy containing—

83·5 of silver.
9·3 ,, copper.
7·2 ,, zinc.

The Japanese employ, for the purposes of ornament or currency, several such alloys. The Nebus, now withdrawn from circulation, contained 22·75 per cent. of gold, 76·00 of silver, and 1·25 of copper, and I am informed by Mr. Tookey, who was formerly assayer in the Imperial Mint at Osaka, that the composition of these coins was extremely uniform. It is to be regretted that they were extensively and successfully counterfeited by western visitants to Japan, in an alloy which contained, when melted, only 0·47 per cent. of gold.

Triple alloys, in which silver is the main constituent, have often been used. A singular alloy of silver, copper, and zinc, has been extensively employed in Switzerland for the manufacture of subsidiary coins. A very low alloy of silver and copper has long been employed for coins of small value; such an alloy is called *billon*, and was formerly widely adopted on the Continent generally in modern as well as ancient times. The precious metal contained in the mass is not present in sufficient quantity to give the alloy the colour of silver, and, therefore, the copper is removed by the action of a solvent from the surface of the "blanks" before they are coined, but this layer of silver soon wears off when in circulation, and the coins assume the normal tint of the alloy from which they are made.

The advantage of employing precious metal in this way consists in the possibility of striking subsidiary coins of some value, but of comparatively small weight; the objections to the use of such metal are numerous, and were well expressed in 1790 by M. Gabriel de Cussy,† who pointed out that the manufacture of such coins was expensive, that when withdrawn from circulation they are very difficult to refine, and, finally, they may very easily be counterfeited in alloys which contain no precious metal whatever. Much force was imparted to this latter objection by the statement that one-third of the *billon* then in circulation in France was either of foreign

* Lenormant, loc. cit., t. i., p. 205.

† Rapport au Comité des Finances, Paris 1790.

origin or spurious. The use of such coins of *billon* still lingers in Europe, but as M. Mirabeau said, in a speech delivered before the National Assembly of France in 1790, to which I have already referred, this "detestable money" should be abolished, if only because "a false coiner, with less than 20 sols, can counterfeit 12 livres at a profit of 1,100 per cent." * The base alloy he had in view contained only one-sixth of its weight of silver, the rest being copper. He appears, however, to have advocated the use of an alloy of about equal parts of silver and copper, and pieces of 15 and 30 sous, of standard fineness 667, were struck in 1791.

The alloy next in importance to those we have hitherto considered is bronze, which, as has already been stated, played an important part in ancient currency. Its modern use on an extended scale is due to the Government of the late Emperor of the French, Napoleon III., by whose direction the old sous circulating in France afforded the basis for a triple alloy, containing ninety-five parts of copper, four of tin, and one of zinc, the weights of the respective coins of one to ten centimes being a gramme for each centime. The law regulating this coinage was passed by the Assembly in May, 1852, and the issue of bronze from that time up to the year 1868 amounted to no less than 59,300,000 francs. All the facts connected with this coinage have been elaborately described by M. Ernest Dumas in a valuable work to which I have before had occasion to refer.† It is an extremely durable alloy, as will be shown in the fourth lecture. Its coinage was undertaken in England in 1861, by the advice of the late Professor Graham, Master of the Mint, and the amount of bronze coin now in circulation is estimated to be about 3,000 tons.

Brass was extensively used by the Romans for subsidiary coins, and, in fact, silver does not appear to have been employed until "the first Punic war, 269 B.C."‡

Savot mentions the use of a triple alloy of copper, zinc, lead, and a small quantity of tin, to which the name of *potin* was given; and Lenormant states§ that it was only used for money by certain tribes of Gaul, between the wars of Ceasar and the organisation of the Gaulish provinces by Augustus. The coins were always cast, and prove, on analysis, to contain :—

60	of copper.
20	,, lead.
10	,, zinc.
10	,, tin.
100	

The use of nickel is extremely ancient. Dr. Walter Flight, F.R.S., has shown* that coins of the 2nd century B.C. were struck in an alloy containing :—

77·585	of copper.
20·038	,, nickel.
0·544	,, cobalt.
1·048	,, iron.
0·038	,, tin.
trace	,, silver.
0·090	,, sulphur.
99·343	

Pence and half-pence, to the value of £3,000, were coined at the Mint, in the years 1869-71, for use in the colony of Jamaica, of an alloy containing—

75	of copper.
25	,, nickel.
100	

but when a further coinage of nickel of the nominal value of £500 was required, Mr. Fremantle reported that the charge to the colony of Jamaica, for the metal alone "would exceed the nominal value of the coin,"† a fact which points to the difficulty of determining the weight that may be safely given to the individual pieces of a token coinage when the metal employed is liable to serious fluctuations in commercial value. Pieces of 5 and 10 centimes of the same alloy, have long been in circulation in Belgium. In Germany also, the pfennige are of this alloy, and it is also employed for the subsidiary coinage of Brazil. Certain American nickel coins contain 12 per cent. of nickel, and 88 of copper. The important contributions of Herr Fleitmann to the metallurgy of nickel have rendered it possible to use the pure metal for coinage, and the 20 rappen pieces of Switzerland, are now struck in nickel without alloy.

The claims of platinum to be used for coinage did not escape M. Rochon,‡ and the fact is remarkable, considering how comparatively rare the metal was when he wrote in 1786.

‡ Loc cit. pp 17 and 45.

With regard to metals which have not as yet been employed for coinage, I would direct your attention to those very light specimen coins of pure aluminium, and of aluminium alloyed with 2 per cent. of nickel, for which I am indebted to the distinguished metallurgist, Mr. G. Matthey, F.R.S.

The points with which we started were, you will remember, that the base metal added to a precious one may be viewed, first, as a useful constituent of an alloy, and, second, as a source of gain. I trust it will have been evident that. within certain limits, the standard selected for the alloy is not a matter of much importance, provided the base metal be added to precious metal in such proportions as to combine the maximum convenience with the best physical properties.

Viewed as a source of gain, it must be borne in mind that "any person" has the right to coin gold, provided the actual manipulation of the precious metal is entrusted to the officers of the Mint, and, as has been well remarked by M. Dalsème, of all its ancient rights the governing body in the State alone preserves the privilege of issuing coins, the intrinsic value of which is slightly less than the value at which they are current, and this right is guarded by law, and exercised in the public interest. In the next lecture, I will attempt to show what precautions are taken to secure accuracy in weight and fineness of the coinage, more especially in the case of the sovereign, which is so widely circulated, and the integrity of which is so implicitly trusted, that it may be said to epitomise the financial honour of the nation.

CONFERENCE ON WATER SUPPLY.

The Conference of the Society of Arts on the Water Supply at the International Health Exhibition, was opened on Thursday, 24th inst., with an address by Sir Frederick Abel, C.B., F.R.S., Chairman of the Council, who presided, followed by Mr. Andrew Cassels, Vice-President of the Society.

Papers on the Sources of Supply were read by W. Whitaker, W. Topley, C. E. De Rance, J. Lucas, C. J. Symons, E. Bailey-Denton, E. Easton, and J. Mansergh, and a discussion followed. A report of the Chairman's address, and of the discussion will be printed in the next number of the *Journal*. The Conference was adjourned to Friday, 25th inst.

ON THE AREA OF CHALK AS A SOURCE OF WATER SUPPLY.

By W. Whitaker, B.A., F.G.S.,
Of the Geological Survey of England.

It is only of late years that we have had the means of measuring the area of the great water-bearing formation of the south-east of England that can be reckoned on as a gathering-ground with certainty; and now we can do this for only a limited part of the chalk tract. As it will be a long time before we can do it for the whole, even so far as the London basin is concerned, I have not hesitated to bring forward the subject in its present imperfect state.

On ordinary geological maps, including the greater number of those as yet issued by the Geological Survey, the chalk, beyond the parts where it is covered by the eocene tertiary beds, is shown as bare, except for outlying patches of those tertiary beds (mostly on the high grounds), and for strips of alluvium (or marshland) along the bottoms of the chief valleys. For some years past, however, the Geological Survey has carefully mapped those varying deposits of clay, loam, gravel, and sand, usually grouped under the name of drift, which cover, in a more or less irregular way, the various divisions of the tertiary beds and the chalk, and which have a marked effect on the nature of the country where they occur to any great extent.

It follows that it is only in those parts of the chalk tract where the Geological Survey has mapped the different divisions of the drift, that we are able to tell, with an approach to accuracy, over how much of the surface the rain has a more or less free access to the chalk, and can therefore sink into it, and add to the supply to be got from it at lower levels.

In the course of a somewhat prolonged and detailed examination of this question, I have constructed a set of maps for the purpose of showing over what areas the chalk is bare, over what areas it is covered by beds of a permeable character (allowing of the sinking of water through them to the chalk), and over what areas it is cut off from the reception of water through being covered by impermeable beds. This may seem, on first thoughts, a simple matter; but, on trial, it is hardly found so, and instead of confining myself to three colours, one for each of the three areas above noticed, I was obliged to use a fourth, for various beds of a doubtful character, either from their being of a mixed composition, or of a changeable one, at this place permeable, at that the reverse.

With these four colours I was at first content; but the fact that in some areas where the chalk is protected by impermeable beds, the water flows over the surface until it reaches the chalk, and then sinks into that rock, has led me to show those areas by a lighter tint, as they contribute somewhat to the water in the chalk, and should, therefore, be distinguished from tracts that do not.

Beyond these five divisions the maps now exhibited do not go; but it may, perhaps, be needful to make a sixth, and to mark off from the rest of the bare chalk those parts where the base of the formation, the chalk marl, is so clayey as to be out of the question of water-supply. This tract, however, would be a very narrow band along the outer edge of the chalk.

Possibly too, in extending the work (as I hope to), it may be well to mark areas where beds below the chalk may contribute to its water supply, or where rather the water system of the chalk may join that of some underlying bed. This, of course, would take place where any mass of permeable upper greensand is not divided by clayey chalk marl from the chalk above, in which case there will be but one water system. There is one remarkable part of the chalk tract surrounding the London tertiary basin, where, from the the absence not only of the clayey chalk marl and the underlying (but much more local) upper greensand, but also from the thinning out of the usually persistent gault, a markedly impervious bed of clay, it results that the hard ferruginous sand (or carstone) of the lower greensand at once underlies the hard massive chalk. In the north-western corner of Norfolk, where this takes place, from Hunstanton southwards to near Sandringham, the water systems of the chalk and of the upper part of the lower greensand join; though the lower part of the latter formation is divided off by clayey beds. The supply at Hunstanton Waterworks, close to the base of the chalk, may, therefore, be derived from this composite source, whereas the supply for the Sandringham estate is from the chalk, the clayey chalk marl coming in at that part, and causing an outflow from the more permeable beds above.

The maps which form the text on which this paper is founded, though based on the later geological maps (with drift), follow the latter absolutely in only one particular, that is in the area coloured as bare chalk. As, however, the object in constructing the maps in question was contrast and conspicuousness, their colours are quite different from those of the geological maps; and, whereas, on the latter the chalk is shown by a very pale green tint, on the former it is emphasized by light carmine. It is only fair to the maps to say that they were not made as diagrams, to be seen at a distance; but to be examined more closely, and that they have been coloured at various times, as occasion enabled me to take them up. When the work has been further extended, and a large set of maps can be coloured at once by a better colourist, a more harmonious effect may result.

We may now consider the evolution of these "Chalk Area Maps" from the Geological Survey Drift Maps. It will be at once seen that the geological maps are the far more complicated of the two, having a great number of colours and tints as against the five of the other set. My geological friends may, therefore, be inclined to regard the evolution as a case of degeneration; but, perhaps, engineers may not object to the comparative simplicity of my maps, and to their disregard of theoretical considerations and of geological classification. It should be clearly understood that these maps are meant to show one thing only, that is the accessibility of the chalk to surface-water: they do not always show of necessity the nature of the surface; but their colours are, in some parts, quite independent of what occurs at the surface, which may be neutralised, for our purpose, by something else that occurs beneath.

1.—Bare Chalk.

As in this case the maps follow the geological ones, there is no need to say more than that bare chalk is taken to include those parts where there is merely a thin soil over the chalk, for that soil is practically unimportant as regards water being pervious.

2.—Chalk covered only by Beds of a Permeable Kind.

This includes tracts marked by many colours on various geological maps, permeability being by no means connected with geological age. In colouring these tracts, it was essential to consider not merely the beds shown as at the surface on the geological maps, but to make certain that nothing came between any bed of a permeable character and the chalk, as it is clear, for instance, that ten feet of clay in or beneath 100 feet of sand would stop the downward passage of water through the sand.

The geological beds that fall into this class are as follows: but it should be understood that this is only where one of them rests directly on the chalk, without any bed of an impermeable or mixed kind coming between, or where two or more of them succeed each other without any intervening bed of another kind:—

Thanet Beds, where these are of sand, as in Surrey and West Kent.

Oldhaven and Blackheath Beds, in the few places where they have cut through the underlying Woolwich and Reading beds, and rest on the Thanet sand or as outliers on the chalk.

Red Crag and Norwich Crag, where they rest on the chalk. Parts of the tracts coloured with the latter on the geological maps are not included, however, on account of the occurrence therein of the clayey Chillesford beds, which must stop the downward passage of water.

Sands and Gravels of the Glacial Drift.

Sands and Gravels of the River Drifts.

3.—Chalk Protected by Beds of Mixed or Varying Character.

In this case it is not essential either that the chalk should be directly covered by beds of the kind indicated, or that such beds should be at the surface; it is only needed that they should occur somewhere between the surface and the chalk, and that no absolutely impermeable beds should come in; permeable beds are of course made of no account by the presence of these mixed beds. Many colours of the geological map find themselves massed in this set, as may be seen from the following list:—

Thanet Beds, where to a great extent clayey, as in East Kent.

Woolwich and Reading Beds, from their varying character, here clay, there sand. There are places, however, where it may be well to include this series with the impermeable beds. The overlying Oldhaven and Blackheath beds, in themselves permeable, are almost wholly carried with this underlying series, except where, as above noted, they have cut through the latter.

Loams of the Glacial Drift. Some of the brickearth of this age is so clayey, however, that it has been classed as impermeable.

Loams of the River Drifts.

Brickearth and Clay-with-flints of the high chalk tract. These are beds which commonly occur over the chalk hills, and which, though of a more or less clayey nature, seem not to be wholly impermeable, for they do not give rise to drainage-streams; moreover, they seem, in part at least, to be the result of the dissolution of the chalk by the infiltration of acidulated water. Some outlying patches of sand in East Kent have been classed with these deposits, as they often have a clayey base.

Alluvium.—The silt and peat of our marshes might be thought to be impermeable; but though this may often be the case, these deposits are sometimes sandy, and sometimes very thin, the permeable gravel beneath coming up near the surface.

4.—Chalk Protected by Impermeable Beds.

Here, again, as with the last division, the beds in question need neither rest at once on the chalk nor form the surface; their occurence anywhere between the surface and the chalk is decisive, and relegates the tract where they occur to what, from our point of view, may be called the useless division, save for those parts of it where the surface waters flow towards the chalk. The large tract marked by the grey colour on the maps, owes its classification almost wholly to the two great clay deposits, the London clay and the boulder clay; but some other beds contribute slightly, as shown by the following lists.

Woolwich and Reading Beds.—In North Suffolk, and in Norfolk, where these beds are quite masked by drift and crag, never cropping out to the surface, they seem to consist chiefly of clay, as proved by well-sections, and it is best to class them with impermeable beds. This may have to be done in parts of the Hampshire basin also, when the re-survey of that tract for drift enables us to construct chalk-area maps of it.

London Clay.—As it is not only where this thick mass of clay forms the surface that it stops the downward passage of water, but also wherever it underlies other beds, it follows that all the overlying permeable deposits have now to be classed with it. This includes the whole of the Bagshot series, so largely composed of sand, which forms such large areas in both the London and Hampshire basins, and also the whole of the very local Coralline crag, which occurs only over a few square miles of Suffolk. Great part of the red crag and of the various drift sands and gravels are also included. All such tracts of permeable beds over London clay, are, of course, of some importance as regards water supply, on a comparatively small scale, and over part of Norfolk and Suffolk, no other source of supply from wells is used.

I need hardly say that, in the case of the London clay, my maps add nothing to our knowledge: the position and extent of that deposit being well known, except in East Norfolk and the adjoining part of Suffolk: the above remarks have been made merely to explain the grouping of other beds with it. There are places where the loamy beds at the base of this clay may be sandy enough to allow of the downward passage of water; but such areas must be insignificant.

Brickearth of the Glacial Drift.—In some parts this deposit is not only of fair thickness, but also of an essentially clayey nature, so that it has then to be classed as impermeable. It often, too, extends underneath deposits of a more permeable kind, and so cuts off their water from the chalk; the underground extension is, however, sometimes hard to trace.

Boulder Clay.—This not only covers the chalk, or permeable beds overlying the chalk, over large areas, but also extends under some of the drift gravels and sands, so that it has a great effect in protecting the chalk from the access of water. A good example of this is given by one of the maps exhibited (sheet 50 S.W., in which, on an ordinary geological map (without drift) nearly the whole of the 205 square miles represented, would be coloured as chalk—a most delusive thing, as, in fact, the area of bare chalk therein is very small, and the areas of chalk covered by permeable or mixed beds not large, whilst the protecting cover of impermeable beds spreads over by far the greater part.

The map to the north (50, N.W.) is much the same, though we have here rather more bare chalk; but in this sheet the whole area would be coloured as chalk, on an ordinary geological map, except for the alluvium of the streams.

A larger map, not yet coloured after the plan described (on account of the drift edition not being published) is also a case in point, for, in sheet 47, whilst about half the area (of 820 square miles) is shown on an ordinary map as chalk, the impermeable boulder clay occurs over the greater part thereof, and quite alters the character of the district.

Though for the most part a fairly stiff clay, there is one tract where the boulder clay is so largely composed of chalk, almost to the exclusion of anything else, that one can there hardly take it as absolutely impermeable. I allude to the north-western part of Norfolk; where the thin boulder clay of the higher ground is so like the merely weathered surface of the chalk, that the officers of the Geological Survey often had some difficulty in dividing the two, especially in places without clear sections. In other parts of North Norfolk, too (near Wells), the glacial brickearth seems to be represented by a bed which is little else than reconstructed chalk, a specimen having yielded, on analysis, no less than 91 per cent. of calcic carbonate, the other constituents being, moreover, of a sandy rather than of a clayey character, and the whole having some likeness in composition to parts of the chalk.

From what has been said, it is clear, I think, that the "maps of chalk areas" exhibited are not merely another version, or condensation, of the Geological Survey maps, although depending so largely on the possession of these. They show, indeed, some things not shown on the geological maps, and for which approximate lines had to be drawn, and their grouping of the facts mapped is different from that of the geological maps.

It may be of interest, perhaps, to constrast the areas of chalk, &c., as shown by some of my maps, with those represented on geological maps without drift.

Thus, in sheet 7, whilst in the latter map nearly half the area, or roughly about 400 square miles, is coloured as chalk, half (or a little more) being of tertiary beds, and a small area (in the north-western corner) of beds below the chalk, a measurement of the four different kinds of area, described in this paper, gives the following approximate figures, which seem, however, to err a trifle on the side of excess:—

Bare chalk	about	125	square miles.
Chalk covered by permeable beds	,,	88	,,
Chalk protected by mixed beds	,,	180	,,
Chalk protected by impermeable beds (almost wholly London clay, there being but little boulder clay over the chalk here)	,,	430	,,

Again, in sheet 46, S.E., almost all coloured as chalk on the ordinary plan, we get the following figures, as before erring slightly in excess:—

Bare chalk	about	76	square miles.
Chalk covered by permeable beds	,,	39	,,
Chalk protected by mixed beds	,,	67	,,
Chalk protected by permeable beds..........	,,	27	,,

In 51, S.E., where neither tertiary beds above nor older cretaceous beds below occur, but chalk alone, the figures are about 40, 8, 1, and 155 respectively, various beds of drift (especially boulder clay) generally covering the chalk.

Whilst the general result of the work is to curtail the somewhat excessive estimates that may have been made in bygone years of the amount of chalk area available for the absorption of rain, yet the chalk remains our chief water-bearing bed in the south-east of England; for, though not always coming up to some of the sand-beds in permeability or porosity, it is pre-eminent over all other geological formations in thickness and extent of outcrop.

Although beyond the immediate object of this paper, there is one circumstance connected with the question of water-supply from the chalk which I can hardly help alluding to from its great importance. The present state of the law, as regards deep-seated sources of supply, is the reverse of encouraging to those who advocate the use of pure well-water; for, by a recent legal decision, in the case of Ballard v. Tomlinson, it has been declared to be lawful for any one to pour any filth or noxious matter down his own disused well without any regard to the fact that he may thereby pollute the source from which his neighbours draw their supply! It would be a work of no great difficulty therefore to utterly spoil most well-waters, and this might not only be done by inadvertence, as in the case alluded to, but apparently of malice aforethought. If this is really the law of the land, or rather of the water, there seems to be an opening for law reformers. It is to be hoped, however, that the decision may be reversed in a higher Court than that from which it came. I need hardly say that these remarks apply to all water-bearing beds and not to the chalk only, and, to conclude, I may say the same of the line of observation that this paper brings forward.

ON A POSSIBLE INCREASE OF UNDERGROUND WATER SUPPLY.

By Chas. E. De Rance, A.I.C.E., F.G.S., F.R.G.S.
Secretary of the British Association Underground Water Committee.

For nearly a century the subject of water supply has been constantly before the public, and with the growth of population has become a question of vital importance to the community. The amount of information that has been accumulated is very large, but, investigated by Royal Commissions, inquired into by committees appointed by scientific societies, it is spread over a wide range of literature. It is difficult for any one individual to focus the stores of information already available, still more for him to follow up the numerous lines of investigation these inquiries suggest.

In my work on "The Water Supply of England and Wales," published in 1882, I made an attempt to show what was the probable supply of water available in all the river basins of England and Wales, and what amount was required to satisfy the demands upon that supply, with the result that it appears to be amply demonstrated that the rainfall this country receives is more than sufficient to meet all the requirements of human consumption, manufacturing interests, and the purpose of canalisation; and yet, with these resources, large districts still suffer from all the ills due to a polluted water supply, whilst other large areas are devastated by floods, representing unproductive rainfall passing ro the sea.

It is to this unproductive rainfall that I would chiefly wish to call attention in the present communication. Much has been written on underground water supply since the year 1841, when the Rev. James Clutterbuck stated "the extent of the supply must necessarily be regulated by the quantity of rain falling upon the surface, the rapidity with which it is absorbed, and the reduction to which it is subject by evaporation;" but this definition still expresses the knowledge we have on the subject. Rainfall being the sole source of supply to the waters beneath the surface as well as those flowing upon it, accurate information on the amount of rain falling on a district is a matter of the first importance, and this, to be of any value, must represent the observations of an extended period of years, so that not only may the minimum supply to be expected be ascertained, but the average or mean of several successive dry years also. Happily, through the voluntary labour of Mr. Symons, F.R.S., we have now more than 2,500 stations at which rainfall is recorded, and we are able, by consulting his annual volumes, to obtain the necessary information for a large number of localities; but it is obvious that, considering the direct bearing such observations have on engineering, agricultural, and sanitary questions, the scope of the inquiry should be enlarged by placing it under a Government department, which could enlarge the scope and usefulness of the inquiry without being, as now, partially crippled for want of sufficient funds to carry out the necessary details.

Pervious or permeable formations, by gradually absorbing waters falling on their surface, which slowly percolate through them, act at once as filter-beds and reservoirs, the capacity of which is limited by the area of absorption, and the thickness of the pervious bed. When rain falls upon a perfectly pervious rock, underlaid by impermeable deposits, the water line is generally near the surface; this line or plane of complete saturation, in sandstone and limestone hills intersected by valleys, is found to be slightly above the level on which the deepest valley intersects the various strata, constituting the water-bearing rock.

When bands of permeable and impermeable rocks alternate, each porous band contains a separate sheet of water, which flows down the dip planes of the strata, confined by the impermeable layers above and below. Such water flows with the head, due to the difference of vertical level, of the area of outcrop to that of the area of discharge, less the frictional resistance of the fragments of the rock through which it passes. When the facilities for the discharge of a volume are less than the quantity capable of being received, the porous rock will be full up to the impermeable layer above, which is invariably the case when all outlet is stopped by faults throwing in impermeable strata, or by the dip carrying the strata beneath the sea-level.

Such porous rocks may be regarded, when provided with an outlet, as underground conduits, the depth of which is the thickness of the bed, the width of which is the extent of the outcrop or horizontal strike of the bed, and the inclination of which is the dip of the strata. Where the outlet is blocked, the saturation-level remains unchanged, and unless water is artificially removed, so as to provide space for a fresh supply, no additional water can be added to the existing supply.

In sinking wells, or in boring into a mass of porous rock, the plane of saturation is found to vary within certain limits, being governed by the amount of previous rainfall. This level, by excessive pumping, is artificially and locally lowered, but the old "rest-level" is restored after a certain number of hours' cessation from pumping. The difference between the "rest level" and the pumping level is, in some wells, in porous strata as much as 100 ft. The area of exhaustion resembles an inverted cone, the apex of which rests on the point at which the pumps abstract the water, and the base of which is a circle at the surface around the well. If over-pumping has taken place, the pumps have to be lowered; the cone increases in vertical height, and a larger concentric circle is added to the central one.

In porous rocks of great thickness the plane of saturation is often at a considerable distance from the surface, the annual rainfall absorbed being balanced by the springs run off at low level, and the floods passing across the outcrop too quickly to sink into the strata. In these cases it would be possible to raise the height of the *saturation-level*, and thus increase the storage powers of the rocks by sinking "dumb-wells" in the porous strata, and draining the storm-water channels into them, which would have the effect of increasing the summer discharge of the springs.

From an investigation I made in 1878, as to the area of each of the various rocks in each river basin, which forms the basis of the paper I laid before the Society's Water Congress, convened by his Royal Highness the President, I estimate the area in England and Wales, occupied by porous rocks, to be not less than 26,633 square miles; while the tertiary, gault, weald, oolitic, liassic clays, the triassic and permian marls, and the shales of the carboniferous occupy a further 19,308 miles, in nearly the whole of which occur pervious rocks, a larger portion of which might be rendered available for storage purposes by sinking dumb-wells through the overlying strata, and discharging the land drains into them, which would prevent the water passing away in devastating floods.

Experiments were made simultaneously on the percolation of rainfall by Dr. Dalton, at Manchester, and by M. Maurice, at Geneva. Dalton's gauge consisted of a cylinder, 10 ins. in diameter, and 3 ft. deep, open at the top, closed at the bottom, and filled with earth, and sunk to the ground level; his experiments were carried on from 1796 to 1798, 25 per cent. of the rainfall being absorbed. M. Maurice's observations, from 1796 to 1797, gave 39 per cent. of percolation. Mr. Dickenson's, from 1836 to 1843, gave 42 per cent. Mr. Greaves' observations, extending from 1852 to 1873, with an average rainfall of 25·8 inches, gave the percolation of 26·6 per cent., his gauge being a slate box with an area of one square yard, a yard in depth filled with soft earth, loam and gravel mixed, trodden in, and turfed over. Mr. Greaves states, "the gauge stands at Lea Bridge, $1\frac{1}{2}$ miles west of, and 6 miles north from the meridian of Greenwich." He finds the abundance of water in a river to be more closely dependent on percolation than on mere rainfall; for consecutive months there is no percolation whatever; five times there was no percolation for six months; and only in one year (1860) was there percolation every month. The greatest percolation is after thaws of snow, especially after frequent thaws of small falls of snow. A wet winter gives abundant springs in the following autumn; but if that be followed by a dry winter, it will obliterate the effect of the previous wet winter, this is the case in the present season, 1884, when the springs are remarkably low, as has been pointed out in the *Times* of June 7, by Mr. Baldwin Latham.

Mr. Greaves's experiments show the smallness of percolation through earth on the whole, and its entire absence during warm summer weather; and they also show the small thickness of earth under which water may be safe from evaporation, which he places at a depth of 36 inches; and even at 24 inches he considers it doubtful "whether, in the latitude and temperature of London, capillarity has more than a negative action beyond 12 inches in depth." Probably, in a moderately open soil, capillarity extends only a few inches, but the higher capillary power of clay soil causes a constant summer exhalation. From these facts it is evident that the more thoroughly a soil is underdrained, the nearer it resembles the "percolation gauge," and the less likely is water to pass off as flood in an open water-course. The more free drainage is promoted, and the more "dumb wells," or "inlet drains," are constructed, the greater will be the quantity of water stored; in other words, the percolation period, ending naturally in February or March, will be artificially extended so as to catch a large proportion of the summer rains; and "intermittent springs," which are dependent not on surface-present rain, will be increased in volume, and to some extent rendered more permanent, at times when the heavy rains of summer, through excessive evaporation, are adding nothing by percolation to the underground stores.

The investigation of individual observers, and the ten Reports of the Underground Water Committee of the British Association, which I have drawn up, as Secretary of the Committee, have made well known the large quantities of water now pumped from the millstone grit, the permian sandstone and triassic sandstones, the oolites, the greensands, and the chalk; towns like Liverpool, Birmingham, Birkenhead, and Nottingham, receiving from the triassic sandstones quantities reaching, in the case of the city of Liverpool, $6\frac{1}{2}$ million gallons per day; while the analyses of the Royal Rivers Pollution Commission, show us the pure quality and great value of these waters from a sanitary point of view.

In England and Wales, the pervious portions of the carboniferous, the secondary, and tertiary rocks, occupy an area of not less than 26,600 square miles, while an additional area of 19,000 square miles exists of rocks of this age, which, though impermeable and carrying off the rainfall in floods, yet overlie pervious strata that might, to a great extent, be made available for storage purposes, were dumb-wells carried into them from the surface; such dumb-wells would artificially act as do the swallow holes which feed the chalk and carboniferous limestone waters.

In the chalk, though water is absorbed with great rapidity, and retains a quantity, according to the experiments of Professors Ansted and Miller, equal to one-third of its bulk, it parts with it with excessive slowness; and the water available to feed springs, and to supply well-borings, is mainly due to free water passing down the cracks and fissures which traverse the chalk surface in all directions, the larger fissures allowing the passage of rain water down to the lower portions of the chalk. That the deep-seated impermeable beds occurring at the base of the chalk formed the surface on which the passage of water chiefly took place, was pointed out by Professor Prestwich, in 1851; and the gradient on which water stands in the chalk was described in the Sittingbourne district by Mr. W. Bland, in 1852, which gave an inclination of 47 feet per mile of fall in one direction, and 45 feet per mile in the other; in Hertfordshire, the average inclination between Dunstable and Watford was found by the Rev. J. Clutterbuck, in observations extending from 1842 to 1850, to be only 14 feet per mile. The later observations of Mr. Baldwin Latham on this subject show the remarkable increase of gradient, produced by the temporary rise in the water level of the hilly districts of the chalk, after heavy and continued rains, which becomes gradually depressed after their cessation, before the springs in the low ground has ceased to give their maximum yield.

Over the whole of the area of 26,600 square miles, drawing wells may be sunk with advantage, and their supply increased by sinking inlet or drainage wells to carry into the strata water now almost entirely lost, and rendered not only unproductive of good, but the agent of actual harm, in the destruction of property and agricultural produce by floods. Care will have to be taken that, in constructing such dumb-wells, communication is not set up between drains carrying objectionable matter and the underground sheet of water, and that in draining wells and bore-holes the point at which the water is abstracted is sufficiently removed from the surface to insure the water having naturally filtered through the superincumbent strata.

In the case of the 19,000 square miles of impermeable strata overlying pervious strata, for the most part already containing water absorbed, in the area of outcrop of the pervious, artesian borings will give large supplies, in numerous districts where no attempt in this direction has been made; and where the artesian gradient, or water level, is not as high as the base of the impermeable stratas overlying the permeable bed, dumb-wells may also be sunk with advantage, and in relieving the clay beds of their floods in winter, will help to increase the summer discharge of the rivers, and render the intermittent springs of more permanent value.

Miscellaneous.

BEETROOT SUGAR INDUSTRY IN GERMANY.

In a report recently presented to the United States Department of State, on the sugar industry in Germany, some details are given, showing what rapid strides have, of late years, been made in its development, and how materially it affects the augmentation of national wealth in the country. Consul Kiefer states that the exportation of German sugar, to any great extent, only commenced in 1860, and that, in order to foster and promote it, the Government refunded the taxes paid on sugar manufactured when exported, and as the tax was levied by an assessment on each centner of beets used, and the drawback calculated according to the weight of sugar to be exported, it happened that gradually, in an indirect manner, a premium was paid on exportation. It was agreed, and taken for granted, that 12·5 centners of beetroots (the centner being equivalent to 110 lbs.) were required to produce one centner of raw sugar; the centner of beet paid 80 pfennings tax (100 pfennings being equal to one shilling), and a drawback of about nine shillings was allowed on each hundredweight of sugar exported. By improved methods of manufacture, and better cultivation of the beetroot itself, during the last twelve years only 11·39, and even in the last two years only 10·46 and 10·47 centners respectively of beets were needed to produce one centner of raw sugar, and, therefore, there was refunded on each centner a tax on 1·10 to 2·04 centners of beetroots which had never been paid for, this being equivalent to a premium paid on export. The consequence of this was, that manufacturers found it more profitable to send their products abroad, and it is stated that, from the one district alone, namely, Stettin, the value of raw sugar exported to the United States, which amounted, in 1881, to about £2,750, rose to £27,000 in 1882; and it is expected that it will go on steadily increasing each year. In order to correct this state of things, a commission was appointed last year to inquire into the question of the tax on sugar, and the industry generally. This commission, though it has far from completed its labours, has already decided, as a temporary measure, that the drawback should be reduced 40 pfennings on each centner of sugar for the next two years. In 1871-2, the tax on beetroot sugar amounted to £1,800,000, and the duty on imported sugar to £625,000; and as the drawback paid on exported sugar was £194,000, the net income amounted to £2,231,000. In 1882-3, the beetroot tax was £6,998,000, import duty £86,000, the drawback paid £3,675,000, and the total net income £3,409,000. To those taxes to be refunded must be added those that have not yet been actually paid out, being due only at the expiration of six months, leaving, in fact, only a net income for 1882-3 of £2,582,000. The development of the sugar industry, particularly in Pomerania, during the last twelve years, has made very rapid strides. Comparing the periods 1871-2, and 1882-3, it will be found that during the former year 38,000 tons of beets were in that district consumed, and 3,000 tons of sugar produced; while in the latter, 84,000 tons of beets were used, and over 7,700 tons of sugar obtained from them. The total result of the fiscal year 1882-3 shows an extraordinary increase of production compared with the previous year, caused partly by the establishment of new factories and the enlargement of those already existing, and partly by the cultivation of the beetroot on a larger scale, and it may also be attributed to the exceptionally rich harvests. It is estimated that at the present day there are 525,000 acres of land under beet cultivation in Germany, and it appears that during the year 1882-3 there were 358 factories in operation, compared with 343 in the previous year, and they produced 835,164 tons of raw sugar against 599,722 tons in 1881-2. The taxes paid amounted to nearly £7,000,000, as compared with £5,017,000. It is expected that for the year 1883-4, it will be found that there will be an increase of at least 15 new factories over those in operation in 1882-3. The revolution which has taken place during the last twelve years in the German sugar industry becomes more apparent when a comparison is made of the periods 1871-2 and 1882-3. In the former year, 2,251,000 tons of beets were consumed, producing 186,442 tons of sugar; while in the latter, 8,747,000 tons of beets were used, producing 835,164 tons of sugar. It was found that the quantity of beetroot necessary to produce one pound of raw sugar decreased from about twelve to a fraction over ten pounds. The importation of all kinds of sugar during the same period fell from 50,000 tons to 6,000 tons, and the export rose from 14,000 tons to 472,000 tons; while the quantity used for home consumption increased from a little over twelve pounds to about eighteen pounds per head of population.

THE MINERAL WEALTH OF LOWER CALIFORNIA.

Consul Viosca, of La Paz, in his last report on mines and mining in Lower California, states that the peninsula is divided into several ridges, the northern range terminating on the plains of San Ignacio, running along the western coast to San Borjas, and from thence crossing to the eastern side. A section of the northern range, as well as the central which follows it, extends to the Bay of La Paz, having on their western slopes extensive plains and table lands. The mineral veins in the mountains, which extend from the territory, run north and south, with an inclination east and west; the largest quantity of the veins are superficial, being covered thinly with a kind of stone used for grinding, limestone, &c.; the metallic veins are deeper and richer, although they have not yet been excavated to any very great depth. The chief mineral producing districts are Mulege, Las Virgenes, San Marcos, Comondu, San José, Cacachiles and La Trinchera, and Triunfo. Gold, silver, copper, graphite, sulphur, alum, and magnesia are found. The mountains between San Ignacio and San Borga have numerous metallic veins, among which predominate sulphurous pyrites, carbonates, and sulphurets of gold, silver, and copper, besides a large quantity of oxides of iron. In Las Virgenes mountains, the principal group terminating the range is composed of three conical mountains, volcanic, surrounded at their base by two large streams, the Santa Anna on the north, and the Santa Maria on the south. The principal crater is on the northern slope of the central mountain. The table opposite on the north west is noted for its sterility. An acrid vapour, indicating the presence of sulphurous acid, is almost constantly escaping from the crater. On its borders, and lower down, within a radius of 55 metres, the ground is perforated by innumerable orifices, emitting sulphuric streams, which, coming in contact with the atmosphere, form crystallised needles and threads of pure sulphur. From the principal crater runs a stream of water, strongly impregnated with sulphuric acid, which leaves in its course a whitish sediment similar to chalk, insoluble in fresh water, and of a styptic nature, and presents the remarkable phenomenon of petrifying everything with which it comes in contact capable of absorbing it. Another curious circumstance is the existence of small fishes, called *cabezones*, that are found in the reservoirs which the water has formed in the mountain side. One-fifth of the ground constituting the solid surface of the volcano contains *caliche*, a term given by the natives to earths of pure sulphur. Under this covering there is a mass of fine liquid mud, about 36 ft. deep, and a temperature of 90 degrees. There is also a warm spring running from the side of a low hill, and irrigating with its waters a small piece of land covered with wild palm and fig trees, which forms an oasis in the midst of an arid and solitary desert. The Santa Maria creek, which runs round the southern base of the Virgenes ridge, empties itself in the bay of that name. It runs through hills composed of sulphuret of lime, which presents itself in every form, aspect, and colour, owing to the metallic oxides with which the soil is impregnated. Slabs of gypsum have been found, of magnificent quality, the prominent colours being dark and pale yellow, produced by the oxide of iron, sea-green, emerald, deep red, and even black. In the Comondu district, at a place called Sance, situated on the eastern slopes of La Giganta mountain, some very rich copper veins have been discovered, entirely different in their composition to that of all other copper known. They contain free copper, that is, copper in its metallic state, sulphurous pyrites, and, it is supposed, an alloy of gold. In this district there are also numerous copper and silver veins. In the island of San José there is a vast number of matalliferous veins, and all the sections of the ridge bounded on the west of the bay of La Paz, south of La Trinchera, and east of the Gulf of California, are profusely crossed by metalliferous veins, which contain silver ore of great richness. In these districts the richest productions of the territory differ materially from the minerals extracted from other localities; they are sulphurets of lead, silver, chloride of silver mixed in quartz, together with carbonates. Sometimes these sulphurets are mixed with a layer of clay containing metallic oxides; in some places silver is found. The native Mexicans of California are stated to be excellent miners; they are sober, industrious, and frugal, and their labour can be had to any extent at from 3s. 9d. to 4s. a day. Consul Viosca says, in conclusion, that "the laws of Mexico are generally and specially protective to mining enterprises. That mining can be prosecuted at a profit is without doubt a practical fact. Every material for the treatment of the ores, if not produced in the country, is free of duty, and all possible convenience is afforded by the local authorities towards encouraging miners and mining capital."

PATENT FUEL IN FRANCE.

The United States Commercial Agent at Nantes says that the coal dust, which was formerly rejected as worthless, is now consumed in immense quantities in France in the form of "patent fuel," or coal bricks. The natural supply of dust from the yards of the coal merchants being entirely insufficient for the needs of the brick works, the manufacturers, particularly in the Nantes district, import a large quantity of coal dust from Cardiff, Swansea, and Newport. The process of manufacture is very simple. The coal dust is mixed with pitch, and the mixture poured into cups attached to a belt, each cup containing just enough material for a brick of the size desired. The belt in its movement passes this material through a chamber where it is exposed to steam which fuses the two substances into a homogeneous mass. This is poured by the descent of the belt into moulds, where it is subjected to an enormous pressure by a hydraulic press or by machinery set in motion by a steam-engine. The brick is square in form, its thickness being about one-third of its other dimensions, and it weighs five, ten, or fifteen pounds. Certain of the French railway companies refuse to accept fuel unless at least 10 per cent. of pitch has been used for its agglomeration. It is stated that *briquettes* are preferable to ordinary coal for exportation to the colonies and to warm climates on account of their compact storage and freedom from small fragments and dust, also for use on locomotives both on account of economy of space, and because firemen can always determine the amount of fuel they are employing in a given time, the weight of each brick being exactly known. The manufacturers claim that the "patent fuel" is more healthy for domestic use than ordinary coal, citing in support of this theory the declaration of certain well-known physicians. At the present day a large number of bricks are made for domestic use, of small size, and perforated with circular or longitudinal openings.

SEA FISHERIES OF ALGERIA.

A report has recently been presented by the French Government on the Algerian sea fisheries, from which it appears that in the year 1882, 4,916 fishermen were engaged in this industry, and 1,044 boats. The value of the fish caught amounted to about £163,000, consisting chiefly of mackerel, thon, sardines, and anchovies. Comparatively, few mussels or oysters were taken, but there was a large take of shell-fish. The total weight of fish taken amounted to over 11,000,000 pounds. On the coast of Algeria there is an abundance of fish, and the fishing is particularly good in the Gulf of Oran and Arzew, but from these points to Castiglione, a distance of over 1,200 miles, the industry is little followed owing to the want of a market along the sea coast. Algiers and its neighbourhood is a very important centre for fish, particularly Phillippeville and the bay of Callo. At Bône and La Calle there is less animation, but sedentary species are caught there which are not found elsewhere. Coral fishing is largely followed in Algeria, 40,000 to 45,000 pounds of coral, valued at about £38,000, being the yearly production; La Calle is the centre of this industry, and there are employed annually 160 boats and about 1,300 men. The coral is obtained by means of a wooden apparatus in the shape of a cross, having in its centre a leaden slug or stone for ballast. Nets, the meshes of which are loose, are hung on the bars of the cross and dragged at the bottom of the sea, and among the nooks and crevices of the rocks. These nets, winding about the coraline plant, break up or tear off its branches, which adhere to the meshes. The apparatus is drawn up by the fisherman whenever he thinks it sufficiently laden. There is also a net which is provided with large iron nails, having thus great force to break the coral, but this apparatus is forbidden to be used. The *scaphandre*, or cork jacket, is used only in exceptional cases.

General Notes.

COMMERCIAL EDUCATION IN FRANCE. — In Germany there are no less than 200 institutions for commercial instruction, and efforts are now being made in France to provide similar advantages for the youth of that country. On October 1st will be opened the *Institut Commercial de Paris*, under the direction of M. Bernardini, formerly secretary of the Mulhouse Chamber of Commerce, and director of the Rouen Industrial and Commercial Institute. A company, with a capital of £8,000, has been formed to carry this scheme into effect.

UTILISATION OF SLAG. — It is said that in Germany alone, in the production of steel from phosphoriferous pig-iron, no less than 20,000 tons of phosphoric acid remain in the slag unutilised. Professor Scheibler, of Berlin, has invented a process for extracting this valuable substance. He first calcines the slag in an oxydising flame, then pulverises and sifts it. The powder is dissolved in hydrochloric acid, and the solution saturated with milk of lime. In this way a substance is produced which is said to contain from 35 to 37 per cent. of phosphoric acid, under the form of bi-basic phosphate of lime. A second calcination is reported to afford a product containing as much as 45 per cent. of phosphoric acid.

Journal of the Society of Arts.

No. 1,654. Vol. XXXII.

FRIDAY, AUGUST 1, 1884.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

CANTOR LECTURES.

The third lecture of the course by Prof. Chandler Roberts, on "Alloys used for Coinage," will be published in the next issue of the *Journal.*

EXAMINATIONS, 1885.

The Programme for 1885 is now ready. Copies can be obtained gratis on application to the Secretary.

Proceedings of the Society.

CONFERENCE ON WATER SUPPLY.

The following are some of the papers read at the Conference of the Society of Arts on the Water Supply, held at the International Health Exhibition on Thursday and Friday, July 24th and 25th :—

WATER SUPPLY IN ITS INFLUENCE ON THE DISTRIBUTION OF THE POPULATION.

By W. G. Topley, F.G.S., Assoc.Inst. C.E.

Geological Survey of England. Lecturer on Geology at the Institute of Agriculture, South Kensington.

One of the most essential conditions for the comfort and well-being of a population is water, and a little consideration will show that the early settlements of a people have been where, and only where, water occurs.

In a broad and general sense, this fact is patent to all—the banks of rivers and streams are usually well populated—the wide areas of waterless districts are unpeopled; but the fact is equally true in a very limited and restricted sense, not at first so obvious.

The source of all water is the rain which falls on the land; this acts in two different ways, according to the nature of the soil on which it falls. If the soil is porous, or pervious to water, a certain portion of the rain sinks in; if the soil is impervious, the whole of the water either drains off the land into brooks, or passes back by evaporation into the air. The water which soaks into a porous soil or rock, accumulates there until it flows out again as springs, or is artificially tapped, and drawn away by means of wells.

The conditions under which springs most commonly occur may be illustrated by the following "sections," which represent the rocks cut through from the surface downwards. The positions of springs are marked × × ×, and in all cases these also mark the positions in which villages and towns occur.

Sections Illustrating the Origin of Springs.

Fig. 1

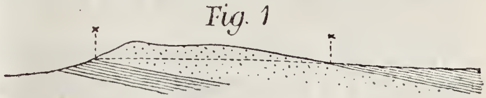

Fig. 2

Fig. 3

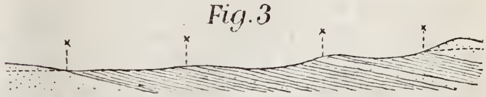

Fig. 4

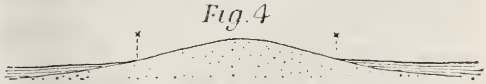

Fig. 5

× × Indicate the more common sites of early settlements; dots indicate porous beds; lines indicate impervious beds.

Springs occur near where a pervious bed overlies or underlies an impervious bed (Fig.

1), or where a valley reaches down to the level at which the rock is saturated with water (Fig. 2). In the case of valleys cutting deeply into the rock, the valleys themselves determine the level of saturation.

A soil which allows water to sink into it is a dry soil, and is, therefore, suited for habitation and for agriculture. Hence the main conditions which favour the settlement of a district are found in the same soil, or along the outcrop of the same bed. We thus see that geological structure controls the distribution of the population; not only in such great features of the earth's surface as mountain-chains, plains, and valleys, but also in the minor divisions of the district.

The outcrop of a narrow band of porous rock, between wide beds of clay, is strongly marked by the occurrence of a long line of villages, each of which obtains its water from shallow wells or springs. The cornbrash, between the Oxford clay and the great oolite clays, is an excellent example of this. So, too, is the marlstone rock-bed, between the upper and lower lias. Even a thin and comparatively unimportant bed of sand, ironstone, or limestone, if it only affords a small space fit for arable culture, will be marked by a line of villages (Fig. 3). A thin bed of ironstone in the lower lias of Lincolnshire is a good example of this.

When rocks rise from beneath a covering of clay there are often springs at the junction. Fig. 4 shows a very common arrangement in East Northumberland, where sandstone rises from beneath the boulder clay.

The base of the chalk escarpment, with the line of outcrop of the adjacent upper greensand, gives another good example. Here the villages always lie thickly along a definite line. There is a well-marked and constant relation between the outcrop of porous strata and the parish or township boundaries, the longer axes of the parishes crossing the outcrops more or less at right angles. A careful study of the distribution of the villages, and of the relation of their parish boundaries to the main physical features, throws much light upon the past history of the country, and often enables us to determine the relative ages of the settlements. This branch of the subject does not now concern us;* we need only note that the arrangement of the parish boundaries depends upon the sites of the settlements, and that these are controlled by the outcrops of water-bearing beds.

The early settlements in England were nearly always controlled by such circumstances as have been here referred to; but the later development of special towns and districts has depended upon a variety of circumstances. In early times it was around some shrine of special fame or sanctity, or under the shadow of the castle of some powerful noble, that the population clustered and the town increased. A little later it was also in places especially well suited for various manufactures. Within the last 200 years the great development of our mineral wealth (especially of coal and iron) has entirely transformed the country. Large towns have sprung up over the coal-fields, often on wide tracts of clay, where few settlements would otherwise have taken place. The natural surface water supply of such places is often bad and small, and the mining operations frequently drain even this.

The water supply of modern towns is, in nearly all cases, either (*a*) obtained from a neighbouring river, (*b*) brought from a distance, or (*c*) obtained from deep wells beneath the town. It thus, except in the first case, differs from that of the original settlement, which always obtained its water from streams, springs, or shallow wells. In far too many cases the primitive source of supply has been continued in use long after the time when it should have been abandoned; and the local source of water supply, essential to the early development of a town, has become a source of danger as the population has increased.

Of the points just mentioned, London affords an excellent example. The old parts of London and its suburbs are built upon gravel resting on London clay (Fig. 5). Where small valleys (such as the Fleet) cut through the gravel, there are natural springs; but everywhere water can be obtained in shallow wells sunk through the gravel. So long as the inhabitants were dependent entirely upon these springs and wells, the houses were confined to the gravel; when a general system of water supply was introduced, the population extended over the intervening area of clay. Meanwhile, the increasing population, without any adequate system of drainage, fouled the shallow wells, and rendered them all more or less impure. It is only within the last few years that some of these have been closed by authority.

Below the superficial deposit of gravel, there are other sources of water supply for London.

* For discussion on this question, see a paper by the author, in "Journal of the Anthropological Institute," vol. iii. pp. 32-55 (with maps), 1873.

The strata beneath lie in a basin-shaped form, and thus favour the accumulation of water. Underneath the London clay there are the lower tertiary sands, holding water which rises in the wells when these are sunk through the clay. Still lower, there is the great mass of chalk in which there is an enormous store of water. Still lower, and separated from the chalk by a bed of clay (gault), is the lower greensand. This, on the south side of London, may yet yield some water, but it can never be the great source of supply which was once hoped for.

There are, then, with the river, four different sources of water supply at or beneath London, each giving a different quality of water. Probably no large city in Europe is better situated than London for supplying itself with water from within its own area; but so vast has London now become, that all these taken together are insufficient, or inefficient.

It is a curious circumstance that some others of the great capitals of Europe are built on "basins" like that of London, and hence are able to obtain deep well-water from beneath. Paris, Berlin, and Vienna are good examples. This is a circumstance that could not have been known to the early settlers, who concerned themselves only with the surface sources of water supply.

WATER FROM THE CHALK.

By Joseph Lucas.

At the first Congress on National Water Supply, convened by the Society of Arts in 1878, I had the honour to read a paper indicating an opinion "that the real stumbling block to the practical solution of the water question of the country in general is not, as has been alleged, its cost, but the general absence of data respecting its sources," and advocating a survey of the water-bearing strata on principles described in the paper, and which I now reiterate.

The proposition met with the support of water engineers, and was endorsed in a leading article in the *Times*, summing up the results of the Congress.

At the next meeting in 1879, at which the Council of the Society of Arts did me the honour to confer upon me their silver medal for a paper on "National Water Supply," in a second paper, entitled "Watershed Lines," I gave the measurements in square miles of the apparent and real areas of chalk country lying within the basins of thirteen rivers between and inclusive of the Medway and the Meon, in South Hants, as determined by my hydrogeological surveys.

In the following year, the Institution of Civil Engineers, who had previously published a map and paper giving the results of a somewhat crude survey of the chalk water system (1872-6), did me the honour to publish a map and paper descriptive of the "Lower Greensand Water System of Surrey and Hants." For this survey the Council of that institution awarded a Telford medal and premium. In its application to the subject of London water supply, the hydrogeology of the question has frequently been called into requisition by the water companies, and was mentioned on the Committee of the House of Commons on London Water Supply, over which Sir William Vernon Harcourt presided, in 1880, by Professor Thorold Rogers, and in the evidence of the late Mr. E. J. Smith. That Committee never got beyond the financial view, and the question of London water supply was practically hung up to await the creation of a Municipal Corporation.

As it appeared to me unfortunate that the survey of the source of water supply should be hung up with it, I have continued to the present time (with the exception of a few months in which I was laid up from ill health) to extend, over large areas, the series of field observations which I have now carried on for nearly twelve years. These materials are in frequent use as evidence before Parliamentary Committees, in the Law Courts, and in arbitration cases at the Surveyors' Institution. As regards special areas, my friend Mr. Baldwin Latham has for years taken a large series of gaugings of wells and streams daily, which are probably unique in this country; and my former colleague, Mr. De Rance, has long edited a collection of observations under the auspices of the British Association, which will be of great value.

This is not the time to go into details of any particular areas, but I may be allowed to present one or two facts from a large mass of unpublished material, in support of any contention that a comprehensive and uniform survey of the sources of water supply is the stimulant required for the flagging water question.

The chalk of the County of Hertford is covered by a varying thickness of drift clay and clay with flints, and the wonderful plains of gravel that occupy nearly all the upland surfaces. From surveys made in 1876-7 and 1884, I have traced out two distinct water systems—one, the deeper, that of the chalk, which at the present time lies far below most of the valley-lines in the chalk basin of the Lea, and another, that of the surface gravels. Many of the various tributaries now in water are surface streams only, and here and there plunge into the chalk beneath. There should be no difficulty in supplying any village in the county, yet such considerable villages as Reed, Kelshall, and Sandon, have no well, and are dependent on ponds, which before the storm of July 9th were reduced to the last extreme of filth.

Essenden is also without a supply, and is under notice from the Rural Sanitary Authority; but I am told by a member of the Board that they have no knowledge how to supply themselves. As compared with some other chalk counties, there are no very deep wells in Hertfordshire. Along the base or boundary of the tertiary clays it occasionally happens that the drainage of considerable clay surfaces is discharged into the chalk, either by large swallows, as at Farnham, South Mimms, and Chislehurst, or by invisible leakage. Such points afford grand opportunities for collecting water, a fact that has not been lost upon the Kent Water Company at Crayford and Chislehurst, and might be turned to useful account elsewhere.

The chalk of the South Downs presents one or two notable points. Taking the geological unit of some 45 square miles area, between the Arun and the Adur, which it was my privilege to survey in the winter of 1878-9, and the summer and autumn of 1883, the water system shows three basins, one draining west, towards the Arun; another east, towards the Adur and coast; and a third, the Finden basin, between the two. The extreme height of the boundary water ridges of the Finden basin, under the escarpment at Sullington Down on the west, and Chanctonbury on the east, is 300 ft.: the distance from the rivers, west and east, which run in at mean tide level, being respectively 4½ miles and 3 miles; and distance from the sea 6 miles. On a cross section of the intermediate or Finden basin, from Sullington Down to Chanctonbury, we find a fall under the valley of upwards of 200 ft. in the water line, the water not attaining 100 ft. above O.D., at 6 miles inland along the valley. In the Michelgrove basin it falls short of 20 ft. above O.D. at 5½ miles inland, under the valley, while 1½ miles to the west it attains 257 ft. A third case is at Lychpole, where, at 3 miles from the coast and the Adur, the water falls to 6 ft. above O.D. I have met with no other area which exhibits such clearly defined channels underground as the block of chalk between the Arun and the Adur.

The upper greensand, generally a slender source of supply, prevents a notable exception. In June, 1882, I was invited to make a survey in search of a supply for the town of Warminster, and in the course of a few days was surprised to find some abundant springs issuing above Sheerwater Lake.

(1.) Sheerwater Spring Pond, discharging 132 cubic feet per minute (or twelve times the requirements of the town) at an altitude of 476 feet O.D., and 68 feet above the highest point in Warminster. (2.) Glasswell Spring, discharging 7 cubic feet at an altitude of 482·79 feet O.D., or 74·74 above Warminster. (3.) A spring rising in boggy ground at Aucombe, discharging 55 cubic feet per minute. This spring I did not recommend, as it is muddy and peat stained. The total discharge of Sheerwater Lake was 200 cubic feet per minute, or vastly in excess of all the above which flow into it. The elevated situation of these fine springs places them out of the reach of contamination, an advantage enjoyed by few towns in England. In the case of Warminster it is the more remarkable, as that town stands on the watershed ridge between the two channels. The Local Board is now taking steps to acquire water from them for the town. It is important to note the millowners of the Alyn, last year, failed to establish their claim to compensation in water for the quantity proposed to be abstracted from that flowing down the Silurian mountains on to the mountain limestone in which it sank, before a Committee of the House of Commons. Gaugings were specially taken last July, a temporary dam being formed above the inflow, and suddenly removed to let down a rush of water, which was found to issue a quarter of a mile below, after which it again sank and re-issued. This decision affects several English rivers and streams. Hydrogeological evidence is of the utmost importance in all such cases.

I must call attention to the recent decision by Justice Pearson in the case of "Ballard v. Tomlinson" (I being a witness as to facts below ground on behalf of the defendant), that the owner of a well is at liberty to pour sewage, or arsenic, down it if he likes, and to suggest that there is need for a change in the law upon this point, which will become more important if London should ever (and the attention of Sir Francis Bolton should be called to this point) draw more largely than at present from the chalk, as would appear possible after the recent demonstrations of Colonel Beaumont's rock-boring machine in the Channel and Mersey tunnels, and the Halkyn drain in the mountain limestone.

In conclusion, I trust that the present Conference will not break up without passing a resolution to the effect "that a national survey of the sources of water supply, both surface and subterranean, to produce maps defining levels, areas, and quantities of water, should be set on foot by Her Majesty's Government with the least possible delay." I trust that the spirited perseverance of the Society of Arts will be rewarded by a practical outcome from their several Conferences.

THE ORIGIN OF WATER SUPPLY.

By G. J. Symons, F.R.S.

This title might possibly be supposed to imply a history of the past, but in this Health Exhibition, *pace* Old London, we deal chiefly with the present and with the future.

I know no better word than origin wherewith to describe the small portion of the great subject of water supply which I am permitted to discuss.

All water supply comes from the clouds, and it is with the products of the clouds as rain (including therein snow and hail) that I have to deal.

Perhaps, before describing the general features of rainfall distribution, it may be permissible to explain (for the use of those who have never done it) how the fall of rain is measured. If we imagine a flat dish—a tea-tray, for instance—placed upon a lawn during rain, it is obvious that (subject to loss by splashing) that tray would at the end of the shower be covered by a layer of water of a depth approximately equal to that which fell upon all portions of the lawn, and the depth of the water on it (say ½ in.) would be the depth of the rain fallen. Obviously, besides the loss by splashing, the water on this tray would soon evaporate and be lost, besides which the depth could not easily be accurately measured. For these reasons, some form of funnel is always used, so that the rain may be, as it were, trapped, prevented from splashing out, and from evaporation. In the gauge before you (a very inexpensive one) all known sources of error are guarded against, and, as the water collected by a 5-in. funnel is measured in a jar only 1½ in. in diameter, it will at once be seen that its vertical depth is multiplied nearly tenfold, and, therefore, even $\frac{1}{100}$th of an inch is easily measured.

There are other patterns specially adapted for observation on mountain tops, where they can only be visited once a month, others for observations during heavy thunderstorms, so as to obtain data needful for drainage questions. others in which every shower that falls writes down its history, the instant of its commencement, its intensity during every minute, and the time of its termination; but I must not stand between you and other papers with a discourse on the many interesting points which these guages bring out.

During the last 25 years, I have done what I could towards establishing a complete system of recording the rainfall in this country. In early days the British Association for the Advancement of Science gave considerable help, but some ten years since they dropped it. Government have never given any help at all, and now the whole cost, or 99 per cent. of it, is borne by the observers themselves, a body which has now grown to the very large number of nearly 3,000. I do not know the precise number, but there are every year new stations beginning, old ones stopping, and others interrupted; yet for 1883, I have just had the pleasure of printing perfect records from 2,433 stations, every record having been previously carefully examined and verified.

Hitherto, I have been so overworked, and my staff has been so small, that the discussion of the data falls behind the collection; for this reason I cannot lay before you such data as I wish. However, the map on the wall is the one I drew many years ago, and which was inserted in the sixth report of the Rivers Pollution Commission. It is not perfect, but as it is tinted with increasing darkness for places with heavy annual falls of rain, it will at least show you the broad features of the distribution over the country.

I refrain from going into the subject in detail, desiring chiefly that you should realise the fact that large tracts of country have twice and even three times as much rain as others. If we descend to single stations, the differences are of course greater, *e.g.*, in 1883, the rainfall at The Stye, in Cumberland, was 190·28 inches, and at Clacton-on-Sea, in

Essex, it was only 18·71 inches; that is to say, the one was more than ten times the other.

Here I should like to interpose a question as to public policy. There is often a great outcry if the water of one district is taken to another. Surely, while there is no relation whatever between the density of population and the quantity of rainfall, one early duty of a Government is to see that all parts are amply supplied with the chief necessary of life. Englishmen have a dread of centralisation, but in many ways they pay a long price for their dread. At present, it is not often that any town can even state before Parliament its views as to the effect upon it of what its next neighbour may be obtaining powers to do. Having suggested one semi-legal question, I may as well mention at once another. Up to the present time, there being no Hydraulic-office (as I hold that there should be) in this country, all the larger water questions come before Parliament as private Bills, and, provided that they get through Committee, they, as a matter of course, become law—law for all time to come. No one can foresee what will be the total population of this country a century hence. No one can tell where the bulk of the people will reside, nor what will be the need for water in various parts of the country. Water-rights are already very valuable, and they will probably become still more so. Would it be possible to safeguard our successors by insisting that special water-rights, if now asked to be created, shall be subject to revision, *without compensation*, after the lapse of 100 years.

However, to return to rainfall, and explain why I stated it to be the origin of water supply. All rain and melted snow must be disposed of, either by evaporation, percolation, or flow into streams and rivers. The first class, evaporation, is, of course, not a supply, and therefore we must not pursue it. Percolation is the source of all springs and of all well-water. Sometimes, as at Lancaster, the springs are so large, that even a considerable town can be supplied by merely laying pipes to the sources whence they burst forth; sometimes they run into the reservoirs of gravitation water-works; sometimes they pass, as in the chalk districts, for miles beneath impervious strata, finally being either pumped up from wells, or even, in rare cases, rising as true artesian wells above the surface of the ground; and sometimes they pass even deeper, as in the red sandstone supplies pumped from extreme depths for Liverpool and other towns.

The water which runs off the surface is sometimes utilised by throwing a bank across a stream, and thereby forming a reservoir behind it, as, for instance, in the new supply for Liverpool from the Vyrnwy, where the reservoir will form a lake larger than many of those in Cumberland. Sometimes the lakes themselves are utilised as reservoirs, as, for instance, Loch Katrine and the surrounding lakes, and sometimes, as at York and London, the rivers are drawn from by powerful pumping machinery.

It is often said that there are few things so uncertain as the rain. That is both true and false. True as regards our ignorance of the future, false as regards our knowledge of the limits within which the quantity of rain will be found to vary.

There are now hundreds of records of rainfalls in this country of thirty or more years each, and in a very large majority of them it will be found that the following proportions will be within 7 per cent. of the truth :—

Wettest year, 45 per cent. more than the average.
Driest year, 33 per cent. less than the average.
Driest two consecutive years, 26 per cent. less than the average.
Driest three consecutive years, 21 per cent. less than the average.

There are many other facts respecting the laws of rainfall distribution, concerning which time prevents my saying anything, but I trust that enough has been said to establish the necessity of a perfect system of rainfall registration as the basis of any efficient hydraulic organisation.

WATER SUPPLY TO VILLAGES AND RURAL DISTRICTS.

By Eardley Bailey-Denton, C.E., B.A., Oxon.
Author of Handbook on House Sanitation.

I believe that I am uttering a fact which no one can discredit, when I state that there is no object in social economy which is more important, having regard to the aggregate number of persons affected by it, than the supply of water to village communities and rural districts.

At the present moment, when the International Health Exhibition may help to draw attention to sanitary objects of varying degrees of importance, it may be well to make clear that the condition of rural districts, in relation to water—the first essential of healthy life—is a positive disgrace to a country represented by a State Department whose efforts, it appears to me, should be specially directed to the protection of small communities less able to help themselves than large ones; and is a sad reflection on the present advanced stage of sanitary knowledge—an admission which the special meteorological condition of the present season, and a possibility of a visit of cholera, brings home to all minds with increased force.

If it should be understood, too, that the existence of this condition of things is to be traced, not so much to the absence of potable water, or the difficulty of bringing it into use, as to the disinclination of local authorities to develop the capabilities at their command.

It may be said with truth that, as a general rule, Local Boards and Boards of Guardians having jurisdiction in rural districts, who have been called into existence to supply the sanitary requirements of those districts, are animated with less desire to perform the duties devolving upon them than to avoid them. It is indeed notorious that the majority of members of Local Boards are elected under a pledge to oppose such works as sewage and water supply, on the ground that the rates will be increased; and knowing this to be the case, and that few persons of superior position are willing to take part in Local Boards, because they would invariably be outvoted, it is easy to understand why rural districts should be the last to move in the water question. It is, however, very difficult to explain why the clergyman and medical man of rural parishes, whose higher education should be a guarantee that the right thing would be done, fail to exercise proper influence. If, perchance, they are elected to serve on Local Boards, it almost invariably follows, that the one forgets what he has said in the pulpit as to the influence on the Future of sudden death; whilst the other ignores the advice he has given his patients in their sick-chambers, in relation to the fatal effects of inhaling and imbibing those germs of disease which float in foul air and impure water. Directly they are easy in their chairs as members, they content themselves with the the *laissez faire* policy of their colleagues.

These influences explain how it is that local authorities abstain from appointing as surveyor or sanitary inspector any man with a capability and courage to expose local defects and requirements, and why, when a medical officer does his duty in explaining the defective character of the water supply of any portion of his district, some reason is soon found for relieving him of his duties, and for appointing another in his stead; the actual result of all this being that the governing bodies of rural and small urban districts exercise their functions, when compelled to act, not by taking the advice and opinion of men technically qualified to guide them, but by the exercise of their own judgment. You may often observe a small publican or a grocer—excellent tradesmen in their respective vocations—directing the sinking of wells in village streets in close proximity to leaky sewers, ditches, or cesspools, by which the water intended for the supply of the poorer inhabitants soon becomes foul and unsuitable for domestic use. So general, indeed, has been this abuse, that it is no exaggeration to state that nineteen out of twenty existing village wells are quite unfit for their purpose, and that if samples were honestly taken and submitted to a competent analyst they would be condemned. Yet they are permitted to exist, and nothing is said about them, because the populations interested are comparatively small, the death-rate is not excessive, the dwellings are low in value, and, above all, because the rates would be increased if a proper water supply was substituted.

I have been induced to offer some remarks upon the present occasion, not because I have anything especially new to lay before you, but because the facts I have just referred to, on the constitution of local authorities and the performance of their duties, have been made more pertinent by the circumstance that, at a time when there exists the apprehension of a visit of cholera, a scarcity of water may occur, owing to a remarkably dry winter being followed by an unusually hot summer, which the recent thunderstorms may not sufficiently counteract. It is unnecessary to explain that the summer supply of water is very greatly dependent upon the fall of rain during the preceding winter, *i.e.*, upon the rain falling in the non-evaporating and dormant months of November, December, January, and February. The mean amount of rainfall in those months of the last winter did not reach two-thirds of the average quantity due to the same months for the preceding 60 years. This deficit would have been much more severely felt at the present time, and would have affected our subterranean supplies much more than it is now likely to do, had it not been in some measure counterbalanced by the excesses of rain which occurred during the last seven years, from 1876 to 1883, which gave us, on the whole, a considerable balance to carry over. This advantage, coupled with the frequent and heavy thunderstorms which have occurred within the last month or two, will go far to prevent the scarcity of water which would otherwise have occurred during the coming autumn; though, unfortunately, this national advantage will be a poor compensation to the agricultural interest, which has suffered so severely from the excessive wetness of the last few years.

Without taking into consideration on the present occasion the use of rain water, which, under careful management, may be collected from roofs, and other impervious surfaces, and stored in tanks, and which will always form a valuable means of supply to private dwellings, and in special instances may be made available even for villages, our rural supply, now so often derived from dirty ditches and shallow wells, more or less polluted by foul matters, may, in the absence of springs, rivulets, and impounded upland surface waters, be obtained from subterranean sources of "wholesome" character. These are to be found in various beds or outcrops of a water-retaining character, which gather water at a comparatively shallow depth below the surface, such as the post-tertiary beds of Norfolk and Suffolk, and the different drift beds covering the London clay; the Bagshot sands; the green sand overlying the wealden and gault clays; the surface sands and beds of the wealden formation; the calcareous grit and coral rag outcropping between the Kimmeridge and Oxford clays, and other beds of like nature; or, from the well defined water-bearing strata of the chalk, the oolite, and the red sandstone formations which are deep lying, and to reach which it is often found necessary to pass through superincumbent impervious beds or strata of varying thickness.

From the first source, it requires comparatively little motive power to raise the supply to the height required; in fact, in many cases, the application of the ordinary lift or atmospheric pump suffices; in others, where the depth exceeds thirty feet, additional power is called for. The second source requires more powerful pumping, and may involve the use of several pumps working in unison. All this has been said and explained before. My desire now is, if possible, through the influence of this meeting, to impress upon Local Boards and Boards of Guardians in rural districts where, in order to obtain unexceptional potable water they are obliged to seek it from beneath the surface, that the experience already gained in tubular wells goes far to prove that, in the majority of instances, the "tubular" system may, with good effect, take the place of the old and more expensive practice of sinking large wells involving brickwork, steining and staging. Economy, important though it be, is however secondary to the more important fact that a tubular well signifies continuous and watertight piping from the surface of the ground to the subterranean water level beneath, so that the entrance of polluted surface or subsoil water (as is so frequently the case in ordinary shaft wells) is rendered impossible. In addition to this advantage, it should be pointed out that tubular wells are very rapidly made, and can be readily removed should it occur that the water found or sought has not answered expectations in quantity or quality. Moreover, the whole of the materials employed may be applied, when withdrawn, to the same purpose in another place.

I may here state that there are some few disadvantages attending the adoption of tube wells which it is right at once to refer to. One is that, if owing to accident pumping is stayed, there will be no supply during such time, and if it should happen that the stored supply should run out before the pumping is resumed, much inconvenience may be experienced; whereas in ordinary shaft wells, there being room for more than one pump, such an objection may be obviated. Another disadvantage is that should the demand for water increase beyond the capability of supply the only remedy is to sink others, and to utilise two or more in combination.

To render the nature and cost of tubular wells, which necessarily vary in character and size according to local circumstances, as intelligible as it is possible to make them to rural sanitary authorities, I may shortly state that, adopting for illustration the two characters of the tubular wells already mentioned, *i.e.*, those that can be worked by ordinary lift and atmospheric pumps at a depth of less than 30 feet from the surface, and those that raise water by more powerful machinery from deep subterranean water-levels, the *modus operandi* and cost will be as follows:—

In the first instance, taking, as examples, cases where the populations may severally be 400 and 1,000, and where there exists a constant supply of water at 20 feet below the surface, recourse may be had to Norton's Abyssinian tube wells. The water is reached by driving tubes down through the ground to the water level. The first tube is pointed and perforated for a few inches with holes varying in size from ⅛ to ¼ inch. Length after length of tubing is driven into the earth at the selected site, and each succeeding length is connected with the last by a screw joint. The perforations at the base are four times as much as is necessary to obtain the full flow of water from the tubes, and they are kept clear by an arrangement adopted by Messrs. Legrand and Sutcliff, of Bunhill-row, City, for forcing out any sediment or matter that may obstruct a free influx of water. This is effected by suddenly liberating a column of water after it has been raised to a sufficient height above its normal level. The number of tube wells required in a village of 400 would probably be two, and in one of a 1,000 people, probably five. From figures kindly given to me by the patentees, it would appear that the capital expended in providing the wells and appliances will not exceed 2s. per head of the population. Of course, this only refers to the provision of the tubes, the pumps, and the cost of fixing them. There are many instances of small villages and hamlets where one well and pump alone would suffice; but there are others besides those given as illustrations where a number of these wells may be necessary, and which should be united by means of a cast-iron horizontal main or mains, with intervals between the vertical pipes, governed by the nature of the water-bearing seam out of which the water supply is obtained. This distance may vary from 18 to 30 feet. The motive power to work the pumps may vary in kind; water-power may be used when it is close at hand, or gas where it can be readily obtained.

In the second instance (deep sources), the tube wells consist of iron piping fixed in bore holes, which latter, in fact, form the well, with the piping to serve as the pump barrel and rising main, to raise the water into a service reservoir. These bore holes will vary in depth according to local features, and in diameter from 5 to 15 inches, according to the quantities of water to be raised. The core of pipes form, as already intimated, a continuous tube from the surface of the borehole to the water level below, and are made perfectly flush both inside and out, and must be watertight. They are sunk for a sufficient depth below the standing water level as to secure an effective discharge. The pump is fixed within the tubing, which forms a cylinder, and it is connected with the engine on the surface, by rods properly guided within the tube. Special pains are taken so to construct and fix the pump, that it may be readily brought to the surface, repaired, and replaced. For the first 15 or 20 feet of the well, a shaft 5 or 6 feet in diameter is necessary, in which to fix the necessary gearing connecting the engine with the pump, and to place the air vessel, &c., regulating the lifted supply to the reservoir. It would appear from figures, supplied me by Messrs. Tilley, of Walbrook, for works which we have now in hand, that the primary outlay varies from £500 in a case where the lift is 100 feet, the supply 40 gallons per minute, the depth of the bore-hole 300 feet and its size 7 inches, to £750 where the lift is upwards of 250 feet, the supply 50 gallons per minute, the depth of the bore-hole over 300 feet, and its size 9 inches.

Besides tubular wells sunk perpendicularly into subterranean water, supplies may not infrequently be obtained by the use of syphons for drawing water out of water-yielding basins, to which there is no natural outlet, by deflected pipes laid over or through the rims of the basins. The extraction of the required supply is effected by dipping the shorter leg of the syphon into the water bed forming a ready-made reservoir, and carrying the larger leg into the village requiring the supply, to act, with proper appliances, as a service main. This automatic mode of raising and delivering water has already been found available for towns as well as villages.

In the cases of Abingdon and Warwick, a syphon arrangement has been found very beneficial. The firm to which I belong, when devising the water supply for the former town (under the immediate supervision of Mr. C. F. Gower), adopted this expedient for raising the necessary supply for a population of over 6,000, which we had intended to obtain from a direct adit driven into the bed of coral rag, or calcareous grit, outcropping between Boars Hill and Abingdon; but which we abandoned in favour of a suggestion from Mr. J. Thornhill Harrison, of the Local Government Board, who, at an inquiry held by him, pointed out that the water bed which we were making preparations to tap might be considered a natural reservoir, from which the required supply could be raised by means of a syphon passing over the bank impounding the water. This object was effected by means of a 9 in. pipe capable of discharging 330 gallons a minute, laid from a reservoir holding 125,000 gallons (which it was found necessary to make within the calcareous grit for storage and ready discharge), the bottom of which was 40 feet higher than the highest part of

Abingdon. The shorter leg of the syphon is about 9 feet in length, and reaches very nearly to the bottom of the reservoir. When the water, finding its way out of the calcareous grit into the reservoir, rises above the crown of the syphon (which it generally does during the night), the discharge is by gravitation independently of the syphon; but when it sinks below that level, then the syphon action is called into play. This arrangement has been in existence at Abingdon for four years, without any hitch or difficulty of any kind.

At Warwick, Mr. Edward Pritchard, C.E., adopted a somewhat similar contrivance, whereby he effected a very great saving in the cost of the works. It has now been in operation for more than eight years, and is stated by Mr. Pritchard to work satisfactorily. Syphons, whilst working automatically, involve very little outlay in maintenance, and they would be adopted much more frequently than they are at present, if their special nature and advantages were more fully understood. They have been used with great advantage for the drainage of land and for the lowering of water standing in bogs. I may mention, as an illustration, that in Scotland the Earl of Stair drained by this means a wet marsh near Culhorn-house, which had rendered that residence unhealthy. The syphon-pipe (seven inches in diameter) was half a mile long, and it has drawn down the water nine feet.

There is yet another means of obtaining water for villages, which it would be wrong to exclude from the consideration of sanitary authorities, as in some instances, we know from experience already gained, that it can be resorted to with advantage; I refer to the use of waters from cultivated surfaces, which the Rivers Pollution Commissioners have designated "suspicious" waters. To raise them above suspicion they should be collected and filtered through a bed of natural soil, extending to about one pole (of superficial area) per head of population. By this means the water would be made very superior to that consumed by the majority of householders in rural districts. The preparation of filter-beds of natural soil is simple enough. A plot of land, as porous and free in its subsoil as can be obtained, should be selected, and made suitable by special treatment, at such an elevation relatively to the land from which the water would be obtained, and to the village which it is intended to serve, as will receive the off-flow from the former on its surface, and allow it, after it has passed through the filter, to collect in a storage reservoir, and thence to reach the village at a serviceable height. The filter itself should be deeply underdrained, and the water to be filtered through it evenly distributed over its surface. No manure whatever should be applied to it.

The water of underdrainage, when found to contain ingredients of an objectionable character, which the analyses of Professor Way have shown may be the case, can be rendered perfectly unobjectionable by a second filtration through a plot of prepared soil, rigidly preserved from the application of manure.

When we are taught by chemists to believe that the extraordinary purifying powers of aërated soil will render innocuous the discharged sewage of towns in which exists organic nitrogen in considerable amount, we must be satisfied that, by a second passage through natural soil, the water of underdrainage, already once filtered, may be freed from any putrescible ingredients it may have once contained.

This expedient is only suggested where a village being in the neighbourhood of an estate which the owner has underdrained, such owner will allow the water to be diverted from a natural stream, and filtered before it is supplied for domestic use.

I will close this short paper by drawing the attention of sanitary authorities in rural districts to the "Reservoirs Act, 1877," by which powers are given to the owners of land to supply water "to any sanitary or other local authority" by contract, and to charge their estates with the outlay on works.

WATER SUPPLY.

By Edward Easton, M.Inst.C.E.

The object of this paper is to put before the Conference, in as concise a form as possible, the considerations which should govern the supply of water for domestic and other purposes, not with the intention of enunciating any new thing, but with the hope of drawing attention to well-recognised principles, which are too often forgotten or neglected.

The three chief points which have to be considered in relation to this subject are:—

1. The source of the water,
2. Its distribution.
3. The conditions under which it is used.

1. With regard to the source, it is evident

that, in designing a waterworks, the engineer has to provide that the water shall be adapted to the purposes for which it is intended to be used, both as regards quality and quantity.

The question of quality will depend upon circumstances. It is essential, of course, that in every case the water shall be free from contamination by organic and other impurities; but the necessity of its being chemically free from other constituents will depend, to some extent, upon the purpose for which it will be used; for instance, in a manufacturing district, where the water is required for dyeing and such-like purposes, it must be free from certain mineral ingredients, whereas for the supply of drinking water and for general purposes, this is a qualification which need not be insisted on.

It is now generally admitted that a soft water is preferable to a hard water, provided that the storage amd distribution are properly carried out, and in every case where there is a choice of supplies, that which is soft, or which can be softened by simple means, should be chosen.

The process invented by Professor Clark for softening hard water by the deposition of a portion of the lime, is of a very simple character, and it has been successfully adopted in many cases.

Sources of water proper for use may be classed under two distinct heads. 1st. Those which are afforded by nature in a state absolutely pure and fit for use, such as water drawn from wells and deep-seated springs. 2nd. Those derived from water-courses or gathering grounds which are open to the atmosphere, and which must necessarily be exposed to the risk of contamination from external agencies.

In the case of the former, no works for storage or purification are necessary, the stratum of rock or other material from which the water springs, forming a natural reservoir and filter.

In the second case, it is necessary (*a*) that all direct pollutions shall be prevented from coming into the source; and (*b*) that in almost every instance, efficient means of filtration should be provided. The filtration ought, wherever it is found impossible to altogether prevent the chance of contamination, to include the use of some deodorising agent, of which there exist more than one capable of practical application.

As instances may be mentioned the filtration at Wakefield, where, for many years, by the use of Spencer's magnetic carbide of iron, a water very much contaminated was rendered perfectly wholesome; and that at Antwerp, where Professor Bischof's spongy iron is employed with an equally good result.

2. Essential as it is to ensure that the source of supply is proper for the required purposes, it is equally essential that the mode of distribution shall be such as shall prevent its deterioration before being used.

To effect this, it is absolutely necessary that the reservoirs, into which the water is collected for distribution, should be covered, and that the mains and pipes should be perfectly air-tight, and laid at a proper depth below the surface, so as to preserve the water in its original state of purity, and, as much as possible, at the same temperature, during its passage from the source to the consumer.

One great cause of the complaints of the quality of the water in most large towns, is the use of cisterns for storing it in the houses, which it is impossible to employ without the risk of some injurious effect upon the water.

In the Session 1877-8, two Bills were introduced into Parliament, at the instance of the Metropolitan Board of Works, for purchasing the undertakings of the London water companies, and for providing a separate supply of drinking water from the chalk. During the exhaustive examination of the waters supplied by the companies, made by the eminent gentleman who so fitly and ably occupies the chair, Sir Frederick Abel, assisted by Dr. Dupré, Mr. G. H. Ogston, Professor Voelcker, and the late able chemist of the Metropolitan Board, Mr. Keates, it was found that, whilst the water delivered in the mains was in almost every case excellent, the position and condition of the cisterns too frequently rendered it utterly unfit for human consumption. A great number of cistern deposits from all quarters of London were examined by these five gentlemen, with the general result just stated.

It is scarcely credible that the favourite place for fixing the cistern from which the water for drinking and culinary purposes is drawn is immediately over the water-closet or next to the dust-hole, whilst even in the better class of houses, where the cisterns are fixed in the roofs, they are very rarely sufficiently covered, and are open to contamination from soot, dust, inroads of black beetles, and other abominations. The latest researches of scientific men show that there is no more fruitful source of disease than such a condition of things affords. Although, doubtless, a great deal has been done by the expansion of the system of constant service in London and elsewhere to remedy this frightful evil, the following extract from Sir F. Bolton's report for the month of May shows that there is still much room for improvement. He says:—

"In the monthly and annual reports on the metropolitan water supply, attention is drawn to the necessity which exists for a regular cleansing of cisterns, and also to the fact that contamination of water from gases generated by sewage is of far more frequent occurrence than is generally understood. Waste pipes from cisterns are still to be found which are in direct communication with drains, so that gases may flow back into the cistern and become absorbed by the water. To prevent this an overflow pipe should be brought outside each house and the end left exposed to the air, instead of being carried into a drain, as is often the case. By the adoption of this plan poisonous effluvia and gases from drains will be got rid of, which would otherwise ascend through the pipe, and not only be partly absorbed by water in cisterns, but be mixed with the air in the houses, thereby becoming a cause of disease.

"The attention of consumers has been drawn to the fact that, in houses supplied on the constant system, all danger of drinking stale or contaminated water from cisterns may readily be avoided if the following recommendation is carried into practice, viz., to attach a small draw-off tap to the communication pipe which supplies the cistern from the main in the street, from which water may be drawn at any moment, day or night, direct from the works, thereby taking full advantage of any efforts made by the companies to purify the water to the utmost extent. This water should be used for drinking and cooking, and the contents of cisterns made use of for washing, flushing, baths, and similar purposes."

An abstract from these reports of the water examiner is printed by the companies at the back of the collectors' rate papers, so that no consumer of water can now be exonerated from the charge of negligence if this abuse is allowed to continue in his house.

3. This consideration naturally leads up to the third division of the subject, viz., the conditions under which water should be used. And first it is essential that a constant supply should be given, without which it is difficult to avoid the deterioration of the water above alluded to.

Not only is it impossible to give an adequate supply by the intermittent system without having storage cisterns in the houses, but there is also a serious danger of contamination by the possible admission of foul air or gas into the mains when the water is turned off. There have been several instances of a water supply being seriously affected from this cause.

But to give constant service it is absolutely necessary also that the supply should be under proper regulations, which shall ensure the prevention of undue consumption and misuse of the water.

Not only are the difficulties of providing the supply greatly increased where waste is allowed to prevail, but the cost to the community is augmented without the slightest corresponding benefit to health.

Nothing is more fallacious than the idea, prevalent among a large section of consumers of water, that the allowing of taps and water-closets to run to waste assists in the flushing and cleansing of the sewers, and therefore conduces to health. These continuous dribblings of water can have no effect whatever in removing any obstructions or accumulations which may exist in the large drains. The only proper and effectual way of removing fœcal matter is so to regulate the use of water that it shall be proportionate to the work it has to do at the moment. Where this is done, by the use of properly constructed water-closets, well-proportioned drains, and by keeping out from the system of sewers the rainfall on the streets and houses, the ordinary quantity supplied to a town is quite sufficient to perform this service without having recourse to extraordinary means. The question of dealing with the sewage of large communities, which is now so full of difficulty, would be much more easy of solution if these principles were more generally acted upon.

For these reasons, it is not desirable that the supply should be unlimited in quantity; on the contrary, every precaution should be taken to make that quantity commensurate with the real wants of the consumers.

It is quite certain that in almost every town a very large proportion of the water delivered through the mains runs needlessly to waste.

To take an example on the largest scale, the quantity supplied to London, according to Colonel Sir F. Bolton's return for the month of May, amounts to 32 gals. per head per day, about 20 per cent. of which, or say 6 gals., it is estimated is used for other than domestic purposes, leaving 26 gals. per head as the quantity supposed to be absolutely consumed in the houses. Now it has been ascertained that, on the average, the water really required is not half this quantity; and there is also no doubt that, by taking proper precautions, the amount delivered can be made to approximate very nearly to the actual use.

At Liverpool, by means of careful inspection of fittings, aided by the use of Deacon's meter, a most ingenious arrangement, by which it is easy to localise, and therefore detect, waste, the consumption of water has been reduced from 33 to 22 gallons per head per day, and, within my own experience, the adoption of the same system has, in six or seven instances, produced even more satisfactory results.

The waste of water, whether it arises from leaky joints in the mains and service pipes, or from defective fittings inside the houses, can only be injurious to health from the increased humidity which is thereby imparted to the soil and atmosphere, and which, as is well known, contributes so much to the spread of infectious diseases and the establishment of epidemics.

At this moment, when we are suffering to a greater extent than usual from the contamination of the Thames, owing partly to the presence of a large quantity of sewage, but also to the abstraction of so large a proportion of the summer flow of the river, it is manifest that the reduction by 33 per cent. of the amount drawn from and discharged into the river would go far to ameliorate the condition of things now complained of.

Among the different proposals which have been made for the introduction of a system which would ensure the prevention of waste, is that of furnishing the supply by meter. This is open to the grave objection that, in order to save money, people would be tempted to go to the other extreme, and to content themselves with an insufficient quantity. To obviate this, some such arrangement as that proposed by the writer to the Select Committee of the House of Commons, over which Mr. Ayrton presided in 1867, might be effectual. The following extract from the evidence given before that committee will explain the proposal :—

"I think a better method altogether might be devised of supplying the houses in London with water—a better system might be adopted to prevent waste. I should provide a constant service by meter, but under different conditions to any hitherto proposed. I think it could be designed with perfect fairness to the water companies and to the consumers, by making certain arrangements, and the general principle upon which I would propose that that should be done would be this: that there should be a sliding scale adapted to the class of house, each house should have a certain amount of water allotted to it. I would take a £100 house, and allot to it 150 gallons per day, and to a £200 house I would allot 300 gallons of water per day, and so on, upwards and downwards, provided that no house should have less than 50 gallons. Let the companies charge the same rate as they do now for that minimum quantity of water, and if more is consumed or passes through the meter the consumer would have to pay for that additional quantity."

Although at first sight the expense of the meters would appear to be prohibitive, both the consumer and supplier would soon be reconciled to the outlay, the one because he would know what he was paying in proportion to the water he received, and the other because they were only supplying water for which they were paid.

The consideration of the subject of this paper would not be complete without a reference to the important question of the conservancy of our rivers.

It is useless to discuss the method and conditions of supply, if the sources of water are not to be preserved to us, and it is quite certain that, with the immense growth of the population of this kingdom, it will not be long before this preservation becomes a pressing necessity.

In the report presented to Parliament by the Duke of Richmond's Select Committee on Conservancy Boards, in 1877, a very workable scheme was recommended by their Lordships. The Commitee say that :—

"In order to secure uniformity and completeness of action, each catchment area should, as a general rule, be placed under a single body of Conservators, who should be responsible for maintaining the river, from its source to its outfall, in an efficient state. With regard, however, to tributary streams, the care of these might be entrusted to district committees, acting under the general directions of the conservators; but near the point of junction with the principal stream they should be under the direct management of the conservators of the main channel, who should be a representative body, constituted of residents and owners of property within the whole area of the watershed."

But although the question of improving the water supply, by preventing the pollution of the rivers, was incidentally mentioned by their Lordships, it is evident that the main object of the report was the prevention of floods, and not the conservancy of water for the supply of populations. Now, it may well be said that the one subject is at least as important as the other, and just as the recurrence of a number of wet seasons at that time brought the question of the floods prominently before the Duke of Richmond's Committee, it may safely be asserted that a corresponding succession of dry seasons will compel the serious attention of the Government to the other part of the subject. We need go no further than our metropolis for the proof of this, for if, in addition to the saving of water by the prevention of waste, the flow of the Thames were properly regulated by works in the higher parts of its watershed, there is no reason why the river should not be in a condition which, although leaving very much to be desired in the way of improvement, would yet be tolerable, and, according to past experience, absolutely not injurious to health.

When presiding over the Mechanical Section of the meeting of the British Association, at Dublin, in 1878, on which occasion the opportunity was taken to very fully discuss, from a variety of aspects, this question of rivers conservancy, I made a suggestion which, I believe, is worth repeating at the peesent time. In my address to the Section it was stated :—

"When it is considered that many lives are annually sacrificed, either directly by the action of floods, or by the indirect but no less fatal influence of imperfect drainage,—when it is remembered that a heavy flood, such as that of last year, or that of the summer of 1875, entails a monetary loss of several millions sterling in the three kingdoms; that during every year a quantity of water flows to waste, representing an available motive power worth certainly not less than some hundreds of thousands of pounds; that there is a constant annual expenditure of enormous amount for removing *debris* from navigable channels, the accumulation of which could be mainly if not entirely prevented; that the supply of food to our rapidly growing population, dependent as it is at present upon sources outside the country, would be enormously increased by an adequate protection of the fisheries; that the same supply would be further greatly increased by the extra production of the land, when increased facilities for drainage are afforded; that, above all, the problem of our national water supply, to which public attention has of late been drawn by H.R.H. the Prince of Wales, requires for its solution investigations of the widest possible nature, I believe it will be allowed that the question, as a whole, of the management of rivers is of sufficient importance to make it worthy of being dealt with by new laws to be framed in its exclusive behalf.

"A new department should be created—one not only endowed with powers analogous to those of the Local Government Board, but charged with the duty of collecting and digesting for use all the facts and knowledge necessary for a due comprehension and satisfactory dealing with every river-basin or watershed area in the United Kingdom—a department which should be presided over, if not by a Cabinet Minister, at all events by a member of the Government who can be appealed to in Parliament."

It is earnestly to be hoped that no further time will be lost in passing an Act to deal with this subject, and that no considerations of a party or private nature will be allowed to prevent a scheme of so important and imperial a character being made as complete and comprehensive as possible.

In conclusion, as I commenced by saying, I have not attempted to say anything new; indeed the subject has already been in the hands of far abler exponents than myself; especially would I refer to Dr. Frankland's very able and comprehensive Sixth Report of the Rivers Pollution Commission, the careful study of which is recommended to everybody who wishes to master the details of the question.

SOURCES OF WATER SUPPLY.

By James Mansergh,
M.Inst.C.E., and M.E., F.G.S., F.M.S.

It used to be a popular belief that if a well were sunk at any place to a sufficient depth into the ground, there would be reached an inexhaustible reservoir of water, a store that had been filled in some mysterious manner at the creation of the world, and would suffice for the use of man for all time.

It is now well known that all supplies of water, whether found upon the surface, or below it, in underground depths, are derived from the rain which falls upon the earth, and that it depends upon the geological character of the surface receiving the rain whether it shall run off in the form of streams and rivers, or soak in and be apparently lost.

Rain is produced from the evaporation of invisible aqueous vapour, principally from the ocean, by means of solar heat, its condensation, primarily into the shape of clouds, and subsequently into the form of drops, which fall to the ground.

The sea is thus a storage reservoir of boundless capacity, and the sun is the great prime mover which pumps the water up from this reservoir, distributes it over the land, and lifts it to the hills, where it may be impounded in natural or artificial lakes, and thence delivered by gravitation to the plains below.

After being discharged on the earth in the shape of rain or snow, a part of the water is re-evaporated, but the greater part begins at once to travel downwards, either over the surface, in the form of rills and streams, and so on to the ocean whence it came, or through the surface, if this is permeable, into fissured or porous rocks below.

A portion of this latter water passing into the ground at high levels, has several courses open to it. It may appear in the shape of springs at lower levels, or rise in the beds of rivers, or run out through fissures on to the sea beach, or sink below sea level, whence it will be recoverable only by artificial means.

Nature has in this way provided water from one great source in ample quantity for the use of man, but works of varying character, under differing local circumstances, must be constructed to store and utilise it.

Altitude and the geological structure of a district are the two principal factors which determine what the source of water supply must be in such district. The two great classes into which sources may be divided are (*a*) above-ground and (*b*) underground sources.

The former (*a*) has several subdivisions, which may be described as follows :—

1. Water may be taken from the heads of streams by laying pipes right up to the springs, to convey it away for supply without any intermediate storage, as in the case of Lancaster. This is a source which in some sense belongs to the two classes, for the water is taken just as it ceases to be underground water, and is being delivered on to the surface above ground.

2. It may be obtained from a natural lake like Loch Katrine, as in the case of Glasgow.

3. It may be collected from a high-lying watershed area, by impounding a number of small streams in artificially constructed reservoirs, as is done for the supply of Manchester.

4. It may be taken from a large river flowing past a town, as is done in the case of the Thames and Lea for the supply of London.

The second class (*b*) is not divisible in the same way as (*a*), but may be taken a sembracing supplies of water obtained from many varieties of geological stratification, such as chalk, oolites, coal measures, millstone grit, magnesian limestone, Bagshot sands, and many others.

All water, when discharged upon the earth as snow or rain, is practically pure, but its character is very soon changed by the material it comes in contact with on the surface, or in passing through underground fissures and channels. Take, for example, the rain which falls upon the chalk downs of Sussex or any other similar geological area. It sinks at once beneath the smooth and rounded surface, and percolates through innumerable minute cracks or larger fissures, dissolving away the chalk which it touches, and finally issues naturally in springs along the coast, or is pumped out artificially, a water which contains from fifteen to twenty-five grains per gallon of carbonate of lime.

Such an alteration in character depends of course upon the nature of the rocks which the water traverses, some rocks being easily soluble, others not.

The taking up of lime or magnesia in this way has the effect of rendering the water "hard," that is, increasing its soap-destroying properties. For many manufacturing processes this is a most undesirable quality, and we therefore find that many of the important industries of the country are located in districts where soft water is easily procurable.

The following are the formations which yield as a rule soft water:—Igneous, metamorphic, cambrian, silurian (non-calcareous), Devonian (non-calcareous), millstone grit, coal measures (non-calcareous), lower greensand, London and Oxford clay, Bagshot sands, non-calcareous gravels.

On the other hand the following geological formations almost invariably yield hard water:—Silurian (calcareous), Devonian (calcareous), mountain limestone, coal measures (calcareous), new red sandstone, conglomerate sandstone, lias, oolites, upper greensand, chalk.

The manufacturing towns of Lancashire and Yorkshire obtain their supplies from sources which, even if the water had passed underground, would leave it comparatively soft, but this quality is fully secured by the character of the works, which consist of large reservoirs impounding the water which has principally run merely over the surface. For dietetic purposes, the quality of hardness, if not excessive, that is if it does not exceed twelve grains on Dr. Clark's scale (equivalent to twelve grains of bi-carbonate of lime per gallon), is not considered objectionable on physiological grounds. For ordinary domestic purposes, and especially for personal washing and cleaning generally, soft water is infinitely preferable to hard, both in respect of comfort, efficiency, and economy.

Taking into account all the purposes for which water is used, it can hardly be questioned that a pure soft water supply is on the whole preferable to a pure hard water supply. The term "pure" is here used to imply the absence from the water of organic impurities as distinguished from the dissolved inorganic matters which have before been referred to. Except as producing hardness, the inorganic matters usually found in water are practically harmless; but organic pollutions may be of the most disgusting and dangerous character, those for instance which are the result of contamination with town sewage or cesspool manure.

It is to avoid the risk of such pollution that many towns have in great measure been led to seek their sources of supply on elevated moorlands, above the level, at which arable cultivation is carried on, and where it follows that there are no towns or villages, and the scattered population is very sparse. In this country the plough is rarely seen above the 800 ft. contour, and as it will not pay to cart manure to such an elevation; these high lands are merely used for the pasturage of sheep and the rearing of grouse.

Water obtained from such sources is practically, therefore, in the condition in which it falls from the clouds as snow or rain. The only impurity it may contain is a little organic matter derived from passing over the peaty soil, which often occurs on high moor-lands, especially where the summits are broad and comparatively flat. This contact with peat, and with growing heather, gives a stain to the water to such an extent that, when seen in deep reservoirs, it looks like dark coffee.

As seen in an ordinary white glass bottle or tumbler, the tinge is rarely deeper than a very faint straw colour. There is nothing harmful in this colouring matter, because it is of purely vegetable origin, and to some extent it may be removed by storage in open reservoirs, or running in open channels exposed to the air.

Many towns are so located in this country that it is practically impossible that they should obtain pure water supplies from elevated watersheds, on account of the enormous expense that would be entailed in the construction of the necessary works. Such places must be content to be supplied from rivers in their immediate neighbourhoods, and which, having run their courses through many miles of highly manured lands and past thickly populated towns and villages, contain water which has necessarily become polluted by the washings from the lands and the sewage from the towns. Such sources as these would be inadmissible, but for the great rehabilitating process which nature silently carries on in a river, and to which chemists apply the term "oxidation." In this wonderful process, the polluting organic matters which the water contains are converted by the agency of oxygen into harmless inorganic salts, and the water again becomes fit for the use of man.

This statement must, however, not be made without some reservation and explanation, because chemists of the very highest standing are not agreed as to the extent to which rehabilitation of the water is carried. This has, in fact, become quite a burning question, and the battle has been fought long and frequently over the water which is taken from the Thames, and delivered for consumption by the inhabitants of London.

The difference of opinion is now narrowed down into a small compass, and to outsiders it would appear that there is a chance, sooner or later, an agreement may be come to between the authorities.

As representatives of the two sides may be named Dr. Frankland and Dr. Meymott Tidy. Dr. Frankland admits that oxidation is effective in burning up, or converting into a harmless condition, even such vile contaminations as human sewage, if this is in a normal or healthy condition; but he contends that the virulent zymotic diseases are propagated by organised germs contained in the sewage which are indestructible, and which may travel scores of miles in a running stream without being deprived of their fatal potency.

Dr. Tidy contends, on the other hand, that there is no evidence of the existence of these animated germs, and affirms that a run of a few miles in a river fully oxygenated, and in which the pure water bears a sufficiently high ratio to the polluting matter, will suffice to render such water again fit for human consumption.

Dr. Frankland's theory is naturally a disquieting one; and his opponents certainly have facts in their favour, for London is undoubtedly one of the healthiest cities in the world, and its inhabitants have never been known to suffer from disease induced in the way suggested.

The "germ" theory is, however, making steady advances under the investigations and researches of competent men, and it is to be hoped and expected that if the historic germ is at last discovered, and exhibited to the incredulous gaze of Dr. Meymott Tidy, he, or some of his *confrères*, may speedily discover a method of scotching it before it has time to do any mischief.

It may now be convenient to describe shortly a few typical examples of the utilisation of the different sources of supply which have been thus generally referred to.

I. Take, first, such a case as that of Lancaster, whose works supply a population of between 30,000 and 40,000. The town is situated on the River Lune, about seven miles above its junction with Morecambe Bay, and is built upon a site which, rising from the river, varies in elevation from 15 to 200 feet above Ordnance datum, or mean tide level. The water is obtained from the high moorlands of Wyresdale, at a distance of eight or ten miles from the town, in a south-easterly direction. These fells, as they are locally called, constitute the extreme north-easterly portion of the watershed of the River Wyre, a small river which also falls into Morecambe Bay near the town of Fleetwood. That portion of the fells which is secured by Act of Parliament as a source of water supply for Lancaster, has an area of 2,700 acres, and an altitude varying from 850 to 1,800 feet above the sea.

The geological formation of the gathering ground is millstone grit, covered with scant herbage suitable for sheep pasturage, and heather. Interstratified with the beds of permeable grit stone there are layers of impervious shale which, at various levels, throw out the water percolating downwards from the surface, in the shape of springs, and a number of these springs have been intercepted by small pipes communicating with mains laid along the hill side, and leading their combined waters to the south-west corner of the reserved area.

One of these mains forms part of the original works constructed under the superintendence of Sir Robert Rawlinson, C.E., C.B., in the year 1852; the other, which runs (broadly speaking) parallel to the first, but about 200 feet lower down the hill side, was laid six years ago, as part of an extention earried out by the writer.

The water derived from these is of necessity of the purest possible character, for the rain which feeds the springs falls upon the clean open moor-land, and sinks at once into the millstone grit rock, in which it finds nothing to dissolve and cause hardness, and nothing to organically pollute.

The water issues from the springs in a bright sparkling condition, at a constant temperature of about 45° F.; it contains only one grain in 15,500 of solid matter, and its hardness is under 1° on Clark's scale.

This may be fairly regarded as an ideally perfect source of supply, and it has been an inestimable boon to the inhabitants, especially as it replaced water obtained from shallow wells in the town, polluted in the vilest possible manner by percolation from numberless foul and reeking privy pits and middens.

Between the fells and the service reservoir, which is situated on the town moor 240 feet above Ordnance datum, the country is intersected by several valleys, across which the water is conveyed in iron pipes.

At two intermediate points the pressure is broken by small covered tanks, and the water is never exposed to the open air from the time it sinks into the ground as rain or snow, and is drawn from the consumers' taps in the town.

Perhaps it may be as well to explain here that, when water is obtained from elevated watershed areas of this character, Parliament almost invariably insists upon "compensation" being made to the river for such abstraction. This compensation is secured by the construction of reservoirs somewhere upon the main river or its tributaries, in which water is stored in time of flood, and given out in a constant stream in times of dry weather, the assumption being that floods are utterly useless, if not damaging, to riparian owners and mill owners, whilst it is of advantage to every interest to have the dry weather flow increased in volume.

Thus, in the Lancaster case, whilst the Corporation have the right to take 2,000,000 gallons a day from the springs for the use of the town, they were put under the obligation to construct upon the River Wyre a reservoir capable of holding 185,000,000 of gallons, from which the millowners have the right to draw water according to their needs during the summer months. By means of such works, all the parties concerned are very greatly benefited.

II. The second type of utilisation of sources which may be referred to, is that which is exemplified on so magnificent a scale in the works supplying Glasgow, and constructed from the designs and under the superintendence of Mr. John Frederick Bateman, C.E.

In this case, advantage is taken of three natural lakes, viz., Loch Katrine, Loch Venachar, and Loch Drunkie. The watershed area draining into these lakes is 45,800 acres in extent, and consists of unpolluted sparsely populated moor-lands, the geological formation being of silurian age.

Loch Katrine has a water surface of 3,000 acres, Loch Venachar 900 acres, and Loch Drunkie 150 acres. They are all of course supplied by the rain which falls upon the 45,800 acres, and as a considerable proportion of this area is of a peaty character, the streams which run down the mountain sides are frequently as dark as London porter. By the deposit of the heavier parts of the peaty matter, and the bleaching action of the air, the water is drawn from Loch Katrine with only a faint tinge of colour.

The two smaller lakes are utilised as compensation reservoirs, the artificial storage necessary being obtained by raising the original normal level of Loch Venachar 5 feet 8 inches with power to draw it down 6 feet, and by raising Loch Drunkie 20 feet, the raising in both cases being done by masonry dams across the outlet valleys, furnished with draw-off sluices.

The storage for the supply of Glasgow is obtained by works which raised the normal level of Loch Katrine 4 feet and admit of drawing down 3 feet. Its capacity is, therefore, 3,000 acres of area, by 7 feet in depth, equivalent to nearly 1,000 million cubic feet, and competent to furnish 50 million gallons a day during a four months' drought.

The water surface in Loch Katrine is 360 feet above mean tide level at Glasgow. The conduit conveying the water to the City commences on the south side of the lake, about three miles from its western extremity, and runs generally in a southerly or south-westerly direction. At 26 miles from the Loch it discharges into an artificial reservoir of 70 acres in extent, and holding 500 million gallons near Mugdock Castle, the top water of this reservoir being 311 feet above mean tide at Glasgow. Two lines of three feet cast-iron pipes, one seven miles long and the other eight miles, convey the water to the city.

For thirteen miles out of the 26, between Loch Katrine and Mugdock, the conduit is formed by tunnelling through very hard rock, such as whinstone, gneiss, and mica slate; the tunnels being seventy in number, nine miles of the remaining length is "cut and cover" work, and the rest consists of cast-iron or wrought-iron pipes across valleys.

The advantage of such a source of supply as Glasgow's is the facility and small cost with which the storage capacity necessary to furnish the requisite daily quantity for consumption and compensation is obtained.

In Loch Katrine, the narrow outlet from the lake had only to be dammed up four feet, requiring artificial works of the simplest character, entailing no risk or contingency in their execution. Having a flat area 3,000 acres in extent to begin with, a simple plank one foot high would have sufficed to impound 816,000,000 gallons. The desirability of securing such a reservoir site as this can only be fully appreciated by those who have had the responsibility and anxiety of forming large storage reservoirs, by the construction of high embankments across valleys. The relative amounts of labour and outlay in such reservoirs, and in cases like Loch Katrine, will be better realised in considering the next type.

III. The third type of works for the utilisation of mountain watershed sources of supply is well examplified in the Longdendale valley, where a number of reservoirs have, during the last thirty years, been constructed for the supply of Manchester. Here, instead of having a level plain 3,000 acres in extent as in Loch Katrine, upon which to commence as the bottom of a reservoir, was a valley with a fall along the bed of its main stream—the Etherow —of between 60 ft. and 70 ft. in a mile. Across this valley five embankments have been constructed of earthwork, one above another, forming five lakes with a combined water surface area of 462 acres. Beginning from the lowest part of the valley, the following is a list of the reservoirs, viz.:—

	Height of Bank. Feet.	Water area. Acres.	Capacity. Gallons.
Bottoms	66	50	407,000,000
Vale House	55	63	343,000,000
Rhodes Wood	75	54	500,000,000
Torside	100	160	1,474,000,000
Woodhead	80	135	1,181,000,000
Total	376	462	3,905,000,000

These embankments, which cost something like £100,000 apiece, have an aggregate height if placed one above another of 376 feet, and the quantity of water they impound is 3,905 million gallons. The raising of the water surface of Loch Katrine 5 feet would create the same amount of storage. The watershed area supplying these reservoirs is 9,300 acres, and the geological formation is millstone grit. The gathering ground is a portion of the western slope of the "backbone" of England, otherwise the Pennine range, upon which, over its whole length on both sides, many similar works are located for the supply of the manufacturing towns of Lancashire and Yorkshire. The rocks in this district are very much fissured and broken, and the rain falling upon the higher grounds percolates below the surface and re-appears as springs at lower levels. Advantage is taken of this by conducting the spring water along special channels into the Rhodes Wood reservoir, from which the supply is taken by a conduit to the town.

Although the quantity of water yielded by the whole gathering ground is that due solely to its area and the rainfall upon it, the fact of there being these springs renders it more valuable, because it implies that water which would have run off a district composed of harder and less pervious rocks, is here absorbed into the mass which thus acts as so much storage or reservoir space. The effect of this is to increase the dry weather flow of the streams, and to furnish water which is clear, cool, and colourless. The average annual rainfall upon the 19,300 acres is about 50 inches, and the works utilising this area are competent to provide 38,000,000 of gallons per day, of which 13,500,000 have to be delivered into the stream below the reservoirs as compensation water. Besides the five reservoirs above-named, there are other large impounding and service reservoirs at Godley, Denton, Gorton, and Prestwich. In the construction of these works enormous difficulties have been encountered, and at Woodhead, the highest reservoir of the series, the embankment, as at first made, was not watertight, so that a second trench had to be put down in which to build the puddle wall, and so much were the measures disturbed and distorted, that on the south side of the valley this trench had to be excavated to 167 feet below the surface of the ground, before sound and tight material was reached upon which the wall could be based.

The three types of works thus described may fairly be said to exhaust the methods of obtaining water from sources situated on elevated mountain gathering grounds. They are good examples of the gravitation system of supply, by which water is delivered at high pressure above the highest parts of the towns without any artificial pumping being required, the sun having done this work in the process of evaporation.

IV. We will now consider a case where the town to be supplied is at such a distance from high ground that the cost of bringing it through conduits or pipes by gravitation is prohibitive.

Take a town built along the banks of a river anywhere above the range of the tide. If this river flows through an agricultural district, and is thus not polluted by manufacturing refuse, and not seriously by either manure or sewage, it may be adopted as the source of supply. In this case the water will have to be lifted by artificial means to such an elevation as is necessary to command the whole town.

The water will also require filtration, because in running its course through the country the river receives the washing from the land; and in times of heavy rain, at all events, the water will be discoloured and turbid through the presence of suspended matters.

The works for the supply of London are in great part of this character, the Rivers Thames and Lea being the two sources.

Three hundred years ago, water was obtained from the Thames at London-bridge, and pumped by means of a water-wheel under one of the arches through wooden pipes into the streets and houses in the neighbourhood. These works were continued in operation for 200 years, and were supplemented early in the 17th century by other pumping stations, taking water from the Thames at Charing-cross, Battersea, Vauxhall, and Hammersmith, all within the range of tidal influence.

In 1848, the Lambeth Water Company obtained powers to go into the non-tidal portion of the river above Teddington Lock, and by the year 1851 they were in a position to deliver water by means of a large steam-pumping establishment erected at Seething Wells.

In 1852, an Act was passed which made it unlawful for any company to supply water taken from the river below Teddington Lock, or from any of its tributaries within the tidal range. This led, finally, to all the companies drawing water from the Thames so rearranging their works as to have their intakes above Moulsey Lock, in order to be above the junction of the River Mole, which frequently brings down very dirty water.

Owing to the changes in the points of intake, the works of the London companies are divided into portions at great distances apart. Thus the Southwark and Vauxhall Company have at Battersea the reservoirs, filter beds, and pumping machinery constructed for the purpose of taking in water from the river at that point. They are well-known to all Londoners by reason of the tall stand-pipes which form a prominent object in the view from the trains running out of Victoria-station.

These works are of so costly and extensive a character, that they could not be abandoned when the source of supply was changed to Hampton, 21 miles higher up the river, but the water abstracted there is pumped down to them through large cast-iron mains, to be filtered and distributed by the original machinery and mains.

In the case of the Lambeth Company, the water is taken from the Thames at Molesey, and sent down to Surbiton, which is the site of the filtering and pumping station, through a large brick conduit, by gravitation.

From these circumstances, none of the London works are good examples of the type now under consideration; but the following description will explain the nature of the works required for the utilisation of such a source as the Thames above London.

First of all, then, provisions must be made to meet the difficulty of the water arriving at the intake in times of flood in a state of great turbidity or muddiness. This is met by the provision of large reservoirs, which are always kept full so long as the water is coming down in good condition, and the inlets into them from the river are closed, and they themselves are drawn upon when the water of the river is turbid.

These reservoirs used to be of smaller capacity than at present, and were worked as subsidence tanks, that is to say, the water (which might be somewhat turbid) was let in at one end and drawn off only from the surface at the other, the suspended matters causing the turbidity subsiding to the bottom during the water's slow passage through the tanks.

In London, since the works of the several companies have come under the official supervision of Sir Francis Bolton, very large sums of money have been spent in increasing the efficiency of these subsiding tanks, by greatly augmenting their capacity, and practically changing their character into that of storage reservoirs.

In some of the works, these reservoirs are constructed at such a level that the water from the river flows into them by gravitation; in others they are elevated above the ground, and the water is pumped into them. In either case it is next delivered on to the filter-beds, the construction of which is shown very clearly in the most interesting pavilion erected in the Health Exhibition by the water companies. These filters consist of reservoirs or tanks made either by excavation in the ground or partial excavation, and partial embanking, as circumstances may dictate, having their sides sloped and pitched, or of vertical brick, stone, or concrete walls. The bottom is formed in many different ways, but it is always furnished with a number of open-jointed or perforated pipes or drains into which the water can pass, and by which it may be conveyed away to a pure-water chamber or pump-well. Upon this floor the filtering material is placed, and consists of clean stones, flints, gravel, shells, and sand, arranged with the largest sized material at the bottom and the finest at the top.

Probably the oldest style of filter shown in the Exhibition is that designed by the late James Simpson, C.E., for the Chelsea Company, and it contains all the materials above-mentioned, and has a total depth of 6 ft. 3 in.

As, however, the really operative and effective portion of the filter is the sand, modern practice is tending in the direction of diminishing the depth of filtering material, and of omitting entirely several of the strata originally used. For instance, the New River Company's engineer exhibits a filter composed solely of 2 ft. of sand, resting upon 6 in. of gravel, the total depth being only 2 ft. 6 in. In working the filters, the water is brought from the storage or subsiding reservoir on to the top of the sand, and stands from 2 to 3 ft. above its surface. It then percolates downwards through the filtering material into the drains below, and is run away to be pumped for distribution.

The speed of filtration may be adjusted by the head under which the filter is worked, that is, the difference in level betwixt top water and the draw-off. In some cases this is only 2 or 3 inches. The speed at which the water should pass vertically downwards through the sand used to be stated as 6 in. per hour, which gave 675 gallons per square yard per day of 24 hours, but the London companies are now not filtering more than 450 to 500 gallons, or from 4 to 4½ in. per hour.

The matter which is arrested by the filters consists principally of finely divided mineral matter washed from the surface of the land, of some vegetable and a trace of animal matter. These impurities are caught almost entirely in the top half-inch of the sand, which in course of time they choke and render impervious. The filter is then put out of use; the water is drawn off, and a skimming of the fouled sand is carefully removed and washed in apparatus which separates the light muddy matter and leaves the clean sand which is again put upon the filter. Of course, the washing process involves some loss of sand, and periodically additions have to be made of new material. After filtration, the water is in a fit condition to be pumped and distributed to the consumers.

Thus far we have been dealing with "above ground" sources of supply, obtained either by gravitation or by artificial pumping, under the four heads numbered—(1) being springs at high elevation, without storage; (2) being surface water from moor-lands drawn from natural lakes; (3) being surface water from similiar watersheds, impounded in artificial reservoirs; (4) being river waters filtered, and artificially pumped for supply.

There are in this country a few examples of hybrid schemes, that is, where water from comparatively low agricultural land is impounded in large reservoirs, and where it has to be subsequently filtered and pumped for distribution in the district. There may also be cases where water collected at a sufficient elevation to supply a town by gravitation has to be filtered before delivery.

We now come to the underground sources of supply, and one or two examples will suffice to explain how these are made available. We need not go far from home to learn all about one of the most important of these underground sources, for it lies under our feet in the chalk forming one great feature of the London basin.

London is actually built upon the tertiary deposits, which consist of Bagshot sands, London clay, and the sands and mottled clays of the lower strata; but underlying all these is a mass of chalk having the southern edge of its outcrop on the north of London about Hatfield, and the northern edge near Royston, and its southern outcrop extending from Croydon to Merstham. On the west the chalk reaches as far as Devizes, and on the north-east to near the coast of Norfolk and Suffolk. Portions of this vast area are no doubt covered by impermeable drifts of varying character, but there is still a very large tract of country upon which the rain which falls sinks below the surface, and goes to charge the great underground chalk reservoir below.

Possibly, the term "reservoir," though a common one, is a little misleading as applied to the chalk, because for water supply purposes, a large proportion of that which percolates into its mass is not recoverable by ordinary means. It is the water which circulates through the cracks and fissures which is really available, and not that which is held in the minute capillaries of the mass. Some chalk will contain 20 per cent. of its own bulk of water, and yet will not yield a drop of this under ordinary conditions.

Of the water which thus sinks into the chalk, a large portion finds its way out again into the bed of the river, another portion appears in the shape of large springs, such as those at Carshalton and Croydon, which go to form the River Wandle, by flowing over the edge of the impervious tertiaries.

Very rarely are there any streams where the chalk itself comes to the surface, but after heavy and continuous rains, streams do appear and flow for a time, and these are known as "bournes." As the chalk is 500 or 600 feet thick, a very large quantity of water is, however, left in it below the level of any of these natural outlets, and this water can be obtained in London by sinking wells through the overlying impervious beds of London clay, and allowing the water to rise, as in an artesian well.

There are a large number of wells in the London basin, and one of the metropolitan water companies, the Kent, obtains its supply exclusively from such wells. The ordinary practice is to sink a well from 5 feet in diameter upwards, and line the same either with brickwork or cast-iron cylinders down to the chalk. This will pass through superficial gravels, blue clay, bands of sand, mottled clay, &c., and sometimes on the top of the chalk a band of flints will be found. Below the bottom of the well a boring is then made from 4 inches up to 15 or 18 inches in diameter, and lined with iron whilst in soft or much broken chalk, and left unlined where the material is more compact.

In those parts of London which are not elevated many feet above the level of the river, the water rises to very near the surface of the ground, and in some cases overflows; but wherever large quantities are required, resort must be had to artificial pumping so as to lower the level of the water in the well, and thus open out a larger cone of exhaustion in the chalk. Favourably situated chalk-wells yield as much as 2,000,000 to 3,000,000 gallons a-day.

In many cases wells and mere borings have been put down right through the chalk to the upper greensand or gault below, and have yielded only a very small quantity of water. This arises from the fact before referred to, that the water circulates freely only in the cracks and fissures, and if some of these are not cut into by the boring, little water is obtained. The most certain way, therefore, of ensuring a supply from the chalk, is by sinking a well down to below the permanent level of saturation, and then driving headings or adits in various directions, for the purpose of reaching some of these fissures. Many of the towns along the south coast of England are supplied by works of this character. It has been found that where the chalk of the South Downs has been undisturbed and is unfaulted, there are large vertical fissures which run, broadly speaking, from north to south, that is, at right angles to the coast. Along these fissures the water travels freely, and has its outlet at the base of the cliffs on the coast, and may be seen running down the beach in many places into the sea.

Parallel to the coast, the water is found to lie with its surface nearly horizontal, because of these permanent outlets, but on lines at right angles to the coast, the surface of the water rises rapidly inland, on a nearly uniform slope, so much so that, at six miles from the coast, it stands more than 200 feet above mean tide level. Advantage has been taken of these conditions at Brighton, and other places similarly situated, to sink wells and drive headings parallel to the coast, at about the level of low water.

At Brighton there are two such stations, one at Lewes-road, on the east, and another at Godstone Bottom on the west. These wells are both about a mile and a quarter from the sea, and headings are driven to a total length east and west, from Lewes-road, of 2,400 feet; and at Godstone Bottom, of 1,300 feet. In the first case, fissures are met with about every 30 feet, but as a rule these are small, and do not yield more than 100 to 150 gallons a minute. In the latter they are further apart, but some of them yield 700 or 800 gallons a minute, or over a million gallons a day. This water, being intercepted by the headings, is led to the respective wells, where, by means of suitable steam machinery, it is pumped up to the several service reservoirs supplying the different zones of the town.

The water so obtained requires no filtration. It is bright and sparkling, but of necessity hard, and although not objectionable for dietetic use, is not well fitted for cooking or cleansing purposes, and would be utterly unsuitable for the manufacturing processes of Lancashire and Yorkshire, though thoroughly well adapted for paper-making.

In addition to the chalk, good supplies of underground water are obtained in the South of England from the Hastings sands and the oolites, and in the north from the new red sandstone, magnesian limestone, and other formations; but in all cases the works required for the utilisation of these sources are very similar, consisting of wells, borings, and adits, with competent pumping machinery.

Comparing very generally "above-ground" supplies by gravitation with "under-ground" supplies involving pumping, there are advantages and disadvantages on both sides which may shortly be summarised as follows:—

"ABOVE-GROUND" GRAVITATION SOURCES.

Advantages.	Disadvantages.
1. No pumping.	1. Distance from place to be supplied.
2. No filtration.	2. Peaty stain.
3. Softness.	3. Costly and somewhat risky impounding reservoirs.
4. Low charges for maintenance.	4. Large works involved to provide water "compensation."

"UNDER-GROUND" PUMPING SOURCES.

Advantages.	Disadvantages.
1. Proximity of source to place to be supplied.	1. Annual charges for pumping.
2. Low first cost.	2. Hardness (generally).
3. Few structural contingencies attending works.	
4. No filtration.	
5. No compensation for abstraction of water.	

Miscellaneous.

HORSE BREEDING IN RUSSIA.

An interesting account is given in Consul-General Stanton's last report of horse breeding in Russia. He says that the horse has played an important *rôle* among the inhabitants of the steppes from the earliest period of the history of the Slavonic breeds. Oley, and succeeding princes, took measures to improve the breeds, and Yaroslaff punished horse stealing by loss of liberty and fortune, but until the middle of the 13th century the Russian Government was lukewarm in the matter of encouraging the breeding or improving their breed of horses. From the time of Ivan III., Government measures became more systematic, imperial studs were established, thoroughbreds purchased, and stallions were lent to boyars and monasteries for breeding purposes. At the present time there are six imperial studs: the Orloff, where English thoroughbreds, trotters, and saddle horses are reared; the Novo-Alexandrofsk, for English half-breds and large horses; the Strelitz, for oriental saddle horses; the Derkulsk, for farm and carriage horses; the Tanoff, for large saddle horses and English half-breds; besides these there was, until 1881, a stud at Orenburg for breeding steppe horses.

There are fifteen covering stations, which are open to all. The stallions are distributed each year from February 15th to June 15th among these stations, and here mares are served by thoroughbred stallions at a fixed rate. In 1881, there were 1,077 stallions at the 15 stations, and 39 stallions were placed at the disposal of the agricultural establishments at separate stations. The imperial studs, after replenishing their stock, dispose of their increase by auction every four years. The thoroughbred Orloff colts are, however, sold each year. In 1880, 555 horses and 15 foals were sold for £11,480; and in 1881, 687 horses realised £10,064. Three thoroughbred English and two Arabian stallions were added in 1880, and eight English thoroughbreds in 1881. The department receives annually about £11,450, to be spent in encouraging private breeding establishments. At present there are eight jockey clubs and twenty-seven trotting establishments. There are 3,430 private studs, with 9,560 stallions and 92,971 mares. Besides these, a large number of horses are bred in herds on the steppes, chiefly in the governments of Semipalitinsk and Akmolinsk. The total number of horses in European Russia, exclusive of Poland, is 17,785,975. In the Caucasus there are about 500,000, in Siberia about 2,500,000, and about the same number in Central Asia. In consequence of the varied elements from which the modern Russian horse has been developed, and the manifold character of the climate, topography, &c., in Russia, the horses are of very different types, viz. :—Mountain horses, to which group belong horses of Oriental extraction, and bred in Caucasia; they are characterised by medium size and great beauty, and on account of their speed and sure footedness they are especially adapted for riding and driving in mountainous districts. Steppe horses, which are the horses of the Don, Calmuck, and Bashkinian races; they are characterised by leanness, great powers of endurance, and a contented disposition. Forest horses; to this group belong the Smudish, Obrimian, Viatkan, and Kasan horses, which are bred in the Northern forest regions. And, finally, horses of the Blackearth districts, which are large and powerful cart horses. Besides these breeds there are also the Polish and Little Russian breeds. Horse dealing is concentrated in the yearly markets, of which there are about 1,090 in European Russia, and the total number of horses sold in these markets averages about 360,000 annually. A considerable sale of horses is also carried out throughout the Empire, irrespective of these markets, and fifteen thousand are annually sold in Moscow alone, at prices ranging from £8 to £9, and a number of Orloff horses, which command from £400 to £500 each. The total value of the horses annually sold in Russia is estimated at £1,000,000. Prices vary considerably, according to season, age, and race, the average price of a common horse being £5, that of a good cart-horse from £10 to £30; a good trotting horse from £400 to £600, and of a good cavalry horse from £8 to £15.

OLIVE OIL IN TUSCANY.

It is stated that the olive crop in Tuscany for 1883 did not exceed 25,000 barrels, or 5 per cent. of a full crop. In some of the olive districts the crop failed completely, in others the fruit suffered much from long drought, and in general the yield was far below the average, not only in Tuscany, but in Puglia and Liguria. A large quantity of Tuscan oil is annually sent to Nice, where it is used to improve the local produce, which is then exported to France and Russia under the name of Nice or Provence oil. The bulk of the Tuscan oil is bought up by the Leghorn merchants, and after undergoing a purifying and refining process by filtering, which makes it brilliant and clear, it is exported to England, France, Germany, Russia, &c., the largest shipments being made to England. The best qualities of genuine olive oil are sent abroad in pipes, half-pipes, and in casks of various dimensions. On the other hand, the oils which are made up in half-chests and square boxes, and sent to England only, containing thirty flasks, are usually very inferior, being mixed with cotton oil. This may be accounted for by the enormous competition prevailing in London, Liverpool, Bristol, and other markets, and the great demand for a cheap article; the consequence is a deterioration in quality corresponding with increased production, so that the price of these descriptions has now gone down considerably. In connection with this subject, the following particulars, from a detailed account of the growth of olives, and the production of oil in Tuscany, recently furnished to the British Consul at Leghorn by one of the principal exporters of that place, will be read with interest. He says that the best quality of oil can only be made from fruits that are perfectly and uniformly sound, well ripened, gathered as soon as they are dropped from the trees, and crushed immediately. The highest quality of olive oil for eating purposes should not only be free from the least taint in taste or smell, but possessed of a delicate appetising flavour. When so many favourable conditions are needed as to growth, maturity, and soundness of the fruit, coupled with great attention during the process of oil-making, it is not to be wondered at that by no means all or even the greater part of the oil produced in the most favoured districts of Tuscany is of the highest quality; on the contrary, the bulk is inferior and defective. These defective oils are largely dealt in both for home consumption and for export, when price and not quality is the object. In foreign countries there is always a market for inferior defective oil for cooking purposes, &c., provided the price be low. Price, and not quality, is the object, so much so that when olive oil is dear, cotton-seed, ground-nut, and other oils are substituted, which bear the same relation to good olive oil that butterine and similar preparations do to real butter. The very choicest qualities of pure olive oil are largely shipped from Leghorn to England, along with the very lowest qualities, often so adulterated. The oil put into Florence flasks is of the latter kind. Many years back this was not the case, but now it is a recognised fact that nothing but the lowest quality of oil is put into these flasks—oil utterly unfit for food, and so bad that it is a mystery to what use it is applied in England. Importers in England of oil in these flasks care nothing, however, about quality; cheapness is the only desideratum. The best quality of Tuscan olive oil is imported in London in casks, bottled there, and bears the name of the importers alone on the label. There is no difficulty in procuring in England the best Tuscan oil, which nothing produced elsewhere can surpass; but consumers who wish to get, and are willing to pay for the best article, must look to the name and reputation of the importers, and the general excellence of the articles they sell, which is the best guarantee they can have of quality.—*The Gardeners' Chronicle.*

Correspondence.

CAPE RAISINS.

I have had sent me, as a present from Montagu, Cape of Good Hope, a small quantity of raisins. They seem to be made of white grapes, but are remarkable for pulpiness and a distinct muscatel flavour. Having long lived in raisin countries, this specimen attracted my notice, and the produce appears to me suitable to be brought to this market by Cape steamers.

HYDE CLARKE.

General Notes.

RAILWAYS IN INDIA.—The length of railway open in India is 10,832 miles, of which 549 were opened dnring the year 1883-4. A report recently quoted in the House of Commons, but not yet published, showed that the capital expenditnre amounted to £142,606,900, including lines under construction; that the average cost per mile came to £11,300; that the net receipts from all the lines were £8,418,900, compared with £7,684,200 of the previous year, the return being £5 13s. 6d. per cent. compared with £5 7s. 3d. The proportion of working expenses to gross receipts was 48·39, as compared with 49·97 in 1882. On the East India Railway the proportion was only 36·91 per cent.

NUREMBERG EXHIBITION.—Further information has been received from the German Consul-General respecting the proposed International Exhibition of Gold and Silversmiths' Work, Jewellery, and Bronzes, to be held at Nuremberg, from the 15th June to the 30th September, 1885, which was noticed in the *Journal* for April 11, 1884 (see *ante* p. 517). Forms of application for space can be obtained from the Director of the "Bayrisches Gewerbe Museum," Nuremberg, and these forms must be filled in and returned before the end of November of the present year.

SOLDERING ALUMINIUM.—The use of aluminium in the arts has been much restricted by our ignorance of any method of soldering it, either to itself or other metals. Now, however, a French engineer, M. Bourbouze, has discovered a way of effecting both classes of the operation with ease. The process consists in plating both surfaces to be soldered, not with pure tin, but alloys of tin and zinc, or tin, bismuth, and aluminium, &c. Good results are obtained with all such alloys, but those containing tin and aluminium are best. They should contain different proportions, according to the work the soldered parts have to do. For parts to be fashioned after soldering, the alloy should be composed of 45 parts of tin and 10 of aluminium, as it is sufficiently malleable to resist the hammer. Pieces thus united can also be turned. Parts which have not to be worked after being soldered, may be united with a soft solder of tin containing less aluminium. This last solder can be applied with a hot soldering iron, as one solders white iron, or even with a flame. Neither of these solders requires any prior preparation of the pieces to be soldered. It suffices to apply the solder, and extend it by help of the iron over the parts to be joined. When, however, it it desired to solder certain metals with aluminium, is is best to plate the part of the metals to be soldered with pure tin. It is sufficient then to apply to the part the aluminium plated with alloy, and to finish the operation in the usual manner.—*Engineering.*

RAILWAYS IN GREECE.—According to an official report, the new line, which is a single one on the narrow gauge system, from the Piræus to Patras, *viâ* Athens, Eleusis, Megara, Kalamaki, New Corinth, and thence along the shores of the gulf of that name to Vostizzia and Patras, is practically completed for a distance of twelve miles to Eleusis, and in the course of the present summer it will be finished to Megara. The same company has constructed a line across the Isthmus of Corinth, a distance of six miles, to be opened about the same time as that to Eleusis, and it is expected that the main line will be completed as far as Corinth before the beginning of next year. A new line is also being constructed from Ergasteria, Laurioum, *viâ* Port Thoriko to Athens, with a branch line from the village of Colandri to Morous and Kephissia. This is also a narrow gauge line, the width between the two rails being one metre, and its construction is being pushed forward with activity. It is expected that the main line of this railway will be opened to the public from Ergasteria to Markopoulo, half way to Athens, by September next. The construction of a new line from Volo to Larissa has been much retarded by the floods during the late severe winter, these floods having done considerable damage to the line, which is said to have been constructed in a faulty manner.

CANTOR LECTURES.

ALLOYS USED FOR COINAGE.

By W. Chandler Roberts, F.R.S.
Chemist of the Royal Mint; Professor of Metallurgy, Royal School of Mines.

Lecture III. — Delivered Monday, March 31st, 1884.

On the Precautions Adopted with a View to Secure Accuracy in the Fineness of Coins.

In the last lecture we considered the changes through which the standard fineness of alloys used for coinage have passed in this country since the Norman conquest, and we saw that at a critical period of our numismatic history the silver coins contained only a quarter of their weight of precious metal, and therefore fully justified Latimer's attribution, "Your silver has become dross."

The questions we have now to deal with relate to no violent changes, and do not comprise the history of either national disaster o national success; but they have a certain importance of their own, as they refer to the methods by which standard fineness can be recognised and maintained.

The want of a method for ascertaining the degree of purity of gold and silver, or for determining the amount of precious metals present in their alloys, must have been felt as soon as the use of metals for currency was established. The history of assaying has yet to be written, but in rapidly reviewing the methods of assay which have been practised or proposed, it will be well to consider them in an order that is in the main chronological, but which enables the physical methods, as distinguished from the chemical, to be dealt with first.

The nation for which the honour of striking the first coins is claimed, gave its name to the "Lydian stone," or, as it is called in more recent times, the "touchstone." It is a dark basaltic rock, of fine texture, upon which a fragment of precious metal readily leaves a streak when drawn over its surface. The comparison of the streak left by the gold to be tested with similar traces derived from alloys of known standard and composition, afforded a ready means of ascertaining, approximately, the fineness of the metal under examination; while further insight into the character of the alloy was gained by submitting the streaks to the solvent action of an acid. There is an abundant literature* showing the degree of accuracy that may be attained by means of this stone; its use has survived for approximate assays until the present day.

Then, again, there was the method of ascertaining the purity of metals by their density, as compared with that of water, devised by Archimedes, B.C., 212, which is applicable to both gold and silver, and is still often resorted to when the metal to be examined must be preserved intact. The usefulness of density, as affording a trustworthy indication of standard fineness, has often been pointed out, notably by W. Symonds,† in 1756, and more recently by Dr. O. Broch.‡

The possibility of ascertaining the standard fineness of alloys by the aid of electricity long ago occupied the attention of physicists. In 1823, Becquerel § suggested that trustworthy indications might be afforded by the electromotive force developed when the alloy to be

§ "Ann. de Chim. et de Phys.," vol. xxiv., p. 343.

tested is placed in an exciting fluid together with an alloy of known composition. The subject was partially investigated by Oersted,* in 1828, and its practical importance was further pointed out by Gay-Lussac,† in 1830. In 1878, the use of magnetic induction for indicating the composition of alloys was suggested by Professor Hughes,‡ who showed incidentally that the induction balance affords a ready means for detecting counterfeits, and I have elsewhere pointed out the degree of accuracy of which this instrument is susceptible.§ The method which involves the use of the spectroscope also deserves mention here, although it is, as yet, more delicate than trustworthy.||

These physical methods, both ancient and modern, are open to the objection that the uncertainty of the results they afford increases with the complexity of the alloys under examination; and further, the indications are complicated by changes in the physical state of the metals, produced either by hammering or annealing.

Pliny states that in his time a method was in use for estimating the amount of silver in an alloy of silver and copper, by the degree of discolouration or blackening which attends the heating of the alloy in air. This method, long practised in France, and known by the name of *essais à la raclure* (scrapings), or *à l' échoppe*, is described by Rochon,¶ who says that it was generally recognised in the Roman mints in the time of Marius Gratidianus, triumvir of the money, and later by Chaudet,** who gives a table showing that silver of the English standard (925), when heated to low redness in a muffle, becomes uniformly grey-white, while intermediate tints are produced by heating lower alloys, until the standard used for the French subsidiary coinage (835) is reached. As this becomes quite black under the treatment, the process ceases to be useful for alloys of lower standard.

In very early times, the need must have been felt of some chemical method of isolating the precious metals—of separating them, that is, from their base associates, so that the gold or silver, when purified, could be weighed, and the amount originally present in the mass deduced by calculation.

The crude method of assay, already described, which depends on the change of colour produced by oxidation of the baser constituent of an alloy, leads up to the method used from very early times, which also depends on the principle that precious metals will resist oxidation, while the metals with which they are usually associated will not.

Its main outlines may be indicated as follows. When lead is melted with free access of air, a readily fusible substance forms upon its surface. This substance may be allowed to flow away, or, if the metal is contained in a suitable porous receptacle, called a cupel, the fusible oxide sinks into this containing vessel; in either case the oxidation of the lead affords a means of separating it from precious or inoxidisable metals, if any be originally present in the lead. I found lead in the ancient ornaments both of gold and silver, which Dr. Schliemann permitted me to analyse, and Pliny teaches that the Roman metallurgist used lead for the purification of gold and silver, for he says, "*excoqui non potest, nisi cum plumbo nigro aut cum vena plumbi.*" The greatest of the early alchemists, Geber, who died in A.D. 777, knew perfectly that the lead "acquired a new weight" when heated in air, and I have elsewhere* tried to show how important the recognition of this fact was to the whole fabric of modern chemistry; it is not a little interesting that, among the very first experiments recorded by our own Royal Society, is a metallurgical series relating to the weight of lead increased in the fire on the "copels" at the assay office in the Tower, the account being brought in by Lord Brouncker, in February, 1661.†

The interest of the art of assaying, from a purely scientific point of view, was generally admitted in the 17th century. Lazarus Erckern, for instance, described it as "the very inlet and mother of many other honourable and profitable sciences, while William Badrock,‡ apparently regarding the art as an element of general culture, pleads its claims to be studied by "all gentlemen."

Having shown the great amount of interest attached to the subject, I will now return to

the actual practice of the art as a metallurgical operation.

Geber, the Arabian, gives, if medieval translations of his works are to be trusted,* a sufficiently accurate description of the process to enable it to be conducted at the present day with no other aid than his; but it must be remembered that it was the object of the alchemist to distinguish silver from gold, and to isolate the metals, rather than to determine the amount of one metal present in admixture with another. Geber calls the process of cupellation the trial of the *cineritium*, and he points out, in the course of a description that deserves to be reproduced here, that "there are two bodies perfect, abiding the trial, to wit, *sol* (gold), and *luna* (silver). Take," he says, "sifted ashes or calx, or powder of bones of animals calcined . . . . moistened with water, and make the mixture firm and solid with your hands, and, in the midst of it, worked into a round flattish lump, make a round and smooth hollowness, and upon the bottom of it strew a small quantity of glass beaten to powder, which lay to dry. When dry, put your metal into the hollowness thereof, which you would try to prove, put coals of fire upon it, then blow with bellows upon the surface till the metal flows: upon which, being in flux, cast part after part of lead, and blow with a flame of strong ignition;" this is to be continued "until the lead is vanished," and precious metal is left "still or quiet, and you see it clean and clear in its surperfices," that is, the lead has dissolved the oxides of the base metals, and has carried them into the cupel, leaving the gold or silver, or an alloy of both, in the form of a button on the cupel.

This operation, as described by Geber, would more nearly correspond to a refining operation conducted on a large scale, with a view to the extraction of silver from lead, rather than to the method of assay as practised at the present day on a few grains of metal.

The method of conducting assays, on what would at the present day be considered to be a very large sample of metal, seems to have been held to be necessary in the 12th century, for in the official trials of the coin in the time of King Henry II., 1154-89, the "Miles Argentarius" and the "Fusor"† are instructed to take before the Barons of the Exchequer a pound of "twenty solidi" of the coin, which they are to place on a "*vasculum ignitorum cinerum quod in fornace est.*" The metal resulting from the trial is then weighed, and the amount it has lost is noted, and, if it is considered that the result of the trial is inaccurate, or "too much metal has been lost, say by the boiling, or by being carried off in the lead" [*illud quasi plus justo consumptum fuerit ignis scilicet exæstuatione vel plumbi infusione*], then it is to be repeated.

The amount of metal which has, for at least two centuries, been taken for assay is 12 grains troy, and this weight, which is known as the "assayer's pound," has the same number of divisions as the troy pound; the fineness of any given weight of metal is, therefore, indicated by the results of an assay, without tedious calculation. It has been shown that the process was officially recognised in this country in the reign of Henry II., and in France the first official mention of it occurs about the year 1314. It is the only method of assaying silver practised at the present day in the English Mint, although another method is used for verifying the composition of its alloys.

With regard to the apparatus required:—In Geber's work "of furnaces" there is no mention or illustration of the "muffle" furnace, so that he seems to have conducted the process in a cupel surrounded by incandescent fuel.

Biringuccio (1540) gives illustrations and detailed descriptions of appliances which hardly differ from those now in use, and so does his contemporary Agricola.* Budelius† (1591) gives a drawing of a furnace which somewhat resembles the type still used in continental mints, except that the muffle, or oven, is placed close to the base of the furnace; and the "Sculptures" of Sir John Pettus, reproduced from the works of Lazarus Eckern,‡ show various forms of muffles and furnaces, some used by the ancient assayers, others adopted in the middle of the 17th century at Nuremberg, where the goldsmiths flourished so vigorously. He also gives an improved form of furnace, "made of armour plates," closely corresponding in its general arrangement with a furnace now lent by the Mint to the science collection at South Kensington, which is specially interesting, as tradition points

* There is a good English edition of the 17th century "The Works of Geber," translated by R. Russell. 1686.

† Quoted by Lowndes, "Essay for the Amendment of the Silver Coins," p. 155 (London, 1695,), from the Black Book of the Exchequer, written in the time of Henry II., cap. 21, Officium Milites Argentarii et Fusoris.

* "De re Metallica."

† "De Monetis et Re Numaria, Coloniæ Agripp." 1591.

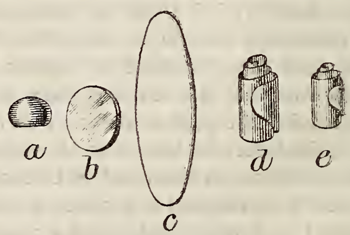
‡ Op. cit., p. 17.

to it as being the furnace used by Sir Isaac Newton in his experiments on cupellation when Master of the Mint. Several transitional forms of furnace between the old one just mentioned and those now used by the Mint* are still preserved in the Assay-office. The tongs and other tools incidentally used do not require special notice, as the changes that have from time been made in them have only rendered their forms more delicate and handy, and have hardly altered their general type.

With regard to the balances employed, it may be sufficient to point out that, for centuries, they have been constructed with great delicacy, and that they now turn with $\frac{2}{1000}$ths of a grain, when loaded with 10 grains. In fact, the use of the balance in very early times, for the purpose of assay, absolutely demolishes the claim of quantitative chemistry to be considered of comparatively modern origin. The indications afforded by the balance as to the result of an assay are not absolute, as the process is liable to error from several sources, and needs to be controlled in the manner which will be described subsequently.

The point to bear in mind at this moment is, that if the silver has been associated only with readily oxidisable metals, especially copper, as is usually the case when silver coins are assayed, then it only becomes a question of providing the amount of lead necessary to furnish, by oxidation, sufficient litharge to dissolve the oxides and carry them away. If, however, the silver is associated with gold, the latter metal resists oxidation, and will remain on the cupel with the silver, for—again to quote Geber—it will in "nowise forsake it." The cupellation stage must then be supplemented by a "parting" operation, that is, the silver must be dissolved away by some solvent which will leave the gold untouched, and for this purpose nitric acid is universally employed. If the silver contains but a minute quantity of gold, the presence of the latter will be indicated by a few specks of brown powder left at the bottom of the vessel in which the silver is dissolved; if, however, the silver contains about one-third of its mass of gold, and has been extended into a strip, the gold will remain after the action of the acid, as a coherent band, retaining the original form of the strip, but much reduced in volume. This action of nitric acid on an alloy of gold and silver was certainly known to Geber and the early alchemists, but the first official mention of the use of the parting assay appears to be in a decree of Philippe de Valois,* in the year 1343, confirming its use in the French Mint. The assay methods for silver and gold are analogous, in so far that both are purified by the action of a solvent, but the base metals are removed from silver by fused litharge, while in its turn silver is parted from gold by nitric acid. There is, then, this difference between the assay of gold and silver. In the case of the cupellation assay of silver, the button of metal has only to be removed from the cupel, and when the adhering bone ash has been removed by a brush, it passes direct to the balance. The process would also be sufficient for gold, if it contained no other precious metal; when, however, the problem is to ascertain by assay how much gold is contained in an alloy, which may contain silver, or platinum and other metals of similar properties, then care must be taken that the amount of gold believed to be present in the alloy does not exceed the one-third part of the mass, as a larger proportion of gold would protect the alloy from the solvent action of the acid, and the greater the amount of gold, the less perfect would be the attack of the acid.

In any case the first stage of assaying a gold alloy, say a sovereign, is to melt it with such an amount of silver as shall yield a button containing rather less than one-third of its weight of gold.



Scale about ½.

For the sake of convenience, and for the incidental advantage that the solvent action of fused litharge removes copper and other impurities, the first stage of the assay of gold is conducted on a cupel, the object to be attained being mainly to secure a button (*a*) of gold and silver in a convenient form for submitting to the subsequent operations. The alloying stage would, however, be just as effective if it were conducted in a small non-porous receptacle, such as a small crucible of glazed porcelain.

The subsequent operations are, flattening the button (*b*), annealing it, rolling it into a strip (*c*),

* A drawing of the modern furnace was prepared for Dr. Percy's work, "Silver and Gold." Part I., p. 256. 1880.

* Boizard, "Traite des Monnoies," p. 176. 1692.

and annealing it a second time. It is then coiled into a spiral, or cornet (*d*), and treated by two successive portions of nitric acid, in order to remove the silver; after this the spiral of spongy gold (*e*), which retains the original form given to the silver-gold alloy, is heated to redness, when it becomes bright, and is sometimes so coherent that it may be unrolled without fracture.

This is an outline of the processes of assaying; the precautions which are adopted with a view to secure accuracy remain to be considered. Inaccuracy in silver assaying mainly arises from loss of silver, which may disappear in small but variable quantities, either by volatilisation or by sinking into the cupel with the litharge. The amount of metal lost varies with the temperature, which is never uniform throughout the muffle; and the results of assays, as indicated by the balance, have, therefore, to be controlled by assays on pieces of metal of known standard, distributed in such a way as to represent the varying degrees of temperature throughout the muffle. The metal lost by any given check-piece is added to the assays in close proximity to it, and, as the amount of metal lost very often amounts to 1¼ per cent., the apportioning of the additions to be made demands great skill on the part of the assayer, who has also to decide from the appearance of the buttons whether they have retained lead or not, in which case they would, of course, be unduly heavy. In gold assaying, on the other hand, although as Geber knew, gold resists the action of molten litharge better than silver does, some precious metal may be lost either by volatilisation, or by retention in the cupel, but the chief sources of error are (1st), solution of gold in the acid used, which would reduce the weight of the cornets, and (2nd), retention of silver by the cornets; but these inverse causes of error may be combined, without neutralising each other. Some means of checking the results must, therefore, be provided, and it would appear that for centuries implicit confidence has not been placed in the indications afforded solely by the assays, as comparisons have invariably been instituted between the pieces of metal taken for assays, and standard trial plates, or pieces of known composition, assayed side by side with the coins, so that any error affecting the coin assays also affects the check pieces, and, therefore, the error can be allowed for.

The trial plates by which silver and gold coin have been tested, possess, it seems to me, an amount of interest that can hardly be overrated. The oldest of them to which a date can be assigned, is a silver-plate, imperfectly impressed with the dies of a coin of the time of Henry III. (1216-1272). A silver plate is alluded to as follows, in the *Rotulus de Moneta*, of the 7th and 8th years of King Edward I.:—"Premerement qe hom doit fere un estandart, qe doit demorer al Escheker, ou en quel lieu qe nostre seignor le Roy vodra," and in 1326 there is a record of the provision of two silver-plates for testing the silver coined by King Edward II., for his Duchy of Aquitaine, "one plate to be of the just weight before the fire, and the other such as it (the metal tested) ought to be after the assays." * This is interesting, because it seems to point to the fact that the amount of silver which should be "lost in the fire," had been experimentally determined at that early period. Many of the old trial plates were formerly kept in the Pyx Chapel Abbey, Westminster Abbey, almost the only relic which remains of the church built by Edward the Confessor, and on the altar tomb believed to be that of Hugolin the first Chancellor of the Exchequer, there is a circular dish-shaped cavity on which a small furnace may have rested, if,† as is probable, the trial of the Pyx was at one time conducted in this building. The trial plates were removed in 1842 from the Pyx Chapel to the office of the Queen's Assay Master in the Mint; and I am fortunate in being able to offer to the Society photographs of some of the more interesting of these.‡ The trial plates were always divided into several portions, and, like the old Exchequer tallies, "this division was effected in rough serrations, so that portions of the original plate entrusted to the different officers, could be readily identified. A table, showing the composition of these ancient trial plates, is appended to this lecture, and I will only add here that most of the standards shown in the diagram § are represented in the Mint collection. Of those which are photographed, the more interesting are probably No. 1, made in the 17th year of King Edward IV. (1477), and No. 2, which marks the introduction of the standard now in use, 916·6̇, by King Henry VIII. All the plates, however, possess peculiar interest, for in relation to the assays of the "alloys used for coinage," they are the signs

‡ These are issued as a Supplement to the present *Journal*. The photographs were prepared by the Autotype Company, and have been reproduced by the "Ink-photo" process of Messrs. Sprague.

§ See second lecture, p. 841

of centuries of responsibilities, which I am fully sensible it is a privilege to be permitted to sustain.

An examination of a series of assays made of the trial plates shows that, although the standards of fineness were always prescribed by law, the plates have, nevertheless, at times been very inaccurate.

The imperfections of the gold plates are mainly due to sources of error which had been recognised, but which were ignored when the last plates were made; and it is well to explain, therefore, that plates were, in former times, authoritatively pronounced to be "standard" simply with reference to the results of an inaccurate process of assay. The process now consists in submitting an accurately weighed portion of the alloy to a rapid method of chemical analysis, whereby impurities are eliminated, and the precious metal, thus purified, is again weighed, but the method is complicated, and the accuracy of the result may be affected by the retention of impurities, or by an actual loss of metal during the process. The weight of gold as indicated by the balance will, in consequence, not represent the amount originally present in the alloy, and it is, therefore, necessary to control the results by assaying, side by side with the alloys under examination, "standards" or check-pieces the composition of which is known. As, however, any error in the composition of these checks will be reflected in the result of the assay, it is preferable to use pieces of pure metal corresponding in weight to the amount which the alloys to be tested are anticipated to contain.*

* The corrections to be applied to a gold assay will be readily understood from the following formula:—

Let 1,000 be the weight of alloy originally taken;

p. The weight of the piece of gold finally obtained;

x. The actual amount of gold in the alloy expressed in thousandths;

a. The weight of gold (supposed to be absolutely pure) taken as a check, which approximately equals *x*;

b. Loss or gain in weight experienced by (*a*) during the process of assay;

k. Variation of "check gold" from absolute purity, expressed in thousandths;

Then the actual amount of fine gold in the check-piece $= a\left(1 - \frac{k}{1000}\right)$, and the corrected weight will be $x = p - \frac{a k}{1000} \pm b$, (*b*) being added or subtracted according as it is a loss or gain.

If (*a*) be assumed to be equal to (*x*) this equation becomes

$$x = \frac{p \pm b}{1 + \frac{k}{1000}}.$$

Formerly, such checks of pure metal were not employed, and a small amount of silver varying from $\frac{2}{10000}$th to $\frac{1}{1000}$th part of the initial weight of the assay piece which remained in association with the gold was consequently reckoned as gold in the assay report. It follows, therefore, that even the more recent plates, when accurately assayed, are usually found to be sensibly below the exact standards which they were intended to represent.

The experiments made with a view to ascertain the composition of the standard gold plate prepared by me in 1873, show that the greatest variation of this plate from the exact standard does not exceed the $\frac{2}{10000}$th part; but the use of even a fairly accurate standard plate is liable to be attended with error, as the actual amount of precious metal in the amount taken for the check-piece may exceed or fall short of the true standard. It follows, therefore, that the assay reports on portions of metal tested by comparison with this check may indicate the presence of too little or too much precious metal.

The objections to the use of a standard silver plate are far greater, as the alloys used for the silver coinage, in this and in other countries, are mechanical mixtures, the molecular arrangements of which are very peculiar, and so far as my experience goes, a plate of the legal standard cannot be prepared of uniform composition.

With regard to the use of pure gold and silver plates, it should be pointed out that, if it were possible to obtain gold and silver of absolute purity, there would be no limits to accuracy in assaying, except such as arise from operations of a purely mechanical nature. Of course, it is not possible to attain to chemical purity, and the presence of traces of impurity in the checks causes the results of assays made in comparison with them to indicate the presence of an amount of pure metal in excess of that actually present in the alloy; but as the converse can never be the case, that is to say, as the gold cannot be more than pure, no danger can arise from this cause, and the error can be easily allowed for.

The supplementary fine gold and silver plates, prepared in accordance with instructions I received from the Lords Commissioners of the Treasury in 1872, proved eminently satisfactory. I have not been able to prepare, or to obtain from any source, gold of greater purity, even in small quantities. The silver plate leaves little to be desired, although it is not quite as pure as silver prepared by M. Stas, in comparison with which it is as 999·95 to 1,000.

In conducting official trials of the pyx, minute accuracy is secured by a final appeal from the standard plates themselves to pure gold or pure silver.

We are now in a position to consider another question, the importance of which has long been recognised by law, and that is, the difficulty of attaining an exact standard, either of weight or fineness, in the case of all the individual coins issued from a mint. The law has for centuries, and in all nations, permitted a certain deviation from the exact standard. The amount of such "remedy," as it has always been termed in this country, has changed from time to time, but has gradually diminished as the art of coining has advanced.

It follows, that although the component parts of the alloy may not bear to each other with mathematical precision the proportion prescribed by the regulations under which they are manufactured, they may, nevertheless, be considered to be of standard fineness. The earliest reference to a "remedy" I have met with is in the reign of Saint Louis, of France, 1253,* who granted an allowance of ¼ carat, for the fineness of Louis d'or. The Mint agreement between King Edward I., and William de Turnemire,† in 1279, provides a remedy of 2½ dwts. on the pound troy of the silver coins. The law does not appear to have contemplated that the "remedy" should be systematically made use of as a source of profit, either to the Crown or to the Master of the Mint; it was rather considered to define the limits within which occasional variations of standard weight were unavoidable, and its true function has been well defined by the late M. de Jacobi, who, representing the Russian Government at the International Monetary Conference, held in Paris, in 1867, said, "the remedy is not an arbitary stipulation, but is the limit of errors which belongs to every thought, to every chemical analysis, to every composition of alloy, and as such depends on the precision of the balances, and the methods employed in the fabrication of money. It may be determined rigorously by applying the calculus of probabilities."

The Mint indentures have been drawn up in just the same spirit. Remedies were accorded "because the said moneys may not continually be made in all things according to the right standard, but, peradventure, through default of the master or workers, they shall be found sometyme too strong or too feeble in weight or alloy," but this has not prevented a very different view having been taken of the privileges accorded by them, both to the Sovereign on the one hand, and the Master of the Mint on the other. Queen Mary, for instance,* seems to have considered that the Sovereign was entitled to add as much base metal to the coinage as the law permitted, the sum so derived after deducting coinage expenses, to be considered seignorage, but she held that the Crown could not debase the coin, or increase the amount of base metal in it for private ends.

With regard to the action of Mint Masters in this respect, the history of the coinage abundantly proves that they frequently availed themselves of the "remedies," viewing them as a legitimate source of profit, or as a means, incidentally provided by their contracts, for reducing the current expenses of working the best known case being probably that of Lonison, Master of the Mint in the reign of Queen Elizabeth

The scale of remedies is fixed by the Coinage Act of 1870, at present we will only consider the remedy of fineness, which, in the case of the gold coin, has a range of + $\frac{2}{1000}$th, and in the case of silver + $\frac{5}{1000}$th. The gold coins of the nations who have joined the Latin Union have also a remedy of $\frac{2}{1000}$th. In America, the remedy in the case of the gold coins has been reduced to $\frac{1}{1000}$th. "I do find," said Rice Vaughan,* writing in 1675, "that some men of great experience and understanding, even in this mechanical part, do hold that the moneys, both of gold and silver, may be made without any remedy to be allowed either for weight or fineness," but he subsequently adds, "I undertook this discourse of the mechanical part of money with scruple, so I do leave it with alacritie." It is certainly not the opinion of Mint officers at the present day that the remedies should be reduced to the lowest possible point, as this would involve the rejection and re-coinage of a large number of pieces before they could be permitted to leave the Mint; but, on the other hand, all agree that a persistent variation, however slight, above or below standard, has never been contemplated by law. The effect of such a mean variation would be remarkable.

If, for instance, the Mint were to issue

* Jean Boizard, "Traite des Monoyes," p. 25, 1692.
† Report on Royal Mint, p. 41, 1849.

* Report on the Royal Mint, p. 39. 1849.
† "Discourse of Coin and Coinage," p. 91. 1675.

sovereigns which were either persistently too rich or too poor in gold, to the extent actually permitted by law, a loss or profit would accrue of over £2,000 on each million coined, and a persistent variation of only $\frac{1}{10000}$th part would be equivalent to a profit or loss of £100 a million. In Mint practice, at the present day, even this comparatively small variation should be avoided, and the public trials of the pyx prove that it does not exist.

I have dwelt on these facts because the maintenance of rigid accuracy in the operations of coinage becomes of great importance in international currency. One Government might, as the late Professor Stanley Jevons pointed out, "coin money slightly inferior to the proper standard, and such money once introduced would, in virtue of Gresham's law, be difficult to dislodge." I admit, with him, that it is hardly to be supposed that a State issuing money under international obligations would wish to make a profit of one or two parts in a thousand, which the remedy would legally cover; but nevertheless, the degree of accuracy with which the coinage is executed would be of much importance, for the following reason. A nation would be bound by the International Convention to withdraw and re-coin such coins of other nations as might be circulating within its borders at the time they were reduced by wear below the lowest weight at which their circulation would be legal, and it follows that any deficiency of standard which might exist would have to be made good by the nation on whom the recoinage happened to fall, and a nation coining with rigid accuracy would suffer from the shortcomings of those who did not.

TABLE SHOWING THE COMPOSITION OF THE ANCIENT GOLD TRIAL PLATES, OF WHICH PORTIONS ARE PRESERVED IN THE MINT.

Date.	Standard Prescribed by Law. In carats and grains.	Standard Prescribed by Law. Decimal equivalent.	Actual Composition.	Remedy or permitted variation in carats and in thousandths.	Remarks.
1349				⅓ carat or 13·9	Amongst the Cotton Manuscripts is preserved the account of a trial of the pyx of gold nobles in the year 1349. The coins were to be compared with one ounce of florins of Florence, kept in the Treasury as standards.
1477	23 3½	994·8	Gold ... 993·5 Silver ... 5·15 Copper* ... 1·35	⅛ carat or 5·2	This, the earliest gold Trial Plate of which there is any record, was made in the 17th year Edw. IV. Special legal provisions were enacted for the protection of the coin of the realm, which appears to have been debased in every possible way. When gold coins were first introduced into England by Henry III., in 1257, they were 24 cts. fine, that is, pure gold. Edward III., in 1345, was the first to use the standard of this plate, 23 cts. 3½ grs. fine, or 994·8. (See **No. 1** of the plate of photographs.)
1527	22 0	916·6	Gold ... 915·5 Silver ... 78·3 Copper ... 6·2	⅙ carat or 6·9	In 1526, Henry VIII. issued a proclamation directing that crowns of the double rose should be coined of the standard 916·6 for concurrent issue with sovereigns and other coins of the original standard of 994·8. This plate was made in the following year. (Photograph **No. 2.**)
Probably 1543	23 0	958·4	Gold ... 954·4 Silver ... 34·8 Copper ... 10·8	⅙ carat or 6·9	This plate was probably prepared to correspond with the debasement of standard which took place in this year from 994·8 to 958·4. In 1544, the standard for all gold coins was reduced to 916·6, and again in 1546 to 833·4; the lowest point ever reached in England.
1553	23 3½	994·8	Gold ... 990·3 Silver ... 9·7 Copper ... —	⅙ carat or 6·9	This is the first plate bearing an inscription, which runs as follows:—STAN9 ∘ OF ∘ XXIII ∘ KARE9 ∘ X ∘ GRE9 ∘ DEMI ∘ FYNE ∘ PRYVE ∘ MARKE9 ∘Φ. It bears no date, but the "pryve marke" (a pomegranate) is the same as that borne by the sovereigns and "angels" issued by Mary in this year. In a proclamation, dated 1553, it is stated that the coins shall be made of "fine gold," which doubtless, means the old standard of 994·8, which, according to Ruding, was in use in this year. (Photograph **No. 3.**)

* With copper are included any minute quantities of other base metals which may be present.

Date.	Standard Prescribed by Law.		Actual Composition.	Remedy or pre-mitted variation in carats and in thousandths.	Remarks.
	In carats and grains.	Decimal equivalent.			
1560	22 0	916·6	Gold ... 913·7 Silver ... 60·8 Copper ... 25·7	$\frac{1}{6}$ carat or 6·9	On her accession to the throne in 1558, Elizabeth took active measures to continue the improvements in the standard of the coinage which had been commenced by Edward VI. (Photograph **No. 4.**)
1560	23 $3\frac{1}{2}$	994·8	Gold ... 994·3 Silver ... 5·7 Copper ... —	$\frac{1}{8}$ carat or 5·2	On the 8th November, 1560 (the year in which these plates were made), an indenture was made with Thomas Stanley to coin gold of both standards.
1593	22 0	916·6	Gold ... 915·9 Silver ... 52·1 Copper ... 31·9	$\frac{1}{6}$ carat or 6·9	In the 35th year of Elizabeth's reign (1593) a commission was granted to Sir R. Martin to issue coins of the standard 916·6; this plate was, doubtless, made with reference to that coinage.
1605	23 $3\frac{1}{2}$	994·8	Gold ... 990·3 Silver ... 8·3 Copper ... 1·4	$\frac{1}{8}$ carat or 5·2	In the first two years of his reign (1603-4) James I. issued coins of the standard of the previous plate, namely 916·6. In 1605, however, he raised the standard back to the original 994·8. (Photograph **No. 5.**) A plate of the standard 916·6, dated 19th November, 1604, is mentioned in "Pollett's Abstracts of Pyx verdicts," but no portions of it remain in the Mint.
1649	22 0	916·6	Gold ... 913·0 Silver ... 51·1 Copper ... 35·9	$\frac{1}{6}$ carat or 6·9	On the 16th of November, 1649 (the first year of the Commonwealth), an Act of Parliament was passed empowering the council of state to administer an oath to a jury of goldsmiths charged with the preparation of this plate. It was accordingly made on the 20th December following.
1660	23 $3\frac{1}{2}$	994·8	Gold ... 990·9 Silver ... 3·7 Copper ... 5·4	$\frac{1}{6}$ carat or 6·9	Charles II., soon after his accession, ordered these plates to be prepared, rejecting those made under the Commonwealth, which had only been employed at one trial of the pyx. (Photograph **No. 6.**) With regard to the 994·8 plate, it may be mentioned that no coins appear to have been issued of this composition after the year 1640. No record of the preparation of these plates is preserved at Goldsmiths'-hall.
1660	22 0	916·6	Gold ... 912·9 Silver ... 53·3 Copper ... 33·8	$\frac{1}{6}$ carat or 6·9	
1688	22 0	916·6	Gold ... 914·6 Silver } 85·4 Copper }	$\frac{1}{6}$ carat or 6·9	
1707	22 0	916·6	Gold ... 917·1 Silver ... 59·5 Copper ... 23·4	$\frac{1}{6}$ carat or 6·9	This plate appears only to have been used at the trial of the pyx, which took place on the 21st August, 1710. After this it was finally abandoned, probably because it contained too much gold, and was, therefore, to the disadvantage of the Master. At the next trial, on the 7th Aug. 1713, the use of the 1660 and the 1688 plates was resumed, both of which were considerably below standard.
1728	22 0	916·6	Gold ... 916·1 Silver ... 50·4 Copper ... 33·5	$\frac{1}{6}$ carat or 6·9	
1829	22 0	916·6	Gold ... 915·3 Silver ... 37·6 Copper ... 46·5	$\frac{1}{16}$ carat or 2·6	It may be observed that in 1817 an effort was made to attain greater accuracy in the coinage, the remedy being in that year reduced from 6·9 to 2·6 parts in a thousand.
			New Trial Plate.		
1873	22 0	916·6	Gold ... 916·61 Copper ... 83·39	2·0	The standard plate was alloyed with copper only, in order that it might correspond with the composition of the British gold coins.
1873	Supplementary Plate.		Pure gold.	[illegible]	Both plates were prepared at the Mint, and verified by the Goldsmiths' Company, 22nd December, 1873.

TABLE SHOWING THE COMPOSITION OF THE ANCIENT SILVER TRIAL PLATES, OF WHICH PORTIONS ARE PRESERVED IN THE MINT.

Date.	Standard Prescribed by Law. In ozs. and dwts.	Standard Prescribed by Law. Decimal equivalent.	Actual Composition.	Remedy or permitted variation in dwts. and in thousandths.	Remarks.
No date.			Silver ... 757·4 Copper ... 246·6		This plate bears no date, nor is it accompanied by any label, but its form would appear to indicate that it belongs to a very early period. Until the year 1842 the trial plates were kept in the Pyx Chapel, in the cloisters of Westminster Abbey, where certain assay pieces of gold and silver, with ancient memoranda relating to them, were also found. One of these pieces is the extremity of a bar or ingot of silver, which has its upper surface rounded and imperfectly impressed with the dies of a coin of the time of Henry III. (1216-1272.) Mr. Black, formerly Assistant Keeper of the Public Records, considered that this had been employed at the trial of the pyx, and that it is probably the remains of the oldest standard piece which has been preserved. It proved on assay to contain 921·0 of silver and 2·0 of gold, a result which points to its representing the new coinage introduced 1267.
1477	11 2	925·0	Silver ... 923·5 Copper ... 76·5	2 dwts. or 8·4	
Probably 1527			Silver ... 855·5 Copper ... 114·5		These three earlier plates differ in form from all those which succeed them. They are chisel-shaped, the ends being hammered out apparently in order to receive the impression of a coin. This impression is, however, only preserved on the 1477 plate. There is no record of any coinage having the composition of this plate, but a label is attached to it, bearing the date "13th October 18th Henry VIII." (1527.)
1542	9 6	775·0	Silver ... 763·6 Copper ... 236·4	Probably 3 dwts. or 12·5	Henry VIII. issued in Ireland, in his 33rd year (1542), coins of this standard. Their circulation in England was prohibited, but within four years he reduced the standard in England to 333·3 parts of fine silver in 1,000.
1553	11 2	925·0	Silver ... 927·0 Copper ... 73·0	2 dwts. or 8·4	Mary, on her accession to the throne, issued a proclamation stating that a coinage of "Silver in fineness of the standard sterling" should be commenced; in the indenture, however, of the same date (1553), the composition is fixed at 916·6. This plate, which bears an inscription similar to that on the gold plate, and the same privy mark (a pomegranate) appears to have been prepared to correspond with the composition named in the proclamation, but no plate having the composition prescribed in the indenture (916·6) exists in the Mint. Several coinage arrangements introduced by Mary were convenient. The standard of silver was the same as that of gold, and their values, therefore, were easily comparable. The weights of the coins were so adjusted that a crown in silver or two sovereigns in gold weighed one ounce.
1560	11 2	925·0	Silver ... 930·2 Copper ... 69·8	2 dwts. or 8·4	On the 27th September, 1560, Elizabeth issued a proclamation, stating that "to make an end of all troubles arising from debased monies, Her Majesty had already begun a coinage of fine money in the Tower of London." This plate probably marks the restoration of the old standard, which took place in this reign. The convenient arrangements introduced by Mary were discontinued, a change which was subsequently regretted by Lord Liverpool, in his letter to George III. (p. 100), as it introduced difficulties in the comparison of the values of gold and silver coin. Had Mary's regulations been allowed to continue, the composition of both gold and silver coins in Great Britain and British India would at the present day have been identical.

Date.	Standard Prescribed by Law. In ozs. and dwts.	Standard Prescribed by Law. Decimal equivalent.	Actual Composition.	Remedy or permitted variation in dwts. and in thousandths.	Remarks.
1600	3 0	250·0	Silver ... 252·0 Copper ... 748·0	3 dwts. or 12·5	This plate is labelled "Standard for Ireland, An° 1600"; and in 1601 Elizabeth decreed that coins of about this standard should be issued in Ireland, or, as the indenture states, "with such provision and moderation as in former times had not been done, and so as none of our Highness' loving and faithful subjects should be thereby prejudiced." Considering how extremely debased this coinage was, it is difficult to understand these expressions. Simon states that the standard was 241·5, but Malynes fixes it at 250, a statement which is confirmed by the composition of this plate.
1601	11 2	925·0	Silver ... 925·1 Copper ... 74·9	2 dwts. or 8·4	This plate was employed at the trials of the pyx up to the 20th June, 1605, and its composition is very closely in accordance with the true standard.
1604	11 2	925·0	Silver ... 922·7 Copper ... 77·3	2 dwts. or 8·4	
1649	11 2	925·0	Silver ... 923·7 Copper ... 76·3	2 dwts. or 8·4	The jury of Goldsmiths empanelled to prepare the gold plate on the 16th November, 1649, were also ordered to make this silver plate of the standard 925, to be used as "Standard Trial Pieces." These pieces were "to be indented and printed according to the pleasure of the Parliament."
1660	11 2	925·0	Silver ... 924·2 Copper ... 75·8	2 dwts. or 8·4	As in the case of the gold plates of this date, there is some uncertainty as to where this plate was prepared.
1688	11 2	925·0	Silver ... 922·0 Copper ... 78·0	2 dwts. or 8·4	
1707	11 2	925·0	Silver ... 922·0 Copper ... 78·0	2 dwts. or 8·4	
1728	11 2	925·0	Silver ... 928·9 Copper ... 71·1	2 dwts. or 8·4	
1829	11 2	925·0	Silver ... 925·0 Copper ... 75·0	1 dwt. or 4·2	Prepared by a jury of Goldsmiths, and verified by the King's Assay Master.
			New Trial Plate.		
1873	11 2	925·0	Silver ... 924·96 Copper ... 75·04	4·0	Prepared at the Mint, and verified by the Goldsmiths' Company, 22nd December, 1873.
1873	Supplementary Plate.		Pure silver.		

CONFERENCE ON WATER SUPPLY.

The following is the discussion on the papers read at the Conference of the Society of Arts on the Water Supply, held at the International Health Exhibition on Thursday, July 24th; Sir Frederick Abel, C.B., F.R.S., in the chair:—

The Chairman, in commencing the proceedings, said the active interest displayed by his Royal Highness, the President of the Society of Arts, on this subject, had led the Council to hope that it might have been in his power to open the proceedings; indeed, at one time, there was no doubt that this Conference would have been the opening one of the series arranged by the Executive Council of the Health Exhibition, and that his Royal Highness would have presided, at any rate, over a portion of the proceedings, when that unexpected calamity occurred which had so deeply afflicted the Royal Family and the nation. The fact that even quite recently the Prince had fixed the present date for this Conference was an indication that, had it been possible, he would have marked his sense of its importance by attending at the opening. In 1878, his Royal Highness addressed a letter to the Council of the Society of Arts, calling attention to the importance of the subject of water supply; pointing out that whereas various large towns were at that time incurring heavy expenditure to improve their water supply, smaller towns, and particularly villages, were left to shift for themselves; and suggesting that it might be desirable to discuss fully the question how far it might be possible to apply the great natural sources of water supply according to some national comprehensive scheme. The Council of the Society, acting on that suggestion, issued inquiries and invitations for papers, and received more than twenty papers in response, some written by men of eminence who had devoted a great deal of attention to this subject. Those papers, and the topics arising out of them, were very carefully discussed, and the general conclusion arrived at was that local conditions and circumstances presented such very considerable variations that it appeared impossible to devise any comprehensive national scheme for the supply of water to communities. But a resolution was passed that it was desirable to memorialise the Government to appoint a small permanent Commission to collect facts connected with the water supply throughout the kingdom, in order to utilise the natural resources, as indicated by his Royal Highness, according to some general system for the benefit of the country as a whole. That suggestion was not acted upon, but, nevertheless, the discussion which took place in 1878 had been fruitful of beneficial results, and it was quite certain that the subject of improved water supply had made an important advance since that time. The influence of polluted water in promoting the spread of epidemics had become more thoroughly understood and recognised, and the mischievous effects of using water derived from surface wells, and from the careless storage of water in houses, arising out of intermittent supply and other circumstances, had received much public attention; but there could be no doubt that many points bearing upon the supply of wholesome water still required further elucidation. Many interesting discussions connected with one branch or another of this subject had taken place since 1878, and probably none were more interesting than those connected with the questions as to what constituted a good water for drinking and domestic purposes, and how a sufficient quantity might be insured. It was scarcely necessary to remind the audience that amongst the most intelligent men who had given attention to this subject there had existed, and still remained, diversities of opinion on some important points more especially connected with the question of how the purity of water was affected, and how it was re-established if the water were once polluted. Thus some authorities had maintained that no river which had been in any way polluted could ever be fit for use afterwards, or, at any rate, that the time when it might become fit for use as potable water was very remote; but that, on the other hand, it was only necessary to sink wells deep enough in order to obtain water absolutely free from injurious organic contamination, so that water could be furnished in any degree of abundance by means of artesian wells. On the other hand, there were authorities, not less well recognised as possessing special knowledge and experience, who had maintained that it was quite erroneous to suppose that river water, when it became polluted by sewage, was thereby rendered permanently unfit for potable purposes; that a river had only to flow a comparatively short distance for its self-purification to take place, a purification which, although it might vary in degree according to circumstances, must ultimately be carried out to a sufficiently perfect extent to render the water absolutely wholesome. Probably the truth lay between the extremes; in fact, it was already recognised that it did so, and there were indications that amongst the most extreme exponents of either view there was a tendency to an assimilation of opinions. These subjects had been lately so warmly fought out on many battlefields that the weak points on each side had become more and more apparent to advocates and adversaries alike; and, therefore, there was a hope that something like that unity of view might, before long, be arrived at, without which any real progress could hardly be looked for. There was probably no subject which could be selected for discussion which involved so many considerations of primary importance as that of water supply. On the one hand there were geological, medical, chemical, and engineering considerations; and, on the other hand, there were financial, legal, municipal, and it might be even political considerations. As the Society met, on this occasion, in conference in connection with the Health Exhibition, he thought they were primarily concerned with the first-named set of considerations, and their hands would be quite full enough if they limited themselves to these, avoiding, as much as possible, any discussion on the extremely debatable ground of financial or legal questions. They would now at once enter upon the consideration of the first branch of the subject, viz., the Sources of Supply.

Papers were then read by W. Whitaker, W. Topley, C. E. De Rance, and Joseph Lucas.

Mr. HENRY ROBINSON said he feared, without some further explanation, that the allusion made by Mr. Lucas to the decision of the Parliamentary Committee, not to give the mill owners on the River Alyn compensation for water abstracted, might be misunderstood. He was engineer of the Bill before the Committee, and the facts were these. There was a petition from the mill owners, asking that the company should give what was regarded as the usual clause, providing that a certain amount of water from the gathering ground should be sent to the stream, but the Committee were of opinion that it was not sufficiently proved that a large volume of the water which went into the River Alyn was connected immediately with the gathering grounds from which the company were to take their supply. There was a doubt whether a large portion of it did not disappear in a swallow, even at the present time; and as regarded the future, the Halkyn level, which had been referred to, having been authorised by Parliament, was in course of construction, for the purpose of draining a large area of mining grounds; and therefore it was put before the Committee that a large body of water, which was part of the river now, would cease to be so. The case, therefore, was exceptional, and could not be relied upon as a precedent for other cases.

Mr. CONDER said he noticed in the four papers which had been read an echo of what was stated in 1878. A number of individual projects were then brought forward, and, to a certain extent, much harmony appeared to prevail on that occasion. Before those projects were entered upon, he ventured to submit to the meeting that, being so far in accord, it would be well to put their accord on record, and to pass a resolution which might be taken as the unanimous opinion of the Conference. With some little modification that plan was adopted, and the result was an application on the part of the Conference, in 1878, to his Royal Highness the Prince of Wales, to suggest to the Prime Minister the appointment of a small scientific Commission for ascertaining those facts, which they were now told still required to be made known. The application was made, but through various circumstances was put aside, and nothing had been yet said which did not tend to show the weighty nature of the application. And he would venture to submit whether it would not be a worthy outcome of the present proceedings to repeat the recommendation of the former Conference, and endeavour to obtain further distinct and definite information as to the subject of water supply. The contrast that existed between the information, or rather want of information, on this subject, in this country and on the Continent, was anything but creditable to us. They owed something to the Ordnance Survey, and they owed much to several gentlemen who had devoted themselves to this subject. It was impossible to touch the subject at all without acknowledging what they owed to Mr. Symons for the information he had collected with regard to the rainfall. That information had been collected, in the first instance, by his unassisted efforts, and afterwards by the efforts of an unpaid and disinterested body of fellow workers, which were an honour to the country, but possibly not so much an honour to the Government that such a duty should be left on the shoulders of private individuals. The Blue-books which had been issued by the different Commissions contained a mass of information, and so did the proceedings of the Institution of Civil Engineers. But when they turned to other countries, a very different state of things was to be found. The Italian Government published, in a form accessible at a small cost to every landowner, information as to the flow, both in summer and winter, and all the other particulars of every river in Italy. But if we turned to our own books and proceedings, there was an absolute absence of this fluviometric information which in Italy was at the command of everybody. He need not point out how important it was to the engineer and landowner, or to any one who had to keep off floods, or seek for water, to possess all this information; and therefore it was not merely as an academical demand, but as a matter of practice, that this knowledge was required. Many of them were aware of the present condition of the Thames, and he apprehended, from instructions recently given by the Board of Trade, that they would shortly be in possession of the actual summer flow of the Thames during July. The lowest account of the flow was that of Mr. Harrison, who put it at 309 million gallons per day. Mr. Bateman put it at 350 million gallons as the summer flow, for days and days together. But the question was whether, with a long series of dry years which might naturally be expected to follow the long series of wet years we had had, a constant supply of 350 million gallons could be anticipated. On the other hand, the demand was constantly increasing. The quantity pumped in July, last year, by the five metropolitan water companies, exceeded 75 million gallons per day; and considering that in the Valley of the Thames, not including that of the Medway, there were now something like seven millions of inhabitants, who require 225 million gallons a day, that was making an unpleasant approach to the 350 millions of possible flow. In forty or fifty years, those seven millions would have increased to something like 14 millions, and the 225 million gallons required now would be from 400 to 500 millions. It was tolerably clear, therefore, that it was desirable to know all that was to be known about the sources and the behaviour of the Thames. With regard to dummy wells, it was a local question how far any individual well might absorb a flood, but as to the general idea, he thought all would agree it was a feasible and good one. There was one point to which he would call the attention of practical men which had not yet been touched upon. The Valley of the Thames and Medway included an area of something like 6,000 square miles, or 5,000 for the Valley of the Thames alone, and of this, according to the figures, something like 4,000 miles was a permeable area, of which 2,000 were chalk and 2,000 miles sand and gravel—a true water-bearing area. The great object of the Geological Survey was to avoid wasting flood water. The natural storage of this water was the pervious water-bearing beds, and the importance of the information suggested as to the percolation from the surface was no doubt very great. They had the facts of the rainfall, and of course they could get nothing more than the rainfall. About fifteen inches evaporated in the course of the year, which would leave only eleven inches to be dealt with in the Thames Valley, of which it was supposed two or three ran down the River Thames. But in whatever mode the water got into the water-bearing strata, there was no doubt it escaped from it very irregularly. It escaped at the lowest lip of the basin, and if a thorough knowledge of the basin were obtained, it occurred to him it would be possible to raise the lip, and place a regulating sluice there, and by that means, to store one, two, or three years of rainfall in these water-bearing strata, to be drawn upon as required, and so keep up the flow of the Thames.

Mr. BALDWIN LATHAM said, with reference to the escape of water from the outcrop of the chalk formation, it was quite clear that all round the escarpment of the North Downs a very small quantity flowed away in the opposite direction to the dip of the strata, which was towards London; in fact, immediately under the chalk there was the upper greensand, which all along the escarpments was worked, at various quarries, both for building and fire-stone; and the level of the water in those quarries varied with the level of the water in the overlying chalk formation; and although there appeared to be the chalk marl intervening between the upper greensand and the chalk, he did not think it was of such an impervious nature as to prevent direct communication between the waters of the two strata. In fact, it was clearly shown where the chalk marl came to the surface all along the foot of the escarpments of the North Downs, there were no ditches or streams all along the formation, and all the rain equally disappeared there as it did over the chalk itself; therefore, practically for all water supply purposes, the chalk, with the chalk marl and upper greensand, might be taken as one stratum. There were immense fluctuations in the quantity which was stored from year to year in these formations. In March, 1883, they had one of the largest quantities of water stored in the chalk of the North Downs and South Downs which had been known for many years, and yet at the end of 1883 they had one of the lowest water periods. That was a thing which had hardly ever occurred before—going from extreme high water to extreme low water in a single year. The maximum probably exceeded the minimum by ten times, and, therefore, when considering the water supply of a particular district, the minimum must be borne in mind, and either the average or the total capacity, seeing there were these immense fluctuations in the quantity of water which were common to all geological formations. The same thing occurred in the new red sandstone, the permian beds, and the oolite, in all of which he had carried on observations for some years. It was absolutely certain, therefore, as Mr. Lucas had pointed out, that a future water supply for underground sources must depend upon correct hydro-geological surveys. When the quantity of water was known, and they could show the yield over certain years, and what area of strata was required to supply a definite quantity of water, there would be nothing to do but to make careful observations in order to get a sufficient supply of water. The question of compensation would naturally crop up, and to his mind there was not the slightest doubt that a single drop of water could not be taken from any of these porous strata without interfering with the flow in some adjoining stream. It seemed, therefore, to be a matter of great injustice that power should be given to water companies to sink wells and abstract water to the injury of those who had property, and often very valuable property, in the water supply, without compensation. The hydro-geological experiments which had been made would tend to show that these areas which were affected contributed their supplies to different rivers, and when it was essential to the public advantage that supplies of water of this character should be procured, it was only right that those who were injured should be properly compensated. With reference to Mr. De Rance's proposition as to the means of storing water in porous strata, of course there were great difficulties in the case of elevated strata, but there were other circumstances in which water might be stored in that way. In the course of his investigations, he had received the most valuable contributions from General Hyde, of the Indian Railways Department, who stated that in Peshawur, from time immemorial, it had been the practice in the rainy season for the natives to cut channels from the water source to the wells so as to fill up the gravelly strata underneath the more impervious surface stratum, and when the wells were filled in that way they were closed, and only opened in the summer time, so that they had at that period an abundant supply of water which had been cooled by coming in contact with the earth at the time at which it was stored. Therefore, what might appear to be a new idea, was really one of extreme antiquity. The whole question of water supply was one of the greatest importance with regard to the public health, and it behoved them, especially in seeking for these underground supplies of water, to take care that they were sought for at points not liable to contamination. Many underground sources of water supply were polluted to a frightful extent; and really the cause of his undertaking these investigations was the repeated outbreaks of typhoid fever in the district with which he was especially connected. Having been able to collect statistics for some fifty years back, he could say with confidence that there was the most marked parallelism between the state of the underground water and typhoid fever. Not only so, but these statistics showed very clearly that there appeared to be a ten years' periodicity in low water times. One of the lowest water periods in this country occurred in the cholera year of 1854; another very low water period occurred in 1864, and another in 1874; and two years ago he predicted, as the result of investigations, that there would be a low water period this year. There was not a shadow of doubt in his mind that over a large portion of England we should have the water lower this year than it had been for years, and the consequence would be that the diseases which followed those periods were likely to be more rife than they had been for some time past.

Mr. W. SMARTT said he understood that the water at Birkenhead was contaminated in a very serious manner, and knowing that a patent was applied for not long since, for a method of draining land in a particular manner into the chalk, he thought it was hardly advisable to go to any great expense in taking water from the chalk, seeing that there was a danger of its being seriously contaminated. Laws might be passed to prevent the passage of drainage from houses into it, but if the level of the water under London were lowered to any great extent, it was quite possible to cause a flow back from the lower part of the river. For instance, there was said to be a fault in the chalk at Woolwich, and on a former occasion it was stated that the water supply at that place was frequently contaminated from that cause. There were also faults under the Thames, and if the water were lowered, there would be a flow back which might not be noticed for a considerable time, and eventually the whole body of the chalk water might become contaminated. There could be no doubt that the water was absorbed by the chalk beyond the amount absorbed in the first instance, for having placed a piece of chalk in water, and allowed it ample time for absorption, and then placed it in a vessel where it remained for some time, he found that not a particle of water ran out. His opinion was that water should be taken from the springs along the course of the river, whilst it was still pure. The water could be obtained at a depth of 30 or 40 feet all the way up the valley of each river, and it might be taken out of the chalk or other porous strata. It was shown that about half of the chalk district about London was covered with an impervious stratum, though the surface might be pervious, as it was reasonable to suppose it would be, because all the marsh land was flat, showing it was formed from sediment washed down from the hills, and being washed down gradually, it must necessarily be more or less porous, and contain a large quantity of water. With regard to swallow holes, it had been stated at a former meeting that there was a passage in Lincolnshire extending some miles under land, and out to sea.

Mr. JOSEPH QUICK, jun., said, referring to the statement of a previous speaker as to the condition of the Thames being at present so extremely low, that only 350 million gallons a day passed over Teddington Weir, he knew that information to be perfectly accurate. The question he wished to ask was, why advantage was not taken of the enormous quantity of water which flowed at other periods over the weir, and which, so far from being useful, was, on the contrary, a very serious detriment to navigation? If those responsible for the water in the Thames stored up the winter floods, they might thereby regulate the flow throughout the year, and the condition of the river would be much improved, with advantage not only to those who took from it, but to those who lived on the banks. With regard to the case of the River Alyn, he had the misfortune to be opposed to Mr. Robinson before the Parliamentary Committee, but he certainly thought Mr. Lucas went a little too far in saying that the decision of the Committee formed any precedent for future cases, and that mill owners were not to be compensated for water of which they were deprived by water companies or others. The circumstances were quite exceptional, but the Committee did not lay down any precedent to prevent mill owners in future cases asking for water compensation.

Mr. W. B. KINSEY desired to corroborate Mr. Baldwin Latham's remarks with regard to the question of periods of drought. From his own investigations he found that ten years ago there was a drought, and again ten years before that, and there was the same drought now. He could also concur in what he said about the water flowing against the dip of the upper greensand. He was now carrying out works in the neighbourhood of Petersfield in the upper greensand, where the facts fully bore out what had been stated.

Mr. W. A. RICHARDSON said he had heard it stated with great surprise that the wells at Birkenhead were polluted. The water at Liverpool was taken from boreholes in the red sandstone, 450 to 460 feet in depth, and the water was frequently analysed, and was considered to be the best and purest in the kingdom.

Mr. LUCAS, with reference to the case of the River Alyn, produced a section showing the exact state of the case, and remarked that what he said in the paper was that it would affect similar cases. The section showed that the water flowing down the slanting strata sank into the limestone and ran a quarter of a mile underground in a course that was not known, and it was on that ground that the Committee refused compensation. Of course rivers which had no such underground course, would not be affected.

The CHAIRMAN then proposed a vote of thanks to the four gentlemen who had read the papers, which was carried unanimously, and the Conference adjourned for a short time.

Mr. Symons's paper was then read.

Mr. E. K. BURSTAL thought Mr. Symons had made out a very strong case indeed for limiting to some extent the period to which water rates should be absolutely unalterable. They had been accustomed to consider that the three driest consecutive years were one-sixth less than the average, but he now showed that they were one-fifth less; and as the difference between one-fifth and one-sixth was considerable when dealing with very large quantities, that was a sufficient reason why some such suggestion as his should receive serious consideration.

Mr. LIGGINS wished to point out the great importance of using rain gauges. Some thirty years ago he spent a month in Santa Cruz, and there he found the rain gauge was the first thing which interested the manager of an estate when he got up in the morning. The next year he visited his own estate in the island of Antigua, and found only two rain gauges in a whole group of islands; but in consequence of what he had seen in the Danish islands, he interested all his friends, from the Governor downwards, in introducing the system. The result was that every estate in the island from that time had constantly used the rain gauge with great satisfaction. The same course had since been adopted in Barbadoes, and he only wished the farmers of England were as enlightened as the planters of those islands, and would see the importance of having rain gauges on every farm in England. He was quite sure they would be pleased with their week's work when they came to tabulate it, and would find the benefit of the information thus obtained. When there were such divergencies as were indicated on the map, there was a clearly proved necessity that, in every district, they should know what they might expect, so as to guide them as to the desirability of commencing the various agricultural operations.

Sir ROBERT RAWLINSON, C.B., remarked that the rain gauge only afforded part of the information, and that a very imperfect part, of that which was necessary for the engineer in pursuing his practice. The rain gauge recorded the rain that fell into it; it did not record the evaporation that took place outside of it. In this country a season might have a rainfall which should take place in a certain order, and which would register in the rain gauge a certain quantity of water, but scarcely any of that water would have been available for the engineer. For instance, in this country, after a continuance of dry weather, a heavy shower on the mountainous districts in Wales, or elsewhere in the kingdom, would do very little for the engineer, because $\frac{9}{10}$ of the water would go back into the atmosphere before it got down into any stream to feed a reservoir. That was a fact which young engineers should know. If in the mountains of Wales, for instance, a rainfall of $2\frac{1}{2}$ inches took place in a week, and then stopped, there would be no feeding water for an engineer's reservoir. Then, if an interval of dry weather should take place, and another $2\frac{1}{2}$ inches of rainfall during a week (which would be a tolerably heavy fall) the engineer would have no feed into his reservoir. He could mention one instance where, on the east coast of England, a reservoir which he had himself constructed was run dry, and for 20 months continously there was no rainfall in that district which was capable of feeding it. Those were important facts which young engineers must take into account.

Mr. MACKNIGHT, with regard to Mr. Symons's reference at the end of his paper as to legislation being very desirable on the subject, said that gentleman had not told them in what direction the legislation he desired should proceed. For his own part he considered that a great deal of injury had been done to the country and to the public interests by premature and rash legislation on these subjects. He thought a great deal more information was required on scientific points before such attempts were made. In Scotland, in various sanitary matters, a great deal of harm had been done by premature legislation, where persons holding particular views on matters of scientific observation had influence enough to get legislation passed in those directions, and it had then turned out that instead of doing good it had done a great deal of harm. A great deal more information should be before the public and scientific societies before such attempts were made, and he deplored the fact that the country should be allowed to suffer from premature sanitary legislation.

A vote of thanks for the paper was then passed.

Papers were then read by E. Bailey-Denton, Edward Easton, and James Mansergh.

Sir ROBERT RAWLINSON said the suggestion of Mr. Easton with regard to supply by meter for large consumers and trade purposes was one of great interest, not only to the public of London, but to the outside public generally. The whole point would turn on the possibility of supplying a reliable meter cheaply, when he did not think a system of supplying water by meter would be objectionable. The great abuse at present in the supply of water for domestic use, under high pressure, was the intolerable waste which took place, which made it almost impracticable to keep up a supply of water at a moderate cost. In the metropolis the supply was equivalent to about 32 gallons per head of men, women, and children, and it needed no great reasoning powers to see that there must be in that vast supply a great deal of waste, for no such quantity could be used legitimately. Some of it the tenant was not liable for, being lost by leaks in the mains; some was lost by leaks in the service pipes, but a great deal was lost by having fittings out of order, and services deliberately left open to flow during the night. That tended to prevent a constant service, and, therefore, he should not object personally to seeing water sold by meter. In another paper the word "pure" had been applied to certain gathering grounds, such as the great moorlands of the country, which were supposed to give a pure supply of water, but this was a great mistake. There was no pure source of supply, as when water came in contact with the earth, even on the mountains of Scotland, which gave a very soft water, they were covered with vegetation up to their summits, and were inhabited by different animals and birds, and whatever the value of that water might be as soft water—and it had its value—for domestic purposes it was very dangerous, especially to strangers. People coming from England to the highlands of Scotland, were almost certain for the first few weeks, if not longer, to be attacked by diarrhœa. He spoke practically, because he and his family had suffered from it; when he was down at Ballater, some time ago, he spoke to the commanding officer at the station where the military were brought down when the Queen was in Scotland, and he learnt that invariably when the soldiers were brought there one-half of them suffered from the softness of the water, and something it contained, which was washed from the mountains. The medical officer also told him that strangers were frequently obliged to leave the district on account of the effect that the water had upon them. A great deal was said against water taken from the Thames, and he was not going to advocate impure water or hard water, but he had had to study the question as a practical engineer, in some respects philosophically, and as it concerned his own health. He had lived three times in districts supplied with what was termed pure soft water, and his experience there had made him very glad to get back again to so stigmatised polluted Thames water. Even for washing, for which soft water was so much prized, he had more pleasure in washing in London water than he had in the lake waters, for if you used soap—and you could not clean yourself thoroughly without it—you had the greatest possible difficulty in keeping sponges and things about the toilet table clean, because the soft water would not easily take the soap out. You might get water from tube sinkings, and deep wells, but you did not then get pure water. The late Dr. Angus Smith—and no one had paid more attention to the qualities and character of water than he had—said that if you gave him the analysis he could tell the stratification the water came from; and, on the other hand, if you gave him the stratification he could predict the character of the water which would come from it. And that must be so, because water as it fell from the clouds was soft water, the purest water in nature, and it was a powerful solvent. It dissolved and combined with any of the salts that it came in contact with. He often regretted that persons travelling in Africa, or in any country not previously traversed by civilised man, that they did not describe the appearance of the rivers and lakes more particularly, and mention whether the water was brown, or what character it had. If you saw a river running bright and sparkling, you might put it down as coming from a limestone source; if it were running bright and brown, it came from a primitive source, slate or granite. Of course when rivers were in flood and turbid, you could not predict anything about them. Water to be used for domestic purposes required special care in treatment and in storage. When a river is the source, the water must be filtered; as from the Thames, the Ganges, and the Nile. Deep well water, from chalk, new red sandstone, or from the oolites, must be stored in covered reservoirs; as if exposed in open reservoirs to sunshine and air, such waters become polluted to a worse degree than river water filtered.

Mr. Edwin Chadwick, C.B., said sanitary science had still to be applied to the instruction of engineering science in this matter of water supply. Originally, he did not object to soft water supplies, for in the then state of knowledge it was stated that the main infusion to which they were liable was from the peat, and a certain amount of tannin, which was not thought particularly injurious; but subsequent experience had shown there were further objections, and he did not think Sir Robert Rawlinson had stated them sufficiently broadly. Very soft waters, the surface washings of moorlands, were in use in Manchester, in Glasgow, and also in Dublin. He had received particular results of the soft water in Glasgow for nearly three months, and found the infusion of peat rendered it unfit to drink, as it produced dyspepsia. In Manchester, the peat-tainted water had the same effect, and he believed the same occurred in Dublin. In Manchester, it not only produced dyspepsia, but had such an action on lead piping as to lead to a large amount of lead poisoning. There was no doubt that in those places the water was not fit to drink during a certain portion of the year. He found that in Glasgow it was customary at some hotels to use glasses coloured, so as to conceal the colour of the water which was supplied. In the face of such experience, what was to be said of the proposal to bring to London 200 gallons per head of peat-tainted water—which for two or three months in the year was not fit to drink. At that time, Clark's process had not got farther than the reduction of hard water to 8°, but now it could be reduced to 4 or $3\frac{1}{2}$, and in those localities, such as Canterbury, where first hard spring water had been thus softened, it produced the finest water possible, which delighted the consumers not only for drinking, but for all domestic purposes. He looked forward to the time when the supply of water would be reduced as it was in Manchester, Sheffield, and other places, to some seventeen gallons per head per day. It might certainly be reduced by half, and if that were accomplished, it would reduce the intakes very materially, and also the establishments of the water companies, and this would be further aided by the chalk sources being utilised. It should be remembered that the Board of Health, some years ago, directed an examination of the spring supplies near the metropolis, and it was found that some forty million gallons of water could then be drawn from perennial springs in the Surrey sands quite free from every objection, in fact free from the greater amount of impurity which was collected by rain water. The consumption then was not more than eighteen gallons per head of population, and it was demonstrated in various ways that fully ⅗ths of the water now pumped into London was actually mischievous, supersaturating the subsoil with additional rainfall, and he believed that evil was still going on, and would continue until the supply was put on a public footing. As to the qualities, they depend mainly on its aëration, which the stomach test, and not chemistry, determined. Water direct from spring sources in chalk was highly potable; taken from cisterns in which it has stagnated, it was charged with bad town air, taken from a slum in which it has been kept, it was charged with the foul air of the slum. Chemistry does not analyse such air, but the stomach does. The prisoners of Millbank Penitentiary had their supplies of water changed from a river source to a spring source, and the medical officer showed that the change was attended by a great improvement in health. Death-rates were adduced to show differences in the qualities of water; but the fact was general that the people of the wage-classes drank, not water, but beer and tea: only children drank water. Not engineering, but sanitary science took cognisance of the principle of circulation against stagnation. In none of the papers did he find any due recognition of the conditions of stagnation which made good supplies bad, and bad supplies worse; in none was there any recognition of the effects of self-cleansing house drainage, which discharged sewage fresh and undecomposed, in conditions which fed fish, and the conditions of stagnation and putrescence which killed fish.

Mr. Bischof said the germ theory had been referred to in one of the papers, and it almost appeared as if the authorship of that theory were imputed to Dr. Frankland. He was sure if that gentleman were present he would be the first to disclaim that idea; he had simply adopted that theory as being the one most in accordance with observed facts. He was under the impression that Mr. Mansergh's paper must have been written some time ago, or he should have expected him to go a step further, and refer to the memorable discovery, by Dr. Koch, of the comma or cholera bacillus. He did not go so far as to consider it finally proved that this bacillus was actually the cause of the cholera, but he thought it extremely likely that the further researches of Dr. Koch and other scientific men would prove that to be the case, and then, perhaps, Dr. Tidy's incredulous gaze might behold the germ itself.

Mr. Maxwell said he wished to refer to a passage in Mr. Denton's paper in which he said that the deficit of the present year would have been more severely felt had it not been, in some measure, counterbalanced by the excessive rain which occurred during the last seven years, which left a balance to be carried over. But as far as his experience of underground water went, he did not consider that they had a bank to fall upon, or that the rainfall in previous years affected the present in the slightest degree. In the waterworks with which he was connected in the neighbourhood of Hull, which was a supply from the chalk, the wells followed very nearly the average rainfall of the three previous months. Thus, in considering their present supply, he had to look at the rainfall of April, May, and June, and depend entirely upon it. Certainly, so far as the water which fell on the Yorkshire wolds was concerned, it found its way into the Humber and German Ocean, and they never could keep any stock. Mr. De Rance had advocated dummy wells, which should be fed in rainy seasons to keep up the reservoirs for dry seasons, but he was satisfied that, in his district, they would be no use. He had a peculiar instance of that three years ago, when there was a heavy snowfall about February. The water in the shafts came up as a rule at a temperature of 50°, but in the June of that year it fell to 46°, which he could not account for until it occurred to him that it was owing to the snows, which lay a long time on the ground and then gradually melted. Mr. Latham had referred to the rapidity with which the water level fell last year, which again was an illustration of there being no storage of previous years to fall back upon. Last year, in June, there were 30 ft. of water in the bottom of his shafts, in July it fell to 20 ft., and in September to 7 ft. This year it came down, in May, to the same level as it was last year in August, simply because after January, which was a wet month, there came February, March, and April, exceedingly dry. He was quite satisfied that the rain of previous years was not stored up as had been suggested.

Mr. E. K. Burstal said he was sorry to differ from Mr. Easton with respect to the supply of water by measure, but his experience of ten years in the management of large works led him to a totally opposite conclusion, mainly on account of the expense. Taking a town of 100,000 inhabitants, one meter would be required to nearly every house, and supposing there were five persons to each house, that would require 20,000 meters, the cost of which, including fixing, would be £100,000. At 5 per cent. that would mean an annual charge of £5,000, and he knew that an inspector could not possibly look after more than 1,000 meters, so that £500 more must be added for their wages, and £5,500 was a large sum to charge on such a town. Now the saving, he calculated, would not be as much as £500 a year. When he took charge of the Oxford Waterworks about five years ago, he had a similar experience to what he previously had at Derby. Oxford was using 42 gallons of water per head per diem, but he had now brought it down to almost exactly 20. A few nights ago, being desirous of learning more particularly the quantity of water used at different hours of the day, he had the whole town supplied from the service reservoir which he had carefully gauged, and found that from 12 o'clock at night to 4 o'clock in the morning, when no water was really used, for there were no manufactories there, the quantity wasted was equivalent to 6 gallons per head. He could safely say, therefore, that 14 gallons per head only was used, and 6 gallons wasted. He had already reduced it from 42 gallons to 20 gallons per head, by means of two inspectors, who had various other duties to perform. That was in a town with a population of 45,000. At Derby, with 75,000 population, he had three inspectors, and if that could be done, he thought there was no necessity for the enormous expense which would be incurred by introducing meters. Meters for measuring water were very different to gas meters. With gas you had a pressure of inches, but with water there was pressure from 150 feet to 200 feet, which made it very difficult to keep any instrument absolutely in order, and there were always disputes with reference to them. The only meter which he knew of which was a good type of a positive meter was Kennedy's, but the great objection to that was that it often let the water pass through it day after day without registering it at all. He certainly had had one in use ten years, which was never touched except to oil it, and at the end of that time it was as perfect as at the beginning; but he had had them in other places where they were often source of annoyance. Parkinson's was very good, but it was only a low-pressure meter. Siemens's was also good, but the public did not like an inferential meter; and, in fact, there was no meter at present which would really answer the purpose, and he was quite certain their introduction would be very distasteful. In London, a reduction in the quantity consumed could easily be brought about, and the companies would be the first to co-operate, but it was necessary for the public to assist; and, unfortunately, at the present time, any one who could oppose the water companies in the police-courts and elsewhere was the popular man, and probably that would be so until the whole of the water companies were transferred to some public authority, and then it would be the old story of Stockton and Middlesbrough over again.

Mr. JABEZ HOGG remarked that London was a very exceptional city to deal with. It was useless to point out what had been done by provincial towns, and this constituted a very serious impediment in the way of procuring a better water supply. In the first place, it would not do to ask the Government to sanction any scheme which would make London dependent on one source of supply; and, therefore, the proposal to bring water from Wales, or from a long distance, was out of the question. If there were an aqueduct bringing water from Wales, what would happen to London if some of the dynamite people determined to cut off the supply; besides the danger there was the enormous expense. Then there came the question of how could we get a better supply than that from the Thames and Lee, for he apprehended no one would say that either of those rivers afforded London a pure and wholesome supply of drinking water; the late discussion in the press made this appear impossible. The water companies had also been accused of taking more water than they should take, thus leaving the river-bed in an exposed and dangerous state; exclusive of this there were a million inhabitants living on the banks of the Thames, and he was surprised the Thames Conservancy should adhere to the statement that the water was comparatively pure, and free from pollution. It was said, indeed, that twenty-one towns situated on the banks were still continuing to pour sewage into the Thames. That was a statement which could hardly be denied. They certainly did not pour the whole of their sewage into the river, but great portion of it found its way, secretly or openly, into the Thames. If any one would go up the river with him, he could point out innumerable inlets where sewage water made its way into the river, in spite of the efforts of Conservators.

Mr. E. K. BURSTAL said that was not the case above the intakes of the London water companies.

Mr. JABEZ HOGG said it could not be controverted that the Thames was miserably polluted above the intakes of the water companies. He would not throw blame upon the Conservators; they did their best; it was simply impossible to divert the sewage of the immense population residing on the banks of the Thames; and even taking it that the sewage went through a sewage farm, or was submitted to the A B C process, the effluent water must pass to the Thames, and was dangerous to health—not always dangerous, but supposing two or three cases of cholera were to occur high up the stream, and the dejections sent into the river, there would be the extreme danger of everyone becoming affected by cholera who might partake of the water. It had been said that the present deficient supply of the Thames might be supplemented by impounding underground water; indeed, one of the water companies obtained a considerable quantity of spring water from the gravel and subsoil, but he denied that this was pure water. With regard to the Lea, there was a letter in the *Times* that morning stating that it was shamefully polluted, the sewage farms on its banks sending in effluent sewage, most dangerous to health, and this could be seen by anyone at the trouble to go up the river. He contended it was impossible for London to look any longer for a supply of drinking water to the Thames or the Lea; there should be an immediate resort to deep well water, which could be had in unlimited quantities from the chalk, where it had been stored up for ages. It was said, however, this water was too hard; it was no doubt discreditable to rich companies to send hard water to their customers without softening it by a process which could be carried out at a small cost in their reservoirs. He considered it a great discredit that a rich company, like the New River Company, should, after sinking deep wells into the chalk, pump a very large quantity of good spring water into a river exposed to pollution, and send it on, open canal fashion, to London, or otherwise keeping it in large open reservoirs where it may become stagnant, and men and dogs may drown. It was impossible to purify such water as that, and convert it into pure and wholesome water such as the companies engaged to supply. The water he drank had 16 degrees of hardness, which was sufficient to produce a large amount of calculous, a disease which he believed was very much on the increase, and besides which it did damage, and marred all domestic arrangements. Mr. Easton had spoken of the damage done to water by cisterns, but he contended that much less damage was done in that way than was alleged. He had gone very carefully through all the poor districts of St. Giles's, and visited house after house to see the condition of the cisterns, and he found that it was less due to the condition of the cisterns than to the quality of the water sent into them. He had just had his cistern cleaned out, and found a very small deposit in it; but of course his remarks applied to covered cisterns, and not to the uncovered cisterns found in some of the poorer houses. It was impossible, with the short supply of water the companies gave, for the poor people to do without cisterns altogether. He was often without water on Sundays, because a short supply of fifteen or twenty minutes daily was thought sufficient by the company.

The CHAIRMAN said he must say a word in support of Mr. Easton's statement with regard to the cisterns. He thought Mr. Hogg would have to inform himself a good deal more with regard to the real condition of cisterns in London, before speaking so decidedly as he seemed inclined to do.

Captain E. BURSTAL said he had only just come into the room, but had heard some astounding remarks, and he was quite sure Mr. Hogg must have been very much misinformed as to the real condition of the River Thames above the intakes of the water companies. That afternoon he had deposited in both Houses of Parliament a report for the year ending December, 1883, signed by the Chairman and himself, which no doubt would shortly be published, when it would no doubt be seen that there were but two towns on the banks of the Thames which passed any pollution into the river. One of these towns was Staines, and they were now beginning to do what they had had notice to do some time ago, and, what they had been prosecuted for not doing namely, adopting some system to deal with their sewage. The other town was Henley, from which a very small quantity of sewage found its way into the river, but however small it might be, it was the duty of the Conservators to arrest it, and do everything they possibly could to prevent any pollution, and every source of pollution which had been found above the intakes of the water companies had been stopped.

Mr. HOMERSHAM said he had seen sewage from the outfall at Windsor, of a most disagreeable nature, coming into the Thames. The fact was, every drop of liquid sewage now went into the Thames; he agreed it had passed through some treatment, but if anybody contended that urine, one of the most deleterious matters that could go into water, was thereby purified, he was grossly mistaken. The sewage was purified to some small extent; but to say that no sewage entered the river, when the whole of it went in except some solid matter, was not correct. He should like to ask particularly about Reading as well as Windsor.

Mr. E. K. BURSTAL said he was the engineer who carried out the Windsor sewage arrangements, and after the precipitating process, the whole effluent was passed through land.

Mr. WALKER said he was manager of the Reading Waterworks, and had a great deal to do with the sewage works of that town. The sewage did not go into the River Thames. Reading had expended over £300,000 in diverting the sewage of the town from the Kennet, which was one of the principal tributaries of the Thames. But while Reading had done that, the sewage of Newbury, sixteen miles above the intake of the Reading Waterworks, went into the Kennet, and from thence might find its way into the Thames. From what had passed that day, he felt quite at a loss to know what would be the best source of supply—one recommended getting it from the chalk, and then they were told the water was too hard, and if they got it from the rivers, that was too soft. With reference to the sewage of Reading, he had simply to say that it had not gone into the Kennet for the last seven years.

A GENTLEMAN asked where it did go to?

Mr. WALKER said it went to the "Manor" Farm, and the effluent flowed into the Kennet.

Mr. ROBERT SUTCLIFF said Mr. Denton, in his paper, mentioned some supposed disadvantages attending the adoption of tube wells, namely, that if an accident happened to the pump, the supply was stopped until it was replaced, and that if the supply was insufficient, another well had to be constructed. As these points were important to the system which he had the honour to be connected with, he wished to say a word or two upon them. With regard to the first, if a pump got out of order in an ordinary dug well, as a rule, another pump must be put up in its place, but in a tube well that could be done in a few minutes. With reference to the supply running short, he could mention one town (Watford) in which sometime ago they doubled the supply, their dug well having got into the very position which it was supposed the tube wells might get into, and not giving a sufficient supply; they put down a single tube well of 8½ inches, and that gave double the supply previously obtained. In reality, having to add other tube wells has really in many cases been an advantage. Sometimes people would say they did not want to incur a great outlay at present in order to provide for future possibilities, and by having a tube well they could have a supply requisite for the present which could be added to as it was wanted. If more water were required, all they had to do was to sink two or more tube wells, and couple them to the existing arrangement. Being at the present time engaged in some ten deep artesian borings, he might make a remark on the general question. There seemed to be a great difference of opinion as to whether water, after it was purified, was prejudicial or not, but he always felt that he would very much rather have water which had not been contaminated, even if the contamination were afterwards removed. His idea was to get the water pure, and keep it pure, not to allow it to be contaminated, and then put it through a process of purification, which seemed to him objectionable and contrary to common sense. On the banks of the Thames, in many places, the sources which supplied the river were beautifully pure, and though he did not approve of shallow sources as a permanent supply, yet, temporarily, an enormous quantity of pure water might be found on the banks of the Thames, which went to add to its volume. In one case, even at Gravesend, within a stone's throw of the river, which was then in a most disgusting state, having put down a tube well, he had water which was analysed, and pronounced to be as pure as that of Loch Katrine. There was a vast body of this water flowing towards the Thames, and if it could be taken temporarily, it would save the water companies a great expense in filtration. This reminded him of the manner in which water was filtered. He did not know whether any of the water companies had tried passing the water up instead of down, but it seemed to him very objectionable to let all the stuff they were trying to prevent passing, be caught on the surface of the filter-beds, and let all the other water go through that. He thought the right system was adopted by one of the filter companies, in which they made all the water pass upwards through the filter, so that any sediment which might be deposited was left at the bottom, and could be easily removed.

Captain DOUGLAS GALTON, C.B., F.R.S., with reference to the observation of Mr. Hogg that cisterns were not objectionable, said, if one thing seemed to have been better established than any other with reference to the water supply, it was the danger of cisterns. He did not say that cisterns might not be kept clean, but the general plan was to leave them for weeks, months, or years, without being cleaned, and then it was undoubted that however pure might be the water put into them, it would become contaminated. All who had studied sanitary matters had come to the conclusion that if possible a constant supply was the best thing to obtain, and that such a supply would obviate the necessity for house filtration. Those impurities which were now obtained in London water were chiefly owing to the method of storing it.

Mr. HOGG said what he wished to imply was that the water supply was so short that the cisterns were drained dry every day, and therefore there could be no sediment.

Mr. CHADWICK said, living at Richmond, he had seen water running from market gardens into the river in enormous quantities, the colour of coffee, and he had gone to take a bath there, and found the water absolutely smell of manure. Many people forgot that it was not sewage alone, but the surface washings from lands heavily dressed with manures, which polluted the rivers.

Mr. EASTON said he laid so much stress on the evils of the cistern system because, when he investigated the water supply in 1877 and 1878, an immense mass of information was got from the Metropolitan Board which would have been laid before a Select Committee if the Bill had not been stopped at the second reading, and very conclusive evidence was obtained as to the filth in the cisterns. Five of the ablest chemists in England, with the Chairman at the head of them, were engaged for three or four months, not only investigating the quality of water supply in the mains of the different companies, but the mud which they took out of the cisterns, and however difficult Mr. Hogg said it was to find any deposit, he could assure him there was an ample supply of taint from all parts of London—not only from the poorer class of houses, but they found it in places where it certainly ought not to have been found, and where, if the people took proper care of the cisterns, it certainly would not have been found. With regard to the people generally, it was their misfortune that the cisterns were in such a condition; it was a consequence of the intermittent supply that this filth would accumulate. He might add that they were investigating not with a view to prove that the water in the mains was the best, but on behalf of the Metropolitan Board of Works, who had a rival scheme, so that, if they had any bias, it was to show that the water in the mains was bad.

Mr. MACKNIGHT said there had been a great deal of discussion in Edinburgh on this question of cisterns. The Water Trust were under the necessity of bringing in a very large supply of additional water, and it so happened this was from the Moor Foot Hills, ten or twelve miles south of Edinburgh, where there were no springs; and there were loud complaints on the part of the artisans of its impurity. The Water Trust in defence got up a cry about the state of the cisterns, but they were completely beaten. Most of the houses in Edinburgh were what are called self-contained, and all had separate cisterns, which the owner took care to keep in good order, but the bad water sent into them left a deposit. All chemists knew very well that if water had certain mineral ingredients in it, after standing a short time, it would leave a deposit, but that was due to the water, not to the cisterns.

[The Conference then adjourned.]

Mr. WHITAKER writes:—There having been no time for the authors to reply to the points raised in discussion, I send the following note on what fell from Mr. Baldwin Latham, and from Mr. Kinsey, in regard to the chalk marl on the south of London and near Petersfield, allowing of the passage of water between the chalk above it and the upper greensand below. In my paper the suggestion that another colour might have to be added to those already used on my maps to separate the chalk marl from the rest of the chalk, is not of universal application; but refers only to those parts where the chalk marl is so clayey as to be practically water-tight and not water-bearing. The district in my mind was not that on the southern side of the London basin, but that on the northern side, where, for very many miles in Hertfordshire, Bedfordshire, Cambridgeshire, and part of Norfolk, this basal part of the chalk is so impermeable as to throw out water from the permeable bed of hard and somewhat sandy chalk that overlies it. The outcrop of that permeable bed, known as the Totternhoe stone, and which has been largely used in building, is marked by a line of springs, the occurrence of which has determined the site of the many villages to be found along the base of the chalk hills from Hertfordshire to Cambridgeshire. The conditions here are clearly different from those that hold on the southern side of the London basin; but I doubt if in the latter district the chalk marl everywhere allows the passage of water through it, and evidence in this direction is given by the experimental drift-way of the Submarine Continental Railway, near Dover, which, driven through chalk marl, was practically dry. To show, however, the varying nature of this bed, as regards water, we need only cross the Channel, to the corresponding experimental works of the French Company, where many springs were met with in the chalk marl. At Dover the only fluid found was champagne, and it is said that this was dry!

Miscellaneous.

*EDUCATION IN ENGLAND.**

The building in which we are assembled marks a new departure in English education. Like most good things in England, it is the splendid result of local munificence, of local effort to satisfy a want long felt, at last acknowledged. The *genius loci* will, I hope, impart itself to the Conference, and it too will, I trust, show us new channels of enterprise, and give to our thoughts on many subjects a new starting-point. We are not here to codify a system of education. We are aware that toleration of opposite views is the first result of a liberal education—that nothing could damage education more than fanatical adhesion to preconceived notions. In England, hitherto, we have been hospitable to every possible method of education, and we do not intend to ostracise any. The Standard School, which all other schools are forced to follow, is a despotic institution which will not meet with favour in England. I crave your indulgence for a few remarks on some of the burning questions of the day. If science is a constant inquiry into the causes and probable effects of the phenomena by which we are surrounded, it follows that we can never allow the process of inquiry to remain dormant. Constant observation of the various forces which are operating is the main element of education. The development of the powers of observation, to satisfy an ever-expanding curiosity, is at the root of every system of rational education. How to observe, and what to observe, in the past and in the present, is the ever-recurring function of education through life. Apply the test to the humblest and to the most exalted professions, you will see that the test does not fail. The agricultural labourer, whose work is of the most uninteresting description, will be efficient or inefficient exactly in proportion as his faculty of observation has been developed. Nature will teach him something every day of his life, if he has been taught how to watch her workings. It is the same for the astronomer; observation is to him the first necessity. In primary education this truth is more and more recognised, and drawing as well as elementary science and manual work are being put in their proper place. Belgium is moving vigorously in that direction, following, with reference to manual work, Sweden, where the *slöjd*, or school of domestic industry, may well claim our attention. Two French Ministers of Education, M. Bardoux, and the present Premier, M. Ferry, have given their verdict in favour of the extreme importance of drawing. Sweden also contributes to

* Opening Address by Lord Reay, at the International Conference on Education, at the Health Exhibition August 4th, 1884.

gymnastics that efficiency of training which—as we are so near to hygienics—I need only indicate with a word. The monopoly of the three R's is doomed, and the enthronement of the three D's—drawing, drill, adroitness—approaching. The primary school must not degenerate into a mere workshop. I do not agree with the Procureur-Général de la Chalotais when he complained of the subversive influence of the Jesuits in teaching children to read and write who ought only to learn how to handle a hammer or a plane. In pleading for rational being substituted for mechanical methods, I simply desire to arouse those inquisitive tendencies which in many cases now are deadened; to make the primary school, not the early grave of individuality, but an attractive spot where the productive use of leisure as well as of the hours devoted to work, coupled with the surroundings of prints and flowers, shall give pleasure to the boys and girls who frequent it. I need not say how important the invaluable report and recommendations of the Royal Commissioners on Technical Instruction are, and none more so than those bearing on agricultural education, to the effect that "in rural schools instruction in the principles and facts of agriculture, after suitable introductory object lessons, shall be made obligatory in the upper standards"—as it is in Ireland—and "that encouragement should be given, by way of grants, to practical works on plots of land attached to such schools." Agricultural education is considered in certain quarters as a luxury. I may be allowed to use the strongest expressions to deprecate this extraordinary error. At the present moment the future of rural society is a great problem. The bearings of this problem on society in general are obvious. The land question is in all countries one of paramount importance. *Ad nauseam* we are told that land is a limited quantity, and then almost immediately afterwards we are told that, for that reason, it should be made common property. The deduction to be drawn from that palpable axiom seems to me an entirely different one, namely this—that we should throw into the management of land the highest possible skill. Gold is a rare commodity, therefore you only give it to a skilled artisan; on the other hand, the management of the soil, which raises a host of scientific and economic considerations of the utmost delicacy, is left in most cases to those who have not had any training in science or in the technicalities of agriculture. Farming is a pursuit which requires in these days the utmost skill and versatility. The fact is admitted, not by mere theorists, but by the most practical agriculturists in every country. We used to hear a great deal of the practical soldier as opposed to the academic soldier; but since recent wars we hear a great deal less of the former, though I do not wish that often great character to become extinct. So it is in the agricultural world. Three years of depression have been the death-knell of unskilled farming. The notion of farming—of estate management—not requiring previous technical education, is quite as absurd as entrusting H.M. ironclad *Inflexible*, with its complex machinery—a floating laboratory—not to a scientific officer like Captain Fisher, but to the skipper of a Yarmouth fishing smack. I shall not inflict any statistics to-day on you; but I should like to know what the loss was resulting from unskilful agriculture? Transform agriculture into a skilled pursuit, multiply men like Lord Walsingham, and we shall probably hear as little of the wish to reduce the surface of the globe to encampments of squatters as we now hear of a division of commercial navies, which are also a limited quantity, which cannot be expanded indefinitely. Not to be misunderstood, I should like to point out that, in this case also, science will not rob the people of enjoyment, but add to it. My friend, Sir John Lubbock, has insisted on forestry being taught. How much of enjoyment has been lost by the wanton destruction of forests and the neglect of planting forests? The preservation of Epping Forest answers this question. By how much could the consumption of milk be increased if dairy farming were conducted on scientific principles? How are you to feed humanity in the next century, if population continues to increase at its present ratio? How are you to stem the tide of immigration to the large towns? Only by giving to the rural districts that sense of pride which their inhabitants can only have if they realise that they are members of a body which commands universal respect, like the army and the navy, whose scientific branches have, in recent years, made gigantic progress You see that, in this respect, as in most other respects, I do not agree with Voltaire when he wrote to De la Chalotais, "I am grateful that you disapprove of learning for agriculturists. I, who am an agriculturist myself, do not want *savants* for that purpose." We do want *savants*, and I am happy to say that the University of Edinburgh has recognised this; but, in addition, we want trained agents, trained farmers, and trained farm labourers, just as much as we want trained merchants, trained manufacturers, trained mechanics, trained foremen, trained artisans. Through technical education we must recover ground lost since the Middle Ages, when, in Italy at all events, an artisan was an artist. There is some injustice in the favourable view we entertain of our enlightened century, as compared with the dark times which have left those splendid monuments of art. The great controversy about the relative merits of the gymnasium and of the realschule has not yet invaded England. Is it because the classical school enjoys a sense of perfect security, or is it because the Technical Instruction Commissioners have only sounded the first note of alarm? One thing is certain, we shall have to make up our minds for a large increase of schools with a modern curriculum. What is called the perfect school, which embraces every branch of learning, would certainly never meet with favour in England. It would only lead to ancient and modern languages and science being all equally badly digested by the pupils. Such programmes, if approved by the Whitehall

Inspectors, would, ere long, attract the notice of sanitary inspectors of the Local Government Board. The only chance of anything being taught thoroughly would be, not the efficiency of all, but the inefficiency of some of the teachers. This was illustrated in a German gymnasium, where the director, on being asked how it was that the Latin of his pupils was so satisfactory, replied, "Oh, because we are fortunate enough to have a very inefficient mathematical master." The exclusion of the study of the ancient languages does not mean the exclusion of the study of the institutions of ancient Rome and Greece. It is a fair question whether a student of German, reading German authors on the literature and institutions of Greece and Rome, will not have a deeper insight into their character than the youth who has been victimised to write hexameters. Will Mr. Warre make the study of German compulsory for all Etonians, as the Bishop of Chester recommends? Will he put a stop to classics in all cases where the mind shows no capacity for their profitable influence? I do not go so far as Herbert Spencer, who quarrels with the sculptor of the Discobolus because, unfamiliar with the theory of equilibrium, he placed him in a position which must cause him to "fall forward the moment the quoit is delivered." I do not believe that the Discobolus will cease to be admired by those who are versed in the laws of equilibrium, by German staff-officers, for instance, because Moltke approves of a scientific education in preference to a classical training. There is a great deal of truth in Thiers' apprehension when he said—"At a time when religious convictions are weakened, if the knowledge of antiquity also became faint, we should have become a society without moral links with the past, exclusively acquainted and busy with the present—a society ignorant, lowered, only fit for mechanical industries." I also agree with M. Saint Marc de Girardin, "that if we were to clear out of our brain all the ideas we have received from the Greeks and Romans, we should be frightened how little remained." But the spectacle of Claude Bernard, the founder of French physiology, working in a cellar of the College de France, and shortening his life by the martyrdom inflicted on him through the absence of a laboratory, is quite as potent an educational factor as the philological research which culminates in the restoration of the original text. A lawyer ignorant of Roman law, a theologian ignorant of the Greek Testament, an artist without classical training, seem to me imperfectly educated; but then an architect, an engineer, a doctor, not trained in science are equally unsound. The whole contention is simply one of possibilities. The hatter of a great statesman lately told him that his head had grown larger within the last ten years. We are told that a French physiologist has come to the conclusion that in generations who, from father to son, have constantly used their brain, an enlargement of the skull has taken place, which, in ten centuries, would make a difference of six millemetres. The power of expansion is therefore limited, and we must have bifurcation; and if we give a variety of instruction in both schools by the teaching in both of modern languages and history, which cannot be neglected, we shall find a common ground for those who take up science and those who take up classics. Not a mere smattering of "Allgemeine Bildung" is the aim of English education; it has alwas striven after thoroughness—"non multa sed multum." The bifurcation is rendered necessary by the very fact that a combination of both curricula would damage them both. If we are to give secondary education of any value to a large part of the population, this is the only way of doing it, because they cannot afford to waste time on classics. The complaint is as old as Montaigne, who in his day bewails the fact of the great number of people whose mental growth was stunted by the inordinate desire to learn overmuch. By education you do not want to enervate, but to strengthen, the will of the individual, and to give to his character a manly independence. The highest culture, undoubtedly, is found among the representatives of the classical school. It would be sheer ingratitude not to recognise that to it we owe writers like Newman, theologians like Lightfoot, orators like Gladstone, statesmen like Goschen, poets like Browning, artists like Alma Tadema, historians like Lecky, metaphysicians like Flint, essayists like Lowell, biographers like Trevelyan, critics like John Morley, not to mention names equally illustrious among the living and the dead, here and abroad. The numbers of authors, poets, orators, and artists must inevitably be limited, as Goëthe tells us:—

> Wer in der Welt Geschichte lebt,
> Wer in die Zeiten schaut und strebt,
> Nur der ist Werth zu sprechen und zu dichten.

The study of the ancient world is undoubtedly one capable of attracting the noblest instincts; but what are you to say to those who, having attained a mere smattering of Greek and Latin, either turn their backs on all further self-education, or swell that literary proletariate which, good for nothing, declaims hollow theories or panders to bad taste? The great bulk of the nation is not intended to speak and write, but to work, and must therefore be trained to satisfy the requirements, not of ancient Rome and of ancient Athens, but of society as at present constituted, with its extraordinary development of international relations. It is the realschule which makes it possible for young Germans to write letters in three or four languages besides their own, and to fight their way into the offices of our merchants at Manchester and at Bombay. Michael Chevalier said of the Ecole Centrale des Arts et Manufactures—"If it were not in existence, it would be necessary to create it, as the complement of the treaties of commerce." We have too long neglected that side of our educational system, forgetting that such schools are much more likely to benefit the greater number of those who frequent them than classical schools, which only benefit a select few. But if you have admitted that one type of secondary school is as impossible as one type of primary school or one type of university, you have recognised another great truth—namely that you cannot centralise your education. The needs of nations, of localities, of individuals, are so varied that it is impossible to draw up one code. It will be unnecessary for me to remind this audience of the utter failure to assimilate English, Scottish, and Irish education, though perhaps not everybody here would be prepared to consider this a satisfactory phenomenon. But let us ask our French friends whether they are satisfied with centralised machinery. What does Pasteur say? How does he answer the question, "Pourquoi la France n'a pas trouvé d'hommes supérieurs au moment du péril?" As follows:—"While Germany was multiplying its universities, and establishing among them a most salutary emulation; while it was surrounding their masters and doctors with honour and consideration; while it was creating vast laboratories furnished with the best instruments, France, enervated by revolutions, always occupied with sterile aims at a better form of government, gave only a heedless attention to its establishments of higher education." The late eminent Dumas, one of the eight inspectors of superior instruction in the Uuiversity, speaks not less positively. "If the causes of our marasmus appear complex and manifold, they are still reducible to one principle—administrative centralisation, which, applied to the University, has enervated superior instruction." A professor in the Faculty of Medicine, Loraine, boldly says:—"We demand the destruction of the University of France, and the creation of separate universities." The Germans do not centralise; there is no "Reichs Ministerium" for education at Berlin. Ask Döllinger whether he would sanction the destruction of autonomy in matters of education in the various States of Germany. My friend Sir Lyon Playfair assures us—"A free country like England will not tolerate State unity in education, any more than it has tolerated it in any region of her politics." Notwithstanding this gratifying assertion, he must allow me to look with considerable suspicion upon his conception of a Minister of Education. I am told that Herbert Spencer on one occasion maintained the opinion that we might, perhaps, be all the better for absence of education, leaving it to the friction of life to develop individual powers. This is an extreme view; but it is more human than that of our poet Gascoigne, who says, "A boy is better unborn than untaught." Adventurous and enterprising men, though uneducated, have done great things. The tyranny which would compel the human race to be educated on identical lines seems to me to have nothing human in it at all; and I am quite certain of this, that our empire can only be maintained if we give free scope to the greatest variety of methods of education. The French Canadian, the settler in New Zealand, the Parsee in Bombay, the ryot in the Deccan, the Scottish bursar at Aberdeen, the Connemara peasant, are all entitled to have that system of education which will develop on national and historical lines the strongest features of their race, though none of them may be able to compete for the Hertford scholarship. If every nation were to give full play to the variety of talents which it contains, instead of trying to press their schools into one mould, we should hear less complaints of want of originality. Are the universities to take cognisance of the technical part of education, or are they to take no part in this great movement? If the universities train our statesmen, our doctors, our lawyers, our clergy, our literary and our scientific men, I can see no reason why they should not also give us the highest engineering, artistic, financial, commercial, and agricultural skill. Why should the great Institute which gives us its hospitality to-day not form part of the University of London of the future? The idea of a university is not to grind a certain number of individuals in a certain limited number of studies, and then to invite them to write down answers to printed questions. The idea of a university is to supply the highest wants of a nation in every direction, not in one. "Discite vitæ non scolæ." If the best scientific teaching is to be represented at the universities, and if technical education in its most advanced stage is to obtain it, why not at the university? It is a gratifying fact to me, as Rector of the St. Andrew's University, to be able to recall the fact that in the organisation of that university after the Reformation, one of the three colleges was to devote itself to teaching dialectics, mathematics, including arithmetic and geometry, cosmography, astronomy, and natural philosophy. After attending this course for three years, and passing a successful examination, the student "shall be laureat and graduat in philosophy." I do not forget that a university is not merely a place for professional training, but for the highest research. I prefer the German system, where both objects are united, to the system which has obtained in France, where the Collège de France and l'Institut Pratique des Hautes Etudes overshadow all the universities from which they are separated, though, we must recollect, the two professional schools, "l'Ecole Normale et l'Ecole Polytechnique," have given to France its most eminent *savants*. This question is a question of division of labour. Huxley and Ray Lankester will not grudge lecturing to those who are capable of benefiting by their teaching. The important element in university training is that those who attend the lectures should be quite fit, by previous training, to follow the lectures; that the lectures should be given by the most learned men, and should have a stimulating influence on those who attend them. Any pupil of Jowett's will agree to this proposition. You will, of course, have to graduate your lectures for those who intend to give up their lives to study, and for those who wish to enter on a profession; but the best teaching will be at the disposal as well of the one class as of the other. The object is not to burden the men who are the highest representatives of learning, but to increase the number of those who come under their influence; to make the influence of the university felt in a wide circle. That is, I know, the object of the best men at our universities; and I may, perhaps, couple the name of Professor Stuart with these efforts. What you want is to reduce the necessity of artificial intermittent examinations, by increasing that unremitting self-examination which is the natural result of constant attendance at the best teaching. An examination can never become a corrective of indifferent teaching, and I had rather not answer the question whether it is an unerring test of the results of good teaching. I can only say that I was glad lately to be told confidentially, by one of the most eminent men engaged in the higher education of France, that he held very heretical views on the subject of examinations. The task of the universities is to collect as great a number of eminent men as they can find. The triple task of these men will be, firstly, to fill every profession and every walk of life with men who will be able to grapple with the problems they have to face, because they have been taught what is implied by scientific method; secondly, also to reproduce, as it were, themselves by training new leaders of future generations; and, thirdly, to add to our intellectual capital by research. I am opposed to the professors at universities degenerating into what M. Renan has stigmatised as "amuseurs publics," who give entertaining and brilliant lectures. The class-room of a professor should only be filled with the flower of the youth of a country, but that flower should be recruited from all classes of the community. The luxury of idleness alone ought not to be tolerated at a university; every other luxury, in the way of bursaries and scholarships, should at once be absorbed. I say this in London, where we have this variety, but where we keenly feel the want of the "Alma Mater" which will gather these wandering orphan lecturers. Let us hope that the next Conference will be welcomed by the chancellor of a teaching university in London. I do not wish the universities to stand in solitary grandeur, remote from the life of the people. An eminent Radical statesman said to a professor who was putting in a good word for the existence of other agencies than the mere impulse of the multitude—"It is the like of you who are worse than Peers." The remark was significant. The French aristocracy is destroyed. The French University retains its ancient lustre. Science is never sensational, but from its very nature progressive, because always constructive, and using, not wasting, the materials of the past, to build the future on a solid foundation. A cynical plutocracy and an uneducated democracy both are inclined to be wasteful and destructive; both are inclined to set up shams. Science cannot set up shams, but invariably destroys them. The patient, the cautious attitude of true science, in dealing with obstacles to progress, will not always suit the impatient and often generous impulses of democracy. One of the great dangers of the future is a collision between these two forces. How can we prevent it? Only by giving the democracy confidence in the aristocracy of science —an aristocracy which is self-made, and can only perish with science itself. It is an independent aristocracy, because the moment science becomes servile it loses its *raison d'etre*. Its labours are the main causes of the prosperity which is enjoyed by the people, and of the greater prosperity which is in store for them if they listen to the voice of wisdom. The notion of equal comforts for all—*le régime des appetits*—has nothing but a ruinous collapse of civilisation to commend it. The antidote to these poisonous precepts is to be found in the extension of university teaching. Its administration should be on a large scale. Emerson was not far wrong when he wrote—"We shall one day learn to supersede politics by education." Those who are painfully aware, by the fulness of their knowledge, of the greatness of their ignorance, will have to inculcate that greatest of all lessons to those whose ignorance draws pictures of a future paradise, in which *à priori* theories will secure universal happiness. In such an earthly paradise, I am afraid, the tree of knowledge would be sought in vain. The doctrine of human fallibility is not impugned by scientific progress, but rather the reverse, when we think of the darkness from which we are only just emerging. Faraday gave expression to this conviction when he said—"Society is not only ignorant as respects education of the judgment, but it is also ignorant of its ignorance." Such a complex machinery as modern society, with its manifold wants, makes the organisation of education more complex every day. Not by centralisation, not by programmes, not by circulars, not by examination papers, not even by lavish expenditure alone, will success be attained. What is wanted is that public spirit, that strong conviction in every man, woman, and child, that education is a privilege; that the more education a man has, the more he is to be respected. Does it exist? Yes; you will find it among the scattered population of the Highland glens of Scotland and of Switzerland, along the canals of the Netherlands, in the forests of Germany. It is a precious heritage. To increase it is our object. The great Chancellor of the German Empire once compared the struggle for gold between the central banks of Europe to a struggle among individuals for a blanket of insufficient size. The same process is at present going on in the various States of Europe with reference to education. We are all struggling for golden wisdom, with this great difference, that the gold we bring to the surface at once becomes the property of all. The discoveries of the biological marine station at Naples can be tested at St. Andrew's, and the scientific work done at Strasburg can be utilised in Edinburgh. Science cannot render men equal. The princes of science constitute a separate order, and when we enjoy the pleasure of contemplating or reading the works of genius, we cannot help admitting our own inequality. A nation ceasing to reverence its great men is on the decline. Inequality is a law of nature; but so is liberty, and liberty is incompatible with equality. But if education alone makes liberty possible, by learning its uses and preventing its abuses, it also teaches us to be generous. The best educated man will also have the widest sympathies. The best educated people will also be the people which cements peace and goodwill among nations.

TECHNOLOGICAL EXAMINATIONS.

The Report, by Mr. Magnus, on the 1884 Technological Examinations of the City and Guilds of London Institute, has just appeared.

A considerable increase is shown in the nnmber of candidates at the recent examination, as compared with that of the previous year. In 1883, 2,397 candidates were examined, of whom 1,498 passed. In 1884, 3,635 were examined, of whom 1,829 passed. There is also shown an increase in the number of centres at which the examinations have been held.

From the returns received at the office of the Institute in November last, it appears that 5,874 persons were receiving instruction, with a view to these examinations, in the registered classes of the Institute. The number of students at the corresponding period of the previous year was 4,052, this being 585 in excess of the number in 1882.

Of the candidates who received instruction in the registered classes of the institute, about one-half presented themselves for examination; of the remaining candidates who came up, some had received instruction in colleges the professors in which do not accept payment on results, whilst others had supplemented their workshop practice by private study.

This year, as last year, Glasgow heads the list of centres from which the largest number of candidates have passed, the number being 139, as compared with 123 in 1883. Of the other centres, Manchester sent up 115 successful candidates, as against 76 in the previous year; Bolton 98, as against 117; Bradford 90, as against 51; Leeds 70, as against 64 (50 coming from the Yorkshire College as against 43); Preston 59, as against 46.

In carpentry and joinery, which was added this year to the examination progamme, 369 candidates were examined, of whom 125 passed. Nottingham sent up this year, for the first time, 19 candidates in lace manufacture, of whom 13 succeeded in satisfying the examiner.

Examinations were held this year in 43 subjects, as against 37 in 1883, the only subjects included in the programme in which no examinations were held being the mechanical preparation of ores and salt manufacture.

Practical examinations were held this year for the first time in weaving and pattern designing, and in metal pattern work.

Of the 23 candidates for honours who, besides undergoing a written examination in pattern designing and weaving, sent up specimens of their work, 13 succeeded in obtaining a certificate. In metal plate work, two candidates presented themselves for honours, but neither succeeded in obtaining the institute's certificate. In all subjects of examination, the honours certificate of the institute is intended to be regarded as a diploma of proficiency, and is awarded in those cases only in which the candidate shows a sound theoretical and practical knowledge of the subject.

The percentage of failures on the results of the examinations in all the subjects has increased from 37·5 in 1883 to 49·7 in 1884. This increase in the number of failures is due to many causes, prominent among which is the want of skill in drawing, and of previous science teaching on the part of the candidates. In many subjects, too, there is still experienced the serious want of competent teachers, which it is hoped will, to some extent, be remedied when the central institution is in working order.

The large accession to the total number of candidates is due mainly to the increase in the number of candidates in cloth and cotton manufacture, in weaving, and in mechanical engineering, and to the addition of the subject of carpentry and joinery to the programme.

"Looking at the general results of the examination," Mr. Magnus says, "the large increase in the number of students under instruction, and of the candidates who presented themselves for examination, may be considered satisfactory, as indicating the more general desire of artisans, and of those engaged in manufacturing industry, to take advantage of the opportunities now offered to them of receiving technical instruction. At the same time, the larger proportion of failures consequent upon this accession of candidates, the majority of whom are already familiar with the practice of their trades, but possess a very imperfect knowledge of the application thereto of the principles of science, shows the need that still exists of improved and of more systematic technical instruction for those who are employed in factories and workshops.

"Although the Royal Commissioners on Technical Instruction have spoken encouragingly of the facilities now offered to artisans of obtaining in evening classes good scientific and technical teaching, it would appear that the number of persons engaged in manufacturing industry who avail themselves of the Science and Art Classes under the Department is still comparatively small, and that the proportion of children who learn drawing in the public elementary schools is, as yet, inconsiderable. These causes, doubtless, prevent our artisans from deriving the full advantage of the technical classes now organised in different parts of the kingdom."

THE CHANNEL TUNNEL.

At the invitation of Sir. E. W. Watkin, Bart., M.P., and the directors, some members of the Society's Council and other gentlemen visited the Channel Tunnel works on Saturday, the 2nd inst. Amongst the party were the Duke of Buckingham, Sir Frederick Abel, Sir Frederick Bramwell, Sir Joseph Bazalgette, Lord A. S. Churchill, General Cameron, Captain Douglas Galton, Sir R. Rawlinson, Mr. Andrew Cassels, Colonel Webber, Mr. Brudenell Carter, Mr. J. B. Eads, Mr. Henry Doulton, Mr. Alfred Carpmael, Mr. Owen Roberts, Mr. B. Francis Cobb, Professor Dewar, Mr. J. R. Crampton, Mr. H. Trueman Wood, Mr. Myles Fenton, and Mr. Shaw.

The party inspected the works and the boring machine, which, by permission of the Board of Trade, was set to work for a few minutes experimentally. At the luncheon which followed, a few toasts were drunk.

Sir FREDERICK BRAMWELL, whose health was drunk as consulting engineer of the Tunnel, said he could scarcely trust his temper or his good manners, after a visit to the great work they had seen that day, the progress of which had been arrested. When one considered that the proposition was that the military power of England and the scientific power of England were incapable, in the event of war, of doing away temporarily with a couple of holes 14 ft. in diameter, and twenty miles in length, he was ashamed of it, and it was positively scandalous, for a scare of that kind, that one of the most important works in the world should have been stopped. It had been authoritatively said, "We shall be glad to see you do the work, but you cannot," and now that they had shown that they could carry it out, they were not allowed to. They had spent a large sum of money, and the French on their side had been induced to spend a large sum, and now the work was stopped, not for any reason, but for the most groundless scare that ever disgraced a nation.

Short speeches were also made by the Duke of Buckingham, Lord Alfred Churchill, Sir Frederick Abel, and others of the guests.

CANE AND BEET SUGAR.

By G. BUCHANAN.

(Continued from p. 818.)

In Germany, 12½ cwts. of sugar beets were formerly assessed to make 1 cwt. of crystallised or grain sugar, equal to a yield of 8 per cent. But now, owing to improved cultivation and manufacture, it is believed that in good years, 1 cwt. of sugar is obtained from 11 cwts. of roots, being a return of 9 per cent. In France, not more than 5½ per cent. of grain sugar is made from beets containing 10 per cent. of saccharine matter. About 2 per cent. is procured in the form of molasses, and of what remains, rather more than 1·3 per cent. is given up in the pulp to the farmers. The losses in manufacture will account for the rest. In Demerara, 12 cwts. of canes, with an assumed extraction of 66½ per cent. of juice, make 1 per cent. of grain sugar, equal to a yield of 8⅓ per cent. In Jamaica, the exports, on an average of the five years before mentioned, with the sugar made by the small settlers, which is mostly consumed on the island, show a production of less than one ton of sugar per acre, or a yield of 5 per cent. But on many of the estates, it may be noted, a large proportion of rum is made, Jamaica rum fetching more money than the rum of other places. In Martinique, 13 cwts. of canes, with an extraction of 65 per cent. of juice, are taken to make 1 cwt. of sugar, giving a return of 7·62 per cent. The yield, however, at one of the usines, as the works are called, with an extraction of 77·94 per cent., is stated to have been 8·91 per cent. of grain sugar. In other words, 11¼ cwts. of canes made 1 cwt. of sugar, a result as good as it is perhaps exceptional to have accomplished. The theoretic out-turn gives, nevertheless, a greater yield. For instance, taking the sugar in the canes to be 18 per cent. and the juice 90 per cent. of their weight, the amount of sugar in the juice is found to be 20 per cent. Then $11\frac{1}{4} \times \frac{20}{100} = 2\frac{1}{4}$ cwts., of which an extraction of 77·94 per cent. is 1¾ cwts. And this, allowing for the change of a fourth of the sugar into molasses, shows a loss of one-third of a cwt. in every cwt. manufactured. No account is made of the juice abandoned in the megass from inability to get it, or the loss would appear considerably more. But take the exponent 1 to 13 as a better index of the proportionate production of sugar to cane in good mills. Then $13 \times \frac{20}{100}$ as before = 2·60 cwts., the full contents. And if 85 per cent. of juice be extracted, we get 2·21 cwts. of sugar and molasses. A result that is tantamount to a loss by the ordinary mode of manufacture of cwt. per cwt. In such a case it becomes a pertinent question, how to avoid this loss. In practice there must of course be some waste, and unripe and damaged canes will also cause a destruction of sugar. Yet as it is possible to get the sugar in the beet with a discount of little more than 1 per cent., it cannot be thought a thing impossible to obtain it from the cane without the forfeiture of as much almost as is made. And it is evident that, if the pressing mill has failed to do it, the diffusion process gives promise of greater success. In the Louisiana trials diffusion used only 9⅗ cwts. of canes, when the mill took 13¾ cwts. to make 1 cwt. sugar and molasses, equal to a yield of 10·37 and 7·27 per cent. respectively. At Aska works the yield is much larger, amounting to from 13 to 14·8 per cent., and more than has been obtained by the mill anywhere. It has been objected to the diffusion process that an excess of molasses is produced, and the first run of diffusion in Louisiana showed an excess of 6·79 per cent., the proportion being—

Diffusion .... 50·43 sugar, 49·56 molasses.
Mill .... 57·22 „ 42·77 „

But in the second run of diffusion there was no excess, the proportion being—

58·48 sugar, 41·51 molasses,
or 1·26 per cent. less than the mill.

It will be noticed how large was the quantity of molasses made both by the mill and diffusion, caused probably by the weak character of the cane juice, which does not always ripen successfully in that region. Whether there would be a continued diminution of the amount, the nearer diffusion was brought to perfection in working, it is hard to tell.

Since the failure of the process in Louisiana, the attention of the planters has been given to the better grinding of the canes, by adding to the 3-roller mills in use a 2-roller mill of greater strength and capacity. But seeing what has been done at Aska by diffusion, it may be fairly concluded that the ratio would be decreased. Less than one-third of the product manufactured there is molasses, the proportion on an average of the three years before cited being—

Sugar, 68·06; molasses, 31·93,

and hitherto they have been working the process in wooden vessels made in the country.

To recapitulate, the comparative production may be approximately shown thus:—

	Sugar.	Molasses.	Pulp and Begass.	Loss.	Total.
Diffusion..Germany ......Beet, 11 cwt. make 1 cwt. sugar..........	9·09	2·00	0·70	1·21	13
Mill......France .... „ 18 „ 1 „	5·50	2·00	1·32	1·18	10
„ ......Demerara ......Cane, 12 „ 1 „	8·33	3·00	4·66	2·01	18
„ ......Martinique .... „ 13 „ 1 „	7·69	2·75	5·00	2·56	18
„ ......Full extraction.. „ 13 „ 1¾ „	13·46	2·54	1·00	1·00	18
Diffusion..Aska .... „ 10½ „ 1 „	9·45	4·45	1·30	2·80	18

This Table illustrates the superior skill and enterprise displayed by the beet sugar manufacturers, and their success in dealing with materials of an inferior natural character, in the competition with cane sugar. It does not, however, give a full statement of the case between the beet and the cane, nor does it show how utterly the cane sugar producers have failed to turn to profit the advantage afforded them in the relative yield of the two plants. If the growth of an acre of canes gives a crop of 20 tons, it would, at the rate of 1 to 13, afford a yield of 1½ tons of sugar, or by a full extraction of the juice, 2¾ tons per acre, and the produce of an acre of beets of the richer sort being only half that quantity, or 10 tons, the yield of beet sugar cannot be put higher than 18 cwts., or at the very most, one ton per acre. Now, comparing the great productive capacity of the cane with the largest return obtainable by skilful management from the beet, it would not be too much to say that it will be a reproach if a continuance of the present state of things should be allowed. The sugar planter, not generally well-found in means, may certainly see it to his advantage, when harvesting his large crops of cane, to make a small extraction of the juice, acknowledging to himself that, as was said of old, "He is a fool who knows not how much more the half is than the whole." But if the planter is content to take what he can and not what he may, and expedite his work, the impolicy of this waste, and the need of a reform in the practice, will be recognised by the merchant and the refiner. The coming-in of beet sugar upon us like a flood is not a desirable thing to contemplate by anyone interested in the prosperity of cane sugar making, and it is only by aiding the development of this great source of wealth which the country now holds in neglected possession that the invasion can be met and stayed. In any remedial measures to be taken, the first thing is, as directed in an analogous case of some note, to "catch the hare," that is, to obtain from the cane a saccharine fluid not only as pure and rich as possible, but in as large a quantity as may be shown to be practicable. The further operations of concentrating the juice and refining the sugar are, it will be admitted, of secondary importance. It is proved the sugar is there, in the cane, and is procurable in a greatly increased amount. The call, then, for improvements in the manner of manufacture will not, it may be hoped, when sustained by the Society, be uttered in vain.

(To be continued.)

Correspondence.

PATENT FUEL IN FRANCE.

Briquettes cannot be treated as a new manufacture in France. In 1828 I saw coal dust prepared under that name in small cakes in an hotel at Lille, where they made a hot fire in an English style of grate.

HYDE CLARKE.

32, St. George's-square, S.W.,
26th July, 1884.

Obituary.

CHARLES MANBY.—Mr. Charles Manby, F.R.S., the Honorary Secretary of the Institution of Civil Engineers, died on the 31st ult., at the age of 80 years. He was born in February, 1804, and was the son of Mr. Manby, the founder of the Horsley Iron Foundry. He was originally intended for a soldier, but soon gave up the idea of a military career, and began to study engineering in his father's workshops. In 1835 he came to London, and then for four years practiced the profession of a civil engineer in partnership with Mr. H. H. Price. In 1839 he was appointed Secretary of the Institution of Civil Engineers, and this post he held till 1856, when he became Honorary Secretary, Mr. James Forrest, the present holder of the office, succeeding him as Secretary. On his retirement he was presented with a service of plate, and a sum of two thousand guineas, a portion of which sum he asked might be devoted to the foundation of an annual premium which should bear his name. Mr. Manby became a member of the Society of Arts in 1853, and maintained his connection with the Society until 1880, when advancing years and ill-health caused him to resign.

General Notes.

POPULAR EDUCATION IN AUSTRALIA.—The New South Wales Minister for Public Instruction says, in a recently published report, that there are very few children in the Colony who do not for some period of each year receive instruction, either in schools or at home. The greater number of exceptions are amongst children from 12 to 14 years of age, whose labour is of value to their parents. Many of these, however, especially those in the country, learned to read, write, and cipher before they left school. In places where State Schools are opened for the first time, it might be supposed that the children to attend them had previously been without schooling, but in most cases the necessity for a school in any locality has been caused by a recent movement of population thereto from other settlements, and the children when enrolled are generally found to have been at school elsewhere.

PATENT FEES.—The Board of Trade, with the consent of the Treasury, have made the following modification in the manner of paying certain fees prescribed by the Second Schedule of the Patents, Designs, and Trade Marks Act, 1883:—In the case of patents granted before the commencement of the said Act, a patentee who has paid the prescribed fee of £50 before the end of four years from the date of his patent may, in lieu of the prescribed fee of £100, payable before the end of seven years from such date, pay the following annual fees:—Before the end of the seventh year from the date of the patent, £10; eighth, £10; ninth, £10; tenth, £15; eleventh, £15; twelfth, £20; and thirteenth, £20. This alteration came into operation on the 1st of this month.

POSTAL BUSINESS IN AUSTRALIA.—The estimated number of letters posted for delivery within New South Wales during the year 1883 was 31,258,300, as against 25,737,300 for 1882; the number of letters posted for delivery in the Australian Colonies and New Zealand was 1,401,900, as compared with 1,202,600 for 1882; and the number of letters posted for foreign dispatch was 585,200, as against 498,300 for last year. The total number of letters posted in the Colony during 1883 was 33,345,400, as compared with 27,438,200 for last year. The number of newspapers posted in the Colony was 18,344,500, as against 16,970,100 for 1882. The total number of parcels, &c., was 1,435,900, as compared with 1,087,400 for 1882. The total number of post cards was 259,400, as against 222,800 for 1882. The increase in the number of letters posted is at the rate of about 21 per cent., in the number of newspapers about 8 per cent., in the number of packets about 32 per cent., and in the number of post cards about 16 per cent. The average number of letters posted in 1883, in proportion to the population of the Colony, is estimated at 38 to each person.

SORGHUM EXPERIMENTS.—Experiments with the amber cane have been made by Professor Failyer, of the Kansas Agricultural College. Beginning when the sorghum seed was in the state of stiff dough, and making an analysis at intervals of three to five days until three weeks after the seed was ripe, Professor Failyer found that the quality of the juice increased until perfect maturity of the stalk, and that the maximum contents of cane sugar remained the same while the cane stood in the field. It was further shown that the middle portion of the stalk is far richer in crystallisable sugar than the ends, and that the reverse is the case with the glucose. This difference in favour of the central portions of the stalk increases as the sorghum seed hardens and then declines slightly. The quantity of juice yielded by these parts varies also, being an average of about 44 per cent. for the extremities, and about 55 per cent. for the middle portions. For making syrup, it will pay to use the whole stalk exclusive of the lower joint and of the extreme top. But it is pointed out that in sugar making it will frequently happen, on account of the inferiority in the cane from immaturity or other cause, that the tops and butts should be worked separately for syrup, using four or five central joints for making sugar.—*Times.*

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

PLANT LABEL COMPETITION.

The judges appointed by the Council of the Society of Arts to examine the plant labels submitted in response to the offer of prizes have reported, after careful testing of the labels, that, while among those sent in there are many of considerable merit, there are none showing such distinct advance as to deserve the award of either of the prizes offered. The prize of £5, offered by Mr. G. F. Wilson, F.R.S., was for a wooden label treated with some preservative preparation, and the additional prize of £5 5s. offered by Mr. E. G. Loder, was for the best permanent border label suitable for private gardens.

Proceedings of the Society.

CANTOR LECTURES.

ALLOYS USED FOR COINAGE.

By W. Chandler Roberts, F.R.S.
Chemist of the Royal Mint; Professor of Metallurgy, Royal School of Mines.

Lecture IV.—Delivered April 7, 1884.

We have now to consider the means adopted to secure accuracy in the weight of coins issued from the Mint, and to examine the questions connected with the loss in weight sustained by coins during their circulation. Before the invention of coined money, the precious metals circulated by weight. Examples of such currency are presented by the gold and silver "talents" of the Schliemann collection, which bear a definite relation to the Babylonian "mina;" and so completely has the spirit of this method of circulation by weight been retained, that the best definition we possess of coins represents them as "ingots, of which the weight and fineness are certified by the integrity of the designs impressed upon the surfaces of the metal."*

Rice Vaughan,† whom I have before quoted, has some interesting remarks on this point in the section of his little work devoted to the consideration "of coining moneys without distinction of weights." He says the proposition is, "that there should be coined no pieces of a certain [*i.e.* definite] weight, either of gold or silver, but that, the allay being certain, the weight should remain uncertain; all money now currant should be valued by a certain weight." For example, every ounce of silver should be valued at five shillings, and every ounce of gold at such a proportion as shall be thought most equal. He points out that, among other incidental advantages, this plan would prevent the "culling, washing, and clipping" of money, that is, its fraudulent reduction in weight; but on the other hand, the objection would be, as he says, "the extreme molestation which the people should receive in the practice of it, when every man should be bound to carry scales in his pocket, and upon every little payment be bound to weigh their money." Few people at the present day bear in mind that this is precisely what, in the case of the gold coin, the existing law requires them to do, for the Coinage Act of 1870, now in force, directs, in Section 7, that "where any gold coin of the realm is below the current weight provided by this Act, every person shall, by himself or others, cut, break, or deface such coin tendered to him in payment, and the person tendering the same shall bear the loss." Compliance with this demand would, of course, render it necessary for each individual, who has reason to expect the tender of a sovereign, to carry scales and weights, as well as shears to cut such pieces as should be found to be deficient in weight.

It will be well for us to examine—1st, what degree of accuracy as to weight the law requires in pieces issued by the Mint; and 2nd, how long gold coins may be expected to circulate without incurring the "extreme penalty of the law." The law takes the same view of coins as is expressed in Butler's "Erewhon" with regard to humanity, and considers defective organisation and decrepitude in a coin to be criminal, and punishable by "cutting and defacing." Mr. John Biddulph Martin, whom I shall again have occasion to quote, well

* Stanley Jevons, "Money," p. 57. 1876.

† "A Discourse of Coin and Coinage," p. 214. 1675.

observes, "We are wont to speak of the life of a coin, but whereas the term 'life' is in all other cases associated with a period of growth, of maturity, and of decay, in this instance the process is one of degradation only."

The first schedule of the Coinage Act of 1870 prescribes the weight at which each coin shall be issued; it also defines the lowest weight at which the gold coins may be permitted to circulate, and it sets forth the "remedy" of weight—that is, the range above or below the exact standard within which the issue of coins would be legal. The silver and bronze coins, being merely tokens, have no "least current weight," but are withdrawn from circulation, and re-coined, when they become defaced by wear. The standard weight of a sovereign is 123·27447 grains, the remedy is $\pm$ 0·2 of a grain, and the least current weight, 122·5 grains. In the case of the half-sovereign, the standard weight is 61.63723 grains, the "remedy," $\pm$0·1, and the least current weight, 61·125 grains. In order to ensure that the coins issued from the Mint shall be well within the remedy allowed by law, it is necessary to adopt in practice a still more minute margin, or allowance for unavoidable error. The "working remedy" adopted in the Mint in the case of the sovereign, is therefore fixed at 0·17 of a grain, instead of the 0·20 which the law allows, and the weight which denotes whether a sovereign is or is not within the remedy, is represented by a piece of wire of fine gold, 0·1355 of an inch in length, and 0·018 of an inch in diameter, and weighing 0·17 of a grain. It will be obvious that the possibility of restricting the weight of coin within such narrow limits, entirely depends on the degree of accuracy which may be attained by the process of rolling the strips of metal from which the discs destined to form the finished coin, are cut; and we have already seen, in the first lecture, that in the case of the fillet prepared for the manufacture of the half-sovereign, a variation of $\frac{1}{20000}$th of an inch above or below the accurate thickness, or a range of $\frac{1}{10000}$th of an inch in the thickness of the fillet would cause the rejection of the coin, on the ground of excess or deficiency of weight. The question then arises—Is it not possible to supplement the operation of rolling by some mechanical operation, conducted on the blanks themselves, in order to bring them within a closer approximation to the exact weight. The problem has long proved an attractive one in Mints, but the earliest suggestion I can find for securing absolute accuracy in weight, occurs in the "Records of the Scotch Mint,* from which it appears that J. Acheson claimed, in 1597, to have discovered a method of making coins so that none shall be "ane grane heavier or lichter nor another."

On the Continent it is very generally the practice to adjust blanks by the aid of a file, the weighing being performed by hand; the process is, however, open to the objection that the marks of the file are never quite obliterated when the blanks are struck into coin, and the same objection applies to most of the machines that remove a fine shaving of metal from the surface of the blank. An additional objection to such a mechanical adjustment of blanks arises from the tendency, in Mints where it is adopted, to produce "too heavy" blanks in the rolling and cutting departments, as it is impossible to adjust blanks which are too light. Some years ago, Mr. J. M. Napier † devised for the Indian Mints an automatic machine of great beauty, which first ascertains how much it is necessary to cut from each blank in order to reduce it to the standard weight, and then removes the necessary amount of metal and no more. The initial cost of such machinery is, however, considerable. Another machine, having the same object in view, has been devised by Herr Seyss.‡

Chemical aid has not been wanting in the attempt to solve the question of the adjustment of blanks. In 1849, M. Diereck, Director of the Mint in Paris, endeavoured to substitute a chemical for a mechanical treatment, by submitting the heavy gold blanks to *aqua regia*, which, it was anticipated, would bring them within the prescribed limits of accuracy, by dissolving away metal. The results were not satisfactory, and the attempt was abandoned.

Having myself attacked the question in 1870, I may, perhaps, be permitted to refer to the results which attended my experiments. It was found that gold, alloyed with copper, might be removed from heavy blanks with singular regularity by means of a suitable solvent, aided by a battery. The blanks were arranged in a frame of wood, and submitted to the action of a solution of cyanide of potassium, the heavy blanks forming the dissolving pole of the battery. The process was not used in the London Mint, as it became evident that

* "Records of the Coinage of Scotland," by R. W. Cochran-Patrick, Esq., M.P. 1876. Introduction, p. clx.

† Patent, No. 108. 1866.

‡ "Dingler's Polytechnisches Journal," ccxlv 61; plate 6. 1882.

it could not replace the present system, under which finished coins alone are weighed, and the manufacture of good coin only is paid for. The late M. de Jacobi, one of the earliest workers in the field of electro-metallurgy, visited my laboratory while the first experiments were in progress, and we discussed the possibility of re-depositing the metal removed from the heavy blanks on those that were too light, the problem being to obtain a tenacious film.

I was greatly interested to find, long after my experiments were made, that an eminent firm of electrotypers had suggested officially that the worn gold coins in circulation could be restored to the legal weight by the electric deposition of a film of gold on the surfaces. The process was, introduced into the Bombay Mint, in 1873, by the late Mr. L. G. Hines, who transferred the metal dissolved from the heavy blanks to blanks which are too light, the latter being by this means raised to the prescribed weight. Its importance in mints where its use is possible may be gathered from the fact that, in the Indian mints, no less than 1,300 tons of silver were converted into coin in one year (1879), so that the saving effected by its use must be considerable.

Whether or not a method for adjusting the blanks be adopted, the finished coin must be weighed before it leaves the Mint, and this, as before stated, is the great obstacle to the introduction of the electro-chemical method into the English Mint. In former times the weighing was effected only in bulk, but more recently, individual pieces have been weighed in this country. I have already pointed out that the weighing may be effected by hand, and this method is very generally adopted on the Continent and in America, where each operator is provided with a delicate pair of scales.

In the Mint of this country, very beautiful automatic machines are used, for a full description of which reference may be made to the "Encyclopædia Britannica."* [The general nature of the appliance was made clear by the aid of a model.] The balance was originally devised in 1851 by the late Mr. William Cotton, of the Bank of England, and has since been improved by the officers of the Mint, and by Mr. J. M. Napier, who has secured several patents in connection with this machine.

In the Vienna Mint, a balance devised by Herr Seyss is employed, which depends upon a somewhat different principle. The beam resembles that of an ordinary balance, with pans suspended from it; one pan contains the weight, and a slide brings forward the coin to the other pan; the depression of the beam produced by a heavy coin brings the balance pan opposite one of several slits, the lowest slit corresponding with the extreme depression of the beam produced by a very heavy coin. The pan is then momentarily fixed, and the coin is allowed to pass away into the slit against which it stands. If the coin is very light, the pan which contains it will rise and stand opposite the highest of the series of slits.

* Ninth edition, art. "Mint."

The life of a coin, after it leaves the Mint, may now be traced, and it will be seen that the conditions of its existence are far less severe in modern than they were in ancient times. The actual wear to which coins are subjected may, no doubt, be rougher at the present day than in the past; but, on the other hand, they are not subject, to anything like the same extent, to ill-treatment from enemies in the shape of clippers and sweaters.

It is difficult to overrate the importance of some system of protecting the edge of the coin against fraudulent treatment, and it is hardly less difficult to understand, at the present day, the extent to which the ill-shapen hammered coins were tampered with. The earliest protection seem to have been afforded by a circle or beaded ring on the surfaces of the coin, and that such circles have been used from early times, is proved by the fact that many Greek coins bear them. Attention is specially directed to the outer circle in an enactment of King Henry VII., which provides that "every piece is to have a circle about the utter part thereof, and also that all manner of gold hereafter to be coined shall have the whole sculptuie without lacking any part thereof, to the intent that the King's subjects might have perfect knowledge, by that circle or sculpture, when the coins were clipped or not." No protection, however, is as efficient as the addition of letterings or devices round the edge of the coins. I have already stated in the first lecture that the practice of marking the edges was adopted, for another reason, in Roman times in the case of the *Nummi Serrati*, mentioned by Tacitus.

Coins may be fraudulently reduced in weight by the action of a solvent aided by a battery, but there is reason to believe that the practice is only carried on to a very limited extent.

Removal of metal by drilling holes and filling them up by base metal has sometimes been resorted to, and the Mint Museum contains interesting examples of American coins which have been sawn so as to leave two thin flat discs, which have subsequently been soldered over a disc of base metal, the precious inside of the coin having been removed. It has been proposed to make the American gold double-eagle dish-shaped, in order to render the centre so thin as to prevent this method of falsification. In mediæval times, tampering with the coin caused the gravest anxiety, and was punished with dreadful severity.

In 1381, the first equivalent of the modern Royal Commission on the Coinage met, and the following was the evidence, or rather were the recommendations, of the individuals who took part in it. Richard Leyc advised that the practice of clipping the gold coin could only be checked by a proclamation directing individuals to weigh coins when they took them, and Richard Aylesbury, a goldsmith, also held that gold pieces which had been reduced by clipping should be universally weighed by those who received them.* I will take only a few more historical instances of instructions as to weighing the coins tendered to individuals. The Mint Records† contain a copy of a proclamation given in the 17th year of King James I., which states that the people, instead of refusing such light gold moneys as were without the remedies * * * * do now for the most part accept in payments, indifferently and promiscuously, all such coins whatsoever tendered unto them, without weighing," which shows that the practice of weighing the coin had been adopted, and was falling into disuse. In 1619, the person who tendered the gold coin was instructed to give twopence for every grain the coin was light, and individuals were directed to brand every piece abnormally light by striking a hole through it, returning such pieces to the owners thereof, thus re-affirming a proclamation made in 1587 by Queen Elizabeth, which directed that the defective coins should be "stricken through and cut into pieces." In 1632, it is stated that "in and about London and Westminster, people carried scales in their pockets, to weigh gold on all occasions."‡ I mention these facts to show that the directions of the present law

* Ruding, vol. i., p. 240.

† Record Book, vol. i., p. 56.

‡ Ruding, vol. i.. p. 386

(Coinage Act, 1870) as to the cutting and defacing of worn coin, rest on ancient precept.

The condition of the silver currency in the end of the 17th century may be gathered from the statement of Lowndes, who computed the amount of all the silver moneys coined in the reigns of Queen Elizabeth, James I., and Charles I., at £15,109,476. Writing in 1695, and allowing for the sums coined in the reign of Charles II., James II., and William and Mary, he did not consider that the silver circulation consisted of more than £5,600,000, of which only £1,600,000 was heavy;* and he further pointed out, as the result of careful weighing of the coin in bulk, that the weight of "the moneys commonly currant are diminished near one half." Not, it must be remembered, merely by legitimate wear, but by the fraudulent practice of "clipping," from which, I believe, modern coinages suffer to a hardly appreciable extent.

It is now necessary to consider the conditions affecting the circulation of a metallic currency, more especially as regards its power of resisting legitimate wear. An experimental inquiry conducted by the officers of the Mint towards the close of the last century, showed that $78\frac{1}{10}$ of the shillings then in circulation were required to make a pound weight, which should have been represented by 62 shillings; eleven years later, $82\frac{9}{40}$ shillings weighed a pound. With regard to the gold coinage, the Mint officers found, in 1807, that 1,000 guineas withdrawn from circulation, had lost 19s. per cent. in value. Parcels of 300 sovereigns, coined in each of the years 1817-21-25-29, were weighed by the officers of the Mint in 1853, and the results proved that they had sustained an average rate of wear of 0·047 grains per annum.

The rate of wear, in the case of gold coins, is dealt with by Jacob;† but we owe an authoritative determination of the annual rate of wear of the gold coin to the late Professor W. Stanley Jevons, F.R.S.‡—formerly assayer of the Sydney branch of the Royal Mint, and subsequently Professor of Political Economy at University College, London—who brought to the consideration of the question an acute intellect and perfect knowledge of the conditions which govern the metallic currency. He proved, as the result of an exhaustive inquiry, that "just about eighteen years' wear will reduce a

* "Essay for Amendment of the Silver Coins," p. 105 1695.

† "The Precious Metals," vol. ii., p. 168. 1831.

‡ *Journal of the Statistical Society*. 1868.

sovereign below its point of legal currency;" and he shows conclusively that the average rate of wear per annum of the sovereign is 0·043 grains, which led to the conclusion that, at the time he wrote, 1868, "31·5 per cent. of the whole of the sovereigns in the kingdom are now no longer of legal currency." He estimated the annual average wear of the half-sovereign at 0·069 grains. Mr. Martin * has since repeated and extended Professor Jevons's inquiry. He has greatly added to the value of the work by bringing it down to the present time; and his researches, which deal with no less than 105,364 sovereigns, confirm, in a remarkable manner, the average rate of wear deduced by Professor Jevons, who adopted a different method of calculation. It may safely be assumed, therefore, that any sovereign which has been in circulation more than eighteen years has been reduced to a point at which it is not legally current, and should, therefore, be withdrawn from circulation, in order that it may be re-coined.

The questions now present themselves—Can this average rate of wear be diminished? Is the form of the coin well adapted to enable it to resist wear; and is it possible to adopt a more durable alloy for our gold coinage? First, with regard to the form; no doubt a sphere which contains the maximum weight in the smallest surface is better adapted than a disc to resist the abrading influence of friction, and it follows, therefore, that the Siamese money, which is nearly globular, will retain its weight longer than any other coin now in circulation.

A short cylinder is the geometrical form which, next to the sphere, presents the smallest surface for the greatest weight, and, consequently, in order to reduce the wear of coins to a minimum, their thickness should be equal to their diameter. Such a form would present many inconveniences; but, on the other hand, coins should not be made too thin, and much may be gained by even a small approach to theoretical requirements. A good practical rule for calculating the most useful diameter of a coin from its weight is given by the following formulæ:—

$$D = P \sqrt[3]{G}$$

D = Diameter in millimetres.
G = Weight in grammes.
P = A certain number found by experiment.

* *Journal of the Institute of Bankers*, June, 1882.

Take the cube root of the weight of the coin, multiply by the number for the particular coin, and this gives the most suitable diameter in millimetres. The value of P for all kinds of gold coins is 11·3.

I have thought it advisable to make the above reference to the matter, although it is not likely that the form of our coins will ever be greatly modified. The mean thickness of the coin does not differ much from the initial thickness of the blank, because in virtue of the "flow" of metals, to which allusion has already been made, the portions of metal diminished in thickness are about balanced by the raised part of the device. Sharp new coins do not wear much more rapidly than old ones, as is shown by the experiments of Professor Jevons and Mr. Martin, that is, the rate of wear of coins at different periods of their career is fairly normal. There is no doubt that a coin in high relief becomes disfigured much sooner than one in low relief, as the unity of a design is greatly impaired by the loss of a prominent feature, and the lovely Renaissance works in low relief [now before you] present a much better appearance after prolonged circulation than their classical predecessors, which are almost lenticular in form. The power of the metal to resist, not wear, but deformation by impact, therefore demands attention, and from this point of view a soft metal is far less useful than a hard one. Coins of lead, for instance, have been found, in experiments to which reference will be made presently, to become rapidly defaced, and reduced to the state of mere blanks, when submitted to mutual action in a revolving drum. Coins of pure gold also become rapidly defaced, although their weight is but little reduced by such treatment. As has already been pointed out, the reason for using an alloy instead of pure metal is the greater durability of the former, and accurate experiments on this point have not been wanting. Their history may be briefly stated as follows:—In 1792, the unfortunate French Statesman Clavière * proposed that pure metals should be used for coinage, and that they should be current by weight. The Académie des Sciences was consulted on the subject, and experiments made by this distinguished body† showed that while the pure metals were rapidly reduced in weight by friction, the addition of even a small amount of base metal had a notable effect in enabling

* "Traité des Monnaies," par. P. F. Bonneville. p. xxiii. 1806.

† "Annales de Chimie" (1793), tome xvi., p. 230.

the metals to resist abrasion by wear. In 1798, the Privy Council appointed a committee "to take into consideration the state of the coins of this realm," and they directed Mr. Henry Cavendish, F.R.S., and Mr. Charles Hatchett, to ascertain experimentally whether the loss of gold coins by wear was "occasioned by any defect, either in the quality of the standard gold, or the figure or impression of the coins." The result was an elaborate investigation, conducted by Mr. Hatchett,* on the "comparative wear of gold," the results of which have since been frequently quoted, and have, in fact, become classical. Hatchett operated both on unstamped blanks and on discs struck by dies, which produced small "rounded prominences, regularly disposed over the surface of the coin." Such blanks, or coined discs, were arranged in two frames, so that the flat surfaces of the metal could rub against each other when the frames were pressed together. Each frame was moved rapidly backwards and forwards by suitable mechanism, the path of each frame being at right angles to the other. The discs were in this way subjected to mutual friction, and the gearing was so devised that while one frame was moving with its greatest velocity, the other was at the extremity of its path, the result being that the coins were prevented from moving always in the same line. The numbers of "revolutions" or contacts of the pieces varied from 20,680 to 229,000. He also used a cubical box of eight inches, in the side, in which the coins were made to revolve; and the discs were also rubbed on a table covered with either flour, fine chalk, or metallic filings, fixed in isinglass. Hatchett's main conclusion was that the "extraordinary loss which the gold coin of the kingdom is stated to have sustained within a certain limited time, cannot, with even a shadow of probability, be attributed to any important defect in the composition or quality of the standard gold."† He further observes "that the experiments on the various alloys of standard gold (that is gold standardised with various metals) concur with established practice and opinion to prove that only two of the metals, viz., silver and copper, are proper to be employed in the reduction of fine gold to standard for the purpose of coin." Notwithstanding the care and skill employed by Hatchett in conducting his experiments, some of his deductions appear to demand confirmation. The subject possesses additional interest

* Phil. Trans. Roy. Soc., 1803, p. 43.

† Loc. cit. p. 190.

at the present time, because it is probable that much of the light gold coin now in circulation will soon be withdrawn; and it has therefore been considered advisable that Mr. R. A. Hill, Superintendent of the Operative Department, and myself should resume an investigation on the relative wear of coins of different metals and alloys, which was begun by one of us during the Mastership of the late Mr. Graham. After several preliminary experiments, in which a sliding motion was given to pieces of metal along a smooth surface of oak, we satisfied ourselves that revolving the pieces in a box represents more faithfully the kind of friction to which coins are subjected in the varying conditions of their circulation, and this view was fortified by the opinion of the late Professor Jevons. We addressed ourselves mainly to ascertaining whether the alloy used for the British gold coin, the standard of which is 916·6 is, or is not, more durable than the alloy of 900 fine, which is so widely used by other nations; and we are satisfied that the experimental evidence proves, as regards rate of wear, that there is not much to choose between standards 916·6 and 900. On the other hand, differences in mechanical treatment, resulting from a heavy as compared with a light blow, or in thermal changes produced by annealing, exert greater influence on the rate of wear than the small variation in composition comprised between the limits 900 and 916·6. We agree with the view taken by M. Feer-Herzog* that differences of wear of coins of these two alloys is very slight.

Our experiments are in progress, but the results hitherto obtained are published in the Mint Report for last year.†

The use of aluminium has often been suggested for the manufacture of subsidiary coins, this metal being known to possess the great tenacity when equal volumes of it and other metals are compared. We have been much interested to observe that coins of aluminium, especially if they be alloyed with about 2 per cent. of nickel, are very durable, as are also coins of pure nickel; but in one case the durability results from toughness, and in the other from hardness.

There is one other point in connection with the gold currency to which I would now direct your attention. The Coinage Act of 1870 fixes the remedy on each individual piece, and

* See "Enquête sur la question Monétaire" (Paris, 1792), vol. i., p. 344.

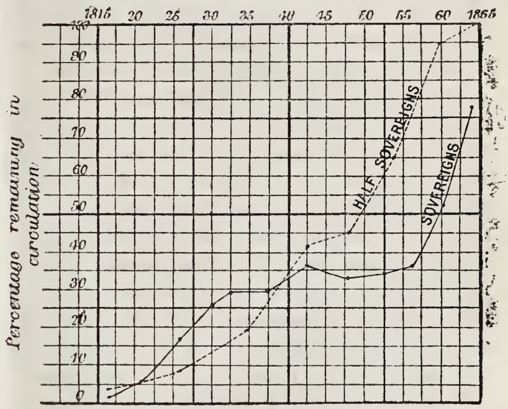
† Fourteenth Report of the Mint, p. 45, 1883.

not, as was the case formerly, on the pound weight of the coin. The object of this provision is to prevent the "culling" the heavy pieces, which would be a profitable transaction if the inequalities of weight were considerable. The heavy pieces so selected might either be exported or used in the arts, and the annals of the coinage abundantly indicate the extent to which the practice was carried on in former times. A notable case occurred in 1637,* when the Attorney-General charged several persons before the Star Chamber with "culling out the weightiest coins, and with melting down his Majesty's moneys into bullion;" and, on examination, it appeared "that between the years 1626-1631, one Timothy Eman culled £500,000 a-year, which yielded £7,000 or £8,000 of heavy moneys yearly, and in five years he melted down £15,000, his profit therout amounting to £100." Another offender was Violet, whose name deserves mention, as his work "An Appeal to Cæsar" contains so much curious information as to the export of bullion.†

I regret to say that the practice of culling is not absolutely unknown at the present day. Professor Jevons stated in 1868, that he "received overwhelming evidence that this picking and culling of the coinage, as it used to be called, is practised as an ordinary business transaction by all banks which need to make remittances to the Bank of England," in order, that is, to avoid the loss which would be entailed if light coin were sent to the Bank, where it would be cut and the deficiency charged for. "It will thus be apparent," Professor Jevons adds, "that there exists a regular system, whereby the older coins are continually returned into the hands of the public, and the new heavy coins alone are returned to the Bank of England, or to those who would melt or export them."

The amount of gold actually in circulation is estimated to be £100,000,000, but the coinage returns show that the amount of sovereigns and half-sovereigns issued since 1816, when their coinage was begun, is £247,521,429. What, then, has become of the 147 millions not in circulation? The coinage returns show that between the years 1864-83, £57,492,842 in sovereigns were coined. A considerable proportion of these have been exported never to return. The following figures, which I offer with some hesitation as they may not be rigidly accurate, show that, while during the same period sovereigns were exported and imported, the excess of exports over imports was no less than £25,991,445, or a yearly average of £1,299,572.

With regard to the disappearance of gold coins from circulation, Professor Jevons has some observations of extraordinary interest. He says it appears "that of the sovereigns coined in 1817-19, not more than one-fiftieth part remain in circulation; and the proportion rises until, between the years 1840-1858, it is about one-third." He suggests in his paper that these curves should be plotted graphically, and this I have done.*



Gold coins in circulation.

In both cases there is an elevation in the period 1840-45, arising probably from the recoinage of the years 1841-43, when £14,000,000 of gold coin were called in and redistributed in an unusual manner, so that more than a common proportion became fixed in the circulation. The most important peculiarity of the numbers is the very small increase which takes place in the proportion of sovereigns preserved between the years 1832 and 1854; this indicates that there is a residuum of coin which is no longer subject to be exported or withdrawn, like the rest of the circulation; for if the proportions of coins exported were taken indifferently, the curve would rise as rapidly as is the case with the half-sovereign curve, those coins not being liable to exportation.

It will be evident, therefore, that in tracing the analogy between the life of a coin and ordinary vital phenomena, we are abruptly checked by observing that the "fittest" coins are not

* Ruding, vol. i., p. 389.

† "An Appeal to Cæsar,' by Thomas Violet, of London. 1660.

* Since the above was written the late Professor Jevons' "Investigations in Currency and Finance" has been published, and this valuable work also gives similar curves.

those which survive as the fittest; that is, the heavy ones drop out of the struggle of active circulation they were created to sustain, and are either exported, or exist as part of a "hoard" of coin. It may, of course, be urged on this ground, that a full-weight coin, issued to the public without charge, is not the fittest to retain its place in circulation, and that a small amount of metal lost by wear really tends to its preservation.

With that Darwinian problem, I must bring these lectures to a close.* You have seen the great change and depreciations through which the "alloys used for coinage" have passed in times gone by, but there is no probability that in this country similar changes will take place in the future, and I cannot find better words to offer you than a quotation from Professor Jevons, whose perfect grasp of the question of metallic currency enabled him to realise its difficulties in a way few of us are able to do. He points out that, in times past, the rulers of nations have been the most notorious false coiners and depreciators of the currency; but that now "the danger lies quite in the opposite direction—that popular governments will not venture upon the most obvious and necessary improvement of the monetary system without obtaining a concurrence of popular opinion in its favour; while the people, influenced by habit, and with little knowledge of the subject, will never be able to agree upon the best scheme."

I can say with Rice Vaughan that "my scope was not to render the reader able to find out the fittest course to govern this matter of money and coin, but able to judge of what should be propounded by others;" but we need no longer fear the state of things described by him when he says "that for want of that ability the wisest states and the greatest Councils of Christendom, for many ages, have been abused by mysterious names and perplexed subtleties of Mint-men."

CONFERENCE ON WATER SUPPLY.

The following are some of the papers read at the Conference of the Society of Arts on the Water Supply, held at the International Health Exhibition on Thursday and Friday, July 24th and 25th:—

* Since the above was written, I find that Mr. J. B. Martin incidentally pointed to this analogy in a paper read before the Institute of Bankers in March last.

WATER FOR DOMESTIC USE.

By S. C. Homersham, M.Inst.C.E.

Water for domestic use, and for distribution through pipes into dwellings in cities, towns, villages, and other places, should be derived from sources that afford adequate quantities at all seasons, characterised as being:—

1. Wholesome for drinking, for culinary and for other uses.
2. Soft without having the power to dissolve or injure lead, and well adapted for washing the person, for use in baths, and for use with soap.
3. Of a normal uniform temperature at its source equal to the average of the climate for the year, which in England differs but little from 50° Fah.
4. Well aërated, holding in solution eight or more cubic inches of gases per gallon, namely, about two of oxygen, six of nitrogen; agreeable and refreshing when drunk.
5. Clear, transparent, colourless, bright, and, when seen in large bulk, pure blue, the natural colour of uncontaminated water.
6. Unable to cause a deposit or fur in the utensil in which it may be heated or boiled.
7. Free from organisms, animal or vegetable, living or dead, and any matter in suspension.

Water in its natural or normal condition characterised by all these seven qualities may be abundantly obtained in some portions of the globe. It abounds in parts of Brazil, in parts of New South Wales, and doubtless in other places. Such water, however, is not abundant in the United Kingdom.

Here it is difficult to find a source that will yield a considerable quantity of soft water associated with the other six named qualities; or to find a source that will yield an abundant quantity of soft water associated with qualities 1, 3, 5, 7.

Water, inland, is all derived from rains that fall on the surface. Land, composed at or near its surface of sand, gravel, chalk, and some other limestone, absorbs nearly all the rain that falls upon it and stores in its pores the greater portion below ground. Other land, consisting of clay, granite, millstone, grit, and other impervious rock, absorbs hardly any of the rain or snow that falls upon its surface. For the most part it flows off the land into valleys, and forms brooks, rivers, or floods. Sometimes the rivers or floods are collected in natural impervious hollows or basins, thus forming natural lakes.

Sometimes artificial hollows or reservoirs, or lakes, are constructed in valleys to catch and impound river and flood water, to supply or feed canals, or to be stored for domestic use. Thus the sources from which water can be obtained for the supply of a population, or for manufacture, or other uses, are—

1. Brooks, rivers, and natural or artificial lakes. These may all be called surface waters.

2. Springs that often naturally issue from the sides of valleys into brooks or rivers, and other subterranean water stored in the pores of rocks below ground may be collected above ground or by means of wells, bore holes, and underground adits or tunnels. Such water may all be termed subterranean or spring water. Water, however, whether surface or spring, is all derived from rain falling on land, mostly on uplands or hills. All brook, stream, or river water, ultimately finds its way by gravitation into the sea through uncovered channels, or rivers, that may be seen, and are often navigable, providing inlets and outlets for vessels from the land into the ocean, or from the ocean inland.

All deep subterranean water also ultimately finds its way into the ocean, through subterranean pores, fissures, or channels, often penetrating to great depths before doing so. Thus, at present, a bore-hole at Richmond, in Surrey, derives a supply from the surface carried down to a depth of more than a quarter of a mile below the surface of the ocean. The water from this bore-hole will naturally rise to an altitude of more than 120 feet above Ordnance Datum, or the mean level of the sea.

As a rule, for domestic uses, subterranean or spring water is greatly to be preferred to river or surface water, more especially when it is derived from certain beds of sand, as then the water often possesses the whole of the seven characteristics before described. Large quantities of subterranean water, however, are derived from the chalk formation in the south and south-east of England, and in Yorkshire, and used for the supply of urban and other populations. Thus a considerable portion of inner and outer London, and numerous towns situated on or near the chalk formation, are supplied by subterranean water absorbed by the chalk. Aylesbury, Brighton, Canterbury, Charlton, Deal, Dover, Greenwich, Gravesend, Hull, Margate, Plumstead, Ramsgate, Tring, Woolwich, and many other places, are entirely supplied by spring or subterranean water obtained in this way from the chalk formation. This water has five out of the seven characteristics I have mentioned, but is wanting in two, namely, softness and non-ability to deposit fur when boiled. By a simple process, however—invented by the late Dr. Clark, and described in a paper read before the Society of Arts on the 14th May, 1856—both the quality of hardness and the power to deposit fur when boiled are got rid of. The process is a simple one, and has now been in practical use for more than a quarter of a century with great success. Water so treated is greatly admired and valued by those who are supplied with it.

Surface water, whether derived from brooks, rivers, or lakes, though the latter be natural or artificial, is usually soft, and less liable to deposit a fur when boiled than most spring or subtaranean water. On the other hand, it is not well adapted or so wholesome for drinking; (3) it is cold in winter and liable to freeze in distributing pipes; warm in summer, and (7) pervaded by numerous living organisms.

(5.) It is not always clear and bright without being filtered (2) and dissolves lead.

Thus, in these most important respects, spring or subterranean water is to be preferred to river, lake or surface water. Those who care to follow this subject more in detail, will find both the quantity and quality of spring or subterranean water, fully discussed in a paper I read before the Society of Arts, on the 31st January, 1855.

It is obvious, also, that all brook, river, or lake water is liable to be greatly contaminated by becoming mixed with faded blossoms and fallen leaves; by mud, mainly composed of decaying vegetable matter and pervaded by numerous living organisms; by manure from off the land; by the excreta of fish, animals, and man, both liquid and solid washed into it, and more especially in times of floods; by the action of frost and other contaminating causes that it would be difficult or impossible to prevent. Indeed, streams and rivers, in a greater or less degree, must always remain the sewer of a district, and the means by which surface washings are conveyed t the ocean.

All river, lake, or surface waters, mor especially in warm seasons of the year, are found to be pervaded by minute livin organisms, vegetable and animal, none of which are found in uncontaminated spring water.

A paper read by Mr. Jabez Hogg, before the Society of Arts, on the 12th May, 1875, will be read with interest by those who care to pursue the subject.

In the Parliamentary Session, 1852, a body of householders deposited plans, and applied to Parliament for powers to supply a large portion of London with softened spring water at a very moderate charge for drinking and personal ablution, thus leaving the old established companies who supplied the Thames water to continue the supply of such water for watering roads, for flushing sewers and closets, and for other gross purposes. At that time, however, the Water Companies had great influence in the House of Commons, so much so, that the Government of the day, very much, as I know, to their regret, felt themselves obliged to exert their influence to prevent the powers sought being granted, in order to secure the passing of a Government measure affecting Imperial interests.

As respects the metropolis, no physical difficulties exist to prevent the whole of the four millions of souls inhabiting the inner and outer circle from being copiously supplied with uncontaminated softened spring water, possessing all the seven characteristics I have named. Indeed, a considerable portion of the inner and outer circle is already supplied with uncontaminated spring or subterranean water, though not (2) of a soft character or (6) free from depositing a fur when boiled.

It is not from want of ability to supply the metropolis most abundantly with subterranean or spring water possessing all the seven characteristics that the inhabitants are not so supplied. The want of an uncontaminated supply to the greater portion of the inhabitants mainly results from want of the necessary technical information among these who have to put up with the present supplies.

Such Conferences and discussions as these we are now concerned with cannot fail to afford much useful information to many, and it is to be hoped will ultimately result in securing a more wholesome, a softer, and a cheaper supply carried into the dwellings of the mass of the population.

SOFTENING OF WATER.

By Baldwin Latham, M.Inst. C.E., F.G.S., F.R. Met. Soc., &c.

Introduction.

From the remotest period of antiquity, of which we have any record, the art of softening water for the purposes of washing and cleansing, appears to have been known and adopted. Long anterior to the invention of soap, of which the elder Pliny gives us the earliest account, as having been first manufactured by the Gauls, caustic alkali derived from wood ashes, and from natural earths, was used as a lye. The process of making an alkaline lye was mentioned by Aristophanes (434 B.C.), and also by Plato (348 B.C.). We have also a record in the volume of Sacred Writ, in Jeremiah ii. verse 22, "For though thou wash thee with nitre and take thee much soap." The Hebrew word *borith* used in this passage is stated by authorities to refer to the vegetable lye of potash, but in another passage of Sacred Writ, Malachi iii., verse 2, where reference is made to "fuller's soap," the Hebrew word *nether* is there believed to apply to a mineral lye or soda. The people of Egypt were known to use mineral alkali and ashes of plants for the purpose of making a lye for washing from an early period, as recorded by Pliny.

Nitrum, a natural lixivious salt which is found in many southern countries, was well known, and was used for washing at a very early period. Certain plants, too, the juice of which is of a saponaceous nature, were used in early days, instead of soap. Meal and many kinds of seeds and bran were also used in connection with washing operations. The urine of various animals kept until it became stale, and alkaline was used in eastern countries, at a very early period; and in the Avesta, special directions are given for cleansing and purifying with the urine of the sacred cow. Pliny, in his "Natural History," states that if water be nitrous or brackish, or bitter, if some fresh barley meal is put into it, that within two hours it will be so amended and sweet, that a man may drink thereof; and a translation made from Pliny, by Dr. Philemon Holland, in 1634, goes on to recount that the same operation of sweetening water may be effected by a kind of chalk which is found in the Island of Rhodes; and a description of clay which is found in Italy will do the same. Pliny, who died A.D. 79, records the manufacture of soap as being composed of tallow and ashes, the best being made of goat's suet and beechwood ashes. That the amount of mineral matter in water, as affecting the conditions of health, was studied at a very early period, is known from the fact that the hydrometer was probably first used for the purpose of ascertaining the quality of the water used for dietetic purposes. Although the principle of the hydrometer has been ascribed to

Archimedes, there is no record of this instrument having been made by him. The earliest record, according to Beckmann, appears from a correspondence between Synesius and Hypatia, the latter of whom was assassinated, A.D. 415, in which Synesius states that he found himself so ill that he proposed to use the hydrometer, and requested Hypatia to at once procure one for him. The mode of strengthening ordinary lye by the addition of lime was known in the time of Paulus Ægineta, a physician who flourished either in the 3rd or the 7th century.

Soap is mentioned by Geber in the second century, and at a later period is frequently referred to by Arab writers, as being used not only for detergent purposes, but also for external application.

Soap is very largely used, or rather wasted, in many places in the present day for softening water. It is now well understood that no useful effect in washing is produced until sufficient soap has been used to soften the water.

For the purposes of this investigation, water may be divided into two classes, hard and soft. *Hard water* is a water which contains salts of lime, magnesia or iron, and sometimes an amount of free carbonic acid. A hard water, commonly considered, is one that destroys soap in washing, while a soft water is one that does not destroy soap. A *soft water* may derive its properties from an absence of earthy salts, or it may have become soft by reason of the presence of certain alkaline salts in the water, notably the salts of soda and potash.

Hard waters may be divided into two classes, those which are permanently hard and those which are temporarily hard. It is often found that a single sample of naturally hard water partakes of both these properties. A water which is said to be be temporarily hard becomes soft by boiling, as the hardness is due to salts of magnesia or lime dissolved in the water by the agency of carbonic acid, or due to the presence of this gas in a free state in the water. Under either circumstances, the effect of boiling the water a sufficiently long time is to drive off the carbonic acid gas, and a natural softening of the water takes place from the absence of this gas, and the earthy salts that have been held in solution by it in the water.

Water that is permanently hard derives this property from the presence of the same salts as under water temporarily hard, but instead of being combined with carbonic acid, they are combined with sulphuric acid, and to soften water that is permanently hard requires very different conditions than is the case with waters that are only temporarily hard.

The qualities of a good drinking water have been described as :—

1st. Freedom from vegetable and animal matter.

2nd. Pure aëration.

3rd. Softness.

4th. Freedom from earthy mineral or other foreign matter.

5th. Coolness and delivery at the minimum temperature.

6th. Lucidity or clearness.

7th. Absence of taste and smell.

Although many authorities insist that for the sake of health a soft water is beneficial, on the other hand, there are those who contend that there is no evidence whatever to show that even a hard water had any influence upon health. It is clear, so far as the health statistics of this country are concerned, that if anything the results come in favour of persons inhabiting districts having hard waters. On the other hand, it has been thought that particular diseases which affect particular localities, such as cretinism and goitre, are due to certain salts of magnesia, which have been found in the waters of the district. Some waters which are of remarkable softness, in which the softness is due to the presence of certain alkaline salts, especially those of soda, may be quite unfit for drinking purposes. A type of this water is found in the well supplying the Trafalgar-square fountains, as it is stated by some authorities that the large amount of soda contained in it, if taken habitually, acts medicinally upon the kidneys. It is also unfit for washing, as the water is liable to destroy certain colours, and stains glass. It is said to be unfit for bathing, as the soda combines with the oily matter of the skin, producing a roughness and liability to chapping. Water, however, which is naturally soft, or which has been softened by means of a process like Dr. Clark's, which does not add any new element to the water, has great advantages for many purposes, it prevents incrustation of steam boilers and household utensils, it results in a saving of fuel, less wear and tear in washing linen, and in the labour of cleansing; it saves soap in all washing and cleansing operations, the water cleans better, and gives a better colour to linen, and it is also stated to lead to greater economy in tea-making and brewing, but whether this is correct or not is very doubtful, as water used for such purposes is always boiled, and when used in that state should be as soft as softened water.

The processes which have been used both in ancient and modern times for softening water may be comprised under the heads of Boiling, Chemical Processes, Distilling, Exposure, Freezing.

Softening by Boiling.—Pliny, in his "Natural History," states that water that hath been once sodden, that is boiled, is far better than that which is raw. There is little doubt that the boiling of water, both as a means of reducing its hardness, and also to effect its purification, was very extensively practised in ancient times, and the practice of boiling water is still carried on amongst some of the older nations, such as China and parts of India, with the greatest possible advantage, both from an economical and from a sanitary point of view. The Emperor Nero (A.D. 50 to 68), both boiled water for drinking purposes, and subsequently cooled it in glass vessels to which snow was externally applied. The effect of boiling water is to liberate the carbonic acid which holds certain alkaline salts in solution, and on the liberation of the acid these salts are precipitated, and forms the coating which furs our kettles, accumulates in our boilers, blocks the circulating pipes of our water-heating apparatus, and is often a source of danger, and always of expense. The effect of boiling water, in order to soiten it, can only be secured when this operation is sufficiently prolonged. The Commissioners appointed to inquire into the chemical properties of the water of the metropolis in 1851, made some experiments on the effects of boiling an artificially prepared hard water containing 13·5 grains of carbonate of lime per gallon, and it was found to decrease in hardness from 13·5° to 11·2° by being heated to the boiling point; after boiling for five minutes, it was reduced to 6·3°, for fifteen minutes to 4·4°, for thirty minutes to 2·6°, and for one hour to 2·4°, so that the softening effect does not take place at once, but a prolonged boiling is required in order to produce the greatest degree of softening. In order to get rid of the temporary hardness of water, sharp boiling for not less than twenty minutes is requisite, but boiling water does not remove the hardness occasioned by the salts which are neutral; in fact the permanent hardness of the water is increased by boiling, as all the water evaporated leaves a concentration of the neutral salts in the remaining water. It has also been shown that the alkalinity of water is more after boiling than when softening has been produced by an alkaline salt such as lime, but both have the effect of reducing the hardness to about the same degree. This increase of alkalinity after boiling is attributed to the concentration of the neutral salts consequent on the loss by evaporation. The temporary salts held in solution by water are precipitated by boiling, and it is these precipitated salts which cause the furring of kettles, hot-water boilers, steam boilers, and hot-water pipes, and have led to the adoption in certain cases of means either for retaining the salts in solution in the water or of preventing their deposit in steam boilers, but as a rule with only partial success.

Chemical Processes of Softening Water.—In a paper read before the Literary and Philosophical Society of Manchester in 1781, by Thomas Henry, F.R.S., a description is given of a mode of preserving sea-water by means of quick lime, in which the author pointed out that the earthy base of magnesia was precipitated in sea-water by lime, and its place taken by a calcareous salt. He also referred in this paper to the well known action of quick-lime on common water as a preservative. The effect of the lime, doubtless, upon the sea and fresh water was to induce abundant precipitation, which dragged down with it certain organic impurities, and as a consequence the water remained free from putrefactive influence afterwards, as was clearly shown in the course of his experiments.

The first patent for purifying water by chemical agency in this country was taken out in 1838, for precipitating by muriate of zinc and salts of soda, the latter salts precipitating the zinc from the water, leaving the water in a purified state.

In 1841, Dr. Thomas Clark, of Aberdeen, took out a patent for his well-known and beautiful process for softening water, and which has, more or less, been the basis of all other patented processes of this description which have been adopted since that period. Dr. Clark thus describes his process, in a paper published in the *Journal of the Society of Arts* of the 16th May, 1856:—

"In order to explain how the invention operates, it will be necessary to glance at the chemical composition and some of the chemical properties of chalk, for, while chalk makes up the great bulk of the matter to be separated, chalk also contains the ingredient that brings about the separation. The invention is a chemical one for expelling chalk by chalk. Chalk, then, consists, for every one pound of sixteen ounces, of lime nine ounces, carbonic acid seven ounces.

"The nine ounces of lime may be obtained apart by burning the chalk, as in a lime kiln. The nine ounces of burnt lime may be dissolved in any quantity of water not less than forty gallons. The solution would be called lime water. During the burning of the chalk to convert it into lime, the seven ounces of carbonic acid are driven off. This acid, when uncombined, is naturally volatile and mild; it is the same substance that forms what has been called soda water when dissolved in water under pressure.

"Now, so very sparingly soluble in water is chalk by itself, that probably upwards of 5,000 gallons would be necessary to dissolve one pound of sixteen ounces; but by combining one pound of chalk in water, with seven ounces additional of carbonic acid —that is to say, as much more carbonic acid as the chalk itself contains—the chalk becomes readily soluble in water, and when so dissolved is called bicarbonate of lime. If the quantity of water containing the one pound of chalk with seven ounces additional of carbonic acid were 400 gallons, the solution would be a water of the same hardness as well water from the chalk strata, and not sensibly different in other respects.

"Thus it appears that one pound of chalk, scarcely soluble at all in water, may be rendered soluble in it by either of two distinct chemical changes; soluble by being deprived entirely of its carbonic acid when it was capable of changing water into lime water, and soluble by combining with a second dose of carbonic acid, making up bicarbonate of lime.

"Now, if a solution of the nine ounces of burnt lime, forming lime water, and another solution of the one pound of chalk and the seven ounces of carbonic acid, forming bicarbonate of lime, be mixed together, they will so act upon each other as to restore the two pounds of chalk, which will, after the mixture, subside, leaving a bright water above. This water will be free from bicarbonate of lime, free from burnt lime, and free from chalk, except a very little, which we keep out of account at present, for the sake of simplicity in this explanation. The following table will show what occurs when this mutual action takes place:—

Agents.			Products.	
Bicarbonate of lime in 400 gallons	Chalk	16 oz.	= 16 oz. of chalk	= 2 lbs.
	with carbonic acid	7 oz.	= 16 oz. of chalk	
Burnt lime in 40 gallons of limewater ...		9 oz		

"A small residuum of the chalk always remains not separated by the process. Of $17\frac{1}{2}$ grains, for instance, contained in a gallon of water, only 16 grains would be deposited, and $1\frac{1}{2}$ grains would remain. In other words, water with $17\frac{1}{2}$ degrees of hardness arising from chalk, can be reduced to $1\frac{1}{2}$ degrees, but not lower.

"These explanations will make it easy to comprehend the successive parts of the softening process.

"Supposing it was a moderate quantity of well water from the chalk strata around the metropolis that we had to soften, say 400 gallons. This quantity, as has already been explained, would contain one pound of chalk, and would fill a vessel 4 feet square by 4 feet deep.

"We could take 9 ounces of burnt lime made from soft upper chalk; we first slack it into a hydrate by adding a little water. When this is done, we would put the slacked lime into the vessel where we intend to soften, then gradually add some of the water in order to form lime water. For this purpose at least 40 gallons are necessary, but we may add water gradually till we have added thrice as much as this; afterwards we may add the water more freely, taking care to mix intimately the water and the lime water or lime. Or we might previously form saturated lime water, which is very easy to form, and then make use of this lime water instead of lime, putting in the lime water first and adding the water to be softened. The proportion in this case would be one bulk of lime water to ten bulks of the hard water.

"It is of importance that the lime, or lime water, that is the softening ingredient, be put into the vessel first, and the hard water gradually added, because there is thus an excess of lime present up to the very close of the process, and this circumstance is found to render the precipitatation of the carbonate of lime produced in the process more easy.

"But what you will wish to know now is, by what mark is the conductor of the process to find out when there is enough of water to take up the last of the excess of lime, so as to be enough, but no more.

"This is done by what has been called the silver test, the only test necessary to the operator after the process is fairly set a-going. This test is a solution of nitrate of silver, in twice distilled water, in the proportion of an ounce per pint. In making use of the silver test with ordinary waters, we get a white precipitate; but if the water have in it a notable excess of lime water, there is a light reddish brown precipitate produced; but if the excess be very slight, we only get a feeble yellow precipitate. The way we make use of the test is to let two or three drops of it fall on the bottom of a white tea cup; then add the water somewhat slowly; then, if there be the slightest excess of lime, a yellow colour will show itself."

It may be here mentioned that a more delicate test than the silver test for ascertaining if there is an excess of lime in the water, consists in using a solution of cochineal, the natural colour of which is yellowish red, which is turned violet in the presence of alkalies; and other agents are now used to show, by distinct colour, or its absence, if there is an excess or not of lime in the softened water.

According to Dr. Clark's scale, 1° of hardness means that there is one grain of chalk in a gallon of water. According to the scale introduced by Dr. Frankland, in the sixth report of the Rivers Pollution Commissioners, parts per 100,000 are used, or one grain of chalk in 100,000 grains of water, so that it is necessary, in considering the reports of the Rivers Pollution Commissioners, to bear in mind this difference of degrees of hardness. To reduce the hardness to parts per gallon, or to the Clark scale, it is necessary to multiply by 7 and divide by 10.

Hard water decomposes soap. The amount of soap ascertained by Dr. Clark to be wasted before softening the water, is equivalent to 2 ounces for each degree of hardness for every 100 gallons. Dr. Clark introduced a soap test, or a means by which a solution of soap is made to at once indicate the degree of hardness of a water. When pure chalk is burnt into lime, one pound is converted into 9 ounces of lime, and this quantity is soluble in 40 gallons of water. Beyond this, lime is not soluble in water, so that clear lime water always possesses a known composition. This amount of lime is equivalent to 98·43 grains per gallon. As one particle of lime will remove $\frac{16}{9} = 1·777$ of chalk, it follows that $98·43 \times 1·777 = 174·9$, or the number of gallons of water 1° of hardness which one gallon of lime water will soften. In practice, however, while theoretically 175 gallons of water of 1° of hardness may be softened by one gallon of lime water, owing to the impurities in the lime, probably not more than 130 to 150 gallons would be softened, so that, to arrive at the amount of lime-water necessary to soften hard water, if we divide 130 by the degrees of hardness according to Clark's scale, it will, generally, roundly represent the number of gallons of water which can be softened by one gallon of lime water.

It is found in practice that neither by boiling nor by the lime process can all the hardness which is termed "temporary hardness" be removed; in fact, a small quantity of chalk, to the extent of one part in 50,000 parts, is soluble in water, and still remains in solution after the process. In practice, however, 10-11ths of the whole of the temporary hardness may be moved by the lime process. In carrying out the Clark process, the lime water is usually applied, owing to the fact that it is a standard liquid containing a known quantity of lime, although cream of lime is sometimes used with advantage. Large tank space is required to carry out the Clark process, three tanks ordinarily being required, one for filling up, another for drawing down, and a third in reserve while cleansing is going on, and each tank should hold a day's supply.

It is a point of importance to know that the salts of iron may be readily removed by the application of lime. This the author found in the case of a water works at Horsham, where the water was so highly charged with iron, that everything it touched was discoloured; but by the application of lime the whole of the iron was removed. It should also be noted that the process has a marked effect in removing organic matter from water. This was shown by the Rivers Pollution Commissioners and by the analysis published by Prof. Wanklyn, especially in the marked diminution in the amount of albuminoid ammonia. The great objection raised against soft water has been its liability to produce lead poisoning; but the consensus of opinion is that water softened by the Clark process is not liable to attack lead, which is a point of very considerable importance in favour of the process.

Dr. Clark's process was first carried out by the Woolwich and Plumstead Waterworks Company, where it was shown that the water was successfully softened from 23° to 7°. These works were subsequently bought by the Kent Waterworks Company, and the process of softening the water was discontinued. An experiment was also made at the Chelsea Waterworks Company's works, the result of which is set forth in the following Table:—

THAMES WATER AT THE CHELSEA WATERWORKS.

1851	Degrees of Hardness.		REMARKS.
	Before liming.	After liming.	
February 24	14·0	4·5	The river was in good condition. The mixing was completed in 10 hours.
March 1	14·1	3·75	The river was in good condition. The mixing was completed in 9¾ hours.
" 18	10·5	5·0	The river was in flood, and the flood tinge was retained after liming.
" 22	11·6	4·8	Recovering from flood. The yellow flood tinge not removed.
April 17	15·5	3·6	The river in an average condition.

In the course of experiments made in softening various waters, it was observed that, if the water was at all tinted, the softening process did not clear it; but there was a tendency for the matters separated to remain in suspension in such water, so that it was considered expedient, in softening river water, that the water should be filtered until quite bright before it undergoes the softening process.

It may be here mentioned that, in 1852, a patent was applied for (W. B. Bowditch) to treat water with clay and alkali, and subsequently filtering.

Mr. Phillip H. Holland, M.R.C.S., late Inspector to the Burial Act Office, suggested, as an addition to the Clark process, the use of oxalate of ammonia or soda, to further reduce the hardness of the water after treatment by this process. The use of carbonate of soda for softening water has been known throughout the whole country by tea-makers from an early period. This salt added to water acts on the bicarbonate of lime and magnesia, and precipitates chalk and carbonate of magnesia. It also decomposes the sulphates of lime and magnesia, precipitating the lime and magnesia, while the soda remains in solution, so that the permanent hardness of the water is reduced by the use of this salt. The Rivers Pollution Commissioners of 1874 state, in their sixth report, with reference to the use of carbonate of soda, that "the hardness of water is almost exclusively caused by the presence in solution of the bicarbonates and sulphates of lime and magnesia. These salts are all decomposed by carbonate of soda, slowly in the cold, but rapidly when the water is hot, insoluble carbonates of lime and magnesia being deposited or precipitated as a fine mud, whilst soluble bicarbonate and sulphate of soda are formed." The process, however, of using soda is much more expensive than the ordinary lime process, about 4¾ times as much soda being required to produce the same results as in the case of lime. An old receipt for softening water, and useful for some domestic purposes, is as follows:—Dissolve 6 lbs. of pearlash or subcarbonate of soda in a gallon of soft water, boil the solution, and when boiling add 2 ozs. of soap, and stir until all the soap is dissolved. When this solution is added to water to be softened, the carbonate of soda and the soap combining with the salts producing both temporary and permanent hardness, form an insoluble compound by the combination with the soap, which coagulates and rises to the surface of the water, and may be skimmed off.

As any of the earthy alkaline earths may be used instead of, or in addition to, lime, it is not surprising that, since the date of Clark's patent, numerous patents have been taken out for softening and purifying water in which lime, in combination with other alkaline earths, have been proposed. For example:—

In 1849, Mr. John Horsley took out a patent for the use of calcined or caustic barytes, phosphate of soda, oxalic acid, or preparations of these substances.

In 1850, lime, in combination with chloride of barium, was patented.

In 1852, hydrate of potass and hydrate of soda, clay, and alkalies were the subject of separate patents.

In 1853 and 1854, hydrate of barytes, and hydrate of strontia formed the subject of patents.

In 1855, a patent was taken out for a powder containing oxalate of ammonia, peroxide of manganese, and charcoal.

In 1856, silicate of soda, in combination with carbonate of soda, was patented.

In 1856, bicarbonate of soda, and oxalic acid, in crystals, were again proposed to be used.

In 1856 and 1857, carbonic acid was proposed to be introduced in conjunction with hydrate of lime.

In 1860, bicarbonate of soda, and silicate of soda were again twice patented.

In 1862, the ordinary lime process was repatented.

In 1863, the use of chloride of barium was patented.

In 1865, hypermanganate of potash, carbonate of soda, alum and neutralised aluminite, or a solution of iron was proposed; and in another patent, sequi-sulphate of alumina was proposed as a means of purifying water. In another patent taken out in 1865 the use of soda and lime is again patented.

In 1866, a patent was taken out by a Mr. J. W. Tobin for an improvement on the Clark process for mixing the lime and filtering.

In 1866, the use of chlorine and permanganates, in combination with any alkaline earth, was patented.

In 1867, a patent was taken out for a preparation in a portable form, consisting of marsh mallow, linseed, bran, starch, gum, or any softening emollient, for the purpose of softening water for ablution purposes.

In 1868, the use of barytes was again patented, and the precipitate removed in vessels of a cellular form.

In 1869, the use of steam applied to water as a means of softening it was patented, the particles subsiding on shelves arranged in a vertical vessel.

In 1872, unslaked lime and sulphate of soda were patented as a means of purifying water.

In 1873, the lime process, in conjunction with a mixing and filtering arrangement, was patented; also lime, carbonate of soda, chloride of barium, or other reagent in conjunction with filtering.

In 1874, the treating of water with lime and carbonate of soda in combination with filtration was proposed.

In 1875, the lime process pure and simple, and in combination with other reagents and filtering, was patented.

In 1876, the lime process in combination with filter presses was first patented by Mr. Porter

In 1877, the use of oxide of magnesia and basic carbonate of magnesia was proposed; also the use of a carbonate of potassa, silicate of soda, and nitre cake, used separately or combined.

In 1878, a patent was taken out for combining bicarbonate of soda with the lime process, and filtering upon the Porter-Clark plan.

In 1879, Mr. Porter took out an additional patent for carrying out automatically the softening and purifying of water. In the same year phosphoric acid and phosphate of lime were proposed as a means of softening water.

In 1880, the means of automatically carrying out the softening process, and adjusting the quantities by means of an arrangement of ball valves in a cistern, was patented.

In 1881, Mr. Porter took out a further patent for the automatic regulation of the supply of the solution of lime.

In 1881, Mr. Atkins took out a patent for treating water with lime, and subsequently filtering through a specially constructed filter.

In 1882, an apparatus for softening and clarifying water was proposed, in which sloping shelves in a vertical vessel were used, the water entering the bottom of the vessel and flowing off at the top; or concentric cylinders overflowing from one to another might also be used with the same object.

In 1883, Messrs. Gaillet and Huet's apparatus for softening water was patented, consisting of sloping and V shaped shelves in a vertical vessel, the water entering at the bottom and flowing out at the top.

The use of steam and caustic soda was also patented.

A patent was also taken out for the use of phosphate of soda, and an apparatus for measuring the water and lime to be used in the softening process.

Modern Inventions for Softening Water.—The modern inventions for carrying out the Clark process may be described as the application of machinery to the saving of time, space, and labour. Of those in general use, dealing with them in the order of date, the Porter-Clark process comes first. In the ordinary Clark process, lime water, in known quantity, is first admitted into a tank, to which the water to be softened is added. However, in some cases, the lime water and the hard water are allowed to flow in together into the tank, but it was considered by Dr. Clark to be an advantage, in carrying out his process, for the hard water to be brought into contact with an excess of lime water in the first instance, which was led into the tank before the water to be softened was added. In the ordinary Clark process, not less than 16 hours were required for the softening and subsidence of the matters separated from the softened water. In the Porter-Clark process, instead of allowing the particles of carbonate of lime to separate and subside, a brisk agitation is maintained, so that these particles remain in suspension to permit chemical reaction with the lime, and the purification of the hard water which, when completed, is passed onward to filter presses, where the carbonate of lime adheres to the filtering cloth. The subsequent operations of filtering through the deposit on the cloth then takes place, and the water is passed away at once in fit state for use, so that the process is continuous in its action, and may be carried on just as quickly as water can be pumped from a well, provided the apparatus is of sufficient capacity to allow time for the water to remain in contact with the lime in passing through the machine. The lime in this case is passed through horizontal cylinders, which are termed lime churns, and is constantly churned up with water, and the lime water so made is, by suitable arraugements, allowed to mix with the ordinary water in proper proportions, after which it is again agitated. Mr. Porter has also an apparatus by which, instead of using ordinary filter presses, he can use filter frames, and where power is not available, he also suggests a means of working the process without such power. In some cases the power obtained from the pressure of the water is utilised for working the apparatus. An apparatus of this description may be seen at the Camden Town locomotive sheds of the London and North Western Railway, and the apparatus may also be seen at work within this Exhibition.

The Atkins Process is also a modification of the Clark process, by which the space formerly required is reduced. The lime is put into a vessel where lime water is formed, and this water is allowed to mix in its proper proportion with the water to be softened in a specially arranged mixing vessel, after which it passes into a reservoir of small dimensions. From this reservoir it is conveyed to filtering vessels which contain a special arrangement of filter, consisting of a series of chambers mounted upon a central hollow shaft, these disc chambers being covered with prepared canvas, npon which the deposit of chalk, &c., adheres, and through which the softened water filters. The filters are cleansed by means of revolving brushes. The apparatus does not require power to maintain it while at work, the only power used being that necessary to give motion to the brushes when the apparatus is cleansed. The system may be seen at work at the Henley-on-Thames Waterworks, and at other places.

In the Process of M. Maignen, a powder is used which the inventor calls "Anti-calcaire." This powder is made of variable composition, in order to suit the special characteristics of the water to be treated, the ingredients used for ordinary hard water being lime, soda, and alum in suitable proportions. In the apparatus, which is at work at the International Health Exhibition for softening water for some of the breeding tanks, the water entering the apparatus gives motion to a water-wheel, which in its turn works an arrangement for distributing a given quantity of the softening agent, and causing it to pass into the water. The water is then allowed to subside in a small tank, and is eventually filtered through filters covered with asbestos cloth, the basis of the filter being similar to that of the "Filter Rapide." A part of the carbonate of lime and magnesia deposited from the water adheres to the filtering surface, and the softened water filters through it. The apparatus may be seen at work in this Exhibition.

The Process of Messrs. Gaillet and Huet.—In this process, which was patented in February, 1883, the patentees make use of certain known agents, the patent itself applying to the apparatus used for the purpose of producing the results after the chemicals have been applied. The agents they propose are lime and caustic soda. Whenever the water contains organic matter, they use salt of alumina or iron in addition. Iron, however, is not recommended in any case where the water is required for washing purposes. The apparatus consists, virtually, of a series of tanks in duplicate, in which the chemicals are mixed, and these enter a vertical pipe in proper proportion to the water to be softened, and which communicates with the bottom of an upright chamber divided by a series of sloping shelves, through which the water gradually works upwards in a zig-zag path. These shelves slope in one direction, and are of V shape, so that as the deposit takes place it accumulates at one point, at which there is an opening ordinarily closed by a tap, and when any tap is open the deposit on the sloping shelf communicating with it is washed out. The apparatus appears to be extremely simple in its design, but its efficiency has yet to be tested, although it is at work at Messrs. Duncan's, Victoria Docks, where the water is reduced from 24° to 6°, and the Thames water is reduced from 16° to 2°.

Purification by Distilling.—It is not necessary to devote any large amount of attention to the question of purifying water by the process of distillation. The process is one which has been used from remote periods in order to produce absolutely pure water, and during the last forty years very great improvements have been adopted in order to bring this process into more general application in connection with the purposes of water supply. The difficulty of obtaining absolutely pure water is practically exemplified by this process, for in attaining this result, unless the water is distilled some two or three times, and every time a large proportion of the residue is discarded, pure water cannot be obtained. In the case, however, of water distilled for dietetic purposes, it is not necessary to carry out the process to the extent required in procuring water for some chemical purposes. It has generally been considered that distilled water lacks æration, and on this account it has been strongly recommended that it should be filtered. The great improvements in the process of distillation are due to Dr. Normandy, whose first patent, taken out in 1851, has been improved upon by many subsequent patents. The process has been adopted with the greatest possible advantage in many of our ocean steamers, and the preservation of the health of the crews and passengers visiting countries liable to the ravages of epidemic disease is, in a great measure, due to the use of this process. It is generally believed by many high sanitary authorities that if this system were adopted at malarious stations, one of the largest channels by which infection is disseminated would be effectually closed. Dr. Macnamara states that on our ocean steamers, "as a general rule, condensed sea water is employed for drinking purposes which, although it may not be always very palatable, must obviously be free from all chance of choleraic contamination;" and this is one of the great safeguards to Europe against the spread of cholera.

Softening by Exposure.—The exposure to the air of water containing salts which are held in solution by carbonic acid causes a loss of carbonic acid. Water of deep wells which has been in contact with chalk and other rocks often contains free carbonic acid by exposure, especially under the inequalities of diurnal temperature, the original charge of ground air is got rid of, and pure atmospheric air takes its place. On exposure to air, hard waters are especially liable to develop vegetable growth. A few days' exposure of very hard water in the summer time will soon develop green confervoid growth, and so soon as this growth takes place, carbonic acid is rapidly used up by it, so that the bicarbonates in the water are soon converted into simple carbonates, and are precipitated. Water, therefore, exposed to air undergoes a chemical metamorphosis; the bicarbonates of lime and magnesia are converted into carbonates, and are precipitated, and it is in this way that exposure assists in softening water.

Softening by Freezing.—Pliny, speaking of the quality of water and of the controversy going on in his time amongst physicians as to the use of water, says that some people preferred rain water above all others, because it is the lightest. He also says that some prefer "snow water before that which cometh down in showers; and the water of ice dissolved before the other of melted snow," and he goes on to say that the rain, snow, and ice are all lighter than those which spring out of the earth, and ice amongst the rest far lighter than any water in proportion. Ice taken from hard or other impure waters, if found to be perfectly crystalline and free from air bubbles, will produce, on melting, a water as soft as that of distilled water. If, however, the ice contains air bubbles or cavities of any description, such water will not be entirely pure. Some years ago the author made an extensive series of experiments upon the degree of purity which might be arrived at by freezing water, when it was shown that the act of freezing may be carried to such an extent as to produce, in the remaining water, a precipitation of the salts in solution, but ice frozen upon very superficial water was found liable to have the impurities frozen in it which adhered to the under sides of the ice, and which became embedded in it by subsequent freezing, but water which has been largely deprived of air by boiling or exposure, upon being frozen, if perfectly crystalline, will produce absolutely pure water. Several patents have been taken out with a view to freezing sea water so as to furnish a supply of fresh water on board ship, but such processes will not compete, from an economical point of view, with the process of distillation.

Geological. — The geological formations which furnish water of a quality suitable to be softened are those of the dolomitic or magnesian limestone, which gives great hardness to water, for while salts of lime render water hard and troublesome in washing, those of magnesia cause the water to curdle, and render it considerably more disagreeable for washing and ablution. The mountain limestone, which is ordinarily of an impermeable nature, does not yield water of such a hard quality as those of the magnesian limestone. The waters of the oolite and chalk are chiefly hard from what has been termed temporary hardness, that is due to the presence of bicarbonates of lime and magnesia in the water, which may be got rid of by boiling, or by the lime process. The waters of the new red sandstone and Permean beds vary considerably in hardness; many of them have a considerable permanent degree of hardness, but there are none of them which may not be softened to a great extent by the adoption of the lime process, while this process, in combination with the other alkaline earths, such as soda, when the water is not intended to be used for dietetic and washing purposes, will still further reduce the hardness of these waters.

The surface wells of the country, usually sunk in drift covering various geological formations, furnish water of various degrees of hardness. Scarcely any such wells yield a soft water, and in most instances, when these wells are sunk in populous places, in addition to their natural hardness, the waters are highly polluted, and such waters ought never to be used for dietetic purposes, unless they are first boiled.

ON THE DETECTION OF SEWAGE CONTAMINATION BY THE USE OF THE MICROSCOPE, AND ON THE PURIFYING ACTION OF MINUTE ANIMALS AND PLANTS.

By H. C. Sorby, LL.D., F.R.S.

By studying with the microscope the solid matters deposited from the water of a river, the previous contamination with sewage can usually be detected without any considerable difficulty. If the amount be serious, the characteristic particles of human excrement can easily be seen; and even if it is small, and has been carried a long way by the current, it can usually be recognised by means of the hairs of oats derived mainly from the droppings of horses, which resist decomposition for a long time, and are not consumed as food by minute animals. I, however, do not propose to enter into detail in connection with this part of my subject, but specially desire to call attention to the connection between the number of minute animals and plants, and the character of the water in which they live, and also to their influence in removing organic impurities.

For some time past I have been carefully ascertaining the number per gallon of different samples of river and sea water, of the various small animals which are large enough not to pass though a sieve, the meshes of which are about $\frac{1}{200}$ part of an inch in diameter. The amount of water used varies from ten gallons downwards, according to the number present. By the arrangements used there is no important difficulty in carrying out the whole method in a satisfactory manner. I confine my remarks entirely to general mean results.

The chief animals met with in fresh water are various entomostraca, rotifera, and the worm-like larvæ of insects. I find that the number per gallon and per-centage relationships of these mark, in a most clear manner, changed conditions in the water, the discharge of a certain amount of sewage being indicated by an increase in the total number per gallon, or by an alteration in the relative numbers of the different kinds, or by both. All my remarks apply to the warm part of the year, and not to winter.

It is known that entomostraca will eat dead animal matter, though probably not entirely dependent on it. I have myself proved that they may be kept alive for many months by feeding them on human excrement, though they soon died without it. If the amount of food in any water is small, not many of such animals can obtain sufficient; but, if it be be abundant, they may multiply rapidly, since it is asserted that in one season a single female cyclops may give rise to no less than four thousand millions of young. In stagnant muddy ponds, where food abounds, I have fouud an average of 200 per gallon. In the case of fairly pure rivers the total number of free-swimming animals is not more than one per gallon. I, however, found that where what may be called sewage was discharged into such water the number per gallon rose to twenty-seven, and the per-centage relationships between the different groups of entomostraca were greatly changed. In the Thames at Crossness, at low water, the number was about six per gallon, which fell to three or four at Erith, and was reduced to less than one at Greenhithe.

There is, however, a very decided limit to the increase of entomostraca when the water of a river is rendered very impure by the discharge of too much sewage, probably because oxygen is deficient, and free sulphide of hydrogen present. Such water is often characterised by the great number of worm-like larvæ of insects. Thus, in the Don, below Sheffield, in summer, I found the number, per gallon, of entomostraca only about one-third of what it is in pure waters; whilst, on the contrary, the number of worm-like larvæ was more than one per gallon.

Now if the minute free-swimming animals thus increase when a certain amount of sewage supplies them with ample food, it is quite obvious that they must have a most important influence in removing objectionable impurities. The number of the excrements of entomostraca in the recent mud of such rivers as the Thames is most surprising. In one specimen, from Hammersmith, I found that there were more than 20,000 per grain; and the average number at Erith, in August, 1882, was above 7,000, which is equivalent to about 200,000 per gallon of water at half ebb, from the surface to the bottom. This enormous number must represent a very large amount of sewage material consumed as food; and though, as in the case of larger animals, a considerable part of their excrements no doubt consists of organic matter capable of putrefaction, yet there can be no less doubt that the amount entirely consumed in the life processes of the animals is also great.

As named above, I kept cyclops alive for many months by feeding them on human excrement. It is thus easy to understand why, when they abound in the Thames, the relative amount of human excrement is very considerably less than in the winter, when their number must be much smaller.

We thus appear to be led to the conclusion that when the amount of sewage discharged into a river is not too great, it furnishes food for a vast number of animals, which perform a most important part in removing it. On the contrary, if the discharge be too great, it may be injurious to them, and this process of purification may cease. Possibly this explains why in certain cases a river which is usually unobjectionable may occasionally become offensive. It also seems to make it clear that the discharge of rather too much sewage may produce relatively very great and objectionable results.

Though such comparatively large animals as entomostraca may remove much putrefiable matter from a river, we cannot suppose that, except incidentally, they remove such very minute objects as disease germs, but it would be a subject well worthy of investigation to ascertain whether the more minute infusoria can, and do consume such germs as a portion of their food. If so, we should be able to understand how living bodies, which could resist any purely chemical action likely to be met with in a river, could be destroyed by the digestive process of minute animals. Hitherto I have had no opportunity for examining this question critically, but have been able to learn certain facts which, at all events, show that it is well worthy of further examination. It is only during the last month that I have paid special attention to the number of the larger infusoria, and various other animals of similar type, met with per gallon in the water of rivers and the sea, which can be seen and counted by means of a low magnifying power. At low water in the Medway above Chatham, in the first half of June, the average number per gallon has been about 7,000, but sometimes as many as 16,000. Their average size was about $\frac{1}{1000}$th inch. Possibly the number of still more minute forms may be equally great; but, even if we confine our attention to those observed, we cannot but conclude that their effect in removing organic matter must be very considerable; and judging from what occurs in the case of larger animals, those 1 th of an inch in diameter may well be supposed to consume as food, particles of the size of germs. Up to the present time, I have however collected so few facts bearing on this question, that it must be regarded merely as a suggestion for future inquiry.

So far, I have referred exclusively to the effect of animal life. Minute plants play an important part in another way. The number per gallon of suspended diatoms, desmids, and confervoid algæ is, in some cases, most astonishing, and they must often produce much more effect than the larger plants. As far as I have been able to ascertain, their number is, to some extent, related to the amount of material in the water suitable for their assimilation and growth. In the mud deposited from pure rivers their numbers is relatively small, but in the district of the Thames, where the sewage is discharged, I found that in summer their number per grain of mud at half-ebb tide was about 400,000, which is equivalent to above 5,000,000 per gallon of water. This is two or three times as many as higher up or lower down the river, and, out of all proportion, more than in the case of fairly pure rivers like the Medway. Their effect in oxygenating the water must be very important, since, when exposed to the light, they would decompose carbonic acid, and give off oxygen, under circumstances most favourable for supplying the needs of animal life, and counteracting the putrefactive decomposition so soon set up by minute fungi when oxygen is absent.

Taking then, all the above facts into consideration, it appears to me that the removal of impurities from rivers is more a biological than a chemical question; and that in all discussions of the subject, it is most important to consider the action of minute animals and plants, which may be looked upon as being indirectly most powerful chemical reagents.

ON THE CHEMISTRY OF POTABLE WATER.

By Professor Odling, M.B., F.R.S., F.R.C.P.,
President of the Institute of Chemistry.

1.—Sources of Water Supply.

The water of most towns is derived, as is well known, from one or other of three typical sources, constituted respectively by springs, or streams, or lakes, this last named source being taken to include not only natural lakes, but also those huge artificially formed reservoirs, in which the surface water collected from more or less extensive gathering grounds, is retained by means of embankments, and stored up for distribution to consumers. Although some streams, indeed, are fed largely by springs, and some lakes are little else than local expansions of streams or rivers, still a general distinction in character between supplies derived from the three just spoken of typical sources, is, on the whole, broadly recognisable; and this, notwithstanding the fact of the considerable differences in composition manifested by individual spring waters, derived from different springs or wells, by individual stream waters, derived from different streams or rivers, and by individual lake waters, derived from different lakes or reservoirs. Despite the marked preference of a few authorities for some one variety of source to the exclusion of the others, the majority of engineers have come to recognise each variety as having its own characteristic excellencies and concomitant defects, and are accordingly ready to avail themselves, in different cases, of whatever kind of source is rendered by local circumstances most available and suitable for the particular town to be supplied. From all three varieties of source alike, numerous large populations have been furnished for generations past, with an abundant, and, as the result has shown, with a satisfactory and wholesome supply of water; although, indeed, in a few special instances, supplies from all three varieties of sources alike have, in different ways and under exceptional circumstances, proved detrimental to the health, and even, in certain cases, fatal to the lives of some among the population supplied. All three varieties of source have, under the best advice of the time, been continually resorted to from the earliest period of water supply undertakings, nearly three centuries ago, down to the present day. Thus, while the youngest of the companies supplying London has obtained its supply, since 1862, wholly from deep wells sunk in the chalk, the new works for the supply of Liverpool and Manchester respectively, which may both take rank among the greatest hydraulic undertakings of the century, are intended to introduce and distribute river water in the one town and lake water in the other. All experience, indeed, goes to show that the supply of excellent water is not confined to its supply from any single variety of source; and that for the purpose of water supply, there are alike good wells and bad wells, good lakes and bad lakes, good rivers and bad rivers. Just, moreover, as the best of river waters or lake waters will fall short in regard to an excellency characteristic of well water, so will the best of well waters fall short in regard to an excellency characteristic of lake water or river water. The comparison of the one sort with the other sorts of water must be made as a whole. To select arbitrarily the special good point of one sort of water as a standard, to the neglect of the countervailing good points of other sorts, and to measure the quality of the other sorts solely in reference to this selected standard, is clearly the conduct rather of an advocate than of a judge.

2.—Purity of Water.

Water, as conceived of by the chemist, is a definite compound of 100 parts by weight of oxygen, united with 12·5 parts by weight of hydrogen. So exceedingly difficult is it of production, even if it ever has been produced in an absolutely pure state, that it may be regarded rather as an ideal than a real chemical substance. All natural water, besides the matter, never entirely absent, which it holds in suspension, is a solution of various mineral matters, of various organic matters, and of various gases in the ideal water, or protoxide of hydrogen, of the chemist. Of the different kinds of foreign substance habitually or exceptionally present in natural water, some kinds are beyond question prejudicial, and in particular cases highly prejudicial; most kinds are simply innocuous; while not a few kinds, as saline matter in moderate proportion, and more particularly dissolved aerial matter, are positively beneficial. Looked at, however, from a strictly chemical point of view, any matter whatever foreign to the ideal chemical compound, water, constitutes an impurity of the natural water in which it occurs, whether this foreign matter be a prejudicial or a beneficial constituent, whether it consist of sewage matter, by which the water is fouled, or of healthful oxygen, by which it is aerated. The chemist uses the word pure, not in the sense of opposite to nasty, but much in the way it is often used in ordinary language, to express the exclusion from one thing of anything else, whether better or worse. Thus, we talk no less familiarly of pure rubbish or pure dross than of pure gold. We speak of pure nonsense as readily as we speak of pure truth, irrespective of the circumstance that the nonsense would be benefited, though to the prejudice of its purity, by its contamination with a few grains of sense. So chemists speak of pure water, irrespective of the circumstance that, for all the needs of life, the water is benefited, though to the prejudice of its chemical purity, by the presence both of its dissolved gases, and of a proportion of dissolved saline matter. Chemists, then, are in the habit of using the word "purity" to signify oneness of chemical nature. Accordingly, in the eyes of a chemist, the matter, for example, of an old copper penny would have its degree of purity equally lowered by the same addition made to it of any kind of other matter, whether of base metal, like tin, or of noble metal, like silver, or even gold. Similarly, in the case of natural water, the small proportions of other substance existing together with the main substance, protoxide of hydrogen, interfere with the oneness of its chemical nature; or, in other words, constitute the natural water a mixture of substances, instead of being a single substance, which is alone looked upon by the chemist as a pure substance. It follows, that the water of the chemist is one thing, the water of nature another. The ideal water of the chemist is a single substance; the water of nature, like the air of nature, is a mixture of substances. Just as this last is a variable mixture of the pure chemical substances—nitrogen, oxygen, water vapour, carbonic acid and ammonia, with traces of various other kinds of matter, so is the water of nature a variable mixture of the pure chemical substances—protoxide of hydrogen, common salt, saltpetre, gypsum, limestone, carbonic acid, nitrogen, and oxygen, &c., together with various kinds of organic matter. Air, from which the minor constituents of atmospheric air have been carefully abstracted, is sometimes spoken of as purified air; but air, deprived in this way of its so-called impurities, is absolutely incapable, in relation alike to animal and vegetable life, of fulfilling the functions of an atmosphere. The substitution of such purified air for actual atmospheric air would mean the cessation on the earth's surface of all life as it now exists. Similarly, with regard to natural water, some of its minor constituents we know to be essential, others of them we have reason to think advantageous to the fulfilment of its functions in nature. Bearing in mind, indeed, the interaction everywhere of life and the conditions of living, we can scarcely doubt that the actual mixed substance, water, is better suited to supply the wants of our daily life, than the ideal unmixed substance would be; and, further, we have no reason whatever to look upon this ideal substance as furnishing a standard of excellence, to which it is desirable that our daily supply should, as far as practicable, and in all respects, approximate. What we really desiderate is not chemical purity, but hygienic freedom from anything hurtful. In some water, as in some air, an objectionable constituent may be met with; but in the case neither of water nor air, is there any presumption on the score of wholesomeness, in favour of a single substance as such, rather than of a mixed substance as such. The presumption is indeed the other way. No one desires unmixed oxygen, or even oxygen and nitrogen free from commixture with the minor constituents of our native air; so neither is there any reason to desire unmixed protoxide of hydrogen, freed from the minor constituents of wholesome natural water. It is clearly open to a chemist, addressing himself to chemists, to speak of the constituents of ordinary water, other than protoxide of hydrogen, as impurities in the water; provided of course that he is consistent, and includes the desirable dissolved gases of the water among its impurities and as contributories to the sum total of its impurity. It is also open to a chemist, addressing himself to chemists, to make a comparison of different natural waters, in respect to the relative proportions of their total impurity, or of their saline impurity, or of their calcareous impurity, or of their organic impurity, or of their aerial impurity, &c. But it is not, I take it, open to a chemist addressing the general public, to speak as a chemist of some particular selected constituent, characteristic of the class of natural waters derived from one kind of source, as an impurity, and to leave it to be inferred by the general public that because this constituent is, in a strict chemical sense, an impurity, it is therefore a something nasty and unwholesome, and that the class of waters in which it is more especially met with are, in proportion to the extent of its presence, nasty and unwholesome. The general public do not know that the chemical impurity of a water may be good or bad, noxious or innoxious, desirable or undesirable, wholesome or unwholesome. They are unaware that no scale of wholesomeness or desirableness can be inferred from a scale of chemical purity, with respect to some particular constituent stigmatised as an impurity, until it has been established by evidence that this particular chemical impurity is of an unwholesome or prejudicial character. It is a mere dialectic artifice, and not a very worthy artifice, to use the word impurity in a strictly scientific sense, with intention to have it accepted in a popular sense as bearing a meaning which, scientifically, by no means belongs to it.

3.—Organic Matter of Water.

The saline matter of water is a useful expression to denote the sum of the dissolved mineral constituents, and the organic matter of water a useful expression to denote the sum of the dissolved organic constituents of natural water. The saline matter of one water is not necessarily, or yet commonly, identical with the saline matter of another water; nor is the saline matter of the selfsame body of water necessarily identical throughout its entire extent, or from one period of time to another. The same holds good with regard to the organic matter of water. It is a different thing in one water from what it is in another; and may be different in the same water from place to place and from time to time. But just as there is a character or nature more or less common to the usual varieties of dissolved saline matter, so also is there a character or nature common, within certain limits, to the usual varieties of organic matter met with in potable water. So far, a certain parallelism holds good between the saline matter of water on the one hand, and its dissolved organic matter on the other. But in many important particulars the parallelism fails. Thus the saline matter occurs, for the most part, in appreciable proportion, say from $\frac{1}{100}$ to $\frac{1}{20}$ of a per cent. It is constituted of definite chemical substances, possessed of well-determined properties; and its amount is capable of estimation with all desirable accuracy—with considerable accuracy by direct weighing, and with yet greater accuracy indirectly, by the separate estimation of its several constituents. The dissolved organic matter of potable water on the other hand, never amounts to more than an exceedingly minute proportion, say from $\frac{1}{5000}$ to $\frac{1}{1000}$ of a per cent.; what are its separate constituents, and what their chemical nature, is almost, if not wholly, unknown; its amount is moreover incapable of direct determination, and the different means for its indirect determination are far from satisfactory. Chemists are capable, however, thanks to Dr. Frankland, of determining with a considerable degree of accuracy, the quantity of carbon that exists in any water, in the form of organic matter. Evidently, if all organic matter contained the same proportion of carbon, a determination of the organic carbon present in any water would be tantamount to a determination of its organic matter. But in reality the proportion of carbon existing in different individual varieties of organic matter has, on the contrary, a very wide range of variation. Still, it would appear, from such imperfect investigations as have been made, that the proportion of carbon existing in the organic matter of water—that is to say, the mean proportion of carbon present in the whole of the several individual constituents of the organic matter, taken together—is not subject to any such considerable range of variation, and that it may, without risk of serious error, be valued at about 40 per cent. Disregarding then for the moment the consideration of the nature of the dissolved organic matter present in natural water, and confining attention only to its quantity, it may be taken as admitted that the determination of the organic carbon in water is an absolute, and more then fairly accurate determination; that the organic matter of water is in a general way proportionate to the amount of its organic carbon; that the amount of organic matter may accordingly be represented by some multiple of the organic carbon; and that for purposes of comparison, at any rate, this multiple may be taken provisionally as 2·5, corresponding, of course, to the occurrence of 40 per cent. of carbon in the organic matter.

The inquiry next presents itself as to what, on the basis of these propositions, is the quantity of organic carbon, and consequently of organic matter present in the three classes of water derived respectively from each of our typical varieties of source. Speaking generally, it may be said that the proportion of organic matter is decidedly least in spring or well water—that is to say, if we limit our attention to such waters only as would be taken for town supply, for there are, of course, foul well waters, in which the amount of organic matter is in excess of anything ordinarily met with in the water of lakes and natural rivers. As between lake sources in general, and river sources in general, it is not easy to assign the order of seriation. The proportion of organic matter found in different lake waters is, on the whole, more uniform than the proportion found in the waters of different rivers. Accordingly, while in some river waters the proportion of organic matter is somewhat higher, there are other river waters in which it is very considerably lower than the proportion commonly present in lake water. On the whole, it would seem that river water in general must take precedence of lake water in respect to the smallness of its proportion of dissolved organic matter, subject, however, to the observation that the proportion of this constituent is more variable in river water—that it is liable to a greater range of variation, both as between the water of one river, and the water of another, and as between the water of the same river at different seasons. In order to give some idea of the quantities of organic carbon, and consequently of organic matter, present in the water, furnished from different varieties of source for town supply, I have made an abstract of the results set forth in the Registrar-General's monthly reports for the last year and a-half, beginning, that is to say, with the report for January, 1883, and ending with the report last made, for June, 1884, in respect to the supplies of London, Birmingham, and Glasgow. I have resorted to the reports of the Registrar-General, in part, because they alone furnish the results of a regular series of analyses of the water supplied to other towns than London; and, in part, because, with regard to London, I have, for the purpose of this address, preferred to bring before you the results of analyses for which I am not in any way responsible. There is not, however, any appreciable difference between the mean results for the period obtained by Dr. Frankland, on the one hand, and by my colleagues and myself on the other, in respect to the composition of the London waters examined by both of us.

The five Thames waterworks companies, as is well known, take their supply from the river at Hampton, Ditton, and Molesey. They furnish just under 50 per cent. of the total supply of the metropolis. The East London Waterworks Company take their supply from the River Lee, some distance below Ware. Their subsiding reservoir at Walthamstow has the enormous area of 222 acres, equal to that of a good-sized lake. The company have power to take in addition ten million gallons of water daily from the Thames at Sudbury. It is but seldom, however, that they resort to the Thames at all; and very rarely indeed to the extent of more than one-quarter of the daily amount they are privileged to obtain. Substantially, the water of the East London Company is water from the Lee. The New River Company take somewhere about four-fifths of their supply from the Lee, above Ware, and the remaining one-fifth from Chadwell springs and a series of deep wells sunk in the chalk. The East London and New River Companies jointly, furnish about 44 per cent. of the total supply of the metropolis. The Kent Waterworks Company take their water entirely from deep wells in the chalk, and furnish from this source rather more than 6 per cent. of the total supply of the metropolis. The water supplied to the town of Birmingham by the Corporation, is taken from various sources, lake or reservoir, stream and well, but in what relative proportions I am unable to say. The water supplied to the town of Glasgow by the Corporation, is taken, as is well known, from Loch Katrine. The underneath table shows the actual quantities of organic carbon, expressed both in parts per 100,000 and in grains per gallon, and the estimated quantities of organic matter in grains per gallon, present in these six several supplies of water, as determined by monthly analyses of the waters conducted during the last year and a-half.

MEANS OF EIGHTEEN MONTHLY ANALYSES, 1883-84.

Source.	Proprietary.	Organic Carbon.		Organic Matter.
		Parts per 100,000.	Grains per gallon.	Grains per gallon (estimated).
Chalk Springs	Kent Company	·047	·033	0·083
River Lee and Springs..	New River Company	·089	·062	0·156
Mixed	Birmingham Corporation ..	·132	·093	0·231
River Lee	East London Company	·139	·098	0·245
Loch Katrine..........	Glasgow Corporation	·147	·103	0·257
River Thames	The Five Companies	·164	·115	0·286

It will be seen that the organic matter of the Kent Company's water, which is a spring water, is under one-tenth of a grain per gallon; that the organic matter of the New River Company's water, which is mainly a river water, is considerably under two-tenths of a grain per gallon; that the organic matter of the East London Company's water, which is a river water, that of the Birmingham Corporation's water, which is a mixed water, and that of the Glasgow Corporation's water, which is a lake water, are alike about two and a-half tenths, *i.e.*, a quarter, of a grain per gallon; while the organic matter of the Thames Companies' supply of river water is under three-tenths of a grain per gallon. It is to be noted, however, that, although the average proportion of organic matter in the Thames-derived water supplied to London, is a little in excess of that in the Birmingham and Glasgow Corporations' supplies, the excess is entirely due to the effect of the winter floods. Comparing the results in the summer nine months, March to September, 1883, and March to June, 1884, the proportion of organic matter in the Glasgow Corporation's supply is somewhat in excess of the proportion found in the Thames supply, the number of grains of organic matter, being for the Thames-derived water ·22, and for the Glasgow water ·25 grain per gallon. Similarly, the organic matter of the East London Company's water, during the summer months, falls appreciably below that of the Glasgow Corporation's supply at the same season of the year,—the season, that is to say, during which a high character of water is considered to be more especially demanded. The above statements, as to the particular fractions of a grain of organic matter ordinarily present in a gallon of different kinds of water, serve to convey some idea of the always exceeding smallness of the quantity. A better notion, however, of the minuteness of even the highest proportions of organic matter found, say, in any London water, is afforded by stating the results in another way. Thus, if we suppose for an instant that the Thames companies' water, instead of containing under three-tenths of a grain, contained seven-tenths of a grain of organic matter per gallon—a maximum which has been occasionally approached in the supply of one or other of the Thames companies at a period of flood—even this exceptional proportion would but correspond to the presence in the water of exactly the thousandth part of one per cent. of organic water. Whether or not, variations within the limit of such a small proportion of dissolved organic matter present in potable water, ranging from about the one-thousandth part of one per cent. exceptionally met with in a Thames-derived water, down to the eight-thousandth part of one per cent. habitually met with in a chalk-spring water, are matters of any real significance, must obviously depend on the character of the dissolved organic matter present in the different waters. It will suffice for the present to observe that, so far as mere quantity of organic matter is concerned, the water supplied to London from the Thames and Lee takes, on the whole, precedence of the highly reputed, and deservedly reputed, water furnished to Glasgow; as, doubtless, it will take precedence of the water about to be furnished to Manchester.

As regards range of variation, it is noticeable that, while the mean proportion of organic matter present in the summer supply of the Thames Companies, as calculated from the average of forty-five analyses reported to the Registrar-General, is ·22 grain per gallon; and the mean proportion present in the yearly supply, as calculated from the average of ninety analyses, is ·28 grain per gallon; the proportion in one particular sample of water out of the ninety samples analysed, fell to ·17 grain, in two samples it rose to ·50 grain, in one sample to ·53 grain, and in yet another sample to ·60 grain; but that in no one sample out of the ninety did it reach the maximum of ·70 grain per gallon, so as to constitute the thousandth part of 1 per cent. of the water. It happens similiarly in nearly all natural waters, that while the absolute variation in the proportion of organic matter present at different times is almost infinitesimally small, the relative variation is, on the other hand, strikingly large. Thus, the proportion of organic matter present in the Glasgow Corporation's lake water at different times varies as 1 to 2; that in the Kent Company's spring water, in the East London Company's water, and in the Thames Companies' water, varies as 1 to 3 or $3\frac{1}{2}$; that in the New River Company's water varies as 1 to 4; and that in the Birmingham Corporation's water varies as 1 to 7; but the larger range of variation in the water of these last two supplies is dependent, doubtless, on the circumstance of their being mixed supplies, constituted of unequal proportions of their several contributories at different times. In the official phraseology with which we are so familiar—phraseology of but little meaning, though the words are strong—it would be said that while the degree of "pollution by organic impurity" of the Glasgow water is twice as great at one time as at another, the degree of "pollution by organic impurity" of the Birmingham water is seven times as great at one time as at another. The large extent of relative variation thus noticeable in respect to the organic matter of water, is common, as might be expected, to those other of its constituents, which also exist absolutely in very small quantity, and is, indeed, almost a consequence of the smallness of their absolute quantity. A somewhat parallel comparison may be adduced in the case of personal wealth. We know that while the wealth of a capitalist will, for the most part, vary only by a small percentage from month to month, the whole fortune of a beggar, his utmost riches being a matter of no consideration, may vary manyfold in the course of a day, although by the absolute amount of only a few halfpence put into or taken out of his ragged pocket.

4.—General Considerations.

So far, attention has been directed to the organic matter of potable water, solely from the point of view of its quantity. A much more important inquiry, however, has reference to its nature or quality. But this is too large and important a matter to be taken up at the fag end of an address, limited strictly to the duration of a short half-hour. That the organic matter of potable water is constituted, in the main, of dissolved, unorganised, and non-living matter, does not admit of question. Anything like an adequate discussion, however, of the origin, nature, and possible hygienic influence of this main portion of the organic matter, could not but involve a very long story. It may suffice here to say that, having regard to its origin and nature, and to the minuteness of its proportion, the presumption against any unwholesomeness attaching to its presence is very strong. To what extent living and organised matter may be also present; how far such living organic matter may include a something capable of developing zymotic disease; and, admitting all this, how far the liability of different waters to contain more or less of noxious living organic matter is related to the varying amounts which they contain of innoxious non-living organic matter, are questions far more difficult of solution. They are questions on which, in the present imperfect state of our knowledge on the subject, it behoves every one to speak with caution; but in my own view, having regard to what is observed and recorded respecting the health of differently supplied populations, and to what little is known of the natural history of disease-producing organisms, the preponderance of evidence does not, I think, favour an alarmful answer. Other persons, however, are of a different opinion. But the address which I have been asked to read at this Conference, is on the chemistry of potable water; and my concern to-day is solely with the chemical aspect of the subject. It is not from biologic or pathogenetic inquiries, but from the results of the chemical analysis of the water supplied to London—from the mere determinations of the quantity of its organic matter—that its wholesomeness is month after month, by suggestion, impugned. On this point I join issue altogether. Further, it seems to me an abuse of chemistry, that a chemist, who on other than chemical grounds may, rightly or wrongly, have satisfied himself of the unwholesomeness of a particular water supply, should state and summarise the results of his analyses in such a fashion as to make it appear that the unwholesomeness, which he really infers on other grounds, is deducible from the results of his periodical chemical examinations. It is well understood that a statement, of which the verbal accuracy cannot be challenged, may, nevertheless, be far from a warrantable statement. It may convey a *suggestio falsi*, and include a *suppressio veri*. Such I take to be the case with the statement, paraded month after month, in what is an official, and should be a scrupulously impartial report, as to the relative "amounts of organic impurity" contained in individual samples of metropolitan water, compared with a particular decennial average amount present in the Kent Company's water,—a standard, by-the-bye, of which the value is known and used only by the reporter, whose comparison, accordingly, it is impossible to check. This monthly statement suggests, I take it, the notion that spring water is the proper type of what river water, or at any rate of what metropolitan water, should be—a notion entirely without foundation, and discordant with the reporter's own strong recommendation of lake water for the supply of London. It further suggests the notion that the desirableness and general wholesomeness of different waters are inversely proportional to their relative "amounts of organic impurity," irrespective of the origin and nature of this so-called impurity,—a notion equally devoid of foundation. On the other hand, the statement in question suppresses the fact that spring water, lake water, and river water, have each their special characteristics, excellencies, and defects. It suppresses the fact that the so-called "previous sewage contamination" of the standard spring water is as relatively high, as its "amount of organic impurity" is relatively low. It suppresses the fact that the "amount of organic impurity" in the metropolitan river supply, though threefold or fourfold that present in the spring water supply, is nevertheless almost infinitesimal in absolute quantity. It suppresses the fact that the "amount of organic impurity" in the highly reputed Loch Katrine supply is, during the summer months, in excess of, and is on the average of the year substantially identical with, the summer and yearly amounts respectively present in the metropolitan river supply. It further suppresses the fact that the head waters of the Thames, by the time they reach Lechlade, about 22 miles only from their source, and 120 miles above the Companies' intake, have exchanged their character of spring water for that of river water, and irrespective of urban contamination, contain an "amount of organic impurity" identical in quantity with, and chemically undistinguishable in kind from, that met with in the river water at Hampton. I dispute altogether the notion, suggested by the mode of statement adopted in the monthly reports made to the Registrar-General, that the relative unwholesomeness of the Kent Company's water, the New River Company's water, and the Birmingham Corporation's water, was, during the last eighteen months, approximately as the numbers 1, 2, and 3; or, in other words, that it was in the proportion of the 8-hundredths, the 15-hundredths, and the 23-hundredths, of a grain of dissolved organic matter per gallon, present in the three supplies respectively. I contend, further, that the New River Company's water would have been no more wholesome or unwholesome respectively, if, instead of actually containing 15-hundredths of a grain of organic matter per gallon—this organic matter being chiefly of vegetable origin, and a product of ordinary fluviatile life—it had contained, like the Kent Company's water, as little as 8-hundredths of a grain, or, like the Birmingham Corporation's water, as much as 23-hundredths of a grain of organic matter, the absolute variations of a tenth of a grain or so of such dissolved organic matter per gallon, being too small to have any real hygienic importance whatever.

If it were indeed the fact that the dissolved organic matter of potable water, taken as a whole, is of such a nature that, in the proportions in which it is met with, it is capable, on occasions, of developing and spreading epidemic disease, it is manifest that no plea, based on the actual smallness of its proportion, would be of any avail to save it from hopeless condemnation. It is manifest also, on this assumption, that the determination of the variations in the proportions of organic matter present in a water, notwithstanding the minuteness of even the maximum proportion, would be a determination of the highest significance; and further, that any information furnished in intelligible language to the general public, as to the results of a comparison of different waters with one another in regard to their respective proportions of organic matter, would have an extreme degree of interest and value. But all this is based on the hypothesis that the dissolved organic matter of water, or at any rate the dissolved organic matter of some water, taken in its entirety, is a noxious constituent of the water, capable, in proportion to its quantity, of setting up epidemic disease; a view, it need scarcely be said, which is sustained by no sort of evidence, and supported by no weight of authority. If, indeed, the organic matter of water were really of this noxious character, the conclusions above set forth, with regard to the propriety and value of a comparison of waters with one another in respect to so noxious a constituent, would be undeniable. But if, on the other hand, the minute proportion of dissolved organic matter met with in potable water is constituted mainly of innocuous vegetable extractive, with a trace or more of innocuous animal extractive; and if, at the same time, this organic matter does not affect in any appreciable degree the taste, or colour, or appearance of the water, clearly all variations in the amounts present in potable water, that fall within the limits of an exceedingly minute proportion, are matters of no consideration whatever; and this whether they be variations in the proportions existing in different waters, or variations met with in the same water at different times. And the same conclusion would hold good, even if the organic matter of water, while constituted in the main and at most times wholly, of innocuous extractive, was, nevertheless, liable to include at other times a sub-proportion of an effectively noxious agent; unless, indeed, it could be shown that the liability of different waters to contain this noxious agent was in proportion to their relative amounts of dissolved organic matter—a proposition so preposterous as never to have been seriously put forward. Whether or not there exist any good grounds for calling in question the excellence and wholesomeness of the water, supplied to probably the healthiest great city in the world, is another matter

Speaking as a chemist, I represent that there are no chemical grounds for such a contention. In support of this position, I would call to mind that the last Royal Commission on Water Supply, after hearing very varied evidence, much of it of the usual alarmist character, reported to the effect that the presence of a small quantity of organic matter in drinking water was not necessarily prejudicial; and that there was not any evidence to satisfy them that the particular organic matter present in filtered Thames water was prejudicial. Their conclusion on the general question is expressed in the following words :—" Having carefully considered all the information we have been able to collect, we see no evidence to lead us to believe that the water now supplied by the companies is not generally good and wholesome."

[This paper was not complete at the meeting of the Conference, and Dr. Odling, therefore, only read the first portion, and the conclusions at which he had arrived.—Ed.]

Miscellaneous.

CANE AND BEET SUGAR.

By G. Buchanan.

(*Concluded from p. 909*)

Worthy, however, as the cane must be acknowledged to be of receiving our exclusive attention, it is yet fortunate that there is at hand in the beet an ancillary sugar bearer to which, when stinted in the supply of cane, we can turn for the relief of our wants. And deserving the sugar beet (it is a mangel wurzel) is to be called " scarcity root," considering how large a quota it furnishes to meet the requirements of our greatly increased consumption, the needs of which would, with cane alone, have caused ere now a sugar famine. According to the Board of Trade returns, the imports of sugar into this country amounted in the year 1882 to 1,130,267 tons, of which more than a third, or 395,915 tons were beet sugar. But the unrestrained admission of this portion of the supply is objected to by the home trade, and strenuous endeavour has been made to restrict the importation of beet, by the imposition of a countervailing duty of £2 per ton, which, as was shown before the Select Committee on sugar, would suffice to equalise the foreign bounties given to the exporters. That the claim has not been conceded is scarcely surprising; the wonder is that it was ever made. The rules of free trade have never been shown to be so considerate of the growers of corn or sugar, as to give reason to suppose they would be indulgent to the second-hand traders in the same products, the millers and melters. And an artificial bar of this kind put up in the way of beet sugar would be surmounted by the manufacturers improving their machinery, and adopting new processes to extract all the sugar possible from the saccharine of the root. The diminution in value by the tax would be compensated by the augmentation in quantity of the sugar; when the controversy would begin again, and a cry be raised to have the barrier made higher. A surer way to stop the influx of the objectionable commodity would be to lower permanently the price. The present low quotation prevailing in the sugar market will, doubtless, lessen for a time the production of beet on the Continent, but so soon as the demand overtakes the supply, and prices rise, the cultivation will be followed up and extended. One-half the time and pains that have been taken in an unavailing opposition to the foreign bounties on beet, would, if given to the introduction of improvements in cane-sugar making, have furthered the object of the planters and refiners more effectually. And that without injuring the consumer, who, when provided with better and cheaper cane sugar, could have no cause to complain of the displacement of beet sugar from the market. But it almost seems as if our people had lost a great deal of their relish for the sweet cane, and had more liking for the unsavoury beet. For instead of applying skill and money to the development of cane sugar works in the Indies, the habitat of the plant, the manufacture of sugar from beetroot is to be commenced in this country. A former attempt to make sugar in Suffolk failed, and it may be doubted if the present trial will be more successful in meeting foreign competition. As although home-grown beet will have a considerable advantage over that from abroad in the saving of freight, &c., the humidity of our climate is almost as great a natural disadvantage. In Germany the wet bulb thermometer shows 2 to 3 degrees more cold than here, indicating the air to be less damp, which is conducive to more richness of sugar in the root. But the depreciation in value from over production is a greater discouragement to beet sugar, for if it was unable, as supposed, to bear the burden of a tax of £2, how can it endure the fall, as reported, of £4 in the market. This decline must be a very serious thing for the growers, and yet sugar can scarcely be said to be too low in price, compared with other articles of food, if the equivalents of their value for food are considered. The natural effect of low prices is to stimulate consumption, and seeing how extensively sugar is employed in the diet of the people, it is for the public benefit that it should be cheap. If the beet-sugar manufacturers have no margin left for working on with profit, and cannot eke out the failing price with a fuller quantity of sugar from the root; the cane-sugar makers are not in the same evil plight. Their situation compares favourably with that of their rivals, and they may look forward with hope and conviction that cane-sugar planting can be made to pay well, although the day of such high dividends as 30 per cent. on the capital employed be past and gone.

Correspondence.

MR. SORBY ON THE DETECTION OF SEWAGE CONTAMINATION BY THE MICROSCOPE.

The short space of time allotted to the discussion of the several groups of papers, read at the Society of Arts Water Supply Conference, precluded me from making a few remarks on Mr. Sorby's paper on the "Detection of Sewage Contamination by the use of the Microscope." I, therefore, venture to put what I intended to say in the form of a communication. As the material constituents of all potable river waters must rather be studied biologically or physiologically, than under low powers of the microscope or chemically, to become of any value, it is obvious that Mr. Sorby's examinations of the coarser and more palpable contaminations of water will, under any circumstances, be of little moment. It is the minuter forms of organic life with which medical men are much concerned, and which are known to be of vital importance as matters of hygiene. These are only discernable by using high powers, and their effects on health and life are only seen by applying the "physiological test." But as Mr. Sorby seems to attach importance to his investigations, it will be as well to inquire if these can be followed to any useful purpose. "The chief animals," he says, "met with in fresh water are various entomostraca, rotifera, and the worm-like larvæ of insects;" and he finds "that the number of these per gallon, and per-centage relationship of these, mark in a most clear manner the changed conditions in the water, the discharge of a certain amount of sewage being indicated by an increase on the total number per gallon, &c." In another paragraph, however, a contradiction to this proposition occurs. He says, "a very decided limit to the increase of these forms of animal life takes place when the water of a river is rendered very impure by the discharge of too mnch sewage in it. Thus in the Don below Sheffield, I found the number per gallon of entomostraca only about one-third of what it is in pure waters." This latter statement is, certainly much nearer the truth than the former; it agrees with my own observations and that of others. Most certainly the minute animals enumerated by Mr. Sorby have a decided preference for water uncontaminated by sewage; they are in truth the denizens of lake water, shallow pools, and bogs, in short, of all water abounding in water plants. Moreover, the late Dr. Baird, who wrote an elaborate and valuable "Monograph on the Entomostraca," found most of the species he describes in standing waters of a fairly pure nature. In summer, when the temperature of lake and river waters is much augmented, entomostraca, "minute animals and plants," increase and multiply enormously—I may say alarmingly—since they have often been known to produce serious outbreaks of illness and numerous deaths. For instance at Dorpat, and Boston, America, the lake water supplied to these towns for drinking, became so much infested by entomostraca that whole communities suffered severely from choleraic diarrhœa, and dysentery, and numbers of young children died from these diseases, thus becoming deleterious rather than salutary.

I doubt much whether "the minute animals" enumerated "eat dead animal matter," if they can obtain a sufficient supply of living vegetable matter. I have more frequently found their stomachs filled with the spores of unicellular plants, and their ova sacs glued to the under surface of such weeds as duckweed. Nevertheless, it is quite possible, "to keep them alive for a few weeks or months by feeding on human excrement," as Mr. Sorby did, but we must not lose sight of the fact, that even sewage excremental matter is generally composed of two-thirds of vegetable tissue, while a too concentrated form of sewage as that of Crossness will kill even entomostraca, the water there being found to "contain only six per gallon, and at Erith three or four per gallon." The rotifera are also denizens of water unpolluted by sewage.

Mr. Sorby has omitted to include among his "minute animals," the *gordiaceæ*. The Thames mud—hair-worm, cannot fail to attract considerable notice from its blood red appearance in the mud banks of the River Thames. This genus belongs to the *entozoa*, and although it revels in sewage excrement, is dangerous both to man and animals. As the embryos escape from their eggs, they rise to the surface of the water in millions, to be swallowed by the lower animals when they come to drink, or by insects, in the bodies of which they are developed into parasites of a deleterious nature. Mr. Sorby will, I am sure, admit that investigations which have only "extended over a month" are insufficient to warrant his conclusion, that, "if the minute free swimming animals thus increase when a certain amount of sewage supplies them with ample food, it is quite obvious that they must have a most important influence in removing objectionable impurities."

Obituary.

SIR ERASMUS WILSON.—Sir Erasmus Wilson, late President of the Royal College of Surgeons, died on Friday, the 8th inst., at his residence, The Bungalow, Westgate-on-Sea. He was born in 1809. He studied anatomy and medicine in London and at Aberdeen, and became a member of the Royal College of Surgeons in 1831. He was made a Fellow of the College of Surgeons in 1843, member of the Council in 1870, and President in 1881. In 1869 he founded the chair and museum of Dermatology in the College of Surgeons, and was elected the first professor. He also instituted the chair of Pathology in the University of Aberdeen. Having amassed considerable wealth by his practice and his medical works, he gave his money away for charitable objects with great liberality. He erected a chapel and new wing to the Sea Bathing Infirmary at Margate, he built the master's house at the Epsom Medical College in 1872, and restored the church of Swanscombe, Kent, in 1873. Her Majesty conferred the honour of knighthood on Mr. Wilson in 1881, after he had been the means of bringing "Cleopatra's Needle" to England. Sir Erasmus became a member of the Society in 1861, and served on the Council in 1878 and 1879.

RICHARD GARRETT.—Mr. Richard Garrett, of Saxmundham, who had been a member of the Society of Arts since 1868, died on the 30th ult., at the age of 55. When only 14 he became apprentice assistant to his father at the Leiston Works, Suffolk. On the death of his father, in 1866, he became senior member of the Leiston firm. It is stated in a memoir of Mr. Garrett, in the *Engineer*, that he devoted his life to the construction and development of the thrashing machine. He also devoted much attention to the improvement of the portable steam-engine. He was elected a member of the Institution of Civil Engineers in 1877.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

"*OWEN JONES*" *PRIZES*, 1884.

This competition was instituted in 1878, by the Council of the Society of Arts, as trustees of the sum of £400, presented to them by the Owen Jones Memorial Committee, being the balance of the subscriptions to that fund, upon trust to expend the interest thereon in prizes to "Students of the Schools of Art who, in annual competition, produce the best design for Household Furniture, Carpets, Wall-papers, and Hangings, Damask, Chintzes, &c., regulated by the principles laid down by Owen Jones." The prizes are awarded on the results of the annual competition of the Science and Art Department.

Six prizes were offered for competition in the present year, each prize consisting of a bound copy of Owen Jones's "Principles of Design" and a Bronze Medal.

The following is a list of the successful candidates:—

1. Sidney G. Mawson, School of Art, Cavendish-street, Manchester—Designs for calico printing.
2. Alfred G. Weatherstone, West London School of Art—Design for the side of a dining-room, and decoration of a ceiling.
3. Charles B. Aylward, South Kensington School of Art—Designs for carpets.
4. Mary Lloyd, School of Art, Dublin—Design for wall decoration.
5. Marie H. Burghardt, School of Art, Cavendish-street, Manchester—Design for calico printing.
6. Albert E. Godwin, School of Art, Macclesfield—Design for silk hanging.

Proceedings of the Society.

CONFERENCE ON WATER SUPPLY.

The following papers complete the list of those read at the Conference of the Society of Arts on the Water Supply, held at the International Health Exhibition on Thursday and Friday, July 24th and 25th. The report of the second day's discussion will be printed in the next number of the *Journal*.

WATER DISTRIBUTION AND DUAL SUPPLY.

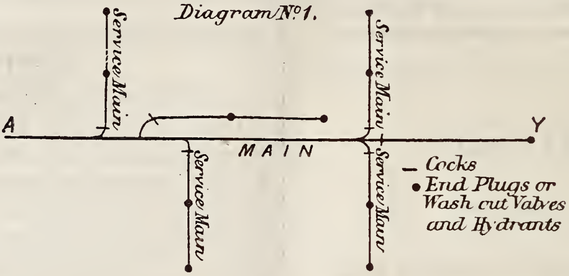
By Col. Sir Francis Bolton.

In former times it was customary to lead water through aqueducts to public fountains, whence it was taken by water carriers to those consumers who could afford to pay for it, while the poorer classes fetched the water from the fountains for themselves; and this system still exists in certain large cities abroad, such as Constantinople and Venice. In some towns, indeed, even in ancient times, this primitive mode of delivering water was found insufficient for the better class of houses. In luxurious Pompeii, for instance, which was destroyed A.D. 79, a very complete system of distribution appears to have existed by means of pipes, which delivered the water direct to the houses. This mode, however, was by no means general, the inhabitants of most cities contenting themselves, as above mentioned, with the services of water carriers.

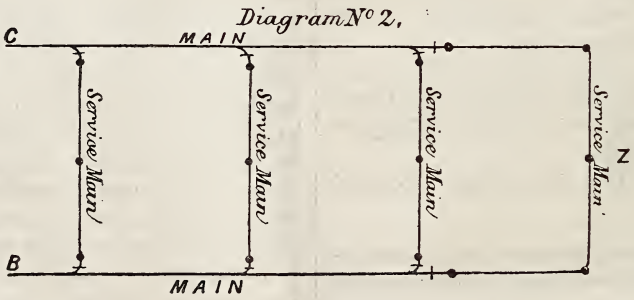
A very noticeable want in connection with those towns which derive their water supply from public fountains is that they are, for the most part, without any sewage system, and the evils arising from this serious drawback may be readily imagined, although it is not the object of this paper to describe them. On the other hand, it should be mentioned that the difficulty of carrying large quantities of water in such towns to the houses separately has, from time immemorial, been remedied to a certain extent by the construction of public baths, and other public conveniences for the general health and benefit of the inhabitants.

The mode of distribution which may now be said to be almost universal is by means of cast-iron pipes, and as far as our knowledge goes, in the present state of hydraulic engineering, this system may be considered perfect. Towns are divided into districts, according to position and level, and in each district mains are laid, usually following the course of the principal streets. From these mains service pipes supply all the streets within the area. Each service pipe is provided with a cock at the junction with the main, and a wash-out valve at the other end, fire-plugs or hydrants being inserted at convenient distances, usually about 100 yards apart. In those districts which are supplied on the intermittent system, the service-pipe cocks are opened and closed at certain ntervals; but where the plan of "constant supply" is adopted, they are always left open, except in case of accident, or during repairs.

On reference to Diagram No. 1, showing part of distributory mains on this system, it will be seen that the water, on entering the service pipes, enters as it were a *cul de sac*, where, unless there is a large draught or consumption, it is apt to remain practically stagnant, thus allowing the impurities held in suspension to be deposited on the sides and bottoms of the pipes. It is for this reason a wash-out valve is placed at the end, which, if opened sufficiently often, allows the impurities to be washed out; but if this precaution is neglected, the impurities accumulate, and when a sudden call is made on the service pipe, find their way to the consumer.



By having no "dead ends," as shown in Diagram No. 2, this difficulty is obviated, as the water is continually circulating in all directions. This arrangement is of great advantage where there is constant supply, as in case of accident at C, the main, B, would supply the service pipes entirely, whereas if an accident occurred at A (Diagram No. 1), the whole district beyond would be without water until the repairs were completed. It has the further advantage that should a fire occur at Z (Diagram No. 2), both mains, B and C, would supply that and the adjoining hydrants, whereas a fire occurring at Y (Diagram 1), would only have the water passing through the one pipe. Equal facilities occur for washing out the service pipes, if found necessary, by closing the cock and opening the adjoining hydrant.



The pipes should be of iron, of good tough quality, as, if the metal is brittle, difficulty is found in cutting the holes to receive the house service pipes; 2 in. pipes are usually cast in 6 ft. lengths, 3 in. to 12 in. 9 ft. lengths, and 12 in. and upwards, in 12 ft. lengths. In order to ensure uniform thickness, the pipes are generally cast upright, and socket downwards; and to prevent oxidation of the interior, they generally either receive a coating of lime inside, or are dipped whilst hot into a mixture of pitch, oil, and tar, which is usually known, from the name of the inventor, as Dr. Angus Smith's composition. The protection of the interior of the pipe is particularly necessary if iron is used in the filtering medium, as otherwise the water becomes distinctly chalybeate if the consumption is slow.

The mode of connecting the pipes together is by slipping the spigot end of one pipe into the socket of the next, and then making the joint. Diagram No. 3 shows the ordinary method of joining pipes. No. 1 is the ordinary "yarn and lead" joint, and No. 2 the "turned and bored" joint. In No. 1 the best white yarn is caulked in to a depth of about 2½ inches, and the rest of the space run in with soft lead, which is afterwards well set up or caulked one-eighth of an inch within the rim of the socket. The chief point to be observed is that no part of the yarn should find its way into the interior of the pipe. In No. 2, the turned spigot is simply brushed with cement or paint, and pushed home into the bored socket. The extra space is sometimes run with lead and sometimes left. The most approved modern system is to run the joint solid with lead without the yarn, a strip of drawn lead being inserted in the bottom of the socket in lieu of yarn.

For connecting the service mains suitable cast-iron branches are introduced. The cocks used for regulating the flow of the water consist of a door, which is raised or lowered by means of a screw worked from the surface, as shown in Diagram No. 4. For the purpose of supplying water in case of fire or other emergency, openings are left in the mains, which are closed in some old waterworks by wooden plugs, but in all recently constructed ones by hydrants, which are undoubtedly to be preferred. The description of these, however, properly belongs to the section treating of the supply of water for extinguishing fires, and a full account of the various forms in use will be found in the special paper on "Water Supply for Fire Extinction," by Mr. J. H. Greathead, C.E.

Diagram No. 3

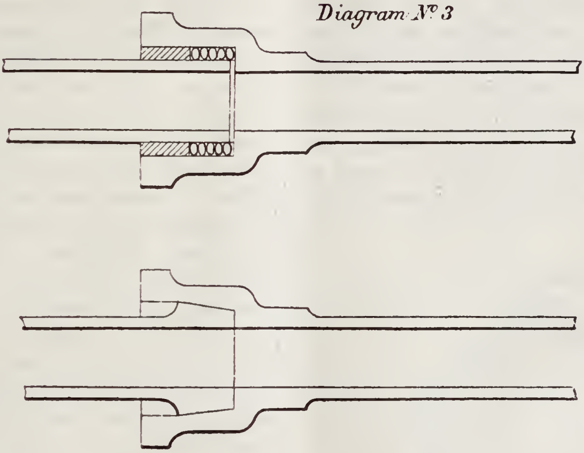


Diagram No. 4.

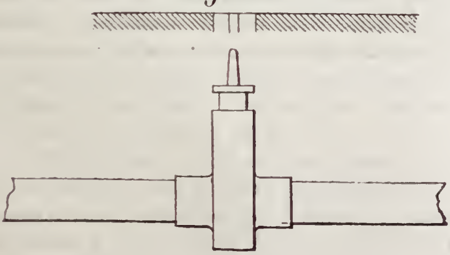
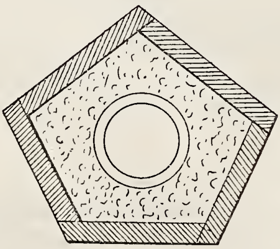


Each house is connected with the service pipe or main, by a pipe called the "house service pipe," the connection being made by means of a ferrule screwed into the main. The house service pipe is generally of lead, but as some waters have a chemical action upon this metal, drawn-iron pipes, either glazed, galvanised, or otherwise protected, are substituted. Where the system of "constant supply" prevails, an apparatus is used in order to avoid inconveniencing the consumer, which enables the ferrules to be inserted while the main is still charged and under pressure.

The depth at which mains should be laid varies according to circumstances, but may be taken in temperate climates to be from two to three feet from the surface of the ground to the top of the pipe. In colder climates the mains should be laid at sufficient depth to escape the action of frost, which, generally speaking, does not extend below four to five feet. When mains are laid at this depth, the cost of laying as well as making house connections and effecting repairs is considerably increased. When the temperature of the water varies considerably at different seasons, the length of main is affected. Where "socket joints" are used, little damage is done, but with "turned and bored joints" it will generally be found in autumn that some tightening up of the joints is necessary, unless special provision is made for the contraction that then takes place.

Where pipes are carried across openings they should be protected from the changes of temperature, which can conveniently be done as shown in Diagram No. 5, in which the pipe is shown enclosed in a wooden casing, the circular space being filled in with felt, sawdust, or other non-conducting material. In laying mains across bridges, great care should be taken for their protection. It will often be found that there is not sufficient depth from the surface to the arch or girder of the bridge to allow of the pipes being laid; when this is the case, it is convenient to carry the mains on cantilevers at the side of the bridge, the pipes being enclosed in a casing of wood or other material, as shown in Diagram No. 5.

Diagram No 5



In new bridges it is generally arranged to leave sufficient space for a subway below the footpaths; this, as a rule, is a very convenient way, as it allows of repairs being effected without interfering with the ordinary traffic.

The system of distribution hereinbefore described refers mostly to the distributing pipes within the town. In some exceptional cases, owing to local circumstances, wooden pipes, similar to those which were used before the introduction of iron pipes, are still used, and in places where freight and carriage are difficult, pipes formed of sheet iron or steel can, owing to their lightness, be more economically used than those of cast iron. Pipes have been made of paper prepared with bitumen and several other substances, but have not been proved able to withstand the severe tests to which water pipes are subject. Where the pressure is very great, as for instance where water is distributed for hydraulic power, the pipes are cast of extra thickness, and a "faced" flange joint with an india-rubber ring inside a recess, into which a projection on the next pipe fits, is sometimes substituted for the socket joint.

The construction of the aqueduct conveying the water from the source to the distributary mains varies with circumstances. If the water is conveyed under pressure, one of iron is necessary, and preferably of cast-iron, which, being laid under the surface of the ground, is better in all respects (apart from cost) than any other. The pipes are so placed as to follow pretty closely the undulations of the ground, an emptying valve being fixed at the bottom of every fall, and an air escape valve at every summit. When large quantities of water, however, have to be conveyed, aqueducts of masonry, brickwork, or concrete have to be adopted. These, unlike pipes which can be made to follow the inequalities of the ground, have to be laid to a regular gradient. Provision is made for draining such aqueducts, and overflows are placed along their length to prevent damage in case of the flow of water being interrupted. All aqueducts of masonry, &c., should be covered, but this is not always possible when they are of large size. Size, indeed, renders the covering less necessary, provided precautions are taken to prevent the infiltration of land drainage, as the large quantity of water flowing down is less liable to be affected the by sun, while the conduit, being uncovered, can be easily and completely cleansed at all times.

The cross section varies with the materials employed; those of brickwork and concrete being generally of an oval or circular form, whilst those of masonry are usually constructed with a rectangular section, and when covered, are sometimes arched over, and sometimes covered with slabs. For the aqueducts, tunnels often have to be made through hills, and conduits over valleys. These latter, when there is sufficient head of water available, are usually crossed by syphons of cast-iron pipes. When, however, the head of water cannot be spared, the aqueduct is carried across the valley at the regular gradient, and supported by piers of masonry, or other suitable material. In this case, the aqueduct is sometimes continued in masonry, brickwork, or concrete, or a trough or tube of wrought iron is substituted. This trough is sometimes made of pipes of sheet iron or steel, riveted together throughout the full length of the crossing, and suspended and braced by wire cables or rods, similarly to a suspension bridge.

One of the most important of modern aqueducts is that bringing the water of the River Vanne to Paris, the length of which is about 90 miles, with 23 syphons of wrought-iron pipes.

The chief points to be observed in the designing of a complete distribution should be—(*a*) that the water, which before entering the mains is in its purest state, should be delivered to the consumer in a similar state, and suffer no contamination on the way; (*b*) that the mains should be of sufficient area to allow an ample quantity of water to pass to meet all contingencies; and (*c*) that a constant circulation should be maintained of about 3 ft. per second, so as to prevent any deposit taking place.

Dual Supply.

In the case of many large towns, an abundant supply of water of inferior quality is found in close proximity, while further off, but still within reasonable distance, a limited supply of better water exists. In considering such cases, it often becomes a question as to the advisability of adopting both sources of supply, the latter for drinking purposes, and the former for domestic and manufacturing uses. In the opinion of the writer, a system of dual supply is not practicable for domestic purposes, but only for municipal or manufacturing requirements. In cases where water is used for power, a dual supply may also be considered indispensable, as the great pressure necessary for its economical use for this purpose is undesirable for a domestic supply. Again, a separate supply for municipal purposes can be used for road watering, sewer flushing, fires, &c., without affecting the domestic supply. In most manufacturing towns the factories are grouped together, and require large quantities of water at a very cheap rate, which, supposing the water is not used in any way for alimentary purposes, can often be supplied from sources sufficiently pure for purposes of manufacture, although the water may be unfitted for household consumption. Such a supply exists at Roubaix, in France, where the cheapness of the water contributes to the prosperity of the town.

Paris also is supplied in the same manner, there being a double set of mains in the streets, one for domestic purposes, and the other for street watering, &c. The supply of potable water, however, is limited, and in time of drought has to be supplemented by water drawn from the Seine.

A dual supply for domestic purposes would entail a considerable extra outlay on the construction of works, as a double line of mains would be necessary in every street, and the cost of most of the house fittings would be doubled, as they would have to be in duplicate. Another objection is the probability that the excellent quality of the water supplied for potable purposes would cause the quality of the other to be little considered, and the latter might deteriorate, or become subject to great contamination. Consumers, bearing this in mind, would probably use the purer water almost entirely. In ordinary times, this might not be of much consequence, but in times of drought it might be serious. This difficulty, it is reported, has just occurred in Paris, which, as just stated, is supplied under this system, and where now, in the heat of summer, with the cholera possibly approaching the town, the drinking water is said to be failing, so that nearly all the supply will have to be taken from the other source, the Seine. Unfortunately, this water is not as carefully filtered and aërated as it would be if it were usually used for domestic purposes, and it may consequently prove a source of danger and disease.

When only one supply exists for domestic purposes, means are generally taken to render it as pure as possible, either by efficient filtration, or by such other means as may be found necessary. Should such water not be considered of a sufficiently high standard of quality, a pure source is selected, and the old one abandoned; when this is impossible, the use of household filters becomes universal.

When the Chelsea Water Company first moved their intake to Ditton, in carrying out the works an extra reservoir was constructed, and extra mains were laid for supplying unfiltered water for road watering and other purposes; but in practice this arrangement was found to be no saving, and to possess no advantage over supplying filtered water for these purposes, so it was discontinued, and now none but filtered water is supplied.

It may be contended that if water were sold by meter, the difficulty of supplying the two kinds of water for domestic purposes would be overcome, inasmuch as the extra cost of the purer water would prevent its excessive use, and so conduce to its conservation and the greater use of the inferior water. This argument, probably, would prove fallacious, as the servants who use the water are unaffected by any such considerations.

It might, further, be urged that the inferior water should only be laid on to the closets, and that the supply to them should be independent of the general domestic supply. This arrangement would leave the remainder of the domestic supply to be furnished by the better water. Baths even would have to be supplied from it, for when it is remembered that they are very frequently supplied with hot water from an apparatus from which water is drawn for other purposes, it will be seen that it would be practically impossible for them to be connected with an inferior supply. Apart from special cases, in which water is distributed under great pressure for power, and under smaller pressure for ordinary consumption, only one plan of dual supply seems feasible, which, however, from the necessity for duplicate mains, &c., must necessarily be costly, though it might prove advantageous in many respects if carefully worked out. The writer would hesitate to advise such a scheme, except under exceptional circumstances. It is that the domestic supply should be entrusted to a company selling water by meter, and the general supply (including supplies to closets) should be in the hands of the municipal authority, and paid for by a general rate levied on all property. In addition, the municipal authorities would receive payment for any water they might dispose of for manufacturing purposes. It will be seen that, under this arrangement, the municipal authority would have under its control waterworks (supplying fairly good water it must always be presumed) for supplying closets, road and public garden watering, sewer flushing, fire extinguishing, and to sell for manufacturing purposes. The company which supplied water by meter for domestic use, and for those manufacturing purposes for which pure water is indispensable, should also be under the supervision of the municipal authorities.

Such a system as the above would probably only be found worthy of consideration in the case of a town which possessed a supply of good water, but of so limited a quantity that the rapid growth of the city rendered an increased supply indispensable, and where there was an inferior supply near, which could be made available at small cost. By these means the consumption of the pure water would probably be reduced to such an extent as to be available for a much larger population, and at the same time, from the fact of the municipal authorities controlling the house drains, closets, and flushing supplies, an improved sanitary condition might result. It is, however, not easy to imagine a town in such a position.

Rain water, as it falls, is in a comparatively pure state, and if proper measures are taken to preserve the surplus falling in wet seasons, and to keep it from contamination, it will generally be found that the rain falling in each watershed is amply sufficient to supply the whole of the inhabitants dwelling in their districts. If any scarcity exists, it is owing, generally speaking, to the want of proper care, or to the fact that the district is so subdivided under different authorities, that joint action for the proper conservation of the rainfall is impossible.

MODE OF DISTRIBUTION, WITH SOME REMARKS ON DUAL SUPPLY.

By Henry J. Marten, M.Inst.C.E.

Until comparatively recent times no attempts were made to afford what we now term "a domestic supply," that is to say, a supply of water distributed to and available within each house for general domestic purposes.

The large supplies of fine water introduced into the principal cities of ancient times, by means of the magnificent aqueducts of which there are many remains to this day, were directed, so far as distribution is concerned, to the supply of public baths and fountains, and possibly here and there to the supply, for similar purposes, of a few of the private residences of the wealthy classes.

A house to house supply, such as we have in modern times, was unknown and undreamt of. The supply for domestic purposes had to be obtained by the occupants of the houses either from the public fountains, or from the streams flowing from them, or was supplied in detail by water carriers, somewhat after the fashion in which milk is now supplied from house to house. Although, according to Pliny, the ancients were aware that water under pressure rises to the height of its source, little practical advantage was taken of the knowledge of this fact. Water under pressure was occasionally conveyed for some distance through stone or earthenware tubes or in leaden pipes. The two former were, however, difficult to be kept tight, and the latter were not only very expensive, but, at an early period of their history, were found to act deleteriously on the water flowing through them. Although, therefore, immense volumes of water were frequently brought into ancient cities, as into Rome, where, according to Strabo, "whole rivers flowed through the streets," and where the total quantity so delivered probably exceeded three hundred gallons per diem to each inhabitant, there was practically no distributed domestic supply.

The inhabitants of modern London, therefore, although only furnished with a supply per head equal to one-tenth of that which used to flow into old Rome, are, nevertheless, infinitely better off than the ancient Roman, because the thirty gallons supplied to the modern Londoner are delivered exactly where he requires it, "upstairs, downstairs, or in my lady's chamber," and the supply is at all times available by the mere turning of a tap. We have here a good illustration showing how various combinations of applied science, united to the practical skill of modern times, have resulted in a tenfold economy, coupled, at a moderate estimate, with a tenfold advantage to the water consumer.

If modern London were supplied in the same wasteful and unscientific manner as ancient Rome, the quantity of water required for the purpose would exceed in volume the average flow of the River Thames at Kingston, and whilst this immense volume of water would be rushing from public fountains, and down open channels made for the purpose in the streets, the inhabitants would be totally without the comfort and advantage which they at present enjoy of a domestic supply delivered under pressure into each of their houses.

Coming to modern times, the distribution of a domestic supply dates back from the time of Peter Morice, who, in 1582, erected waterworks for the supply of the City of London by means of pumps actuated by water-wheels placed in the first two arches of old London-bridge. He appears to have distributed the water under pressure through leaden pipes, but it is probable that a few years later these were replaced by wooden pipes, which, as early as the year 1628, were being laid down by the New River Water Company. These wooden pipes consisted of the trunks of elm trees, cut into lengths and bored longitudinally to an internal diameter of from 6 to 12 inches, in accordance with the internal pressure they were required to withstand. In the parts of the town lying at the lower level (where the pressure would be greatest), the diameter of the bore would be 6 inches, so as to leave a considerable thickness of wood between the inside of the bore and the outside of the tree. In the higher parts of the town, and near the reservoirs, where the pressure would be less, the bore would be gradually increased to 12 inches in diameter, a less thickness of timber being required in those parts. The joints of these wooden pipes were made by forming one end of the tree into a conical shape, and hollowing out the other to correspond; the several lengths, when laid, being then driven one into the other.

These wooden pipes, however, proved very defective, as the loss by leakage was estimated at not less than one-fourth of the whole quantity flowing through them. From decay and other causes they required also to be renewed on the average about once in every twenty years; and consequently, as at one time the New River Company had 400 miles of these pipes laid down, they had to take up and renew upwards of twenty miles in length each year.

Owing also to the small diameter of these wooden pipes, where they had to bear any amount of pressure, more than one line—and in one case no less than nine lines—of pipes had to be laid side by side in the same street, in order to furnish the requisite supply.

When we reflect on the fact that at this period London was almost entirely without under drains, we may be able to form some slight idea of the terrible amount of moisture with which the foundations and basements of the houses adjoining these lines of leaky pipes must at all times have been saturated, and the disturbance which the constant repair and renewal of these pipes must have occasioned to the roads.

Bad, therefore, as matters are at the present time in London and other large towns, from the disturbance of the streets for such repairs, we of the present generation may congratulate ourselves upon the fact that, notwithstanding we now have gas-pipes, sewers, and underground electric wires in addition to water-pipes laid under the streets, the annoyance which we suffer from street disturbance is as nothing compared with that which our ancestors must have had to put up with in this respect.

There are no records to which the writer has access showing whether, in these early times, the supply for domestic purposes was on the constant or the intermittent system, nor whether the water was delivered at the ground floor of each house only or at a higher elevation. With wooden distribution pipes, such as these described, it would be very difficult to have a proper service of stop or shut-off valves, even if an efficient stop-valve for working under pressure were then invented. The frequent stoppages for repairs would necessarily assimilate the arrangements for supply to those of the intermittent system, which involves the necessity of having tanks, butts, or other capacious receptacles for the storage of water in each house.

In the early part of the present century, cast-iron mains began to be substituted for wooden water-pipes, and by the year 1820 the whole of the wooden pipes belonging to the New River Company had been removed and replaced by cast-iron ones. The substitution of cast iron for wood introduced a new era into the art of water distribution, as much higher pressures were rendered available, and leakage was materially reduced. The early cast-iron pipes, although made of the finest cold blast metal, were very rough productions. They were all cast horizontally, and in numerous cases, owing to the imperfection of the machinery, they were far from being either cylindrical or concentric, and thus were frequently thicker on one side than the other. They often, therefore, gave way when exposed to the working pressures they were called upon to sustain, the methods of testing them, previous to their being laid, being primitive and inefficient.

The first cast-iron distribution pipes were made with flanges, on the same principle as the ordinary cast-iron pump trees. These flanges were fastened together with bolts and nuts, the joint being made between the flanges, with an iron ring covered with tarred yarn or flannel. This method, however, soon had to be abandoned, as, owing to the expansion and contraction of the pipes consequent on the changes of temperature in the water passing through them, the flanges were frequently torn off, and hence stoppages for repairs were numerous.

This defect was overcome by the introduction of the spigot and socket pipe. The early joints of these pipes were made by driving soft wood wedges into the sockets, which were made wide for the purpose. When the wedges had been driven into the sockets as far as was considered prudent, the ends projecting beyond the sockets were cut off, and a few small iron wedges were then driven into the wood for the purpose of giving a final tightening. These joints were found to be a great improvement on the previous system of flanges; but as the wooden wedges became saturated with water, they expanded, and frequently burst the sockets. This led to the abandonment of the system of jointing pipes with wooden wedges, and to the adoption of the plan of filling the back part of the socket with yarn tightly rammed in, and then running the remainder of the socket full of molten lead, which on cooling was caulked up, and so made a tight and permanent joint, capable of withstanding the full pressure to which the pipe might be subject, and, at the same time, of allowing for expansion and contraction without leakage.

This method, for the first time, gave those reponsible for the distribution of water under pressure the advantage of having at command continuous distributing tubes of any length, and practically water-tight under any ordinary pressures.

The lead joint, as above described, with variations only for reducing the weight of lead used, or for adding to its security against being blown out by back pressure, has remained a permanent institution, a bar of lead being occasionally substituted for the molten metal.

In some cases, the old-fashioned method of jointing the wooden pipes has been imitated in their cast-iron successors, by turning a conical end to the spigot, and boring the socket, so that, when fitted together, the pipes practically joint themselves without any other stopping.

With the introduction of cast-iron pipes, and greater pressure, the system of intermittent supply became more completely developed and established.

Under the intermittent system, the supply of water was not constantly laid on, as is now almost universally the case. The arrangement was to turn on the water from the principal main into the subsidiary distribution pipe, in any particular street, for an hour or an hour and a-half a day; during which time all the people in that street had to draw and store a sufficient supply for the remainder of the twenty-four hours.

This system, with which the public were long content, ultimately fell into disfavour. Its inconveniences were great; the water was, as stated, only turned on for a very short time; the system necessitated the employment of a large number of turncocks, whose sole business it was to go round the districts to turn the water on and off. The intermittent system was also injurious on sanitary grounds, as it freqnently happened that the vessels in which the water was stored were exceedingly foul, in consequence of putrifying sediment left in them from previous supplies, and the stored water itself was apt to become impregnated with poisonous gases rising through the waste or overflow pipes of the cisterns which were connected with the sewers.

The sanitary defects thus inherent in the intermittent system were the fruitful source of disease and death, and early engaged the attention of the Board of Health presided over by the late Earl of Carlisle, and of which Mr. Edwin Chadwick, C.B., was the earnest and indefatigable secretary. After much inquiry the Board came to the conclusion that these evils could be remedied by the adoption of the constant supply system, which had been introduced at Nottingham by Mr. Thomas Hawksley, past president of the Institution of Civil Engineers, and was in successful operation there on a large scale.

Under the "constant" system, the supply is kept on the whole 24 hours, so that anyone, at any time of the day or night, by simply turning a tap in the house, can obtain a supply direct from the main without the intervention of any intermediate storage vessel.

When the proposition for affording a supply on the constant system was first broached by the Board of Health, it was met by a storm of opposition, some engineering advocates of the old system going so far as to allege that it would be a sheer impossibility to carry out the constant system, on account of the uncontrollable waste that would result from having the water always "on," and because, as there was no guarantee that everybody would not be drawing water at the same time, the main pipes would in consequence have to be of enormous magnitude compared with those necessary under the intermittent system, under which system it was alleged the supply could be more judiciously and economically manipulated.

The controversy on this question raged with great vigour from 1845 to 1850. About that time Sir Robert Rawlinson, C.B., having occasion to visit Wolverhampton in connection with a local inquiry under the Board of Health, asked the writer, who had then recently converted the supply of that town from the intermittent to the constant system, and who at the moment had the means of doing so with great accuracy, to institute some experiments with a view to ascertain what, under the constant system, was the actual rate of consumption at each hour of the day. As the result of these experiments, the writer found that, so far from all the people drawing from the mains at the same time, the highest rate of consumption was only about two and a-half times the total daily supply; that is to say, that the main and distribution pipes under the constant system should be of a capacity sufficient to supply two and a-half times the ordinary daily consumption. Now, as under the intermittent system it was the practice to make the mains and distribution pipes of sufficient capacity to supply four times the ordinary daily consumption, these experiments proved that, so far from larger mains being required under the constant system, they might actually be made of smaller capacity than those required for the intermittent system. It was also shown that, with proper fittings in the houses, the consumption of water under the constant supply system was actually less than that under the intermittent system.

These facts being reported by the Board of Health, and afterwards given in evidence by the writer before a committee presided over by the late Sir James Graham, and confirmed also by similar results in other cases, brought the controversy to a close in favour of the constant supply system, which is now almost universally adopted, and under which 263,904 out of the 671,888 houses in the London district are now supplied, as stated in the able and interesting report for May, 1884, of Colonel Sir Francis Bolton, C.E., Official Water Examiner under the Metropolis Water Act, 1871.

The introduction of the system of constant supply brought about other advantageous changes in the method of distribution. Under the intermittent system the water lay stagnaut in the distribution pipes for at least twenty-two out of the twenty-four hours each day, and before the introduction of filter beds these pipes were practically small settling reservoirs in which the sediment accumulated, and which sediment, when the water was turned on, was driven with the first rush, in a semi-putrescent state, into the household storage receptacles.

Under the intermittent system, but little attention was paid to fittings in the houses, as neither those supplying the water nor those receiving it troubled themselves much about waste, which in each case did not last more than an hour or an hour and a-half each day.

Hence taps, ball-cocks, house supply pipes, and other internal fittings were old-fashioned and defective almost beyond description.

With the advent of the constant system, new descriptions of fittings were introduced to prevent waste, and to meet the requirements of the greater pressures at which the water then began to be delivered.

It may be safely affirmed that the constant system has brought about an extraordinary change for the better in all domestic water fittings; those now in general use displaying an amount of skill, ingenuity, and good workmanship far superior to anything ever before known.

Under the intermittent system the distribution pipe necessarily had a "dead end" in each street, because the water requiring to be daily turned on or shut off, the pipe could only be connected at *one* end with the feeding main, leaving the other end isolated or "dead." The water near these dead ends became very foul from stagnation, and consequently the dead end required to be frequently washed out. This was effected by drawing a wooden plug fixed in a branch at the end of the distributing main. When this plug was drawn, it was not at all uncommon to see the water spouting out from it tinted with all the colours of the rainbow, from dark purple to the lighter tints, and emitting a most offensive odour, for when the water was shut off, it frequently happened that the distributing pipe was drained by a discharge at some low lying part of it, and it then became filled with an atmosphere drawn through ground full of gas reek.

Under the constant system these evils, including those resulting from dead ends, are done away with; the distributing pipes being now constantly under pressure, no gas reek or other impurities can enter them, and being connected at each end of the street with the adjoining mains, there is a constant circulation throughout the whole system, whereby stagnation is prevented, as the water is always on the move towards the point of greatest consumption.

Very great improvements have also been made under the constant system, in the construction of the sluice valves for shutting off the water for repairs at any particular point. Under the intermittent system, the sluice valves were only made to shut against the pressure from *one* side, whilst they are now universally made to shut against the pressure coming from either side or in any direction. These valves, which are called "double faced," are the invention of Mr. James Nasmyth, so well known in connection with the steam hammer. The writer, then an articled pupil to the late Mr. Wicksteed, Engineer to the East London Water Works, had the privilege of assisting Mr. Nasmyth in preparing the first rough drawing of these "double faced" sluice valves; and he well remembers the instantaneous rapidity with which that great mechanician not only grasped the point to be attained, but within an hour had so completely solved the difficulty to be overcome, that whilst alterations have been made in minor details, no practical improvement has been effected in that first design of his.

The method of connecting the house services with the main pipes has also undergone a great improvement. In early times the connection was made by driving a brass ferrule into a hole chipped or drilled through the main pipe. These ferrules were apt to be dislodged, and frequently blew out, and the fixing of them obliged the water to be shut off from the whole street during this occasionally tedious operation. These connections are now made by screw threaded ferrules, tapped securely into the pipe by an instrument which obviates the necessity for any stoppage of the supply to other houses whilst the operation is being performed.

The arrangements also for the supply of water for fire extinction, have been very greatly improved since the introduction of the constant supply system. In former times, in the event of a fire, the first thing was to find the turncock to turn the water into the main. This done, the old wooden plug had to be knocked out, often a work of time and difficulty; and then until all the empty tubs and tanks were filled up in the street there was practically very little pressure at the plug, and the supply was consequently scanty for some time. Thus most precious moments were lost. Now, on the contrary, the fireman goes to the nearest hydrant, inserts his standpipe, turns on the water from the constantly charged main pipe, and in a much less time than it previously took to call the turncock, he has a stream of water pouring into or over the burning building at the rate of 200 or 300 gallons a minute, and under a pressure sufficient to knock a strong man down at a distance of fifty yards from the nozzle of the fire-hose, and that without the intervention of any fire-engine.

Another little machine which has proved itself to be of great value in connection with constant supply, is the "Waste Water Detector," invented by Mr. Deacon, the engineer to the Liverpool Corporation Waterworks. This machine indicates and registers the flow of water passing through any particular pipe at any moment of time, and by its agency all undue waste and leakage are easily detected and traced. Thus the modern appliances in connection with distribution, if properly used and directed, are now nearly all that can be desired.

Except in very special cases, the writer is not an advocate for the "Dual System," that is a system under which two classes of water are introduced, into a town; the one for dietetic purposes, and the other for washing, street watering, sewer flushing, fire extinguishing purposes, &c. The dual system necessarily involves the laying of a duplicate set of mains, and the fixing of a duplicate set of house fittings, with all the attendant annoyance and expense.

There may be cases where the circumstances are so peculiar as to make the dual system a necessity, and then the difficulty must be faced; but generally it will be found cheaper and better to manipulate the supply so as to make sure that none but water of a high class shall ever enter the mains, and so as to effect the whole work of distribution by one set of pipes and fittings.

WATER SUPPLY FOR FIRE EXTINCTION.

By J. H. Greathead, M. Inst. C.E.

When it is considered how vast is the havoc wrought by fire every year, and that we depend upon a supply of water, in all cases, to prevent much greater ravages, the importance of this subject will be at once recognised.

In London alone, it has been calculated on reliable data that the destruction of property in 1882 amounted to at least 2¼ millions sterling, and last year it was probably more; and it has been stated by a very good authority, Mr. Edward Atkinson, of the Boston Manufacturers' Mutual Insurance Company, that the losses by fire in the United States and Canada, in the five years ending January 1st, 1879, amounted to 82½ millions sterling, while the cost of insurance companies and fire departments in the same period, amounted to 55,000,000 more, or together to an average of 27,000,000 sterling per annum.

It is difficult for the mind to grasp such figures; the last, however, is about equal to the whole rateable annual value of the metropolis.

If such losses as these were inevitable, it would be of little profit to refer to them, but it is because I believe them to be to a large extent preventable, that I have ventured to bring the subject of water supply for fire extinction before you.

In the remarks which I am about to make, I purpose to refer largely to the case of this metropolis as being likely to add additional interest to the general subject, and because the reasoning which applies to this will apply in a greater or less degree to all other similar cases.

It may be useful at once to define what are the requirements necessary to be fulfilled in a water supply for fire extinction purposes.

In order to reduce, as far as possible, the destruction of life and property by fire, the fire extinguishing service should have at hand—

(1) A copious supply of water.
(2) In close proximity to the property.
(3) Easily accessible.
(4) Having sufficient and reliable pressure.

In nearly all cities the water supply has been introduced and distributed without reference to the fulfilment of these conditions. The quantity of water required for the extinction of fires is so infinitesimal as compared with the quantity required for all other purposes, that, except where the conditions have been naturally favourable, the water service has been introduced devoid of some at least of the qualities necessary to fit it for fire purposes. The result, in such cases, has been that mechanical contrivances have had to be provided in order to make good whatever deficiencies existed in the supplies, and dwellers in cities have become familiar with fire-plugs and fire-engines.

There are, however, some cities in this country where, the conditions having been favourable, the authorities having control of the water supplies have wisely availed themselves of Nature's gifts.

The most notable instances are those of Glasgow, Dublin, Liverpool, and Manchester. In all these cases the water supply is almost entirely by gravitation, and the result is that over the greater and most important parts of the cities there is a good pressure, and a copious supply of water which has been made easily accessible by the introduction of numerous hydrants in close proximity to the property in each place. Here, then, we have, as nearly as may be, in four of the most important cities of the United Kingdom, a fulfilment of the necessary conditions (as to water supply) for fire extinction.

An ordinary hydrant may be shortly described as a stop-cock on a water-pipe or main, to which hose may be attached for fire extinction, or other purposes. If for fire extinction, without the intervention of a fire-engine, the hose will, at its other end, be provided with a branch and nozzle. Upon opening the stop-cock, the water from the main, or pipe, will issue from the nozzle as a jet. The height of the jet will depend upon the pressure in the main, the quantity of water available, the length of hose employed, and the size and shape of the nozzle.

A fire-plug is a wooden plug driven tightly into a socket or opening in a water pipe under the road. When water is required for fire extinction the plug is withdrawn, and the water issues from the opening, either into the street, where it is usually received by a portable tank, or into a stand pipe inserted in place of a plug. It is obvious that plugs cannot be used where the supply is constant with a good pressure, and they have not been placed upon the constantly charged mains (the best existing supply for fire extinction) in the metropolis. Several forms of hydrants, and a fire plug and stand pipe, may be seen in the Water Companies' Pavilion in the Exhibition.

In order to obtain a good jet from a hydrant, it is necessary that the pressure of water at the hydrant, while flowing, should be about 65 lbs. per square inch. This will provide for overcoming the friction of the water in passing through an average length of hose, and will give a jet about 80 feet high from an inch nozzle. From the elaborate reports of the chief officer of the Dublin Fire Brigade, which he has kindly furnished to me, it appears that all the fires in Dublin, except those extinguished by small hand pumps, are put out by jets direct from the hydrants, and that the prevailing pressure is about 60 lbs. per square inch.

So much has been written and said about hydrants, and the advantages to be derived from their use, during the last twenty years, that it is hardly necessary for me to discuss their merits as compared with fire-plugs. It is generally conceded that in all cases, whatever the water supply may be, whether constant or intermittent, high pressure or low, hydrants are superior to plugs as a means of letting the water out of the pipes. But it has been contended that so long as it is merely a question as between hydrants and plugs, the advantages of the former over the latter are not sufficiently great to justify any large expenditure upon them. When, however, the question becomes one as between hydrants and fire-engines, a wider view becomes necessary. Hydrants with a constant and copious supply, and good pressure of water, are recognised as being incomparably better agents for extinguishing fires than fire-engines, and the result of the introduction of hydrants into Manchester may be given in illustration. Mr. Bateman, the eminent engineer of the Manchester Waterworks, has stated publicly on more than one occasion, that the introduction of hydrants with a good pressure of water has resulted in a reduction of the losses from fire in Manchester to a small fraction (viz., one-seventh) of what they were before the introduction of the hydrants. And according to the report of Captain Tozer, the superintendent of the Manchester Fire Brigade, the amount of property destroyed has only averaged 4·3 per cent. of that at risk during the last ten years, while it will be seen presently that in places having no efficient hydrant services the losses are many times greater.

In Liverpool, the fire brigade is a branch of the police. The water supply is mainly by gravitation from reservoirs (from 400 to 600 feet above the low parts of the town), and there are numerous hydrants. There are 3 steam and 14 manual fire-engines. The population in 1881 was 548,650, and the area is 8¼ square miles. Of the 180 firemen, 170 do regular police duty. The annual cost of the brigade (average of three years, 1880-1-2) was £5,325, or £9 14s. per 1,000 of the population. The average annual number of fires in the same period was 219, but the loss by fire was not ascertained.

In Glasgow, there is a good supply of water by gravitation; there are about 5,000 hydrants, and the majority of the fires are extinguished direct from the mains. There are 3 steam and 17 manual fire-engines. The 66 officers and firemen are supplemented by an auxiliary force of 52 policemen. The area of the city is 9½ square miles, and the population in 1881 was 510,816. The cost of the brigade to the ratepayers in 1882 was £5,266, or £10 6s. per 1,000 inhabitants; while the annual average loss from fire in the same period was £110,000, or about £215 per 1,000 of the population.

In Manchester, the supply is also by gravitation from reservoirs at a considerable elevation

(200 feet to 600 feet above the Exchange), and there is a constant high pressure supply. There are about 17,000 hydrants in the city and suburbs. Two steam and five manual fire-engines are retained, but are seldom used. The population in 1881 was 341,500. The area of the city is 6¾ square miles, but the fire brigade extend their operations beyond the city. There are sixteen stations, and the annual cost to the ratepayers for the fire brigade is £3,547 (on an average of the three years, 1880-1-2), or equal to £10 8s. per 1,000 of the population. The average estimated annual value of property destroyed in those three years was about £80,000, or about £235 per 1,000 of the population.

In Dublin, the supply of water is again by gravitation, and the pressure varies from about 40 lbs. to 80 lbs., being generally 60 lbs. when the water is flowing through the hydrants. There are numerous hydrants, and though there are 2 steam and 3 manual engines they do not appear to have been used in the three years (1880-1-2), within the city. The brigade consists of 32 officers and men. The population in 1881 was 249,602, and the area of the city is 6 square miles, but the operations of the brigade are not confined to that area. The average annual cost of the brigade for expenses and wages (for the three years 1880-1-2) was £3,286, or about £13 3s. per 1,000 of the population. The estimated value of property destroyed averaged £31,144 per annum, or about £125 per 1,000 of the population.

In Birmingham, the whole of the water supply is pumped, therein differing from the cases already referred to; but a system of fire hydrants has been recently introduced. The population (average of 1882 and 1883) is 411,690, and the area 13 square miles. The fire brigade consists of twenty-seven officers and men, and there are two stations and eight police stations, with apparatus. One steam and five manual fire engines are retained, none of which were used for fire extinction in 1882, and engines were used twice only in 1883. The total water supply is 11½ million gallons daily, with a pressure of 40 lbs. to 60 lbs. per square inch. The annual cost of the fire brigade to the ratepayers (average of 1882 and 1883) is £3,250, or £7 18s. per 1,000 of the population while the average annual loss in the two years was £10,931, or £26 11s. 8d. per 1,000 of the population, and this loss was equivalent to 3 per cent. only of the value of the property "at risk."

In Paris, the water supply is partly pumped, and partly by gravitation. Street hydrants have, to some extent, been introduced. In certain cases, where the pressure is sufficient, they are used without the intervention of fire-engines, but the water supply is not such as to admit of this being done generally. It is intended, however, to increase the number of hydrants to 8,000, and ultimately to make them universal, and to dispense with fire-engines. The total daily supply of water is about 82 million gallons. The population is 2,269,000, and the area 29 square miles. The fire-brigade, numbering 1,743 officers and men, is an armed force lent by the Minister of War for the special service, and it is not called out for purposes of war. There are 11 barracks, 10 steam fire, and 80 small stations in addition to 40 look-outs, and there are 12 steam and 80 manual fire-engines. The annual cost of the fire extinguishing service is £86,600 (average of two years, 1883 and 1884), or about £38 3s. per 1,000 of the population, but this cost does not include the rent and repairs of the barracks, quarters, &c., which belong to the Prefecture of the Seine. The estimated annual average losses for the three years, 1880, 1881, and 1882, were £431,300, or about £122 10s. per 1,000 of the population.

Having now described the operations, and their results in cities having efficient hydrant services, I propose to direct attention to some of the more important of the cities having no such services, and more particularly to New York and London.

In New York, the water supply is very copious, but it has not sufficient pressure for fire purposes without the intervention of fire-engines. Hydrants have, to some extent, been introduced, and it is stated with benefit, as permitting more speedy access to, and preventing waste of, the water. The total supply is, according to the report of the fire department, about 100 million gallons daily; the population in 1880 was 1,206,300, and in 1881 probably 1,240,000. The area served by the fire brigade in about 39 square miles. In 1882, there were 50 engine company and 19 hook and ladder company stations, besides lookouts, fuel depôts, and store houses. There were 57 steam fire, but no manual engines. In the period 1880-82 the average force was 939 officers and men, and the average annual expenditure was £288,190, or £230 8s. per 1,000 of the population. In the same period the average annual fire losses were £880,000, or about £710 per

1,000 of the population. The quantity of water used by the fire-engines was about 40,000,000 gallons annually in the period 1880-2, or about 1-900th part of the total supply.

In London, the whole of the water supply is pumped, and the average pressure is quite inadequate for fire extinction without the intervention of fire-engines. A large number of observations were made all over the metropolitan area by the Board of Works, in 1876, and it was found that the average pressure was only about 30 lbs. per square inch, when there was no extraordinary draught on the pipes, such as that required for fire extinction. And it is not surprising that this should be so. The pressure given by the water companies is that required by statute, or, otherwise, by the customers of the companies, and even if they desired to do so it might be doubted whether, in the words of the Select Committee of 1876-7, the companies would be "justified by their constitution in incurring expenditure for fire purposes," for which purposes alone would it be necessary for them to increase their pressure.

The quantity of water delivered for all purposes is sufficient to meet the demands for fire extinction. There are, according to Captain Shaw's reports, very few cases of short supply, and constant supply is being gradually extended voluntarily by the water companies. Hydrants have been put down by the Corporation throughout the City, and connected directly by branches with the constantly charged mains of the New River Company, and they have on several occasions been found useful, though the pressure is not such as to admit of fire-engines being dispensed with in all cases. A few hydrants have also been recently introduced by the Metropolitan Board of Works in other parts of the metropolis.

In the matter of pressure, however, as already stated, the general metropolitan water supply is undeniably deficient. There is a copious supply of water, in close proximity to the property to be protected, but it cannot be brought to bear upon a fire without the intervention of fire-engines.

The population of the metropolis, in 1881, was 3,814,571, and the Metropolitan Board of Works area is about 121 square miles, including the City's one square mile. There are 55 land fire stations, 12 street, 127 fire-escape, and 4 floating stations; and the brigade consists of 588 officers and men. The annual average cost of the fire brigade for the three years 1880-2, was £99,880, or £26 4s. per 1,000 of the population. It is somewhat difficult to arrive at the value of the property destroyed by fire in the metropolis, but a calculation based upon the contributions of the insurance companies to the support of the fire brigade, and upon evidence given by Captain Shaw and others before the Select Committee on the Fire Brigade, in 1877, would make it appear that in 1882 the value of insured and uninsured property destroyed by fire was probably considerably in excess of 2¼ millions sterling, or about £588 per 1,000 of the population. As compared with the efficiently hydranted places already referred to, it will be seen that the cost of the fire-extinguishing service, and the fire losses, are very high in London. This will be made very apparent upon an inspection of the appended Table A, which gives, in addition to the cost of the fire services and fire losses in the several places referred to, a statement of what the cost and losses would be in the metropolis, were the rates of cost and loss the same as in the other places.

It will be asked why the metropolis should have been allowed to remain year after year subject to the preventible drain of wealth indicated by these figures. The reply is that, the past and existing state of things have not been submitted to in ignorance or willlingly, but the difficulties surrounding the subject in the metropolis have been practically insurmountable.

More than twenty years ago, the Select Committee on Fires in the Metropolis directed attention to the extraordinary facilities for extinguishing fires then existing in Liverpool, Manchester, and Glasgow, and to the efficiency and small cost of the fire services in those places; and more recently, in 1876-7, the Select Committee on the Metropolitan Fire Brigade, having heard evidence as to the advantages of the hydrant systems referred to, recommended that hydrants should be put down in the metropolis at once wherever a constant supply was given, and that the water supply should be improved so as to give constant service everywhere, and increased pressure. But it was found that to comply with these recommendations a permanent expenditure of £337,000 per annum beyond the cost of the fire brigade would be involved. Of this annual sum about £150,000 represented the increased cost of pumping alone; and since the quantity of water required for fire purposes is infinitesimal as compared with the quantity supplied for all other purposes, it is obvious that this expenditure of power, if the whole had to be pumped to the requisite height, would be out of proportion to the result obtained. I have made a calculation, based upon the relative quantities, and upon the evidence given before the Committee, from which it appears that for the purpose of discharging water through a hydrant upon a fire in this way, about 170 horse-power would be required for every gallon of water thrown. And there would be the attendant disadvantages that all the house fittings would have to be altered and strengthened, and the mains and pipes would have to be taken up, and relaid of greater size and strength, and at enormous inconvenience to the householders and the traffic in the streets; and the pressure would, in the greater part of the metropolitan area, be inconveniently great. This proposal also involved the great disadvantage that it could not be carried out until the water companies should have been ranged under one control.

As long ago as 1862, the late Mr. James Easton, who held the view that no satisfactory supply of water for fire extinction with constant high pressure could be secured in connection with the ordinary domestic supply, proposed to lay down a completely new set of mains to be used exclusively for fire purposes, but the cost would have been enormous. His estimate was £72,000 per square mile, and his proposal only extended to forty square miles of the metropolis. This area alone would have involved an annual cost for interest and working expenses of £150,000. A somewhat similar proposal, but with the addition that the water was to be taken from the chalk formation at about 15 or 20 miles from the centre of London, instead of from the water companies' mains, as was proposed by Mr. Easton, and that the supply was to be used for potable and culinary purposes after being pumped to the greatest attainable elevation in order that it might have sufficient pressure for fire extinction purposes, was put forward by the Metropolitan Board of Works, on the advice of Sir J. Bazalgette, Sir F. Bramwell, and Mr. Edward Easton, in 1877. It was estimated that the introduction of this system of hydrants would have resulted in an annual saving of £60,000 in the existing expenses of the fire brigade. This scheme, involving a dual supply to every house, was taken to Parliament, but was withdrawn; and in their annual report of 1878, the Board said that they "came to the conclusion, in view of the disfavour with which the scheme appeared to be regarded by most of the local authorities of the metropolis and others, not to bring it before Parliament again in the following session." Looked at purely from a fire extinction point of view there is one great objection to all the proposals that have been hitherto made, viz., that owing to the great variations of level in the metropolis, there would, in many localities, be insufficient pressure, while in others the pressure would be excessive.

In any water supply for fire purposes, it is certainly desirable that the pressure, in addition to being sufficient, should also be moderately uniform in the hose, whatever may be the elevation of the locality. This uniformity is practically obtained at present by the use of fire-engines, but with the great drawback that the power requisite for giving the pressure is not available on the instant that the occasion for its use is discovered. The diagram B on the wall illustrates among other things the result of the vigorous efforts made by the fire brigade to reduce this evil to a minimum. It shows that since the year 1870, when Captain Shaw first began to publish the distances travelled by his engines—the distances run have increased from 11 miles to 34¼ miles (in 1882) per fire. The number of journies made has increased from 8,000 to 29,000, and the total distances run from 22,000 miles to 66,000 miles in the year.

According to the evidence given before Sir H. Selwyn Ibbetson's Committee in 1877, the fire-engines were then only used for pumping at about one-fifth of the fires. If that was still the case in 1882, then it follows that for each time the engines were used for pumping upon a fire they must have run on an average 172 miles.

When it is considered under what unfavourable conditions, and how uselessly the journeys are often made, some idea may be formed of the superiority of a system of hydrants where the power as well as the water is always on the spot ready for instant application. The same diagram illustrates also another feature of the fire brigade service, viz., the growth of its cost from the commencement of the old fire-engine establishment in 1833. It will be seen that the growth has been, and is very rapid as compared with the growth of the population. In the first year of the Metropolitan Board of Works' administration of it, the cost of the brigade was under £41,00; in 1882 it was £106,552, or an increase in the period of sixteen years of 160 per cent., while the population increased only 28 per cent., and the number of fires 44 per cent. And in the year 1883, the cost had further increased to over £115,000. It must not be supposed for a moment that this increase is to be regarded as unnecessary under existing conditions. The cost of the London Fire Brigade is, thanks to Captain Shaw's admirable organisation, still small as compared with some other unhydranted cities. In New York, as already stated, the cost is very much greater for less than a third the population and area. There the average annual cost for the three years, 1880-3, was over £288,000, and it appears to be growing almost as rapidly as that of London, though on the other hand the population there is growing more rapidly. Paris, also another practically unhydranted city with half the population, spends proportionately more than London for fire extinction.

The question of the cost of fire extinction, again, is not the sole consideration; behind that there is the question of fire loss, or the destruction of property by fire, and the loss of life. Putting aside the last and highest question as being one not altogether dependent upon the extinguishing service, I propose now to direct attention to the question of fire losses as affected by the absence or presence of efficient hydrant services.

In describing the hydranted cities, I have already given the fire losses in four of them, viz., Glasgow, Manchester, Dublin and Birmingham, in accordance with the published estimates, and I have shown that the losses are—in Glasgow £215, in Manchester £234, in Dublin £125, and in Birmingham £26 11s. per 1,000 of the population. In the case of New York, the losses are published in detail, and amount to about £710 per 1,000 of the population, as compared with £588, the loss in the metropolis, as estimated by myself.

The Table A has been prepared in accordance with the facts I have stated; but in order to give the figures a practical bearing in the case of the metropolis, I have added two columns which give the costs and losses of a place having the population of London, at the same rates as each of the places considered. It will be seen that the annual cost of extinction by hydrants, if it were at the same rate as Liverpool, Glasgow, Manchester, and Birmingham, would be from £30,000 to £40,000; and at the same rate as Dublin, £50,000; while if it were at the same rate as New York, the cost would be £886,000, instead of £99,880, the average annual cost in London in the years 1880-2.

The diagram H (shown on the wall) has been prepared from Captain Shaw's table, already referred to, and it seems to place the value of efficient hydranting in a very striking light. From the table referred to have been plotted the figures, giving the cost of the fire brigades in a number of important towns at the date of the compilation of the table (in 1877). The cost in the hydranted cities, viz., Glasgow, Liverpool, Manchester, and Dublin, has been shown in red. The blue line shows the cost in a number of American cities. Paris and London, having populations respectively twice and over threefold as great as New York, are not shown, but from the table and the remarks upon it, it will be gathered that in both those cases the cost would be far above the rates shown by the red colour, which has been extended to embrace a place of the size of New York.

In the foregoing remarks, I have simply taken population as the basis of comparison between the several places. And I do not pretend to say that there are not exceptional considerations apart from the question of water supply, such as areas, character and proximity of buildings, habits of people, and so on, which would, and no doubt do, materially influence results, but the distinction between the hydranted and unhydranted places is so broad and marked where the places are of such different characters on the one hand as Glasgow, Liverpool, Manchester, and Dublin, and on the other hand as London, New York, Paris, and Birmingham, that it must appear to all that the absence or presence of efficient hydranting far outweighs any other consideration.

It now remains for me simply to add that, having for some years devoted much study to the subject, I believe that, notwithstanding all the difficulties, only the chief of which have been adverted to here, there are methods—or perhaps I ought rather to say there is a method—by which such cities as London, New York, and Paris may be efficiently hydranted at a comparatively small cost, and practically with very trifling inconvenience, which method I have already described in papers read at the last meeting of the British Association, and before the Institution of Mechanical Engineers.

It is, however, impossible, within the limits of a single paper, as must be sufficiently obvious, to discuss the whole question; I, therefore, content myself on this occasion by advancing the proposition that efficient hydrants form, as far as our experience goes, the only effective weapon with which fire brigades can successfully cope with fires.

APPENDIX.

TABLE A.—ANNUAL COST OF FIRE EXTINCTION, AND ANNUAL AMOUNT OF FIRE LOSSES. IN SOME HYDRANTED AND UNHYDRANTED CITIES.

Average of 3 *years*, 1880, 1881, 1882.

	Population, 1881.	Area Square Miles.	Cost of Fire Brigade.	Cost of Fire Brigade per 1,000 Inhabitants.	Cost of Fire Brigade of Metropolis at same rate.	Loss.—Property destroyed by Fire.	Loss.—Property destroyed by Fire per 1,000 Inhabitants.	Loss of Property in Metropolis at same rate.
* HYDRANTED.								
			£	£ s.	£	£	£ s.	£
Liverpool	548,649	8·28	5,325	9 14	37,000	—	—	—
Glasgow	510,816	9·55	5,266	10 6	39,290	110,000	215 7	821,542
Manchester	341,508	6·7	3,547	10 8	39,670	80,180	234 16	895,644
†Dublin	249,602	6·0	3,286	13 3	50,200	31,144	124 16	476,050
Birmingham, 1882-3	411,689	13·15	3,250	7 18	30,115	10,931	26 11	101,287
* UNHYDRANTED.								
London	3,814,571	121	99,880	26 4	99,880	2,242,400	587 19	2,242,400
New York	1,240,000	39	288,190	232 8	886,490	880,000	709 14	2,707,150
‡Paris, 1883-4	1,269,023	39	§86,600	§38 3	145,500	‖431,300	‖192 10	734,300

* The term "hydranted" and "unhydranted" indicate the presence or absence in each place of a complete system o hydrants which are used for fire extinction without the intervention of fire engines.

† The cost of the Fire Brigade has been reduced from £3,616 in 1880, to £3,053 in 1882.

‡ A large number of fire hydrants have been put down, and some have been used without the intervention of fire engines, but the average pressure is not such as to admit of this being generally done.

§ Average of 1883 and 1884, exclusive of rent and repair of quarters, barracks, &c.

‖ Average of 1880, 1881, and 1882.

REMARKS ON THE DISTRIBUTION OF WATER.

BY JOSEPH QUICK, JUN., M.Inst.C.E.

Next to the importance of securing a supply of water of good quality for the requirements of a city or town, is that of its distribution, for however superabundant the source may appear to be, the advantages to be derived from its use, and the number of those whom it may benefit, must necessarily be in a great measure dependent upon the way in which it is distributed.

The author does not propose to enter here into the question as to the works necessary to bring an ample supply of water into a city or district, but assumes, for present purposes, that such works have been well executed, and that properly proportioned distributory pipes have been laid, and service reservoirs or other means provided for affording a supply of water at high pressure throughout the district to be supplied.

The history of the water supply in England is eminently instructive, as showing not only the various phases through which it has passed as refinement and sanitation have advanced; but also as proving the absolute necessity of proper control being exercised with regard to its distribution.

Not to weary my hearers with unnecessary detail on this point, it may suffice to refer to the discussions which have taken place during past times, as to the relative merits and practicability of the systems known as "intermittent" and "constant" supply respectively.

It is within the author's recollection when it was the exception, instead of being, as it is to-day, the rule for towns in England to enjoy the advantages of constant supply; but up to this moment there are many instances, notably in the metropolis itself, where the intermittent supply still, either wholly or partially, prevails.

It is hardly necessary to explain that by "constant" as opposed to "intermittent" supply, the author refers to the difference between the mains and house-service pipes being always charged with water, so that it can be drawn off direct from the main at any hour of the day or night by the consumer, instead of, as on the intermittent system, the supply being only turned on for a limited time, varying from half-an-hour to two hours per day, during which time any receptacles, cisterns, &c., provided by the consumer, have to be filled, and suffice for use until the operation of refilling them is repeated on the next and subsequent days.

Of the advantages of the constant supply for domestic purposes, independent of its being immediately in case of fire, it is almost needless to speak, especially for the poorer class of houses in cities and towns, whose only receptacle frequently consists of a dilapidated and uncovered water-butt, the water in which is exposed to all the evils of contamination from the atmosphere and other sources. No one who has travelled by the railway in any part of London can have failed to observe, in the crowded districts traversed, innumerable instances of this kind, which are amongst the most prolific causes of disease amongst the lower classes of the population. It is, indeed, little short of a crime on the part of those responsible for this order of things, that human beings should be compelled to obtain their drinking water from such contaminated receptacles; and it is doubly wrong that, after the suppliers of water have done all in their power to improve, by filtration and other means, the quality of the water, and to prevent its pollution at its source, it should, after delivery to the consumers, be allowed to thus become deteriorated in quality, and a source of danger to health.

One of the great advantages offered by the constant supply system, as already stated, is to abolish the necessity for any of these miserable receptacles; and it is difficult to imagine a greater blessing, or one more conducive to sanitation, than the introduction in their place of water direct from the water mains to the consumer's tap.

Although the author has alluded thus prominently to the evils attendant upon the butts so frequently found in the dwellings of the poorer classes, it is not to be supposed that the evil is limited to them; on the contrary, in some houses of the best class, where cisterns are employed, the same evils, although in a minor degree, prevail. The author feels justified in asserting, as the result of upwards of twenty years' day-to-day experience in connection with the water supply of London, that the periodical cleansing of cisterns, from which it is impossible to exclude a certain amount of dust and dirt, even in first-class houses, is the exception rather than the rule, and that, in a large per-centage even of the better class of dwellings, a further serious evil arises in consequence of the over-flow pipes from such cisterns communicating direct with the drains, without the intervention of a proper trap, thus allowing the foul gases from the drains to communicate with, and thereby contaminate, the water in the cistern.

The obvious question arises, under the above circumstances, why the constant supply is not universal throughout the length and breadth of the land? This is a question which has puzzled many a Parliamentary Committee, and although it has made great progress, it is still but imperfectly understood. The difficulty has usually been ascribed to either the inability or unwillingness of the water authorities to adopt it, on the score of expense; and this argument has frequently been brought forward as one of the reasons in favour of the transfer of the management of the water supply from private companies to a public body; but, on closer investigation, and to the few professionally familiar with the subject, it is apparent that the real difficulty is not to be attributed to this cause, which would have been almost equally difficult to cope with had the water supply been under public instead of private control.

The real difficulty in effecting the change of system consists in having to graft it on to the old state of things, which involves the re-arrangement of the various pipes, taps, closet apparatus, &c., in the houses in such a manner as to prepare them to receive the constant supply, and at the same time prevent waste of water.

It was a long time before the absolute necessity of stringent regulations to prevent waste was understood or appreciated, except by those immediately conversant with the practical everyday working of waterworks; but eventually it became evident, even to those most clamorous for the new system, that the enforcement of such regulations was absolutely necessary to ensure its successful working.

When once this was officially recognised and admitted by Parliament to be indispensable, the necessary powers were granted, both to the metropolis and in the provinces, of which the latter afford some instances of a highly successful result, both in the changing of the system from intermittent to constant supply at the same time, and the effecting of a large reduction in the quantity of water required, after providing an ample supply for all purposes to the inhabitants.

The author may mention as an example, the town of Portsmouth and surrounding districts of Portsea and Southsea, where the Water Company supply a population of 140,000, occupying 27,545 houses, of which a large number are of a very small class. The company was established in 1857, and until the year 1876 the supply was intermittent throughout the borough; but in 1873 an Act of Parliament was obtained, under the advice of the author's firm, entitling them to make the necessary regulations to prevent waste, and these regulations were sanctioned by the arbitrator appointed, Dr. Pole, F.R.S., in April, 1876.

It will be seen by these regulations that while ample power is given to the company to require waste preventing apparatus to be used, the company are restricted from requiring alterations of fittings until the existence of such waste is actually proved; the effect of this has been to necessitate more frequent inspection, and to some extent to cause delay in introducing the new system; nevertheless, the activity of the company's resident engineer, Mr. H. Smith, was such that in March, 1880, or within four years from the official approval of the regulations, the constant supply was given to the whole borough, and has continued without interuption to the present time. Owing, however, to the very extensive supplies for trade and public purposes, and for the use of her Majesty's Dockyard given by the company, the actual supply for all purposes still amounts to 30 gallons per head per day; but there is every reason to believe that by the means the company are still taking to detect cases of waste, as hereafter described, the consumption will be still further considerably reduced.

Probably the extent to which waste of water exists is best tested by asking the question—"What is the quantity really required per head per diem," and comparing it with the quantity actually supplied to any particular town or district; the answer to the former will of course depend upon local circumstances; for instance, in a manufacturing town, or one where unusually large quantities of water are required, for Government establishments, breweries, or trades requiring considerable supplies, the consumption per head per day will be much greater than in a purely residential town or district. When new waterworks are being constructed for a district, it is usual to estimate for works calculated to supply thirty gallons per head per day; but this is not because in well-regulated works the consumption reaches to that quantity, but to provide for a maximum supply being at hand during the driest season of the year, when the consumption is at its greatest. This quantity, however, is in many cases exceeded, notoriously so at Glasgow and New York, while in London it amounts to upwards of 28 gallons per head per day. But as examples of what it should be where proper regulations to prevent waste are adopted, it has been incontestably proved (by Mr. Ayris, M.Inst.C.E.) that in the case of Norwich and Sheffield, that a supply in the former case of 15 gallons, and in the latter of 18 gallons per head per day suffices for all wants, domestic and otherwise. It is evident, therefore, that by a proper system of supervision, and the enforcement of the use of proper waste-preventing apparatus, the supply may be kept, under ordinary circumstances, within the above limits, without in any way stinting the supply.

Another notable case is that of the city of Amsterdam, where the author's firm constructed the works. The supply is constant, and there are no less than 1,137 trade consumers supplied by meter, but the total consumption per head per day, for all purposes, even in the hottest seasons, does not exceed 14 gallons. This company, unlike the London Water Companies, had the great advantage of prescribing proper fittings from its commencement, in 1856; and this circumstance, combined with the fact that the w.c.'s are not connected with any system of main drainage, accounts for the small quantity of water supplied, which, however, is ample for the wants of the inhabitants, notwithstanding the notorious fact that the consumption of water for washing purposes, in Dutch households, is abnormally large.

The most fertile sources of waste of water, and yet the most easily preventible, are those from the w.c., and the overflow pipe from cisterns, which frequently leads direct to the drain; the former is remedied by the employment of a service box placed between the supply pipe and the w.c. ; and the valves for the ingress and egress are so arranged, that before the latter is opened, the former must be closed, so that no direct communication can take place between the main and the w.c. itself. The waste from the overflow pipe is avoided by breaking the connection between the pipe and the drain, by converting the overflow into a warning pipe, fixed in such a position that whenever an overflow or waste of water takes place, it can be seen by an inspector from the outside of the premises ; or it is so arranged as to flow into some inconvenient place ; in either case it insures the cause of waste being speedily discovered and the cause removed.

The "detection" of waste is more difficult than its prevention; for whereas the latter can, when once discovered, be checked or stopped by well known simple mechanical contrivance (*e.g.*, those above referred to and described in Clauses 11, 12, and 20 of the Portsmouth Water Company's regulations annexed hereto), it must be remembered that only a certain portion of the apparatus for conveying the water from the main to the house is exposed to the view of the inspector of fittings on behalf of the water authority; for instance, it frequently happens that, especially in certain soils, the service pipes are defective, and certain leaks may exist and remain undiscovered for years; the waste of water from this cause the author believes to be much greater than that usually attributed to it, and he believes much of it to be due to the employment of wrought iron service pipes of inferior strength and quality. Many (hundreds of) instances could be quoted where such pipes have been found, after only a few years' use, to be decomposed from the outside, leaving the fibres of the iron stretched like violin strings, and barely holding together; imperfectly made joints or connections, or careless workmanship, or broken pipes from unequal subsidence, are also causes of underground leakages. To ascertain their extent and position forms an important feature in any thorough system of water inspection.

Until a few years since, the detection of underground or concealed waste of water by scientific or semi-self-acting means was comparatively unknown, but since the advantages of the constant service system have been more generally acknowledged, and the absolute necessity of preventing water waste admitted, much attention has been paid to the subject, and reliable mechanical means are now available for detecting, isolating, or concentrating at any particular point or district any waste that may be going on. The instrument known as "Deacon's Waste Water Meter," the invention of Mr. G. F. Deacon, M.Inst.C.E., is at once not only a waste detector and localiser, but also a self-acting silent registrar of the exact extent and amount of the waste at any particular spot. A detailed description of that instrument was given in a paper read by Mr. Deacon at the Society of Arts, on May 17th, 1882; it is therefore unnecessary to repeat it here, further than briefly to describe it as a self-acting registrar of the velocity at which the water is passing through it any moment, the result being registered by a diagram on a sheet of paper, placed on a drum worked by clockwork. This instrument is so sensitive that, in the words of the inventor, "in a main supplying 3,000 or 4,000 persons, the opening of a single tap is shown by a sudden fall in the line, and the quantity per hour by the difference in the flow before and after the opening; if the closing of the tap is shown, the duration of the flow is obvious also."

The extent to which waste has has been reduced in Liverpool and other large cities by the employment of this meter, is matter of notoriety in the waterworks world; the author begs to add his personal testimony to the advantages gained by its use at Portsmouth, as shown in the table on page 961.

Waterworks authorities have now, therefore, at their command both the means of detecting waste, and, having detected it, of requiring proper waste-preventing apparatus to be used, *i.e.*, assuming that they possess the necessary statutory powers; in cases where such powers do not exist, their necessity is so obvious that there is but little difficulty in obtaining them from Parliament, under proper restrictions. In the case of the metropolis, the necessary regulations were determined by a committee appointed by the Board of Trade, in 1871, and the operation of the clauses in the Metropolis Water Act, 1852, requiring the London water companies to furnish constant supply, which had lain dormant since that time, at once commenced, and considering the Herculean proportions of the districts included within the radius which those companies supply, great progress has been made. From 52,265 houses receiving the constant supply, in 1873, the number have increased as follows:—

1874	59,281
1875	70,160
1876	75,016

1877	97,343
1878	122,242
1879	138,624
1880	160,674
1881	185,076
1882	203,443
1883	226,376

Hitherto the author has only dealt with the supply as affecting private consumers, whose use of the water is presumably limited to domestic purposes. We have now to consider the question also of the supply to manufacturers, and those cases where water is consumed for other than domestic purposes.

The introduction of water meters, for the purpose of measuring the quantity of water actually supplied to any consumer, has materially simplified the mode both of supplying and charging for water employed for manufacturing, or purposes other than domestic. Formerly, it was exceedingly difficult to form an accurate idea of the quantity used, especially at public institutions or large works, where frequent inspection was almost impracticable; re-surveying of premises, to ascertain whether additional supplies were being used, and the alteration of the annual charge for water, was a source of perpetual disagreement between the suppliers and the supplied. The water meter has, however, put an end to this, and proved equally advantageous to all parties interested. By its introduction an enormous amount of waste of water has also been detected, in many instances, to a large extent. One notorious case occurred in the metropolis. At a well-known popular restaurant, the water company having erected a meter, the quantity registered as passing it was so enormously in excess of the amount previously paid by the proprietor, that he naturally complained to the company. The meter was thereupon tested, but found to be accurate. Unconvinced, however, the proprietor threatened to have the supply cut off, and to resort to a very fine spring which he had in the basement of his premises. He commenced operations accordingly, only to find that the "very fine spring" consisted of a leakage from a broken pipe, which had been, doubtless, running for years, and which of course, accounted at once for the abnormal consumption recorded by the meter.

As regards the most desirable water meter to be used, it is so large a question as to be worthy of a distinct paper. Speaking generally, however, those in practical use may be divided into three classes:—

No. 1. The low pressure meter.
No. 2. The inferential meter.
No. 3. The positive meter.

The disadvantage of the low-pressure meter, which is constructed much upon the same principle as the gas meter, the quantity being measured by the filling and emptying of compartments in a revolving drum, is that it must of necessity be fixed at (or rather above)

BOROUGH OF PORTSMOUTH WATERWORKS COMPANY.

TABLE SHEWING RESULTS OF USE OF DEACON'S WASTE WATER METERS.

District.	Number of services.	Estimated Population.	Date of fixing Deacon's Meter.	Reduction per head in Daily Supply.	Total Reduction per day.
				Gallons.	Gallons.
Queen-street	217	1,085	October, 1882	3	3,255
Daniel-street	626	3,130	September, 1882	13	40,690
North-street	550	2,750	June, 1882	3	8,250
Charlotte-street	1,100	5,550	November, 1882	12	66,600
King's-road	796	4,776	May, 1883	12	57,312

Barrack-street	125	625	February, 1882	25	15,625
Warblington	420	2,100	"	28	58,800

the highest point where the supply of water is required, thus making it more expensive to fix, in consequence of the extra length of service pipe required, and more difficult of access for inspection; it also affords the opportunity to the consumer of fraud, by making connections to the pipe between the main and the meter; and although this latter may not be considered in the great majority of cases an objection, it is at any rate not desirable that the opportunity should be given. On the other hand, there are many instances in which—especially where large quantities of water are supplied in bulk into a large reservoir from one community to another—this meter may be applied with peculiar and especial advantage.

The second, or inferential meter (usually known as Siemens's meter), is based upon the principle of the re-action turbine, or Barker's mill, and is set in motion by the passage of water through it, the velocity of rotation being checked by veins, or plates, projecting from the revolving drum.

The author has some thousands of these meters now at work under his charge, and, taken as a whole, their accuracy is surprising; it is quite true that, under very exceptional circumstances, *i.e.*, when the water is drawn off in minute quantities (or the capacity of the meter is much greater than its work), a certain quantity can be passed without registration; but in practice this does not take place in any appreciable extent, except in the case of large sized meters, as, if the draw-off outlet is reduced to such an extent as to affect the working of the meter, the quantity passing is so small as not to reach the minimum annual water rent which the consumer is usually bound to pay, even if the consumption has been below a certain amount. These meters have the advantage of being moderate in price, compact, and liable to a comparatively small amount of wear and tear.

3. The positive meter, of which there are many varieties—*e.g.*, Kennedy's, the Manchester, and Tylor's—measures, as its name implies, the actual quantity of water displaced by one or more pistons, which are themselves worked by the pressure of the water. These meters are, however (with the exception of Tylor's), more expensive and more bulky than the inferential meters; they are, in fact, machines, and require the attention of machines; at the same time, under proper management, they are not liable to get out of order, nor more costly for repair. At one waterworks which the author designed, every house is supplied by a Kennedy's water meter, at a price per 1,000 gallons; a minimum rent being paid to the Water Company, proportionate to the size of the premises supplied.

In the foregoing remarks the author has endeavoured, he fears somewhat imperfectly, to compress within the limits assigned to this paper a synopsis of the various primary points in connection with the distribution of water. Were he to have attempted to go into detail, the paper could have been materially extended, but he trusts that he has said enough to draw the attention not only of those connected with water and water supply who are already aware of the difficulties of the subject, but of those who are the recipients of the water supply provided for them at so much outlay, foresight, and trouble, to the very great importance of preventing the waste and misuse of so valuable an element. It is a notorious fact that all the available watersheds are being gradually occupied, and that year after year witnesses large communities being compelled to go to long distances for additional supplies of water. Glasgow to Loch Katrine, Manchester to Thirlmere, Liverpool to Vyrnwy, and the metropolis itself bound in the near future to resort to other sources as auxiliary to, or even possibly in substitution of, a portion of its present supply, all afford instances of this necessity; and hence the question of economy in the consumption of water is one the importance of which cannot be overrated. By all means let every individual, rich or poor, use abundantly all that is necessary for every legitimate purpose, but beyond this let them be equally careful that no waste shall be allowed. This is not only a duty of the consumers to the suppliers of water, but to their fellow-men, and while all who neglect it will deserve the reprobation, the gratitude of the community will be eminently due to those who will not allow one of the greatest blessings afforded to us to be diverted from its career of usefulness and benefit to humanity. To an audience like the present, largely composed of brother professionals, the author is aware that a great deal contained in this paper will not be new; but, on the other hand, there are, doubtless, those amongst the visitors to whom the subject is wholly or partially foreign, and he wishes this paper to be regarded not so much as a scientific as a practical paper, addressed to the community at large on an important domestic subject, in which every man has a direct interest.

ON THE PURIFICATION OF WATER BY IRON ON A LARGE SCALE.

By W. Anderson, M. Inst. C.E.

In January, 1883, in a paper on the Antwerp Waterworks, read at the Institution of Civil Engineers, I described the application of Professor Bischof's method of filtration, through a mixture of spongy iron and gravel, to the purification of the waters of the River Nethe. The eighteen months' additional experience gained has shown that, so far as the purification of the water is concerned, Professor Bischof's process leaves little to be desired, but the working of the system has been costly, and the area of land required, as well as the quantity of iron necessary has, in the case of the Antwerp water at any rate, proved very much beyond the inventor's expectations.

The increased demands of the town rendered it necessary to extend the arrangements for purifying the water, and it became my duty to advise the directors of the company on the best means of doing this.

The extension of Professor Bischof's method would have involved so great an outlay, that after trying, unsuccessfully, many experiments on direct filtration through unmixed iron at high rates of flow, I determined to adopt a plan first suggested to me, some years ago, by our chairman, Sir Frederick Abel, of agitating the water to be purified with iron instead of attempting to filter it. The object, in either case, was to expose the water as much as possible to an extended surface of iron, consequently any plan by which the iron could be made to keep itself clean by rubbing against itself continually, would seem to be a more rational way of attaining this object, than of trusting to a partial filtration through a more or less spongy material.

The obstacle to trying Sir Frederick Abel's method at a much earlier date, was the belief entertained by Professor Bischof that a contact of about 45 minutes was necessary to ensure complete purification, and any such time would be fatal to mechanical means of performing the work. The late Professor Way, and Mr. Ogston, it is true, had shown that with very finely divided iron the effect was much more rapid, but there was still a doubt about its permanence.

In the autumn of last year, a revolving cylinder, 4 ft. 6 in. in diameter, and 5 ft. 6 in. long, was adapted to try Sir Frederick Abel's system. It was fitted with inlet and outlet pipes, and with shelves or ledges for scooping up the iron, raising it to the top of the cylinder, and then letting it fall through the water.

At first I began to run water through at 12 gallons per minute, which gave a contact of about 45 minutes, but I found that at this rate the water was very heavily charged with iron; I gradually increased the quantity to 30 gallons per minute, and then found that 1·20 grains of iron were dissolved per gallon, or about twelve times more than experience at Antwerp showed to be necessary. The flow was increased to 60 gallons, and even then 0·9 grains per gallon were dissolved.

The experiment looked so hopeful that I fitted much larger pipes to the apparatus, and having made some other dispositions connected with maintaining a uniform distribution of iron in the cylinder, and preventing it being washed away by the comparatively rapid current that would be possible, I sent the "Revolver," as it came to be called, to Antwerp, where it was put to work at the end of last February, and has continued to operate ever since.

The head available for forcing the water through the "Revolver," is, at Antwerp, limited to 5 feet, but by fitting very large pipes, I have managed to get 166 gallons per minute through; this gives a contact of about $3\frac{1}{2}$ minutes, and is so amply sufficient, that I feel sure that, even for the waters of the Nethe, much less time will be adequate.

The charge of iron is about 500 lbs., and the quantity taken up by the water, including impurities and very fine iron washed away, during a run of 33 days, was 0·176 grains per gallon.

By making suitable arrangements, and choosing a favourable time with respect to the demands of the town, we were able to obtain samples of water that have been purified by the "Revolver" only, and after proper exposure to the air, followed by filtration through one of the large sand filters, the result obtained has been that the colour was very little different from distilled water, the free ammonia was reduced from 0·032 grains per gallon to 0·001, and the albumenoid ammonia from 0·013 grains to 0·0045.

The "Revolver" turns at the rate of about $\frac{1}{3}$ revolution per minute, and requires scarcely appreciable power. The area occupied by apparatus for dealing with 2,000,000 gallons per day is 29 feet by 24 feet, and it can be introduced into any existing system of filters, for by enlarging the in and outlet pipes to a suitable diameter, a head of some 12 inches will suffice to pass the water through.

It can easily be arranged so as to be used or not, as the state of the water to be purified may warrant, and the consumption of iron being only about 20 lb. per million gallons, is quite an insignificant expense. It will be found to remove all colour from water, whether caused by peat or clay, and will facilitate the action of sand filters by the peculiar curdling effect the iron has on the impurities.

During the experiments made at Erith, it was noticed that considerable quantities of gas collected in the upper part of the "Revolver." On collecting this gas, it was found to extinguish a lighted taper instantly, and on analysis was found to contain only 8 per cent. of oxygen.

It was observed from the first, that the animal and vegetable life which was so abundant and troublesome in the natural waters of the Nethe, lying over the spongy iron filters, had quite disappeared in the water, otherwise in exactly the same circumstances lying over the sand filters, and I always supposed that this was due chiefly to mechanical filtration through the spongy iron having separated all the germs, spores, and seeds which come to life above it. But during the recent hot weather it has been found that the water from the "Revolver," though it contains all the impurities of the natural water, has been modified by the action of iron to such an extent that neither animal nor vegetable life is apparent over the sand filters. Without presuming to draw very wide inferences from this fact with reference to the action of iron upon organisms connected with disease, it may, at least, be pointed out that the absence of visible life in water treated by iron on a large scale confirms, in a great measure, the experiments of Dr. Frankland, Dr. Voelcker, Mr. Hatton, Professor Bischof, and others. It is due to the last named gentlemen to state that to his persistent advocacy the introduction of iron as a purifier is mainly due. It must be borne in mind that the system does not depend on filtration only, but, first, on a process of exposure to iron, which decomposes the organic matter, and kills living organisms; and, secondly, on simple filtration, which merely separates the noxious matters which had been previously attacked by the iron. The waters of the Nethe are exceptionally bad, and heavily charged with impurities, so that the test both of Professor Bischof's and Sir Frederick Abel's systems has been very severe.

Miscellaneous.

EDINBURGH FORESTRY EXHIBITION.

In his preface to the catalogue of the Indian Section of this Exhibition, Sir George Birdwood writes, "it may be said that Forest Conservancy in India originated in Edinburgh." Denudation of the earth's surface of its forest covering was first brought under general notice at the meeting of the British Association held in Edinburgh in 1850. Special reference was then made to the uncalled-for destruction of forests in India and America, and a committee was appointed to consider "the probable effects, in an economical and physical point of view, of the destruction of tropical forests." The committee presented an exhaustive report in the following year, in which they drew attention to the wasteful and uncontrolled destruction of forests going on; to the fact that this was checked by proper forest conservancy; and recommended the preservation and maintenance of all indigenous forests, the institution of forest surveys, and the working of the forests on well-devised plans. The discussions to which the report gave rise led directly to the organisation of the Indian Forest Administration for local governments in 1855, and for the whole Indian empire in 1862.

Previously, in 1846, Dr. Gibson had been appointed Conservator of Forests in the Presidency of Bombay, and in 1848, General (then Major) F. C. Cotton urged on the Madras Government the necessity of taking steps to preserve the forests from further denudation by the reckless wastefulness of native contractors.

The engineers required for forest conservancy in India have been sent to foreign schools of forestry at the cost of our Government; and in 1882, the Council of the Society of Arts transmitted to the Secretary of State for India a memorial in which they impressed upon the Indian Government the necessity for the establishment of a department for the teaching of forestry in the Royal Engineering College at Cooper's-hill.*

In the Paris Exhibition of 1867 there was a special pavilion devoted to forestry, and the Russian Government followed with an Exhibition of forest products at Moscow. At the Paris Exhibition of 1878 a still larger display was made. The present Exhibition is largely due to the initiative of the Scottish Arboricultural Society, the members of which, being anxious to establish a forest school in Edinburgh, after the model of those in France, Germany, and other European countries, thought that the scheme might be furthered by the formation of a special Exhibition. The suggestion was made in the autumn of 1882,

* The memorial is printed in the *Journal* for July 14, 1882 (p. 879). For Colonel G. F. Pearson's paper on "The Teaching of Forestry," see *Journal* for March 3, 1882 (p. 422).

and was received with public favour. An executive committee was appointed, with the Marquis of Lothian as chairman, and Mr. Cadell, late of the Indian Forest Department, as secretary. There was at first some difficulty as to the site. West Princes-street gardens were decided upon as being in the centre of the city, beautiful in themselves, and affording the most admirable scope for both indoor and outdoor displays. But the Town Council refused permission, and eventually the extensive grounds of Donaldson's Hospital, situated in the western outskirts of the city, were chosen. The preparation of the plans were entrusted to Mr. Robert Morham, the city architect, and the buildings were erected by Messrs. Wm. Beattie and Sons, at a cost of over £5,000. The design consists of a great nave, 630 ft. in length by 50 in breadth, intersected near each end, and in the centre by transepts 138 feet long by 50 feet broad. Over the intersection of the central transept with the nave is a lofty dome, and at the corresponding intersection of the eastern and western transepts the roof rises in octagonal pavilions. The building is of wood, and is lighted from the roof and by windows in the gables of the nave and transepts. Adjoining the northern divisions of the transepts, and at right angles to them, are large annexes, the central one 200 feet long, and those at the two ends 150 feet each in length. The grounds attached to the building cover a space of eight acres, and have been planted with specimens of coniferæ and ornamental shrubs. There are also in the grounds several châlets, summer houses, &c., and sheds for the machinery in motion.

Before proceeding to notice the special contents of the Exhibition, it may be well to set down a few particulars as to what has already been done for the study of forestry. The forestal decrees of the Middle Ages in France were wise, but they were seldom enforced, and it was Sully who first recognised the importance of forests as a source of national wealth, and promulgated laws to restrain reckless clearances. It was not, however, until the present century that scientific forestry was first taught. Hartig founded his school at Dillenburg, in Nassau, in 1800; and Cotta followed in 1812 by founding a school at Thorandt. In 1820, colleges were established in the chief German states; and in 1824, the great Forest College was established at Nancy. The chief countries of Europe (with the exception of Great Britain) have all schools of forestry, and Dr. Hough has been commissioned to organise one for the United States. Professor Sargeant, of Harvard College, estimates that at the present rate of cutting and consumption of timber, the whole of the great forests of the United States will be cleared in little more than a quarter of a century. He fortifies this opinion by stating that no less than ten thousand million cubic feet of white pine are required for present needs per annum, and that the total annual value of the timber consumed for fuel, constructive purposes, and in the arts, is two hundred millions sterling.

The following are the forestal statistics of the chief countries of Europe. Russia has forests extending to 527,426,510 acres, or 42·38 per cent. of her whole territory. Sweden has 40,636,883 acres of forest, or 40·43 per cent. Baden, 1,337,767 acres, or 35·90 per cent.; Austria, 23,284,174, or 31·39 per cent.; Wurtemburg, 1,494,147 acres, or 31·22 per cent.; Hungary, 19,425,600 acres, or 28·24 per cent.; Prussia, 20,047,014 acres, or 23.35 per cent.; Norway, 17,290,000 acres, or 22·30 per cent.; Switzerland, 1,905,407 acres, or 18·64 per cent.; France, 20,641,953 acres, or 15·79 per cent.; Belgium, 1,073,452 acres, or 14·82 per cent.; Italy, 9,031,310 acres, or 12·34 per cent.; Holland, 486,229 acres, or 6 27 per cent.; and Denmark, 364,474, or 4·25 per cent. But the United Kingdom is less than the least of these. The ratio of woods to the total acreage is 3·7 per cent. Ireland has 328,473 acres of woodlands, or 1·62 per cent. of its total area; Scotland, 734,490 acres, or 3·7 per cent.; and England, 1,325,765 acres, or 4 per cent.

On the other hand, the supply required by this country is enormous. The value of forest products imported into Great Britain is little short of 50 millions sterling. Of this sum about 20 millions are spent for timber alone. Our largest supplies are drawn from British North America, the United States, Sweden and Norway, Russia and Germany. These consist chiefly of fir logs or deals; but we receive teak from Bengal and Burmah; mahogany from Honduras, British Guiana, and Mexico; rosewood, walnut, and satin-wood from the United States, Brazil, and Turkey; and logwoods from Hayti and St. Domingo. £182,000 are expended in the imports of living trees and shrubs from foreign countries, ranging from Belgium to Japan, and £57,500 for tree and garden seeds. Sufficient has been said to show the importance of forests in every point of view—climatic, agricultural, economic, and commercial.

Apart from timber, the forest products are numerous and valuable. Take, for instance, the importation of fruits and nuts alone; these are valued at nearly eight millions. Palm and cocoa-nut oil sent from the West Coast of Africa, India, and the islands of the Pacific, is worth more than a million and a-half; olive oil, from Italy, France, Portugal, Spain, and Turkey, nearly a million. Caoutchouc, is imported from Brazil, Africa, India, &c., to the value of nearly three millions; and gutta percha is got from the East Indies to the value of over half a million. Again, take Peruvian bark, from which quinine is made: nearly two millions are paid to India and Brazil for it, whilst four millions sterling are sent to India for dye-stuffs. Gums to the value of a million and a-quarter are imported from Egypt, New Zealand, India, and Brazil; and turpentine and pitch, valued at a million and a-half, are used in Britain from the forests of the United States, Russia, Germany, and France.

A CENTURY'S PROGRESS IN TANNING.

The *Halle aux Cuirs*, one of the leading organs of the French leather trade, calls attention to the fact that in 1765 the Society of Arts awarded a prize to Mr. John Eldridge, for the discovery of a practical method of tanning with the sawdust and shavings obtained from oak wood.* In 1768, Lavoisier used oak leaves, but their general employment was restricted by their strength for tanning varying with the period of the year and the variety of tree from which they are obtained. Swelling by means of sulphuric acid was introduced by Seguin, who was entrusted in 1792 with the furnishing, in as brief a delay as possible, of a large quantity of leather for military purposes. In 1804, Lawrence utilised Seguin's idea, and in 1823, Spilsbury devised the acceleration of tanning processes by forcing the tanning decoction through the skins to be treated. In 1826, Knowles improved upon this idea with his method. In 1833, Leprieur introduced the employment of vats of graduated force, but immersed the skins, as an initiatory process, in a bath of acetate of lead. In 1837, Herapath, of Bristol, employed the plan of sewing the skins together, and passing them between pressing-rollers. In 1841, Robert Warington used carbonate of potash and carbonate of soda for removing hair, and oxalic acid for swelling. In 1849, Hibbard introduced the process of removing hair with potash and lime. In 1850, Felix Boudet suggested the employment of alkaline sulphurets and sulphuret of lime as substitutes for orpiment. In 1854, Derruys, of Brussels, commenced to use decoctions of cutch for tanning. In 1854, Preller first used the method which results in the production of "crown leather." In 1855, Belfond made the first experiments in mineral tanning by means of iron, the process having already been called attention to by Knapp. In 1860, the use of chromate of potash in tanning was patented by Clark. In 1879, Professor Putz, of Passau, indicated the possibility of tanning by means of alum and albumenoid substances. The most recent invention is the chrome process of Heinzerling, which would seem, however, not to have been adopted by the tanning industry.

General Notes.

Carrara Marble.—The total production of the marble quarries of Carrara last year was 173,593 tons, of which 115,644 tons were rough blocks and 57,949 tons sawn or worked. The exportation in 1883 amounted to 147,188 tons, showing a decrease on that of the previous year of 10,782 tons, and an increase of 24,383 tons on that exported in 1881.

* See Dossie's "Memoirs of Agriculture," vol. i., p. 226.

Antwerp International Exhibition, 1885.—The Lords of the Committee of Council on Education have received information, through Her Majesty's Principal Secretary of State for Foreign Affairs, that the International Exhibition at Antwerp, of which a notice was inserted in the *London Gazette* of the 15th July, 1884, will be a national and governmental undertaking, under the immediate patronage of His Majesty, the King of the Belgians. The President of the Exhibition will be His Royal Highness the Count of Flanders, and the Vice-President, the Minister of Agriculture, Industry, and Commerce. The committee will consist of 450 members, and the Belgian Parliament will be asked to vote a sum of money for the Commission. The State will nominate the jury, and regulate its functions.

The Crefeld Silk and Velvet Industry.—The following interesting statistics have been issued regarding the above industry:—

(1.) Amount of Trade.

	1881.	1882.	1883.
With—	£	£	£
Germany	1,419,397	1,594,948	1,502,173
Austria-Hungary	52,962	55,222	46,090
England	1,048,046	969,225	1,115,283
France	240,022	336,815	382,127
Other European countries	178,821	191,471	166,849
Extra European countries	887,180	1,048,673	1,116,674

(2.) Consumption of Raw Material.

	1881.	1882.	1883.
	Tons.	Tons.	Tons.
Raw silk	431½	456	416
Schappe	215½	274½	360
Cotton	940	1,024	870

(3.) Wages Paid.

	1881.	1882.	1883.
	£	£	£
Weaving	799,453	8[illegible]8,699	955,983

CANTOR LECTURES.

FERMENTATION AND DISTILLATION.

By Professor W. N. Hartley.

Lecture I.—Delivered Monday, May 12, 1884.

Introduction.

The process of fermentation, which is carried out on a vast scale in breweries and distilleries, is one which has for its object the manufacture of alcoholic products, or of alcohol in a more or less concentrated form. Though generally this branch of manufacture is associated with the preparation of alcoholic beverages, nevertheless, alcohol, pure and simple, is an article of commerce which is daily becoming of greater importance as a material employed in the technical applications of organic chemistry, it being *par excellence* the solvent of organic substances. It dissolves essential oils, and such solutions constitute the perfumes of commerce. It dissolves resins, and upon this its value as applied to the manufacture of varnishes and pharmaceutical preparations depends. Products of its transformation are the articles known as vinegar, chloroform, chloral, ether, and certain fruit essences. Converted into ethylic iodide, it is an agent used to produce violet and green dyes from magenta red. Mixed with ether, it dissolves nitrated cotton wool or pyroxyline, and the product is collodion. It is a preservative of fruits, and of anatomical preparations and natural history specimens.

As numerous and varied as its applications are the sources whence it may be derived; thus, for instance, it may be manufactured from—

(1.) Wine, beer, perry, cider.

(2.) Sugar-cane, beet-root, carrots, milk-sugar, maize-stalks, and Chinese sugar-cane.

(3.) Fruits—as apples, cherries, figs, rhubarb, grapes, dates, mountain-ash berries, melons, and gourds.

(4.) Molasses of cane and beet-root sugars, marc of grapes, refuse of grain and honey, and milk.

(5.) Roots and bulbs, beet-root, carrots, potatoes, and dahlia roots.

(6.) Cereals—rye, wheat, barley, maize, oats, and rice.

(7.) Leguminous and other seeds—as peas, beans, lentils, chesnuts, horse-chesnuts, buck-wheat, millet, and black millet.

(8.) Various substances containing saccharose, glucose, glucosides, pectosine, fibre—as sawdust, paper, straw, hay, haws, osier-peelings, moss, rags, and cotton-waste.

(9.) Carob or locust beans.

(10.) Daffodil roots (*Asphodelus bulbosus*).

(11.) Coal gas.

The processes ordinarily carried out in the preparation of alcohol depend upon the following facts: most vegetable substances contain sugar, starch, or some other substance easily converted into a fermentable sugar by the action of a constituent of malted grain called diastase, or by the action of dilute mineral acids. The sugar produced by either means is readily resolved by vinous fermentation into alcohol and carbonic acid.

These operations involve three distinct phases, namely:—1. *Mashing*, or the preparation of a saccharine fluid. 2. *Fermentation*, the conversion of sugar into alcohol. 3. *Distillation*, or separation of the alcohol from water.

Two kinds of spirit are manufactured on a large scale in Great Britain and Ireland, viz.:—

a. Spirit from grain.

b. Spirit from potatoes.

The Preparation of Mash from Grain.

Grain spirit is obtained from a mash prepared from either wheat, rye, barley, maize, or a mixture of two or more of these cereals. It has been found that when more than one kind of grain is used, there is a larger yield of alcohol than from one kind only. Thus, a mixture of wheat and barley, or barley and maize, or rye and barley, give a better result than any one of these materials used singly.

It is not necessary that all the grain should be put through the process of malting.

The first operation consists in grinding the grain to a fine meal, a process which is the more important the harder the nature of the grain, as it is necessary that the meal be thoroughly moistened with water, in order that the starch granules which it contains may swell and burst, and so become soluble.

The meal which is to be infused is mixed with a certain proportion of malted barley, which amounts to one-seventh or as much as one-fourth of the unmalted grain.

The malt is grain which has been allowed to germinate rather more freely than such as is employed in the brewing of beer, and it is dried at a temperature of from 40° C. = 104 F. to 60° C. = 140° F. This special preparation contains a larger proportion of the active principle called diastase, and saccharification thus proceeds more rapidly than with ordinary malt. In order to prevent the liquors being too dilute, it is necessary to employ as little water as possible in the preparation of the infusion, termed technically the mash. The temperature of the water is from 50° C. = 122° F. to 60° C. = 140° F., the mashing being carried out in large iron vessels, each holding as much as 10,000, or even 25,000 gallons. The meal is kept in operation by rotating arms, as in the operation of brewing. The weight of water represents about one and a-half times that of the grain used. The addition of boiling water is made little by little, till the whole attains a temperature of 65° C. = 149° F. or 70° C. = 158° F. This temperature is maintained, the vessels being covered, and the malt which is added in the course of two or three hours, at first converts the whole of the dissolved starch into a sugar termed maltose, and a gummy substance known as dextrin; but when the action is completed, the liquid contains maltose only.

The mashing processes carried out in breweries and distilleries differ in this respect, that, whereas it is of importance to the brewer that a clear wort should be the result, the malt, which is the only grain used, is crushed, but not finely ground; the simple crushing instead of grinding of the malt prevents the complete saccharification of the starch, a portion of dextrin remaining in the sweet wort. The distiller aims at the complete conversion of the starch into fermentable sugar, the clearness of the infusion being of little consequence. With this object, the grain is finely ground, after carefully sifting off all dust, stones, and seeds, such as those of the dock and black rape, and as little water as possible is used beyond that necessary to complete the saccharification of the starch, and the conversion of the sugar into alcohol by fermentation.

Mash has generally an agreeable odour, something like that of newly baked bread, and a sweet taste. The proportion of water does not exceed three and a-half to four times that of the solid matter in solution. When the saccharification process is complete, the mash is cooled down as rapidly as possible to a temperature favourable to fermentation, 23° C = 73° F., either by passing it through refrigerating backs or by the addition of a certain quantity of very cold water. Saccharification is frequently, if not invariably, now carried out by the use of steam, as both the temperature and the proportion of water can be better regulated than by other modes of heating the liquid. In France and Belgium, Lacombe's macerator is much used. This consists, essentially, of a closed copper vessel containing an agitator, into which the meal, the green malt, and the warm water are introduced; at the end of fifteen or twenty minutes steam is blown into a double bottom, which raises the temperature gradually to 65° C = 149° F. After a period of from half to three-quarters of an hour, the contents of the macerator are again agitated, and more steam delivered, and this operation is continued for three or even four hours. When the saccharification is complete, cold water is made to circulate through the double bottom in place of steam, in order to cool the mash. The mash is then run off, and the vessel rinsed with a little warm water, the rinsings being added to the mash.

The formation of a small quantity of lactic acid (the acid of sour milk is lactic acid) during maceration, appears to be rather advantageous than otherwise; and it has been stated that the addition of phosphoric acid, and about 2 per cent. of beer yeast, renders the subsequent fermentation process more energetic and more complete, which in turn results in a larger yield of alcohol. The liquid portion of the mash, the saccharine fluid, may be withdrawn previous to fermentation, and the solid matter of the grain, which abounds in the nitrogenous principles, fatty matters, and phosphatic salts, so necessary as a mineral food both for plants and animals, has proved to be an excellent food for cattle.

Sometimes the solid matter, or draff, is allowed to remain with the liquid extract until the fermentation process is completed. The use of mash which has been separated from the draff is advantageous, on account of the greater facility of obtaining a regular fermentation. Frothy fermentation, which is a great source of annoyance, is caused by the presence of nitrogenous substances, which are, for the most part, removed with the draff. In breweries it is necessary to separate the yeast from the beer, and this is dried by pressure in a filter-press from which it comes out in cakes about two inches thick. It is not necessary in distilleries to separate the yeast from wash previous to distillation.

The proportions of extractive matter and of draff yielded by a satisfactory saccharification when operating on different cereals, are the following:—

	Extractives.	Insoluble Matter.
*100 parts of maize	70	30
,, ,, rye	65	35
,, ,, barley	60	40
,, ,, oats	42	58

Mixtures of rye and barley yield 63·25 per cent. of extractive matters.

The Composition of Barley.

The Preparation of Mash from Potatoes.

Potatoes consist of about 28 per cent. of dry substance, 21 per cent. of which is starch, 2·3 per cent. albuminous matters, and 72 per cent. water. It is of great importance, in calculating the expected yield of alcohol, that this water be taken into account. Thus 100 parts of potatoes, yielding 20 per cent. of starch, give 17·3 per cent. of extractive matter to the mash; if to this be added five parts of barley malt to effect saccharification, this yields three parts of dry malt-extract, and from these materials the yield of alcohol has to be calculated. In making a thick mash, therefore, the proportion of water to be added must depend upon the large quantity of water in the potatoes, which varies between 68 and 80 per cent. Sometimes the malt amounts to as much as 10 per cent. It will thus be seen that it is essential, for the purpose of getting the best possible yield, to ascertain the quantity of starch in the potatoes.

* "Wagner's Chemical Technology."

Fresenius and Schultze have devised a simple plan for ascertaining the proportion of starch, and of solid matter insoluble, contained in potatoes; it depends upon observed facts relative to their density. Potatoes, carefully washed, are weighed, first in air and then in water, the less the loss of weight in water, the greater the proportion of starch.

The treatment of potatoes consists in (1) washing and cooking, (2) crushing or mashing and mixing with malt, (3) the saccharification and cooling of the mash.

The washing is effected in a cylindrical cage, inclined at an angle of about three or four degrees, to the horizontal position, and nearly half immersed in water. A rotatory motion given to the cage rolls the potatoes over and over in the water, all earthy matter falling through the bars into the tank of water below. This arrangement is imperfect, as it does not separate stones of large size. To effect this, a spiral of arms, fixed to a central axis, placed longitudinally in a water trough, carries the potatoes forward with a screw-like motion, while stones sinking immediately remain undisturbed. The potatoes are carried upwards by an endless chain and buckets and delivered thereby into the boiler to be steamed. The potatoes are cooked in a vessel, by means of steam, and are allowed to fall on two toothed hollow cylinders, 2 ft. in diameter, which, revolving in opposite directions, crush and mash them. The crushed potatoes, which are hot, are mixed in a copper with 5 per cent. of crushed malt, and 25 per cent. of water, at the ordinary temperature. The temperature of the liquid rises, but care should be taken to prevent it exceeding 62° C. = 144° F. to 65° C. = 149° F. The copper is covered, and the maceration is allowed to continue for two or three hours, during which period complete saccharification of the starch is effected. Sometimes the pasty mass is too tenacious, and in such a case rollers on the bottom of the copper are set in motion to crush and divide it, in order to permit the diastase to act on all the starchy matter.

Preparation of Mash by Sulphuric Acid.

This mode of saccharification, first recommended by Leplay, is carried out in the following manner. The raw potatoes are converted into pulp, which is thrown into a large vessel containing water. The starch cells separate and settle to the bottom mixed with the cellular tissue of the pulped potatoes. The supernatant liquid containing the albumenous matter of the potatoes is syphoned off, otherwise it would interfere with the action of the sulphuric acid. While this operation is in progress, the required quantity of dilute sulphuric-acid is heated in another vessel by steam pipes, and the washed raw potato starch is added to this in small quantities at a time. The boiling is continued for about five hours, that is, until the whole of the starch as well as the dextrin is converted into sugar. The liquid is run off through a strainer into another vessel containing chalk, which neutralises the excess of acid. The gypsum settles down, and the liquid is transferred to a fermenting vat.

The Chemistry of the Process.

Starch and sugar both belong to a group of substances of complicated structure, known as the carbo-hydrates. The simplest of them, grape sugar, contains no less than 72 parts of carbon, united to 10 parts of hydrogen, and 80 parts of oxygen, in all making a free and independent particle of matter known as sugar, having a relative weight 162 times as great as the lightest particle of its constituents. The hydrogen and oxygen in all of them are in exactly the proportions which will form water, hence they may be easily decomposed with the production of carbon and water. By heating starch, this change is effected; it is charred or carbonised, and much water separates. By mixing sugar with oil of vitriol the carbon is set free, water being withdrawn from the substance by the action of the powerful acid. Cellulose or woody fibre, if moistened with sulphuric acid and moderately heated, is resolved into carbon and water.

The carbo-hydrates as a class are divisible into three groups, each with a generic formula representing the composition of the group, thus:—

I. The Amylose, or Starch group. $nC_{12}H_{20}O_{10}$	II. The Saccharose, or Cane-sugar group. $C_{12}H_{22}O_{11}$	III. The Glucose, or Grape-sugar group. $C_6H_{12}O_6$
Starch	Saccharose	Lœvulose
Dextrin	Maltose	Dextrose
Gum Arabic	Synanthrose	Inosite
Cellulose	Melitose	Sorbite
Lichenin	Melizitose	Arabinose
Mucin		Eucalyte
Tunicin		Dambonite
		Bornesite

By a comparison of the above formulæ, a close relation between the groups will be noticed; thus, by adding the elements of water, H_2O, to a member of the first group, we obtain a member of the second, and by performing the same operation in the second, we obtain two members of the third group:—

$$\frac{C_{12}H_{20}O_{10} + H_2O}{C_{12}H_{22}O_{11}} \qquad \frac{C_{12}H_{22}O_{11} + H_2O}{C_{12}H_{24}O_{12} = 2\,C_6H_{12}O_6}$$

The wide distribution of starch in the vegetable kingdom enables us to prepare it from a variety of materials, such as potatoes, wheat, barley, oats, or rye, or to obtain the products of its transformation without the preliminary process of separation from the other constituents.

For the benefit of those who are not conversant with the use of such formulæ as those descriptive of the carbo-hydrates, I have prepared a series of illustrations, consisting of weighed amounts of carbon and of water contained in tubes of the same diameter, so that the length of the columns of carbon and of water represents the proportional weights of those substances in the molecules, or, more correctly speaking, obtainable from them.

The integral particle of starch, called the molecule, consists of n times $C_{12}H_{20}O_{10}$ where n is intended to represent a certain whole number. By C we understand twelve parts by weight of carbon, the smallest portion of that substance which can enter into combination; H represents in the same way one part by weight of hydrogen; and O, in like manner, sixteen parts by weight of oxygen. Hence, the smallest particle of starch which can have an independent existence will weigh at least three hundred times as much as the smallest particle of hydrogen which enters into its constitution. These smallest particles of the constituent substances are termed atoms, because they are indivisible proportions; hence we learn from these symbols that the atom of carbon weighs twelve times as much as an atom of hydrogen, an atom of oxygen sixteen times as much. Now, in order to illustrate the *relative* quantities of these three kinds of matter entering into the molecules of the carbo-hydrates, we may compare the following weights:—12 grains of charcoal and 18 grains of water represent the symbols $C\,H_2\,O$, or formic aldehyde; 72 grains of charcoal and 108 grains of water represent the grape sugar group, six times formic aldehyde; while 144 grains of charcoal and 198 grains of water express in a sufficiently close manner the cane-sugar group.

When tabulated, the numbers appear thus:—

Parts by weight.

$$\left.\begin{array}{l} C = 12 \\ \text{Water}\left\{\begin{array}{l} H_2 = 2 \\ O = 16 \end{array}\right\} 18 \end{array}\right\}\text{Formic aldehyde.}$$

Parts by weight.

$$\left.\begin{array}{l} C_6 = 12 \times 6 = 72 \\ \text{Water}\left\{\begin{array}{l} F_{12} = 12 \\ O_6 = 16 \times 6 = 96 \end{array}\right\} 108 \end{array}\right\}\text{Glucose.}$$

Parts by weight.

$$\left.\begin{array}{l} C_{12} = 12 \times 12 = 144 \\ \text{Water}\left\{\begin{array}{l} H_{22} = 22 \\ O_{11} = 16 \times 11 = 176 \end{array}\right\} 198 \end{array}\right\}\text{Saccharose.}$$

The Properties of Starch.—Starch in mass forms a perfectly white powder, insoluble in cold water. The powder consists of granules which differ in size, for instance, in potatoes they are about $\frac{7}{1000}$ths of an inch, and in wheat about $\frac{2}{1000}$ths of an inch in length. Under the microscope they exhibit a series of concentric markings, the nucleus of which, termed the hilum, lies a little to one side. In polarised light, starch granules show a dark cross, the point of intersection of which coincides with the hilum. If starch granules are crushed in cold water, a small portion of the interior, called granulose, is dissolved; addition of iodine-solution causes the precipitation of fine-grained pellicles of a blue colour. Starch granules, when ground with fine sand, yield a solution of granulose. When starch is placed in water at 55° C = 131° F. the larger and more watery starch grains become soluble, or swell up and form a paste. In small grains, which are of denser material, the conversion into paste commences, according to Naegeli, at 65° C = 149° F. This difference of behaviour of different varieties of starch granules is well observed in the case of barley, which swells at 99° F, and maize starch at 122° F. In these operations, the interior watery parts swell first, the outermost layer scarcely at all; it bursts and remains for a long time recognisable by means of iodine as a pellicle. This effect can likewise be caused by the action of a cold solution of alkali, such as potash or soda. The volume of starch grains may increase 125-fold, and so much fluid can be absorbed that the swollen grains contain only 0·5 to 2 per cent. of solid starch. If the proper proportion, of, say, 1 of starch to 8 of water has been employed, the swelling and bursting of the starch granules yields a paste which gelatinises on cooling. According to Lippman, the behaviour of different varieties of pure starch is shown in the following table:—

THE GELATINISATION OF STARCH.

	Granules swollen	Gelatinisation commenced.	Gelatinisation completed.
	° F	° F	° F
Barley	99·5	135	144
Maize	122	131	144
Rye	113	122	131
Potato	115	137	144
Rice	129	137	144
Wheat	122	149	153
Buckwheat	131	155	160
Sago	—	151	158
Arrowroot	151	151	158
Portland arrowroot	122	137	144
Horse chesnut	126·5	133	137
Chesnut	126·5	137	144
Acorn	135	171	190

Starch in certain grains, as, for instance, maize, is mixed with oily and fatty matter, which retards gelatinisation until this is removed by steaming; or gelatinisation may be effected by heating under pressure.

In 1813, Stromeyer discovered that starch, whether dry or in the form of paste, is deeply coloured by iodine. A liquid containing about $\frac{1}{500000}$ its weight of starch paste, strikes a blue colour. If the starch be not in the gelatinous condition, a much larger quantity of iodine is required to cause this reaction, and the colour appears with comparative slowness. According to Sonstadt, dry starch absorbs 3·2 per cent. of iodine (*Chem. News*, vol. 28, p. 248) which will bear drying at 120° C = 248° F. Soluble starch which will not gelatinise may be prepared by long continued boiling of starch paste, or by dissolving starch in boiling acidulated water, The latter preparation, after neutralisation of the acid and evaporation, yields a substance granular, and without structure, which is insoluble in cold water, but capable of being dissolved at 50° C. = 122° F. (Musculus, Comptes Rendus, vol. 78, pp. 1413-17.)

It has been shown by W. Naegeli that starch is a mixture of several modifications of the same substance, or of several substances of a very similar character. When treated with acids not too concentrated, that portion which is coloured blue by iodine, and preponderates in the softer parts of the starch, is dissolved, and a portion is left to which iodine imparts a yellow colour. This latter is only slowly changed by acids or boiling water. It still possesses the structure of granules, and its hardest part seems to be identical with, or nearly related to, cellulose. The modifications coloured blue and yellow by iodine are capable of changing gradually into each other, and forming others, which take with iodine, a violet, red, or orange colour. Potato starch contains much of the blue, but little of the orange, there being most yellow. In wheat starch there is less yellow, hardly any blue, but much violet and reddish violet. When boiled with water the quantity of the blue modification increases. On boiling yellow starch with water for a long time the greater part dissolves, and the solution gives with iodine a violet colour. Now it is evident that the operation of mashing is to obtain either a solution of starch or a starch paste, the addition to this of malt-extract and the maintenance of the liquid at a temperature of 60° C. = 140° F. being intended to convert the starch into sugar.

The Change of Starch into Sugar.

In 1811, Vanquelin discovered that starch, when heated strongly, can be converted into a gummy substance completely soluble in water. Kirchof likewise at the same time discovered that sulphuric acid largely diluted with water was capable of transforming starch into a crystallisable sugar, and in 1814 he further observed that the same change could be effected by the albumen of grain which was rendered especially active by converting the grain into malt. The gummy substance discovered by Vauquelin was afterwards proved by Vogel, in 1812, to be producible by the action of sulphuric acid on starch, and in 1823 it was examined and fully described by Biot and Person, who gave it the name of dextrin on account of its property of powerfully rotating a ray of polarised light to the right hand.

If the flour of wheat, and especially of rye or any other of the cereals, be mixed with twenty times its weight of water, and be submitted to a temperature of 75° C. = 167° F., it yields a thick paste, which after the lapse of a few hours, becomes a thin fluid with a very sweet taste. It is evident that, as we have added no chemical reagent to effect this work but water, and water alone, the change must be caused by some substance present in the grain, because if the starch be first separated from the other constituents of the grain it is unable to undergo such a transformation. This saccharifying action was discovered by Payen and Persoz to be due to the presence of a nitrogenous body which they named diastase. In the course of this change, the starch of the flour attaches to itself a definite proportion of water, and in consequence of this the constituent atoms become re-arranged, so that there is first produced a mixture of sugar and dextrin, and finally sugar only. The same formation of sugar occurs in the germination of corn, hence the sweetness of malt. All the starch contained in wheat, rye, barley, oats, &c., becomes converted into sugar during the development of the germ. I have stated that when flour is used the saccharification is completed after a few hours; but if, instead of plain flour and water, an aqueous extract of ground malt be used, the same change will require no longer a period than a few minutes. So long as the starch and the diastase are separated, the former remains unchanged, but when they come into contact the change begins instantly. Many plants with woody stems are found in the autumn, containing starch which remains unaltered, but with the renewed activity of life in the spring this is transformed into sugar. In explaining the change of starch into sugar, it is necessary to bear in mind that the starch is not first converted entirely into dextrin, and this subsequently entirely into sugar, nor is the product either dextrin or sugar, because the fact is that dextrin and sugar are produced simultaneously in equivalent quantities, until finally the dextrin itself becomes sugar. Strong experimental evidence was given by Musculus in 1860 to show that this was the action of dilute sulphuric acid on starch; and it was subsequently proved by Mr. O'Sullivan that this was the action both of sulphuric acid and of diastase. Mr. O'Sullivan, in a series of papers in 1872 and 1876 (Chemical Society Journal, vol. xxv., p. 572; xxix., p. 479; xxx., p. 125), has further proved that the sugar produced from malt, grain, or starch, either by the acid or diastatic conversion, is not of the nature it was formerly supposed to be. Although in common with the leading members of the glucose group, it has the property of giving a fine orange-coloured precipitate of sub-oxide of copper with what is known as Trommer's test, it should not on this account be classed as a glucose. Two researches, that of Saussure, published in 1819, and another of Dubrunfant, in 1847, dealt with facts concerning this sugar. The latter chemist prepared it and examined its properties, recognised its distinctive character, and called it maltose.

Maltose, its properties. — Composition $C_{12}H_{22}O_{11}\cdot H_2$. This is a sugar belonging to the saccharose group, obtained by heating starch with dilute acids, or by the action of diastase. If a syrupy solution of maltose be extracted with boiling alcohol, and the alcoholic solution be allowed to stand for some days, maltose crystallises out in hard crusts of acicular crystals containing water of crystallisation in accordance with the formula $C_{12}H_{22}O_{11}\cdot H_2O$. The difference between maltose and glucose is chiefly in the rotatary power and the power of reducing cupric oxide.

Whereas a given quantity of dextrose will reduce 100 parts of copper solution, prepared after the method of Fehling, maltose reduces only 66 parts, or two-thirds the usual quantity. Lactose, a well-defined crystalline sugar reduces 70 parts. This latter substance appears to be isomeric with maltose and saccharose, that is to say, it has the same composition and the same molecular weight, but different properties.

Dextrin, its properties. — Starch is convertible into dextrin—1st, by the action of diastase on starch-paste; 2nd, by the action of dilute sulphuric acid; 3rd, by heating the dry substance to a temperature of 200° C = 322° F.

British gum, or commercial dextrin, is prepared by moistening starch with water containing 2 per cent. of nitric acid, allowing it to dry in the air, and converting it by heating to 110° C. = 230° F. It is a clear yellow powder easily soluble in water. A strong solution of this is frequently sold as gum mucilage. It differs from starch paste in not being coloured blue by iodine. From glucose and maltose it differs in not being reducible by Fehling's solution. It is converted into sugar by diastase. Its rotatory power on polarised light has led to its fraudulent use for the purpose of "correcting," or masking the left-handed rotation of glucose mixed with cane sugar. It has already been mentioned that dextrin gives no blue colour with iodine, but it would be incorrect to say that it gives no colour at all; and it would be equally incorrect to say that it always yields a colour reaction. The fact is, there are several kinds of dextrin, two of which give a brown tint with iodine, these are termed erythro-dextrins; and seven others, which give no colour, are termed achroo-dextrins. Mixtures of these with soluble starch give a violet colouration. That a series of such substances has been proved to exist, depends upon their varying power in respect to the rotation of a polarised ray, and to the reduction of solutions of copper oxide.

The change which takes place when starch-paste is altered by malt extract varies with the temperature, but it is always dependent upon an attachment of water to the starch molecule, and a splitting up of the latter into maltose and a kind of dextrin. Three differing proportions of dextrin, accompanied in each case by maltose, have been recognised by Mr. O'Sullivan as the result of such changes of the starch molecule. The first is producible at any temperature below 63° C. = 145° F., the second between 64° — 68° and 70° = 147° — 155° F., the third between 68° and 70° C. = 155° and 158° F. At 70° C. = 158° F., the activity of the transforming agent is destroyed.

In the year 1878, Musculus and Gruber, and in 1879, Brown and Heron (Jour. Chem. Soc., vol. xxxv. p. 653), recognised the formation of a variety of dextrins differing in molecular weight, but otherwise of the same composition. At the same time, the latter chemists confirmed the views previously expressed by O'Sullivan, relative to these modifications being the result of the action of heat on the transforming agent, and not due to the splitting up of the starch molecule previous to its further change. There are three achroo-dextrins varying in optical properties, and in their power of reducing copper oxide solution, and there are at least four well-defined molecular transformations of starch.

1. The most stable form of dextrin, and the best defined transformation, is that which results when malt-extract acted on starch at a temperature not exceeding 60° C. = 140° F.

2. The next point coincides with the disappearance of the iodine reaction for erythrodextrin when starch is heated with malt-extract to 66° C. = 150° F.

3. That is the most strongly marked reaction which is obtained with malt-extract heated to

75° C = 167° F., or when rendered alkaline with carbonate of soda, and heated to 66° C. = 150° F.

4. The highest stable transformation is effected with a very slightly alkaline malt extract heated to 66° C. = 150° F.

Musculus and Gruber, as also Brown and Heron, regard the constitution of soluble starch as that of a polysaccharide, or a molecule built up of a number of saccharose molecules, which became intimately united or connected by the elimination of the elements of water. In accordance with all ascertained facts, the simplest formula representing the molecule of soluble starch must be 10 $(C_{12}\,H_{20}\,O_{10})$.

Adopting the mode of illustration employed in the case of the sugars, we may represent the starch molecule by about three ounces of charcoal and four ounces of water, more strictly speaking, by carbon 1,440 grains, and water 1,800 grains. By placing the water in tubes of the same bore, and cutting the charcoal into pieces with the same sectional area, we see by the different lengths of the water tubes and carbon sticks the different relative sizes of the molecules of starch; the dextrins and sugars, and the reactions ensuing upon the addition of water to the starch molecule, are easily demonstrated to you by placing on the right hand the representatives of starch and water, and on the left those of erythro-dextrin and maltose.

With this view we may regard the varieties of dextrin as derived by successive assimilations of water and the divisions of the molecule into two parts, namely, maltose and a dextrin, thus:—

Soluble starch. Water. Maltose.

(1) $10\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Erythro-dextrin α

$9\,(C_{12}\,H_{20}\,O_{10})$.

Erythro-dextrin α. Water. Maltose.

(2) $9\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Erythro-dextrin β.

$8\,(C_{12}\,H_{20}\,O_{10})$.

Erythro-dextrin β. Water. Maltose.

(3) $8\,C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin α.

$7\,(C_{12}\,H_{20}\,O_{10})$.

(4) $7\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin β.

$6\,(C_{12}\,H_{20}\,O_{10})$.

(5) $6\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin γ.

$5\,(C_{10}\,H_{20}\,O_{10})$.

(6) $5\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin δ.

$4\,(C_{10}\,H_{20}\,O_{10})$.

(7) $4\,(C_{12}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin ε.

$3\,(C_{10}\,H_{20}\,O_{10})$.

(8) $3\,(C_{10}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin ζ.

$2\,(C_{10}\,H_{20}\,O_{10})$.

(9) $2\,(C_{10}\,H_{20}\,O_{10}) + H_2\,O = C_{12}\,H_{22}\,O_{11} +$

Achroo-dextrin η.

$C_{10}\,H_{20}\,O_{10}$.

Maltose.

(10) $C_{10}\,H_{20}\,O_{10} + H_2\,O = C_{12}\,H_{22}\,O_{11}$

Unmistakeable evidence has been obtained by Messrs. Brown and Heron of the transformations effected in equations (2), (3), (4), and (8); with less certainty experimental evidence of equations (5) and (6) has been obtained. The most soluble form of dextrin is that which results from equation (8).

Maltose is the only sugar produced by the prolonged action of malt-extract on soluble starch.

According to the researches of Baszwiz ("Zeitschrift für Spiritusindustrie," 1879, p. 321), the most advantageous temperature for mashing for distillation is 112° F., the yield of sugar being the greatest in the shortest period of time. The influence of temperatures somewhat higher than this can be illustrated by the following figures:—

	Temperature of mash rising to		
	140° F.		149° F.
Yield of maltose, per cent.	80·9	..	41·3
,, dextrin ,,	19·1	..	58·7
	100·0	..	100·0

Below 140° nearly double as much sugar is produced as between 140° and 149°.

Hitherto, the temperature employed (149°) has been too high, though in the production of sweet wort for brewing this temperature may be suitable because complete saccharification is not desirable. These conclusions are in accordance with the facts demonstrated by Brown and Heron, that at 122° F. the proportion of albumenoids coagulated in malt-extract was 19 per cent.; at 140° F., 53·5 per cent.; at 150° F., 67·4 per cent.; and at 169° F., 80·8 per cent.; while at 176° to 178° F., all albumenoids are precipitated. We thus see that in the mashing of grain the process consists of (1) the preparation of a solution of starch paste, (2) the saccharification of the starch by the addition of malt. In the first operation any convenient temperature may be employed, but in the second, as low a temperature as 112° F. is that most favourable.

CONFERENCE ON WATER SUPPLY.

The following is a report of the discussion on the papers read at the Conference of the Society of Arts on the Water Supply, held at the International Health Exhibition on Friday, July 25th. Sir FREDERICK ABEL, C.B., F.R.S., in the chair:—

The CHAIRMAN, in commencing the proceedings, said the outcome of the previous day's discussion showed that there was agreement, at any rate, on some important points. All agreed that the water supply was derived from rainfall, though perhaps, with the exception of Mr. Jabez Hogg, who spoke of the illimitable supplies stored in the chalk. The importance of the systematic observations introduced by Mr. Symons, and the value of the data derived from those observations as indicating the relative abundance or scarcity of the supply of water in different districts, and their relation to the population of the districts, were also unanimously recognised. In connection with this matter very useful information had been supplied by Mr. Topley, Mr. De Rance, and Mr. Whitaker, and the maps prepared by the latter gentleman promised to be extremely valuable. There could be no doubt that a combination of careful hydrogeological surveys, with a study of rainfall observations throughout the country, would serve to enlarge our knowledge with regard to the conditions to be fulfilled for securing an efficient water supply to different parts of the kingdom. It was only natural that the discussion with regard to the sources of supply should gravitate towards the larger towns, and more especially towards the supply of water to London, which had been of late a question of such serious controversy. Mr. Bailey Denton, however, in his interesting communication, had referred more especially to the supply of rural districts or small communities; and it might be hoped that the disinclination of local authorities, to which he referred as having stood in the way of progress, was rapidly disappearing. There could be no question that the country generally was now thoroughly alive to the necessity for obtaining for all communities, large or small, as pure a supply as could be obtained. In connection with this subject, Mr. Denton gave interesting information with regard to the application of tube wells; he might say that in connection with military matters he had had considerable experience of the usefulness of such wells, and so long as it was not necessary to apply power in connection with them, and a moderate supply only was required, their use would be attended with very considerable advantage. With regard to large towns, there was also a consensus of opinion to the effect that in order to ensure as pure a supply of water as possible, it should, if practicable, be obtained at its source, rather than after it had been more or less polluted by passing along streams and receiving surface drainage or still more objectional matters in its course. With the exception of Mr. Hogg, he also thought they were all impressed also with the fact that the necessity not only for having water pure, but for keeping it until used in a perfectly pure condition, gave rise to a wide spread objection to intermittent supply, and to the consequent necessity of having tanks in houses, in which the water inevitably became more or less polluted. It was somewhat remarkable that Mr. Hogg, in his search for the minute animalcules on which he based such important conclusions, should have entirely overlooked the grosser impurities which everyone else found in the cisterns. With regard to the supply from wells, Mr. Baldwin Latham had directed attention to two or three important points; for instance, to the necessity, in estimating the quantity to be derived from such a source, for ascertaining what was likely to be the minimum supply from those wells, and regulating the number of wells accordingly. There was no question that this might be a matter of considerable difficulty for water engineers to meet. He had also directed attention to an incidental point, which, as he (the Chairman) had pointed out, the Conference could hardly deal with, but which it was impossible to keep entirely out of sight, viz., the influence of wells in reducing the supply of water to streams in their neighbourhood, and the consequent questions of property which would arise. Upon the question whether the water supply should be taken from rivers or wells, there were great differences of opinion. Some believed that, although it would be most desirable to have water absolutely pure, yet there were considerations weighing somewhat strongly in favour of obtaining water from convenient streams, as high up the source as practicable, and to apply, in connection with such supply, the most efficient means of mechanical, and, if possible, chemical purification. Others took a somewhat poetical view with regard to the supply from deep wells, and utterly ignored the possibility of any contamination of such water, and seemed to think that you had only to sink any number of wells as close together as they could be placed conveniently, to obtain any amount of water to supply a town of any size. Those were points upon which differences of opinion would always exist until the matter was put to a practical test on a large scale. Again, many, in referring to the hardness of the water, said that companies had no business to give hard water; that they had only to adopt a softening process, which costs little or nothing; and that if a water company were allowed to supply water they should only supply it in the softest condition in which it could practically be produced.

Of course that was a very natural demand from the point of view of the consumer, but it remained to be seen how, if they drew water from deep wells for the supply of London, a softening process could be carried out on the gigantic scale which would then be necessary. With regard to that point, they looked forward to have some valuable information given them by Mr. Homersham and also by Mr. Baldwin Latham.

Papers were then read by S. C. Homersham, Baldwin Latham, H. C. Sorby, W. Anderson, and Prof. Odling.

Mr. W. S. MITCHELL, wished to make a remark or two with reference to Mr. Sorby's paper. The difficulty had always been to get small spores in such a form that they could be seen, but a plan had now been adopted to cultivate these spores, and in the Exhibition there were two methods shown of doing this. One at No. 193 in the Central Avenue, exhibited by Messrs. Nicholson and Mr. Carpenter, and the other in the Physiological Laboratory, where Dr. Koch's method was exhibited, which consisted of cultivation in a gelatine mixture, a kind of solid soup, and that was under the charge of Mr. Watson Cheyne. A plate of glass was taken on which some of this mixture was spread; on this a single drop of water was placed, which was then covered with glass, so that no matter from the air could reach the surface, and then the spores were allowed to grow. Some could now be seen which had been growing for fifteen or sixteen days. This method had been carried out, he understood, in Berlin for two years, but this was the first time it had been shown in this country.

Mr. JABEZ HOGG wished to say, in reference to certain remarks which had fallen from the Chairman, that he had no intention of defending the conditions of London cisterns in general, and that his remarks of yesterday applied strictly to well-covered house cisterns; he had always acknowledged that pollution must take place in uncovered tanks. He might add that in the evidence he gave at the Kingston inquiry, he stated that the small fish and eels, and other unwholesome things found in some cisterns, could not have spontaneously bred there. With regard to the paper just read, he should have been glad indeed if he could say he agreed with Dr. Odling's conclusions. The meeting, however, would have been in a much better position to discuss his conclusions if they had been put in print, and he was sorry that this had not been done, as they were in fact the most important part of the paper. He was so far in accord with him that purity, as expressed by chemists, had a very different meaning to that attached to it by the public, and he hoped Dr. Odling would, in future, say that they must not take the purity of the water, as he set it forth in his reports, to mean absolute purity and freedom from unwholesome conditions, that is from organic germs, freedom from what medical men knew to be deleterious to human life. Dr. Odling had said that the pure water of the Kent Company contained more organic matter than the water of the Thames; this appeared to be a fiction—a chemical fiction; and Professor Frankland, who originated the previous sewage contamination theory, now put it aside, and told them it had no value whatever; in fact it had so little value, that it merely expressed something that chemists understood, and the public did not. The public were not in a fair condition to say what the chemist meant, but they know what they wanted, they wanted water perfectly free from all organic impurities, and if they got that, they cared little whether it was one grain or a dozen grains of mineral matter to a gallon. The one grain, however, which some chemists despised was more than sufficient if it contained a specific germ, as that of typhoid fever or cholera, to poison a whole town of 40,000 inhabitants. What more did chemists require in the way of impurity? Chemists could tell us of the impurity of water; but they could not assure us of purity and safety. Chemistry could not detect the millionth, or trillionth, part of a grain of deadly organic matter in a gallon of water. That being so, it showed that chemists could only very imperfectly perform the duties undertaken by them; they could not protect the public health, as they had sometimes been led to assert. Dr. Odling had referred to the Registrar-General's reports of June; but he had in his hand later reports, those of July also issued from Somerset-house, and with regard to three or four towns supplied with deep well water, he noticed that Brighton had a death-rate of 13·9 to the 1,000; Hull 19 to the 1,000; Portsmouth 14·1 to the 1,000; whilst London had 24 to the 1,000. That showed that there was a considerable difference in the death-rate of towns supplied with pure and wholesome water, such as he held deep well water to be. In London with the rise in temperature, during the month of July, there was a corresponding rise in the deaths from diarrhœa and dysentery; there were 39 in the first week, then 104 in the next, and 336 in the succeeding week. In the next month they rose again to 533, exceeding the corrected average by 242—435 were of infants under one year of age, and 78 of children between 1 to 5. There was usually a considerable difference in the death-rate whenever the temperature of water ranged above 60 degrees, then it was that the danger of an impure drinking water was greater. He had placed on the table two specimens of deep well water from Canterbury, one taken before being submitted to a softening process, the other after it had been softened by Clark's process. The deposit thrown down he had examined under the microscope, and could find no trace of organic matter, not even a diatomaceous body, which he expected to find under a high power.

Mr. EDWIN CHADWICK, C.B., said the chemical tests for water omitted altogether what was called the biological, or stomach test, of which he might give a remarkable instance—that was that there was a change in the supply of water to the Millbank Prison from the Thames, which had formerly been used, to that of the well at Trafalgar-square, and there was a return by the medical officer of the prison, in which he showed the difference produced in the population by this change. The evidence of the benefit resulting from the change was perfectly overwhelming. In Glasgow, Aberdeen, and Manchester, all the water was found to produce dyspepsia, which chemists did not detect or take account of, but it was perfectly decisive as to the quality of water, especially during particular portions of the year. He thought it would be well if the investigation as to the sanitary results were pursued by asking the officers of prisons to note the difference produced in the health of the prisoners by a change of water; those who have been for a time in a hard-water district, and those who were in a soft-water district, and he had no doubt that results would be obtained similar to those recorded in the instance he had referred to at Millbank, and which were utterly unnoticed by any chemist at present. Again, the Chairman would know very well how the quality of water depended on its aëration. At Pangbourne you might take up water, and find it quite brilliant, showing evidence of good quality, but when that same water was taken to London, and put into a cistern where it came in contact with the air of the cistern, you were really drinking down air with all the impurities which were likely to arise. In going into overcrowded rooms, or low neighbourhoods, medical officers would tell you that in washing, after an operation, their fingers quite smelt of the water they obtained there. He recollected on one occasion, when making an inspection in Rotherhithe, the medical officer cautioned him against taking any water there, for it would be dangerous, because the water beds were situated close by the cesspools and absorbed the cesspool air. Some years ago, he asked Dr. Hofmann if he could analyse a London fog, which carried disease with it; but he could only separate the dust and dirt, and he failed to analyse them. Again, with respect to the paper which spoke of the protection of rivers by the action of plants, he would point out the immense difference between fresh sewage and that which was putrid. When the houses of a town were drained, or water-closetted, so that the sewage discharged fresh, it was noticed that fish returned to the river which they had forsaken. That had been noticed at Carlisle—the fish reappeared, and were finer in quality altogether.

Mr. BISCHOF said it had been a point of the greatest interest to him to learn that spongy iron, after a very few minutes' contact, had such a powerful effect in destroying animal and vegetable life. Mr. Anderson had said that his anticipations at Antwerp were not quite fulfilled, and that was quite true; but he never anticipated the difficulty which had been experienced there. To deal with a small tidal river contaminated with all kinds of polluting matter, and to convert such water into a potable water, every one would admit was a matter of the greatest difficulty. However, the plan introduced by him had been styled a "complete success" by the chairman of the Antwerp Waterworks Company, at the last general meeting. Dr. Odling had been speaking under great difficulties as regards time, no doubt; but to him, as a chemist, it would have been of much interest if he could have given some hint as to how he arrived at the statement that organic matter in water might be said roughly to contain 40 per cent. of organic carbon. As a chemist, he could scarcely conceive that there should not be an enormous difference in different organic matter, because some water was contaminated largely—in fact, almost exclusively—by animal, and other water by vegetable matter, and they all knew that animal and vegetable matter differed very greatly in the proportion of carbon they contained. He wished to refer to only one more point. He had in his hand the return of the Registrar-General for July 20th, 1878, which stated:—"The weekly deaths from diarrhœa and simple cholera, which had been 23, rose to 78, 156, 256, and 349 in the corresponding weeks. The deaths from diarrhœa are differently distributed in the fields of the water companies. Thus, the deaths in the last four weeks were 786 in the districts supplied with the Thames and Lea waters, whereas the deaths in the districts supplied with water drawn from the chalk by the Kent Company were 19; but of the same population, the deaths in the former were to the deaths in the latter as 3 to 1." As there might be a visitation of cholera this autumn, and as they all agreed that diarrhœa and simple cholera, although totally distinct from Asiatic cholera, would still predispose to it, this was a point of very great interest, and he should be glad if Dr. Odling, or any one else, would express an opinion whether these figures which he had just read did not throw an important light on the relative wholesomeness of the different supplies of water to the metropolis.

Dr. BARTLETT said, one observation made by Dr. Odling very naturally led up to the few words he had to say. He stated that certain water, when thoroughly filtered, would then be good enough, and pure enough, for all potable purposes; another leading observation was made in Mr. Anderson's paper, namely, that by mixing iron in a very finely powdered state with water, a far greater efficacy was obtained than can be in the ordinary way, by passing it through coarse filter beds or compressed blocks of porous iron or other filtering substances. He so far cordially agreed with that statement that it formed the very pith of what he wished to say. At the present time the question of filtration, whether in the water companies' sand-beds, or in the domestic filters which persons now used for the purpose of correcting any omissions on the part of the companies, was highly prominent. One section of the public appeared to rely entirely on this process, and another semi-scientific section were apt to place no reliance whatever on it. It had been stated, over and over again, that filtration could not remove matters in solution, but only those in suspension; but to that statement he took objection, because during the last ten or fifteen years, in the process of testing a great number of filters—in fact, almost every kind which was presented to the public—he had found, that to a lesser or greater degree, nitrogenous matters in solution were removed. The manufacture of filters, and the scientific application of filtering media, had improved, but although he said this with great confidence that there were filters which would remove nine-tenths of the nitrogenous matters in solution, still, he was equally certain that nine-tenths of the filters before the public were perfectly worthless, because with the tenth part of nitrogenous matter which was not removed there was that amount of unfiltered water passing through into the storage receptacle. Now, if the tenth which passed through contained any of the germs of disease, or communicable matter of disease, whether germs or not, that would be equally as fatal to the drinkers as if it were entirely unfiltered water. He had been led to this train of reasoning more particularly because during the last six or eight months he had been testing filters which removed nine-tenths of the decomposable organic matter; and the other tenth would have been removed had the filters been mechanically perfect. He had been making experiments on a very fine precipitate, sulphate of barium, and found that that freely passed through many of the filters, and therefore it became obvious that matters which were very much smaller than that would equally pass through. He then went on with salts of uranium, a still finer precipitate, and found they almost invariably went through. Then it occurred to him it would be well to try if he could not stop this. Both these salts were white, and, therefore, were perfectly visible to the naked eye, or, in the finer particles, under the microscope. He tried to stop it by using finely powdered carbon, animal, vegetable, and mineral. The result was that he found that with carbon of all three kinds, when reduced to much finer particles, they also came through the greater part of the filters he tested with it. This was most important, because anyone could go home and make similar experiments for himself. In working this out, he found after having used a considerable amount of very fine carbon, he had stopped very nearly the whole of that one-tenth of decomposible matter, and in fact he had decomposed the greater part of that tenth. Knowing the oxydising influence of spongy platinum, he went one step further, and used platinum black. Of course he would not recommend this as being suitable for ordinary filtering purposes, because of its expense, and there might be other objections also; but it did absolutely oxydise and remove every trace of decomposing nitrogenous matter. That being the case, it was certain that perfect filtration could be obtained. Following this up, he had tried carbon in the finest divided state, so fine that he found by the microscope the particles were finer than the markings on a diatom, for under a 50th power he could not measure them, although he could measure the markings of diatoms. Carbon, therefore, could be obtained, if necessary, in so fine a form of sub-division that an immense amount of oxydising power was thereby obtained. It might be said, how were you going to filter water through that extremely finely divided carbon. He thought possibly that cotton wool, which obstructed all germinal matter passing through, as was shewn in the well-known experiments of Professor Tyndall and M. Pasteur, was a means to the end, but soon afterwards he found that cotton wool decomposed in water, and therefore that upset the experiment. He therefore tried two other media, one a peculiar kind of slag wool, and the other asbestos fibre, both of those retained the finest particles of charcoal, and formed a perfect filtering medium as far as developing the oxydising property of finely divided carbon was concerned. Having obtained this result, he must add that he was not aware of any filter now before the public which had no decomposing matter in its construction. The introduction of the cork caused decomposing matter to be mixed with the water, and under the microscope large quantities of moving organisms were to be found in the decomposing matter of the cork itself. The same thing, in a lesser degree, occurred with india-rubber, and, therefore, he laid it down as a fundamental axiom in filter-making that no decomposing matter of any kind should enter into its construction. Further than that, the filtering media should neither pass the finest possible charcoal, nor should they be choked up by it. These two points formed the most important tests he had to bring forward. If they fell back on the old plan of testing filters which he had been in the habit of using for twenty years, they would be misled as to the mechanical deficiences of which he had spoken of, for it was no use whether one adopted Dr. Frankland's process for the analysis of water, or the estimation of ammonia, to suppose that because you were able to oxydise three-quarters, or even nine-tenths of the decomposible nitrogenous matter, that the filter itself was therefore of any value. If this were recognised, and people would make the experiment for themselves, he believed better filters would be produced, as purchasers would be able to test the filters by these means. There would be at last a possibility of arresting much of that which was injurious to health; and it was not impossible that they might prevent even the smallest germs, which must be of some size, passing through the very fine medium he had suggested.

Mr. THOMAS SPENCER said they had heard a great deal of the necessity of softening water, and a great many processes for effecting that purpose had been mentioned, but they had heard nothing as to the physiological difference to the animal system of very hard water and very soft water. For forty years he had been going through most of the towns in England, and he could never get that question answered—what was the physiological effect on the system of hard water, as hard as that supplied by the Thames, as compared with soft. He might say that he knew most of the water supplies of the world, and he did not know of a better supply anywhere than that which came from the Thames when properly filtered; he did not mean by any chemical means, but when well filtered mechanically. He had constructed waterworks at Calcutta, and knew many of those on the Continent, and if the Thames water were well filtered, it would be one of the best water supplies to any large town in the kingdom. When he put that question he never got a reply, but was told he did not require any explanation—that salts of lime and magnesia were not desirable. Two years ago, he suggested to the authorities of a town with which he was connected, that to settle this question it would be well to get accounts from the authorities of the different towns, and ascertain where the death-rate was highest – whether in towns having a soft water supply, or hard water. That report had now been returned, and no doubt would be in print before long, when it would be found that the death-rate was larger where soft water was used, and this to a much greater extent than he had anticipated. He must say also that he began as a soft water fanatic, but there was no doubt that one reason why soft water was so much recommended was that in many of the towns in the north, calico-printing, and similar works were very numerous, and as soft water was much better for such operations, people naturally supposed that similar water was better for domestic purposes.

Mr. MAIGNEN said he had hoped some paper would have been read on the subject of filtration as a whole. They heard a good deal of how water was contaminated in a very astonishing way, but how to get over the difficulty they had heard very little. He could not attempt to do justice to the matter in the very few minutes he had at his disposal; but what he had to draw attention to was this, that on Thursday last he was in the laboratory of M. Pasteur in Paris, who asked him "how will your filter last?" Now this was a subject worthy a whole day's discussion. The first necessity of filtration was that, when impurities had been collected in the filtering material, it could be easily removed, and thrown away and replaced. Dr. Bartlett had knocked the nail on the head by drawing attention to a very important fact. If a microbe had a body, it was just possible to conceive an impediment, or a series of impedimenta, fine enough to prevent it passing through. Dr. Bartlett told them that he had used charcoal the particles of which were smaller than the smallest known diatom, and if these particles did not come through a particular form of filter, it was conclusive that the diatom itself could not pass through. He echoed the statement made by one of the speakers, that if the London Thames water were properly filtered, it would be the best in the world, and he had reason to hope that this would soon be attained by means of the apparatus shown on the wall.

Dr. HAUGHTON said a great deal had been said in favour of the water they were obliged to drink in London, there being no option as to the source from which it was obtained; and he wished he could heartily endorse all that had been said in its favour, because it was unpleasant to have a bad opinion of that which one had to deal with continually. He listened to Dr. Odling's paper with great admiration until he came to the last sentence; but they were not told there whether his estimate of the London water as compared with the supplies of other towns was founded on its present condition, or on some former period, or on a fair average. He had in his hand an extract referring to the condition of things at the time of the epidemic of 1830; but it was written twenty years later, and those periods were not referred to with reference to the microscopical analyses and examination of the water. It stated that at this time there was hardly a water company in London the water of which did not reveal to the microscope solid particles of sewage floating about in the company of small weeds and sponges, and fine fat pulpy animalcules. At an interval of twenty years there was the same condition; and it was obvious that when such things had happened they might happen again, especially when eels and fish were found in reservoirs where they were not bred. It was not at all infrequent in disputed cases in the Law Courts for chemists to give evidence with regard to the supposed condition of streams; when one would state that the water was dirty, and another would say it was beautiful, and both had made analyses, and both were men of science. With regard to the basis on which this statement with regard to London water was founded, it appeared, so far as he could make out, that the ground upon which Dr. Odling claimed this wonderful excellence was the very ground which, in the earlier part of the paper, he said it was totally inapplicable to put before the general public. For if he only got the chemist's estimate of the amount of organic matter, and that was put forth to the general public as a test for the quality of the water in order to re-assure the said public that the water they were drinking was beautiful, they found Dr. Odling himself saying that it was not a reliable test. Yet at the end of the paper he said London water was very superior because of this very thing, for he brought no other evidence. That appeared to his mind very unsatisfactory, speaking not as a medical man, but as one of the long suffering public who had to drink water which had been testified to be contaminated, not far from the intake of the companies, with organic matter of the foulest description. It was true those cases were not very flagrant, except at particular periods, but they wanted a guarantee that they should not occur at all. What was the use of talking about filters, and telling the public the water was unfit to drink unless it were filtered. It was the grossest cruelty to the poor. They could not buy filters, and even if they were distributed gratuitously, there was not one family in ten who would take care of them, so as to see them renewed. You might filter out the cats and dogs, and the grosser particles of matter; but the better the filter the sooner it became filled with germs, and every kind of contamination. It was the very nature of a filter to become filled with foulness, to breed microbes, to become itself a source for contaminating the water, if it were not renewed within a reasonable time. The gentlemen who spoke so much in favour of filtration had an idea, which was good in itself, that the filtering medium should be so arranged as that it could be renewed; but to say that the general public were to depend on any kind of filter, patent or not, was stark nonsense. This evil was not imaginary, for it was given in evidence before the Metropolitan Medical Commission in 1830, that whenever water was contaminated so as to be nauseous, diarrhœa was invariably prevalent, and affected the health of every person drinking it. He did not want to increase the cholera scare, but he hoped to utilise it, by demanding of the authorities that no money should be spared to give a good supply of water, which should be available for every house in the city, without putting a single inhabitant to the expense of a filter.

Dr. ODLING, in reply, said he had been invited to read a paper on the chemistry of water, and had, therefore, confined himself mainly to chemistry; and for this under the circumstances he did not think he was to blame. At the same time he might say that for many years he was a medical officer of health, and had since attended to hygienic studies, and he came prepared to speak not only as a chemist, but also as a physician and hygeist. As regarded the general question, the influence of the presence of organic matter in water must depend, not on its quantity, but its nature. And any comparisons put forward with regard to quantity, irrespective of nature, fell to the ground altogether. Had there been sufficient time, it was his intention to discuss the question of quality as he had the question of quantity; and he had notes ready for the purpose, but time did not allow of their use. Any general statement, and any conclusion he had formed or expressed, with regard to quality, was formed on a consideration of evidence, and was gone into by him as minutely as he had gone into the question of the influence of quantity. The gist of the whole question in the present state of knowledge seemed to rest on an observation of effects. Of course if you took one week and compared it with another, or one town with another for a short period, you might arrive at almost any result you pleased; but if you took large populations, and examined the statistics for lengthened periods, it would be found that there was absolutely no difference whatever in the health of the population which could be ascribed to the drinking of river water, lake water, or spring water; from which it would seem all these different varieties were, in their different ways, well suited for the supply of large populations.

Papers were here read by Joseph Quick, jun., J. H. Greathead, Col. Sir Francis Bolton, and H. J. Marten.

Mr. T. SUFFIELD wished to enforce the recommendation often made by Sir Francis Bolton, as to the arrangement of overflow pipes of cisterns. The ends of such pipes should discharge into the open air, or into a rain-water pipe unconnected with the drains. He thought it would be well for water companies to make an arrangement with plumbers, and offer small rewards to their workmen, for the discovery and prevention of waste of water. The fittings of cisterns were frequently defective, the ball-cocks being badly made and badly fitted. He objected to the removal of standing waste pipes; he thought that the upper ends of such pipes should be closed, and then, by lifting them out, the means was provided for cleaning out the cistern. The drains should be more frequently flushed, with a view to the removal of the causes of the stoppages. He laid great stress on the importance of a constant supply.

Mr. E. K. BURSTAL desired to say a few words with regard to the use of the waste water meter. He would not cry down the use of that most useful apparatus which Mr. Deacon had invented, but he was quite certain that useful results could be obtained without that instrument. He had known himself, in two towns, that inspectors had to be sent round because that instrument merely showed that there was a waste, and they then had to send inspectors round to see where the waste was. He maintained that the use of that expensive contrivance might be dispensed with, and they might, by sending inspectors round with sounding rods and the necessary appliances, find out where the waste was, and check it, without using that apparatus. He might be thought old-fashioned in saying so, but he believed that to be the case. With regard to the cisterns which were generally in use for the supply of closets, he was much disappointed when he looked upon the exhibits of the London Water Companies in the Exhibition, and found the assortment of curiosities they had brought together. They had brought forward vacuum systems, and every sort of automatic system imaginable, but there was not one single instance of the double valve system, which had been introduced by Mr. Aris, some of which were now in use in Yarmouth, Lowestoft, Norwich, Derby, Leicester, and Oxford, and in all the towns noted for having a model consumption of water. In the towns of which he was managing engineer, they did not allow this automatic apparatus to be used, because they found they were waste-producers, not waste-preventers. In fact, to shew how imperfect they were, one of the syphon systems could be set to run continuously, and that was a system which one of the London Water Companies was recommending for use. He really thought that, instead of introducing these patents to the public—and the public were consequently getting rather puzzled to know what to use—they should adopt such a plain double valve system as was placed before them, so that they could not both open at the same time. The advantage of a cistern upon that principle was that they would have for, say, a fourth or a fifth flushing, eight or ten gallons in reserve, and assuming a constant supply, if the water happened to be turned off for half an-hour during the day, they would still have a reserve in the cistern, and that would render the use of large 100 gallons or so cisterns unnecessary. They would then only have to put their taps on their rising service, and they would not want any cisterns at the tops of the houses at all. That could be done at very little cost in provincial towns, and it could also be done in London. The remedy for the difficulty rested with the ratepayers, but the class of ratepayers who were the owners of small properties were the great obstructives. With regard to the water supply for fire extinction, the size of the service mains had not been taken into consideration for that purpose. It had been provided in all the local legislation that proper water mains should be laid down, and very few mains of less than 4 inches in diameter had been laid down since 1847; therefore, it was not right to say that provision had not been made for protection against fire; $1\frac{1}{2}$ inch mains were sufficient for domestic purposes, but they wanted 4 or 6-inch mains for an efficient fire supply. Mains of that size had been laid in the town with which he had been connected from 1849 down to 1855. With regard to the dual system, they knew it was impossible to construct a service upon a principle of that kind. If one tap was placed beside the other, no one could ever tell which tap to go to, and the expense was a very strong reason against its adoption; and if what they had heard with regard to the quality of the water from the alarmists was true, which he, however, did not think was the case, it would not be a proper thing to put in the power of servants to give them contaminated water from the tap on the right hand sink when they were supposed to give them pure water from the tap on the left.

Mr. CHADWICK would say a few words with regard to the paper on fire prevention. In Liverpool, where a great deal of incendiarism prevailed, the chief magistrate came to ask his advice as to what they should do in the way of prevention, and he suggested that they ought to put the water on the constant system, hydrant the streets, and place the keys of the hydrants in the hands of the police, so that on the occurrence of a fire, there might be no loss of time, no running to distant stations, as the men would be able to apply it at once. That system had been adopted also in Manchester, Glasgow, and in other places. A Committee of the House of Commons had also sat upon the subject, and it was shown that the effect of the adoption of that system was that they could bring the water to bear in about three minutes on the average; whereas, by sending for a distant fire brigade, however well organised, it was twenty or twenty-five minutes before they arrived at the fire. They afterwards improved their organisation, and brought the time down to fifteen minutes, but Mr. Braithwaite, the late Chief of the Fire Brigade, stated, that for the efficient protection of life and property, you must have the assistance within five minutes, and this system brought it within three minutes. What had been the authenticated experience of its employment? Why, it had reduced the insurance risks in Manchester, Liverpool, and Glasgow, where this system was carried into effect, by fully two-thirds, or rather more, and the loss of life had been reduced in the same proportion. The Board of Works had raised objections to putting the keys of the hydrants in the hands of the police. There were 4,000 men always on duty, patrolling the streets at night, but they objected to their having them, and said they must keep the control to themselves. It appeared that in the mere greed of power, which had not hitherto been withstood, they would keep everything in a condition of insecurity to the public, by keeping the keys out of the hands of the police, who could act immediately upon receiving information of a fire, and that in the face of the experience as to the saving of two-thirds of the losses by fire! There were double as many police-stations as there could be fire brigade stations, and he could not imagine how anybody could insist upon their separation for this purpose, at the expense of an enormously great destruction of life and property by fire. That system should also be applied in the theatres; the police had to be there for ensuring order, and they ought to have charge of all waterworks and appliances for the immediate extinction of fire. The most scandalous thing he knew was the ignorance of members of Parliament, who could go on acquiescing with the maintenance of the present system in the face of such facts. As to the dual principle of water supply, if they had any *recherché* system as to quality and quantity of water that was applicable, they might have a separate dual system, but they had heard that the result of softening the water, and bringing in soft water for consumption by a separate system, was that water would be brought in for washing and ablutionary purposes and for baths—for everything in fact which would be benefited by the introduction of soft water—yet in fact, though the benefit would be great, it was obvious enough that the streets could be washed with common water; and, on the whole, he had expressed the opinion that the separation was not worth while, and to that opinion he still adhered. In one district, where an inspector was sent to examine the effects of drinking the Thames water from a place highly polluted with sewage, the people laughed at the idea that they drank water; in fact they drank beer, and beer generally was drunk by the whole of the wage-earning classes. Such was their dread of drinking the water in one case, that when he went to look at a place in London where the finest water was delivered, viz., the Kent water, he was warned against drinking the water on account of the gases from cesspools making it a source of great danger. The reasoning was that the death-rate there, where they had the purest water of all, viz., the Kent spring supply, was higher than it was in other places, and the deduction from that was that the water was positively unwholesome. But it proved to be nothing of the kind, for the people did not drink the water. It was the rarest thing for them to do so; even when a mother went out with her children, she was very careful to provide beer for them, for fear of the danger from drinking the water.

Mr. JABEZ HOGG said it was very evident children did drink the water, and no doubt to that fact was due the increase in the death-rate among the infant population. With regard to the arrangement of the filter-beds shown in the building, no two of them were alike—no two water companies adopted the same size and proportion of filtering materials; some gave six or eight inches of sand for a surface layer, and others gave four or five. There was no uniformity in the arrangements for filtering water, and that showed that filtration was of far less importance than it was generally supposed to be. The water companies evidently felt that it was a matter of very slight importance whether they gave a filter bed of six or eight inches of sand or four or five feet. One of the readers of a paper had remarked upon the companies compelling people to remove their waste pipes; he should like to ask practical engineers a question upon that point. Water companies were not agreed as to the use of the waste pipes. Some years ago, he removed his own waste pipe, which went into the sewer pipe, and converted it into a surface overflow pipe. Two years ago, the New River Company sent him a compulsory order to remove this pipe, and put in another overflow pipe at the top of the cistern. He had to alter all his fittings at considerable expense, and at the end of two or three weeks he found the effect of the overflow pipe was to inundate his house, for on a fire breaking out in the neighbourhood, during the night, the cistern overflowed, and the water came down the staircases and spoiled his carpets. He expected to get nothing from the water company in the shape of compensation for the damage done by the overflow; nor for the great damage done to the basement by the damp. But for the company insisting upon the removal of old pipes, which had been working efficiently in his house for some years, the damage referred to would not have happened, and the only excuse for removal was that the company was going to give him a constant supply of water; two years had elapsed and the constant supply was still promised. A fifteen minutes' supply at 11 o'clock, and no other supply for the day, unless a fire happened in the neighbourhood, when the water was turned on again, and he was liable to an overflow, unless great care was exercised in the examination of ball-cocks. Then there were, again, dead ends of streets, and dead ends of the companies pipes, which greatly polluted our water cisterns, and as one gentlemen had stated, when these got emptied, they occasioned a semi-putrescent rush of waters into the sewers, or into house cisterns.

Mr. CHADWICK said there was one point he would mention with regard to waste prevention. In Manchester they had got it down to 17 gallons a head, and in other cases the same thing had been done. But these were cases were the water belonged to the Corporation, and it was the officer of the Corporation who went in to examine, and not of any trading company. That difference was the great reason for the failure of any attempt towards the reduction of waste in London. If things were done there as in Manchester, Liverpool, and other towns, he had no doubt that waste in the metropolis might be reduced even more than was anticipated. They anticipated a reduction of one-third in the waste, and if the matter were under a public authority, who ought to have the control of the whole apparatus, not merely of the mains at the doors, but the capil laried works within the houses, that reduction could be effected, but until they were placed on a public footing there would be no economy secured.

Mr. WALKER had intended to confine his remarks to the subject of waste, but he wished to answer one or two remarks of the previous speakers. A remark had been made about the warning pipes. They were led to infer, because there was no flow from the warning pipe, it indicated a want of supply. As a waterworks manager, he would say it indicated that the fittings were in good order. At the same time it was not necessary for works to belong to a company to have efficient supervision; and to show how these matters were looked after by a corporation, he would read part of Rule 16 of the Reading Corporation Waterworks regulations. "Every cistern shall be provided with an efficient ball-valve and warning pipe, and shall be fixed in such a position as to be easy of access for inspection." If warning pipes were fixed in such a position that when there was an overflow, or when they indicated that some of the fittings were out of order, and caused damage to the property of the consumer, he would say that the company's officers were to blame for allowing the warning pipes to be fixed in such a position that they would, by overflowing, destroy any property of the consumer. Then, again, with regard to filtered water, the supply with which he had to deal came from a river. He had tried several experiments with reference to filtration, and he had found that filtration took place almost at the surface of the sand. If they had a bed of sand two feet in thickness, they would find, after a few weeks' use, if they let the filter dry, they could lift the film off as if they were drawing a piece of damp paper off a table. He would not say that the thickness of sand should be reduced to a few inches or under two feet, but through even two feet of sand sometimes they would find living things in the mains. Perhaps a consumer would come and make a complaint about finding a fish or an eel in his supply, but it did not follow from finding them in the mains that the water was impure. He thought, however, when they found leeches in the water, they were justified in preventing children drinking it. Much had been said in the course of the morning with reference to cisterns, but as the morning had been wholly devoted to reading papers, and the discussion had been left to gentlemen who were well acquainted with the subject of water supply, he had refrained from saying anything. The remedy he thought was to have a constant supply laid on. If they were to take a bottle of river water that had passed through a filter, to all appearance it would be clear and bright; but put a stopper in that bottle, and seal it down, and in a month or so afterwards they would find there was a considerable deposit at the bottom of the bottle, and to all appearance they would say it was very bad or very impure water. Impure water for public use, he would say, was water that fish would not live in; and water that fish would live in was not impure. The conversation where he was sitting during the morning, turned on water supply to houses, and a lady said she had had the cistern in her house cleaned out, and the deposit found in it consisted principally of soot from the tiles, but that did not show that the water was impure. Then with regard to the remark as to water supply for fire extinguishing purposes, the diagram on the wall was an answer to that. A dual supply is not required. A town having a constant supply, and the fire brigade arrangements being under the control of the police, they could, in a few minutes after the alarm was given, fix a standpipe, and begin playing on the fire, and if the pressure was sufficient, they could do much in keeping down a fire before the engines arrived. With reference to waste prevention, he believed the best means of effecting that is to have a thorough code of regulations, and to have those regulations properly carried out. Much had been said with reference to Deacon's meters. There were no doubt a good many waterworks managers present, and other persons who must have received circulars, in which it was stated that managers were exceedingly pleased with the efficiency of Mr. Deacon's invention. One gentleman had stated that previously to the introduction of that apparatus there was a waste of 80,000 gallons a day going on in one district. He should think if there was a waste existing in any town of 80,000 gallons a day, it showed ignorance on the part of the engineer or the Board of Directors, and that there must have been great neglect. In reference to that subject, he would read a return with regard to the town he was connected with, viz., Reading, which stated that in 1874, the nett consumption was 47·71 per head per day; in 1876, with an increase of population and an increase of services, it was reduced to 30·24 gross, or a nett consumption of 16·99. But the circumstances which affected one town would not apply to another; some towns had a much larger trade supply than others, and they could not, therefore, draw a fair comparison on that account. In 1884, with a population supplied of 52,000, the gross consumption per head during the hot weather was 34·61, and the nett 18·26. This increase was due to the fact that a very great quantity of water was used in Reading for road-making and for new paving works which were now being carried on; and in addition they supplied 130,000 gallons per day to one railway company, also 23,000 gallons for sewer flushing, and in the town there were upwards of 8,430 water-closets. All this was done without waste-preventing meters, and if waste-preventing meters were used, they must increase the cost of management. With all those circulars which were sent, they had not stated anything as to any saving in working expenses, and he considered that to be a very important matter indeed.

Mr. E. K. BURSTAL said he had heard instances of six towns which, under companies' management—although two had recently been transferred to corporations—were the best managed towns in England —Nottingham, Derby, Norwich, Stourport, and Sheffield; and in fact he believed, in two cases, they had been transferred to the corporations because they were so well managed.

Mr. DICKSON said Mr. Burstal had made some observations with regard to the exhibit of the water companies, complimenting them on the admirable collection of curiosities they had shown, but complaining that they had not submitted to the public those apparatus which they considered best adapted to the purposes of the population. He would remind the Conference, however, that when the Commission sat in 1871, the whole weight of evidence tended to show that it was desirable that companies should have the power of inspecting, examining, and approving fittings to be erected in the houses; but, to the surprise of most people who followed the inquiry, the Commissioners, at the end of it, said they felt bound to recommend that no such power should be given, because they feared it would have a depressing effect on inventions and improvements of water apparatus. Consequently, while Manchester had the power of approving the apparatus to be used, the London compaties had no such power, and any kind of water fittings which complied with the standard of ordinary intelligence was deemed to be an efficient apparatus. The magistrates of the metropolis were the authorities to whom this question was relegated, and they were very reluctant to fine persons for having a defective water apparatus, if it could be shown that it would do what would in their opinion be ordinarily expected of some such apparatus. The consequence was that companies, knowing this weakness, were obliged to pass fittings which, if they had proper authority, they would possibly be able to exclude. The companies, therefore, were not in a position to bring before the public any exhibit which they could recommend for adoption, for if they did, there would be an outcry on the part of this or the other inventor that his invention was superior, and the companies would incur a great deal of odium in addition to what they at present experienced. With reference to the question of warning pipes, he would remind Dr. Hogg that the regulation in this respect said that the overflow in connection with drains should be removed within a certain time, or at the option of the consumer should be converted into a warning pipe, and that every warning pipe so connected with the cistern should be placed iu such a position as to be easy of access and inspection by the company's inspector; and he doubted not the reason of the remonstrance of the New River Company to Dr. Hogg on this point was that the pipe which he placed to his cistern, in substitution of the overflow pipe, was not so arranged that it could be seen by the inspector, ortherwise he should not imagine any water company would require a consumer to provide an overflow pipe. In fact, every water company would be glad to see any overflow pipe in the sense of one which took an overflow from a defective valve-cock, done away with. A warning pipe was a very useful thing, if properly placed and connected, as a sanitary convenience, as it introduced fresh air to the surface of the water. With reference to the paper on fire extinction, he thought there was rather too sweeping a condemnation of the London supply, which the writer said was deficient in pressure. It was stated that in London the whole water supply was pumped (see *ante* p. 954), which would very likely be misunderstood; the author was comparing the cities where the supply was by gravitation with other places where it was pumped. In London, as far as the fire supply was concerned, it might be stated to be by gravitation, because the water was pumped into reservoirs, which formed a head for the fire supply, just as much as in other towns where the supply was by gravitation without pumping. Then the writer stated that the average pressure was quite inadequate for fire extinction without the intervention of fire-engines, and again, further on, he said the supply was undeniably deficient. He might appeal to the memory of Mr. Chadwick, who was present at the inquiry referred to, whether the general effect on the mind of the committee was not that the average pressure was quite sufficient for ordinary requirements of the fire brigade. The pressure in any town would scarcely be such as would enable the public authorities to do without engines; in fact, it would be the most injudicious thing for any authority in London to have such a high pressure as to do without engines entirely. He would recommend the author of the paper to inquire of the fire brigade authorities for the results which accrued from the adoption of hydrants in the City of London. He could inform him that at the large fire opposite the General Post-office, there were a set of hydrants provided by firms on their own premises which were found to be of great use, and certain property would inevitably have been destroyed had it not been for those hydrants. Again, with regard to the Kent Company, it was shown before the committee that the pressure throughout the company's district was quite adequate for the purpose of the Fire Brigade if hydrants were provided, but the Metropolitan Board would not provide them until the company said that if they did not they would exercise the power of the Act enabling them to do it themselves, and thereupon they put up a few hydrants which were tried at large fires on the river side, where they were used without the intervention of steam engines, and the Metropolitan Board had since admitted that the pressure was adequate, and they had recently given an order for 200 hydrants to be erected in different parts of the whole district within the metropolitan area.

Mr. Deacon said he had only heard part of the discussion, and none of the papers, and would not have spoken had he not felt it desirable to throw in his experience against the objections which had been raised to cutting off sewer overflows from cisterns or replacing them by warning pipes. He had been instrumental in giving a constant service to a population of 700,000 or 800,000, in one place, and he believed at much less cost per head than had ever before been found sufficient. The quantity supplied was much less than under the previous intermittent service, and the methods he had adopted were now applied to many millions of persons, both here and in America. In Liverpool, the work had necessarily been done with comparatively little alteration of fittings. There were no such powers there as were possessed by some towns, notably Norwich and Manchester, where the corporations or companies had practically unlimited power to require the removal of fittings, and to order any others to be put in. The secret of ultimate success in Liverpool, and in many other places, without oppressive regulations, was the multiplication, by a method often described but not always understood, of the means of detecting actual cases of waste by a given staff of inspectors, and the inclusion of hidden as well as visible waste. Of all methods, that must always be the best which can produce the required result at the least cost, and with the least annoyance to all concerned. Those who still believed in the antiquated method of house-to-house inspection had not tried the more modern method, and were not, therefore, qualified to speak concerning it. The many who had tried it on a large scale were, he believed, unanimous concerning its much higher economy and efficiency. With respect to the difficulty of not getting convictions from magistrates, there was comparatively little necessity for going before the magistrates, when the facility for detecting waste was so greatly increased. Persistent cases of waste were soon brought to bay, when the delinquents found that the trouble and expense to them of attempting to evade the doing of what was reasonably required by the officials was not worth their while incurring. The warning pipe was one of the instruments by which they succeeded, and he was exceedingly surprised to hear it suggested that some form of warning pipe should not be used. There was no doubt whatever that, unless you had some overflow apparatus which either made cistern waste a nuisance to the individual or visible outside to the public, that waste would go on to a very much larger extent than would otherwise be the case. It was not necessary to turn to Liverpool, as they were now discussing matters concerning London. The same thing had been done here. In the Lambeth district the waste had been so far reduced that, where the same methods were applied, the consumption and waste, instead of being between 30 and 40 gallons per head, as formerly, was now down to something between 15 and 16 gallons on constant service. If people had all the water they would take under high pressure and constant service, they had all that it was possible to give them. There should be no desire on the part of the authorities to prevent the use of water, but only to prevent deliberate harmful waste. If this were done, sanitary advantages, as he had elsewhere shown, must inevitably follow, as they had followed in Liverpool and elsewhere.*

Mr. MAXWELL said this question of waste was a very elastic one. They talked about getting the supply to under 20 gallons per head, but in some of the American towns it was up to 60, 80, 100, and 120 gallons. If you had a family of four or five, each of whom had a separate bath in the morning, using 40 to 50 gallons each, that would soon mount up. He was engineer to a town where the waterworks belonged to the corporation, a dead level town. If he were the officer of a private company, it would be his duty, probably, to try and keep down all waste, to have no dribbling taps, and no water running otherwise than for some beneficial purpose; but the health of such a town as Hull depended on the water flowing into the drains, and as they could pay their way very well without being so sparing of water, and as they always had it to spare, he did not set himself so very dead against waste. They did set themselves against it in one way, which he would explain. Inspection was of two sorts; inspectors might go in and threaten and frighten people, but their inspectors did not; they kept all their consumers' valves, and washers, and ball-taps in order, and they found it paid them to do so.

Mr. TARBOTTON, said he wished to say a few words on the general question, and principally with regard to dual supply. In all these public supplies, whether water, gas, or the disposal of sewage, a dual system, as a general principle, was to be condemned. They all knew the practical difficulties which attached to these undertakings, and they also knew how very dangerous it was to allow a double system to be in operation. Of course there were exceptional conditions, and there were towns in Germany, and many other places, where it was perfectly easy to supply two classes of water; but in English towns he hardly knew an exception, except, perhaps, certain parts of the metropolis, where it would be possible and safe to carry out and introduce a double system. They knew what plumbers were in large mansions or institutions, and also what they were in small poor houses, and he was quite satisfied that two supplies ought never to be undertaken in London. The same thing applied to gas. You could supply gas at 12-candle power, or 18 and 20, but it meant duplication of services and mains throughout the whole system, and when you examined the amount of capital which had been expended on gas and water undertakings, it would be found, as a general rule, that the cost of the distributive service was 4-10ths of the whole, and that would have to be multiplied by two if a double system were carried out. With regard to the general question, he believed in the principle of constant high pressure service. They had had a high pressure service at Nottingham for nearly fifty years, without a single intermission, the pressure varying from 40 to 120 lbs. in all parts of the town, the system having been introduced by Mr. Hawksley. With regard to the prevention of waste, in a district which comprised a population of a quarter of a million, they had a very effective system of daily inspection carried out by specially trained men, and by that means they had reduced the domestic supply to a volume of something like 12 gallons per head; the total supply, including manufactories, being under 20. At one time it was something like 55. The same thing had prevailed in some other towns, where a similar reduction had been accomplished by the same means. The fire service was very effective, but they relied in a great measure on the pressure in the mains, which was sufficient to send the water over the highest warehouses and buildings; that, however, was supplemented by an efficient fire brigade.

Mr. SMARTT said he had a miniature farm or

* See final remarks in discussion upon the paper by G. F. Deacon, read to the Society of Arts on the 17th May, 1882.

garden, by experiments with which he found that sewage water passed through boulder clay lost very little of its nutritious qualities.

The CHAIRMAN said he must now bring the discussion to a close, though several other gentlemen had sent up their names, for only a few minutes remained for him to offer some remarks on the chief points which had been discussed that day. It would be presumptuous in him to attempt to go over anything like the large range of subjects which had been dealt with; but he could not refrain from saying a word or two on the question of the quality of water, which had been one of the most prominent subjects under discussion. They must all regret that the very admirable paper of Dr. Odling had not been presented *in extenso* in print, and that they had not been enabled to examine the facts upon which he was quite certain the arguments had been based, which had led Dr. Odling to the conclusions he gave at the close of his paper. With regard to some of those conclusions, they would be all of one accord, viz., that the purity of water should, in the first instance, be considered by the chemist in its entirety; that what chemists called impurities did not necessarily relate to unwholesomeness; that, taking the actual proportion of organic matter existing in water, it was so small as to be of no importance in considering the quality of water for potable purposes, and also that organic matter which at one time might have resulted from decay, might possibly have no real importance with reference to the quality of water; that it might exist to a considerably greater extent in what was considered as the most wholesome spring water, than in the water of a stream. Again, with regard to his fourth conclusion, all who had studied the subject of so-called self-purification of water had come to the conclusion that this self-purifying power of a stream was very great indeed, and that the oxygen dissolved in the water, and continually re-absorbed by it—an action favoured by the agitation of the water in its flow—had the power of removing, to a considerable extent by oxidation, the organic impurities with which the stream might have become polluted. But when they came to the last two conclusions at which Dr. Odling had arrived, he must say that, in the absence of the facts upon which they had been founded, they still remained debatable; these conclusions being—that there was an absence of evidence as to the injurious nature of organic matter which might sometimes be found even in carefully filtered waters, and that there was no evidence that disease-producing organisims were developed or propagated in waters so filtered, so as to be prejudicial to life. All who had given any attention to the subject of the influence of water in promoting disease, would be inclined to hesitate before accepting the latter proposition; and they must, therefore, look forward with great interest to the publication of the complete paper, which would, no doubt, give the facts and reasoning upon which this statement was based. It had been within his experience that water which had been considered as of the very highest quality, and which the advocates of deep wells would unhesitatingly pronounce to be a high quality, had, after its supply for house use, proved a source of disease. This led him to refer once more to the question of tanks. There had been a much greater unanimity of opinion than on any former occasion with regard to the mischievous results which might arise in consequence of the storage of water in houses. Mr. Hogg had explained that, in hesitating to adopt the statement that tanks or reservoirs were injurious, he only referred to open tanks, butts, or reservoirs; but that closed tanks he looked upon as harmless. Even so far he must confess he did not feel inclimed to agree with Mr. Hogg, from the very fact he had already alluded to, that a house supplied with one of the purest of London waters—a deep well water—was visited by disease such as Mr. Hogg pointed out as consequent on the pollution of water by matters connected with zymotic diseases, although the tank was apparently perfectly closed. There was not the least doubt that this was due to the causes insisted on by Mr. Chadwick, that wherever tanks existed there might, unless very great precautions were taken, be a possibility of pollution by gaseous emanations from sources of pollution. This being the case, there could not be a doubt that the constant supply, and the absence of cisterns, were fundamental points in the supply of wholesome water. How far measures could be taken to guard against waste, he must leave to those competent to deal with this part of the subject, by some of whom it had been shown, during the discussion, that, at any rate, considerable advances had been made in this direction. He should imagine that no householder would hesitate, if he desired to obtain a high-class water, to adopt such precautions as might be reasonably within his power to guard against waste, and that everyone would willingly bind himself to use the water carefully, provided he were perfectly sure of the quality. Even though certain arrangements which had been suggested might be inconvenient or unsightly, there was no doubt the advantage they would secure in promoting the supply of thoroughly pure water at a comparatively moderate cost, would counterbalance any of these disadvantages, in the opinion of all sensible people. They had discussed as far as possible the question of the advantages and disadvantages of a dual supply, partly in reference to the large consumption of water for ordinary purposes, and partly in reference to the application of water to fire extinction, but the question evidently still required much further consideration. There had been one or two advocates of a dual supply; but others had pointed out, and he thought correctly, that very great difficulties existed, which some were inclined to think insurmountable. The distinct supply, on a very large scale, of water of ordinary quality, such as they would not use for potable or other domestic purposes, would involve an enormous outlay of capital, and it would be very difficult to insure the use of such water in a manner which would be really safe to householders. It was gratifying to find that, since they last held a Conference, there had been a considerable assimilation of views amongst those who were formerly much opposed on the chemical aspects of the question. There was now a very considerable concordance of views amongst chemical authorities, and so he believed they would find that, amongst practical men, some of the difficulties which appeared insurmountable would gradually vanish, and that by comparing ideas and experience, they would speedily arrive at a very great advance in connection with the water supply of large towns. He regretted that the special attention which London had received in the discussion had led to very little being said about the water supply of villages or small towns. This was a subject which no doubt required so much earnest consideration that it would be desirable, before long, to have a Conference at which to discuss the subject on the still broader basis of a national water supply. In connection with this there were several important subjects which had not been exhaustively discussed, such as the question of the value of different systems of wells which were applicable on a small scale with comparative readiness, and the very important question of the extent to which purifying agents could be applied to water for small communities. They knew how valuable had been the results of Dr. Clark's process when applied so intelligently as it was, many years ago, by Mr. Homersham, and since by various others, such as Mr. Porter and Mr. Atkins. In some instances, water which it was almost impossible to use for domestic purposes, on account of its exceeding hardness, had become an excellent water by application of this method of treatment. He had personal experience of this, inasmuch as he took part in experiments which Dr. Clark made when he softened water at the works at Plumstead, about thirty years ago, and had since had the supervision of softening works erected for the supply of water from deep wells to the Herbert Hospital at Shooter's Hill. What had been so successfully accomplished at this place, and elsewhere more recently by improved processes, had demonstrated how readily water might be treated when the supply required was comparatively moderate. The same system had even been applied to towns and districts of some considerable size; but the question still remained to be determined whether it would be possible to apply this excellent process upon so large a scale as would be necessary in order to supply London, or the more important districts of it, with softened water. That the Kent Company had hesitated to apply this system to the deep-well water supplied to Woolwich and elsewhere, which was most beautiful and wholesome to drink, but ill adapted to other domestic purposes, seemed to indicate that practical difficulties still existed which had to be encountered, not merely by the application of capital, but by science combined with practical knowledge. With regard to other methods of purifying water, considerable improvements had been effected in recent years in the application of filtering media, such, for instance, as charcoal preparations, and iron in a more or less finely divided condition. If water were affected chemically by treatment with either precipitating or oxydising, or otherwise purifying agents, such treatment must be efficient in proportion to the amount of surface of water brought into contact with the agent applied. If iron exerted a purifying influence on water, it would obviously exert that to the greatest extent within a given time, if the surfaces of the iron and the water coming into contact were constantly renewed. That this was done to a considerable extent in a filter there could be no doubt, but when a column of water was passed through a column of filtering material, the latter must present channels in parts, admitting of the free passage of the water. By passing through these the water must to some extent escape being purified; but if you took the same purifying agent, and agitated it for a short time with water, you renewed the surface of contact between the water and it continually and rapidly, and so, as a matter of course, effected in a short time what you had to apply a considerable amount of time, and a comparatively very large amount of purifying material, to effect to anything like the same extent by the ordinary methods of purification by filtration. There could be no doubt that the action of charcoal as a purifying agent, quite apart from its action as a simple filtering agent, was much promoted, like that of iron, by constantly renewing the surfaces of contact between the charcoal and the water, and so he should imagine that filtering on the principle devised by Mr. Maignen, or other filters based on similar principles, would act more efficiently and rapidly than the mere passage of water through charcoal *en masse*. No doubt much had to be learnt with regard to the treatment of water by means of domestic filters, which would always be important in connection with the supply of small communities, and that of groups of people like soldiers on active service. A filter was popularly expected to accomplish two things: in the first place, it simply strained or clarified water, by separating suspended matter, and a properly-built filter might be relied upon to carry out this operation for a considerable period, until, in fact, the passage of the water was too much impeded by the clogging effect of the impurities deposited in the filter. Secondly, some filters would to a small extent purify water of dissolved matters, but it was important to bear in mind that that power could only be retained by a filter for a comparatively brief period. Many people bought a filter, and having set it up, they did not care much what the source of water was which they used, being satisfied that, by having bought one of the best forms of filter, and drinking nothing but the water filtered through it, they were secure against all evils ascribable to water. But that filter might, and was generally, filled month after month, and even year after year, and was supposed to continue perfect as long as the water ran through it, and was not even suspected of being inefficient until it became actually choked up. This was one of the most dangerous points connected with the application of filters to domestic purposes, and too much stress could not be laid upon it. He begged, in conclusion, to congratulate the Society upon the useful nature of the discussion, elicited by the valuable papers which had been brought before Conference.

Mr. Edwin Chadwick then proposed a vote of thanks to the Chairman, which was carried unanimously, and the proceedings terminated.

Miscellaneous.

NOTES ON THE ITALIAN NATIONAL EXHIBITION AT TURIN.

The Exhibition now open at Turin is by no means the first that has been held in that city. As early as 1829, during the reign of Carlo Felice, it was proposed to hold a series of Triennial Exhibitions, the first of which was opened in the same year; but after the second, which was held in 1832, it was considered advisable to extend the interval to six years, so that the third was postponed until 1838, the fourth to 1844, the fifth to 1850. In 1856, no exhibition was held, as too short a time had elapsed since the International Exhibition of Paris of the previous year, in which the kingdom of Sardinia had taken part, and in consequence, another three years was allowed to pass before the sixth and last of this series of exhibitions was held.

The success of the Milan Exhibition of 1881 aroused a spirit of emulation on the part of the Turinese; and on the 6th of December a Commission was formed, and the basis of the undertaking was laid before the close of the year.

The Exhibition buildings have been erected in the Valentino gardens, one of the most delightful situations in Europe, and occupy that part comprised between the Corso del Valentino on the north, and the Corso Dante on the south, the Corso Massimo D'Azeglio forming the western boundary, whilst the River Po to the east, with the picturesque range of hills called the "Collina," on the opposite bank, clothed with vineyards, woods, and gardens, and studded with the villas of the rich Turinese, considerably heightened the beauty of the situation.

The edifices and enclosed grounds cover an area of 340,000 square metres (about 84 acres), of which the buildings occupy an area of 143,000 square metres, and nearly equal to that occupied by the Paris International Exhibition of 1867, and three times that of the Milan Exhibition of 1881.

The principal range of buildings is 650 metres in length, and are built in line with the Corso Massimo D'Azeglio. To the east of this main gallery are others at right angles, which are united at the opposite end by others parallel to the principal one. These buildings are in various styles, and were designed by Signor Camillo Riccio, the architect to the Executive Commission.

There are six entrances to the Exhibition grounds, the principal one from the Turin side being the Porta Reale, situated at the angle formed by the Corso Massimo D'Azeglio and the Corso del Valentino, and close to the palace of the same name. It is an imposing building $72\frac{1}{2}$ metres in length, consisting of a double colonnade between two square towers 35 metres in height. In one of these towers is the Astronomical and Meteorological Observatory, open to the public, and a collection of instruments, apparatus, drawings, and models relating to celestial and terrestrial physics.

A building to the right, which formerly formed the façade to the rifle range (*tiro a segno*), has been adapted for the post, telegraph, telephone, and newspaper offices, whilst the other tower is used as offices for the Executive Commission.

The second entrance, which gives access from the Corso Raffaele, called the Porta Moresca, is a striking building in the Moorish style, with three archways; it is richly decorated with gilding and bright colours. The other entrances are the Porta Dante, Porta Isabella, Porta Eredano, and a small landing stage from the Po, giving access to the mediæval castle; these entrances are in the châlet style and built of wood.

Facing the Porta Reale, and at a distance of 160 metres from it, is the entrance to the principal range of galleries, through a handsomely proportioned salon, octangular in shape, and covered with a cupola 34 metres in height. In this salon, and in a gallery to the left, are contained the exhibits of pottery and glass. Next follows the gallery of manufactures, 155 metres in length and 34 metres in width, at the end of which is the furniture department. A gallery 128 metres in length and 25 metres in width, contains the exhibits of musical instruments, and communicates to the left with the great concert-room, 40 metres in diameter, and covered with a dome-shaped roof. The principal entrance, however, to the concert-room is from the grounds, and is flanked by a colounade forming a semicircle.

Beyond the music gallery, is the great gallery of machinery in motion, 250 metres in length by 34·50 in width, extending nearly to the Porta Dante.

A spacious roadway runs parallel to the buildings, and tramways from all parts of Turin enter the grounds by the Porta Reale, and convey passengers to the Porta Dante. To the right of this roadway are a range of sheds and buildings, the principal being used for the exhibition of the memorials and relics of the conflict for Italian independence, railway plant, public welfare, carriages, and the boiler house. At right angles to the great gallery of machinery in motion are the galleries for machinery for general and industrial purposes; the exhibits of the Minister of War and for military equipment, the international gallery of electricity, the glass-blowing establishment of Candiani, of Venice, the boiler house for the engines that furnish motive power for the electric department, and a building containing the pumps of Messrs. Bosisio and Co., which supplies the ornamental fountain.

Parallel with the Corso Dante, and at right angles with the range of principal galleries, are the buildings containing the exhibits of agricultural machinery, educational, books, extractive and chemical industries, the collection shown by the Minister of Agriculture, agricultural produce, wine, oil, cheese, manufactures, the exhibits of the Minister of Public Works and Minister of Finance.

The Fine Arts occupies a building entirely to itself, and is situated diagonally in the angle formed by the range of principal galleries and those parallel with the Corso Dante. Its architectural features are purely in the Grecian style, with a semicircular portico for sculpture, which portico or colonnade encloses a garden.

This building covers an area of 20,655 square metres, of which 7,970 square metres are occupied by the picture galleries, architecture, and for part of the sculpture; 1,740 square metres by the colonnade, and 10,945 square metres being the area of the enclosed garden.

The mediæval castle and village, with the exhibits of ancient art, is placed most picturesquely amongst the trees on the banks of the river, and forms one of the principal attractions of the Exhibition. It is satisfactory to know that this work, the fruit of the study of eminent artists and archæologists, will form a permanent feature in the gardens of the Valentino after the Exhibition is closed, as it has been purchased from the Executive Committee by the municipality.

There is also a small encampment of the natives of the Bay of Assab, the little Italian colony on the Red Sea, a small exhibit of the principal products of the colony, and of the principal articles imported from Italy; trade samples of exports and imports are marked with the price, and serve as a guide to merchants and manufacturers.

Six natives have arrived in Turin, and are now encamped in the exhibition grounds.

On the banks of the Po are the sheds and buildings containing the exhibits of the Minister of Marine, naval construction and equipment, forestry, hunting and fishing, silkworm rearing, agriculture, divers, the pumping station of Messrs. Cerimedo and Co., and the interesting collection of the Alpine Club (one of the most complete in the Exhibition).

Besides the buildings just described, there are numerous pavilions, kiosques, &c., erected in the grounds, and serve for the different cafés, restaurants, and beer-halls, for the sale of wine, vermouth, tobacco, newspapers, &c.; some are in the Chinese, Moorish, Russian, and Swiss styles, and the restaurant of the Hôtel d'Europe in the Russian style, and covering an area of 600 square metres, particularly is worthy of mention.

The pavilions of the cities of Rome and Turin, with a full-sized copy of the temple of Vesta, must not be passed without remark.

A little steam tramway (two-foot guage) on the "Decauville" system, has been laid in the grounds, and the cars drawn by two miniature locomotives (weighing 3 tons each), the "Regina Margherita" and the "Torino," convey passengers from the Porta Reale to the Porta Isabella.

The periodical exhibitions of domestic animals, poultry, &c., are held in separate grounds on the south side of the Corso Dante, and cover an area of 42,000 square metres ($10\frac{1}{3}$ acres).

A service of steam launches has been established on the Po, between the bridge near the Piazza Vittorio Emanuel I. and the Exhibition.

The grounds are lighted three times a-week with the electric light, and the gallery of electricity is also thrown open to the public.

The following classification has been adopted at the Turin Exhibition:—

Division I. Fine Arts.—Section 1. History of art. Section 2. Modern art (painting, sculpture, and architecture). Section 3. Music.

Division II. Education.—Section 4. School construction, instruments and appliances. Section 5. Methods adopted for teaching literature and general knowledge. Section 6. Methods adapted for teaching the positive and experimental sciences. Section 7. Industrial and special instruction. Section 8. Books and libraries.

Division III. Scientific and Literary Publications.—Section 9. Documents and relics relating to the history of political events in Italy, from 1820 to 1870. Section 10. Scientific and literary publications.

*Division IV. Public Welfare.**—Section 11. Public welfare under a sanitary aspect. Section 12. Public welfare under an economic and moral aspect. Section 13. Public aid under a sanitary aspect. Section 14. Public aid under an economic and moral aspect.

Division V. Extractive and Chemical Industries.—Section 15. Quarries, mines, mineral, and metallurgical industries, mineral waters, &c. Section 16. Chemical arts, chemical products, dying, tanning, &c.

Division VI.—Section 17. General mechanics. Section 18. Industrial mechanics. Section 19. The mechanics of locomotion and navigation. Section 20. Military and naval weapons and equipment. Section 21. Agricultural machinery. Section 22. Scientific instruments, which includes electricity.

Division VII. Manufactures.—Section 23. Pro-

* "Previdenza ed assistenza publica," is here translated "Public Welfare" for want of a better title.

ducts of manufacture. Section 24. Gallery of labour (machinery in motion, and processes in operation).

Division VIII. Rural Economy, Horticulture, Forestry, &c.—Section 25. Agricultural industry, Section 26. Food. Section 27. Forestry. Section 28. Fishing and hunting, products of the animal kingdom, manures, &c. Section 29. Cattle, domestic animals, poultry, &c.

Each section is further sub-divided into categories.

The total number of exhibitors, according to the official catalogue, is 12,776, distributed as follows:—

Division	I.—Fine Arts	1,579
"	II.—Education	1,194
"	III.—Scientific and literary works	191
"	IV.—Public welfare	2,054
"	V.—Extractive and chemical industries	989
"	VI.—Mechanical industries	936
"	VII.—Manufacturing industries	2,663
"	VIII.—Rural economy, horticulture, forestry	2,591
Special Exhibits:—Astronomy, meteorology, exhibits of Ministers of Public Works, Ministers of Agriculture, Alpine Club, City of Rome, City of Turin		579
		12,776

The official general catalogue, a volume of about 1,000 pages, has just been published. There is also a catalogue of ancient art and guide to the mediæval castle, which contains a vast amount of information, both historical and archæological, relating to the 15th century.

TOBACCO CULTIVATION IN BRAZIL.

Some interesting particulars are given in the last report of the United States Consul General at Rio de Janeiro, as to the cultivation and manufacture of tobacco in Brazil. It appears that the cultivation began about the year 1600, in the province of Bahia, and from thence extended to all the other districts along the coast. Among the localities earliest known for their tobacco production was the lake district of Pernambuco, now the province of Alagoas, where an excellent quality was produced, which commanded very high prices. During the following century the cultivation increased so rapidly in Alagoas and Bahia, that at the commencement of the succeeding century, the average annual export had reached 2,857 tons from the latter, and 285 tons from the former province. The earliest export statistics available for the whole empire, are for the year 1839-40, in which the export amounted to 295,966 arrobas, the *arroba* being equivalent to about 32 lbs.; and the value exceeded £65,000. For the next thirteen years, the exports averaged 8,000,000 lbs. annually, with a value steadily increasing. During each of the years 1853-55, the amount exported was 22,000,000 lbs., of the total value each year of £200,000. In 1879-80, the export was 50,000,000 lbs., of the value £659,000; in 1880-81, 44,000,000 lbs., of the value of £650,000, and in 1881-82, 52,000,000 lbs. of the value of £680,000. Though the principal tobacco-producing province of the empire is Bahia, tobacco of good quality is grown in every part of Brazil, from the Amazon to the Rio Grande frontier. Some localities in the province of Amazonas have long been known for the excellent quality of their tobacco, while in the Rio market one of the brands most esteemed comes from the province of Goyaz. The local consumption of tobacco is very great, and principally in smoking. Bahia tobacco used to be largely exported in rolls, weighing eight arrobas, or 256 pounds each; of late years, however, large quantities of the leaves in bales are exported to Hamburg. Cigar factories are established in all large cities throughout the tobacco-growing regions, which give employment to a large number of men, women, and children. The methods employed in the cultivation and preparation of the plant are very much the same as they were nearly 200 years ago. The labour employed is that of slaves, to whom are assigned special descriptions of work. In former times curing tobacco in rolls required much constant labour, the ropes composing each roll being unwound, twisted, and re-wound during a period varying from ten to fifteen days. The Brazilian tobacco is generally characterised by its strength and dark colour, particularly in Bahia. In that province the practice is to manure heavily, which occasions a very rank growth and strong flavour. In Minas Geraes the tobacco is somewhat milder, and some advance has lately been made in a few localities towards improved processes of curing. This seed may be germinated in any season of the year, but the months of June, July, and August, are generally preferred for planting, because germination and transplanting are brought into or near the rainy season. Tobacco plants planted in this season are considered the best growers, and produce the largest leaves. Those, however, which are germinated in the dry season, and sustained by irrigation, grow with greater vigour, and possess a finer aroma. The land selected for the plants is cleared, and the surface worked with the hoe, after which it is marked off into parallel rows about three feet apart, according to locality and the size of the mature plants. In transplanting, the young plants are set from two to three feet apart, and are manured heavily in the pits opened for them. Great care is necessary for a time to protect the shoots from the sun, and to irrigate plentifully when the transplanting occurs in a dry season. The work of cultivation and keeping down the weeds is performed entirely with the hoe, and only two or three times during the season. In gathering in the crops, planters wait until the plants are fully matured, this being determined by doubling and breaking one of the top leaves. In Bahia and other Brazilian provinces the lower leaf is often picked by itself, and in a few days the next, and so on as long as the plant will develop the lower leaves into what is classed first quality. These leaves are hung up two and two, under cover and across poles, twenty-four hours after picking and sweating. When it is intended to twist the leaves into ropes, they are left hanging about two days, when they are taken down, carefully freed from the heavy parts of the midrib, doubled in halves, and laid away for the rope twister. This operation requires considerable dexterity, and is generally entrusted to the best slave on the plantation. The operation requires a rude windlass, which is slowly turned in winding the rope, which is twisted by hand. A boy is usually employed entirely to hand leaves to the twister. These ropes are unwound and re-wound once or twice a-day, for a period of ten or fifteen days, according to the weather, and are twisted a little harder each time. In curing, the tobacco grows darker and darker, until it becomes jet black. The juices exuding from the rolls are carefully caught and preserved until the last winding, when, mixed with lard, syrup, and various aromatic herbs, they are used to pass the rope through, previous to the final winding. The last step is to cut the cured ropes in certain lengths, and to re-wind them upon light wooden sticks, about two feet in length, the winding being very compact and regular. The rolls are then covered with leather or strong canvas, when they are ready for market. Formerly, these rolls were made to weigh 8 arrobas, or 256 lbs., though rolls of 3 arrobas were made for the home markets. At the present day the weights vary according to the locality. The large exportation of tobacco in leaf has considerably changed the character of tobacco growing in Bahia, the process of curing and packing the leaf being simpler than the old process of manufacturing *rolos*. Tobacco growing is heavily protected and taxed in Brazil, nearly all the provinces imposing separate protective taxes, in addition to those imposed by the Government. Besides these, the municipalities are permitted to levy taxes on the article. The present export tax on tobacco, in Brazil, amounts to as much as 18 per cent.

LONDON WATER SUPPLY.

The *Times* of Monday, August 25, contained a leading article on the results of the Water Supply Conference of the Society of Arts at the International Health Exhibition. The article concludes as follows:—

"Few people seem to be aware of the rapid growth of the difficulty. At the beginning of this century the Thames was as sweet in London as at Windsor or Reading. People could bathe in it, wash with it, and cook with it. For no other uses was it introduced into houses. There was no watering of the streets and roads, but in a hot summer evening the plugs were withdrawn, the water was allowed to run down the gutter, dammed at intervals, and dashed with shovels over the road. There were a vast number of surface springs and wells of very slight depth, the water of which was always clear, and generally quite wholesome, unless they happened to be too near a churchyard. Here and there were public pumps, many of them wheel pumps, which people used as they pleased, often for the muscular exercise. Even the poorer people had generally a good pump within easy distance, and the labour of water carrying was always mitigated by the pleasure of a chat with friends at the pump. It is only the recent growth of the present difficulty we are concerned with; for there is no denying that the sanitary condition of the metropolis was then very bad, and that it is much better now. Though so much smaller than now, and consequently so much nearer the green fields and the green lanes, the metropolis was not so healthy then as now by a good deal. Unquestionably we are taking good care of ourselves, and so far have reason to be satisfied. Yet our case as regards the supply and consumption of water bears a suspicious resemblance to that of the man who maintains a large family in comfort, elegance, and even splendour, denying them nothing, and not even permitting them to trouble themselves about the future, but who does not leave them a sixpence to enjoy and disport themselves in like fashion when he is gone. Whatever we do, it will not be for want of information. The present generation is not allowed to flatter itself that all is right. On the contrary, all is wrong, and the world will not have to wait even for expiration of this century to hear a chorus of indignation at the way in which England has squandered and misused the first of Nature's gifts."

THE IRIDIUM INDUSTRY.

Within the last few years, says *Engineering*, a new industry has arisen in the manufacture of articles from iridium, through the discovery of Mr. John Holland, of Cincinnati, that by the addition of phosphorus, the hitherto intractable metal could be easily melted. Previously to the present time iridium, unless alloyed with platinum, has had substantially but one use, viz., for pointing gold pens, and for this purpose it was used in the native state, suitable pieces of ore being selected and soldered in place. The metal itself was discovered in 1803 by Smithson Tennant, while investigating the metallic residues which remained when platinum ores were dissolved in *aqua regia*. In the early history of the electric light, in 1848, W. E. Staite patented the use of iridium filaments in incandescence lamps, and proposed to prepare the metal by fusing the oxide in a cupel of bone ash under the voltaic arc. The ingot thus obtained was to be annealed in an oxyhydrogen jet, and worked under hammers and between rolls at a white heat.

In certain cases thin strips of metal were to be cut from the ingot "in the same way as precious stones are cut by the lapidary." What measures of success he obtained, if any, is not known, but he appears to have devoted the greater part of his attention to arc lamps, and probably the scheme never got beyond the paper stage. The means he indicated, however, were the only ones which attained any success, and by their aid other experiments succeeded in obtaining small globules of the metal.

About four years ago Mr. John Holland, gold pen manufacturer, found it necessary to have pieces of iridium, larger than those generally found in nature, for the purpose of making points for a stylographic pen. After many experiments he found that by heating the ore in a Hessian crucible to a white heat and adding to it phosphorus, and continuing the heating for a few minutes, he could obtain a perfect fusion of the metal, which could be poured out and cast in almost any desired shape. The product was found to be about as hard as the natural grains of iridium, and, in fact, seemed to have all the properties of the metal itself. On chemical analysis it was found that the metal fused with phosphorus contained, according to two determinations, 7·52 and 7·74 per cent. of phosphorus. For many purposes it could be used in this state without further treatment, but when it had to withstand a white heat, as in some kinds of electrical apparatus, this capability of fusion destroyed its usefulness. Experiments for the purpose of removing the phosphorus were tken made by Mr. W. L. Dudley, of Cincinnati, who found that by heating the metal in a bed of lime the phosphorus could be completely eliminated. In the usual operation the metal is first heated in an ordinary furnace at a white heat, and finally after no more phosphorus makes its appearance, it is removed and placed in an electric furnace, with a lime crucible, and then heated until the last trace of phosphorus is removed; the manufactured metal will then resist as much heat without fusion as the native metal.

The principal sources of the supply of iridium are Russia and California. It is extracted from gold and platinum ores as a by-product, and is always found in small grains or fine powder, the largest pieces being about the size of a grain of rice. It is generally found alloyed with platinum or osmium. When pure it possesses a white lustre, resembling that of steel; its hardness is about equal to that of the ruby; when cold it is quite brittle, but at a white heat it is somewhat malleable. It is one of the heaviest metals, having a specific gravity of 22·38. When heated in the air to a red heat the metal is very slowly oxidised; but upon raising the temperature to about 1,000° Cent., it parts with its oxygen, and above that temperature it is not oxidised. It is insoluble in all single acids, and but very slightly soluble, when in a state of fine powder, in *aqua regia*.

According to the new system of manufacture, and in cases where the article is not subject to great heat, the metal is melted with phosphorus, and cast into the desired shape; it is then ground or worked into the exact required form.

Iridium is sawn by a copper disc 4 in. to 8 in. in diameter running at 2,500 revolutions per minute, and dipping into a bath of cotton-seed oil and corundum or diamond dust.

Many new uses are now opening for iridinm since it has been possible to melt and cast it. It is used for drawplates, to replace the ruby plate, in the manufacture of gold and silver wire; for knife edges, for scales and balances; for tipping hypodermic needles, and for many other purposes. It has been tried for the negative pole of an arc lamp, and was found to keep its shape, in spite of the heat, provided the positive carbon was not allowed to strike or fall too heavily upon it. One of the most important applications is for the contact points of telegraphic instruments; these outlive many platinum contacts, and do not oxidise or stick.

Efforts are now being made to effect the electric deposition of iridium, and considerable success has been obtained by Mr. Dudley, who, according to a paper which he recently read before the American Institute of Mining Engineers, hopes to make a commercial success of this art shortly. The solution is made by mixing iridium of iridosmine with common salt placed in a tube and heated to redness. Chlorine gas is then allowed to flow slowly through the tube for several hours, at the end of which time most of the iridium has combined with the salt and chlorine to form a double choloride of iridium and sodium, which rapidly dissolves in water, and forms a solution from which other salts can be prepared.

Obituary.

Henry George Bohn.—Mr. Bohn, the late veteran bookseller and publisher of York-street, Covent-garden, died at North-end House, Twickenham, on the morning of Friday, the 22nd inst., in the 89th year of his age. One of his earliest bibliographical works was the compilation of the catalogue of Dr. Parr's library, and from that time he was busily engaged in literary pursuits. His famous guinea catalogue was published in 1841, but although he continued to be a second-hand bookseller until the period of his retirement from business, he was, after the success of his extensive "libraries," chiefly a publisher and dealer in remainders. Since his retirement, in 1865, he has been employed in the collection of china and works of art, and during the last few years of his life he has been engaged in the compilation of a catalogue *raisonné* of his collections. Mr. Bohn was elected a member of the Society of Arts on November 21, 1849, and continued a member for many years, but soon after his retirement from business he resigned.

CANTOR LECTURES.

FERMENTATION AND DISTILLATION.

By Professor W. N. Hartley.

Lecture II.—Delivered Monday, May 19, 1884.

Diastatic Fermentation.

Diastase belongs to a class of substances known as soluble ferments. These bodies exert a very remarkable series of chemical reactions of a varied character upon certain substances with which they are brought into contact. The exact nature of their action is so unlike that of most chemical processes, that it is by no means easy to understand it. To say that the action is "catalytic," is tantamount to confessing an inability to explain it. Liebig has stated that all substances in a state of decomposition are capable of communicating a change in chemical composition to other bodies with which they are in contact. In his "Chemical Letters," p. 206, he says, in speaking of digestion:—"It was for a long time believed that the accelerated dissolving power which the mucous membrane of the stomach imparts to the hydrochloric acid, depended upon the presence of a particular substance called pepsine, a kind of digestive agent. The same opinion prevailed respecting a substance called diastase, contained in the extract of malt, by which starch is converted into sugar; and these substances have received certain designations." "But what have been called pepsine and diastase are nothing more than a portion of mucous membrane, or of gluten, having passed into a state of decomposition. The action of these bodies depends entirely upon their condition, just as is the case with yeast." "With a piece of the mucous membrane of the stomach, in a certain stage of decomposition, we may render certain animal substances soluble; whilst with the same membrane, in other stages of decomposition, we may convert starch into sugar, sugar into lactic acid, mannite, and mucus, or into alcohol and carbonic acid; and lactic acid into butyric acid, hydrogen, and carbonic acid." Since those words were written, we have learnt much information concerning the phenomena of true fermentation and putrefactive decomposition. We now know that, without the presence of minute organisms, such changes cannot take place, and that certain changes are brought about only by the presence of certain organisms.

I have used a phrase, true fermentation, which requires some explanation. True fermentation is such an action as the conversion of sugar into alcohol by means of yeast, which, being a living organism, is therefore insoluble, and the action of which ceases with its death. More than this, fermentation is active only so long as the yeast fungus flourishes; when it is languid, the production of sugar decreases; and when torpid, the chemical change is suspended. The action of a lifeless and soluble ferment like diastase upon a substance like starch is not a fermentation, but a process which may be distinguished by the name *hydrolysis*. The word was suggested by Dr. Armstrong (*Journal Chemical Society*, vol. xxxv., p. 647), as a fitting one with which to designate those reactions in which the elements of water enter into combination with a large molecule, and resolve it into two or more molecules of lesser weight. The name of the substances which act in this manner are the following:—

Soluble Ferments or Zymases.

Name.		Whence derived.
Diastase	....	Malt, veitches, &c.
Maltin	....	Malt.
Emulsin	....	Sweet and bitter almonds.
Ptyalin	....	Saliva.
Myrosin	....	Seeds of cruciferæ.
Pepsin	....	Gastric juice.
Pancreatin	....	Pancreas.
Invertase	....	Yeast.
Papäin	....	In the leaves of *Carica papaya*.

The action of the majority of these substances is confined to a transformation of saccharides, such as starch, and of glucosides, a class of crystallisable compounds largely contained in the vegetable kingdom.

A list of some of the simplest glucosides, the sources whence they are derived, together with the products of their diastatic fermentation, is here given:—

GLUCOSIDES.

Name.	Source.	Products.
Amygdalin ..	Bitter almonds ..	Glucose, oil of bitter almonds, prussic acid.
Salicin	Willow bark ..	Glucose, saligenin.
Helicin......	....	Glucose, oil of meadow-sweet.
Arbutin	Leaves of the bear-berry	Glucose, hydroquinone.
Potassium myronate..	Mustard seed ..	Glucose, oil of mustard, and potassium sulphate.
Tannin......	Gall nuts and oak bark	Glucose, gallic acid.
Rubian	Madder plant ..	Glucose, alizarine.
Inidican	Woad (*Isatis tinctoria*)	Indiglucin, indigo-blue.

In the transformation of starch, the products are not so strikingly different in character that they can be at once perceived by the senses, though it is true that the palate recognises a sweetness which the liquid did not possess at first; but in the case of amygdalin, and much more so in that of potassium myronate, the sense of smell at once informs us of the great change which has invisibly been wrought in the liquid.

EQUATIONS EXPLAINING THE DECOMPOSITION OF GLUCOSIDES.

(*a*) Amygdalin. + Water. = Glucose. + Benzoyl hydride. + Prussic acid.

$$C_{10}\ H_{27}\ NO_{11} + 2\ H_2\ O = 2\ C_6\ H_{12}\ O_6 + C_7\ H_6\ O + H\ C\ N.$$

(*b*) Salicine. + Water. = Glucose. + Saligenin.

$$C_{13}\ H_{18}\ O_7 + H_2\ O = C_6\ H_{12}\ O_6 + C_7\ H_8\ O_2.$$

(*c*) Arbutine. + Water. = Glucose. + Hydroquinone.

$$C_{12}\ H_{16}\ O_7 + H_2\ O = C_6\ H_{12}\ O_6 + C_6\ H_6\ O_2.$$

(*d*) Potassium myronate. + Water. = Glucose. + Allyl sulphocyanide. + Acid potassium sulphate.

$$C_{10}\ H_{16}\ HNS_2\ O_7 + H_2\ O = C_6\ H_{12}\ O_6 + C_3\ H_5\ CNS + R\ H\ S\ O_4.$$

(*e*) Tannin. + Water. = Glucose. + Gallic acid.

$$C_{27}\ H_{22}\ O_{17} + 4\ H_2\ O = C_6\ H_{12}\ O_6 + 3\ C_7\ H_6\ O_5.$$

DECOMPOSITION OF FAT BY PANCREATIC FERMENTATION.

Suet (Tri-stearine.) + Water. = Stearic acid. + Glycerine.

$$C_3\ H_5 \left\{ \begin{array}{l} OC_{18}\ H_{35}\ O \\ OC_{18}\ H_{35}\ O \\ OC_{18}\ H_{35}\ O \end{array} \right\} + 3\ H_2O = \left\{ \begin{array}{l} 3\ C_{18}H_{36}O_2 + \\ C_3\ H_5\ (OH)_3 \end{array} \right.$$

The above formulæ explain how the different glucosides are split up by the action of water into glucose and a variety of other products.

When bitter almonds are boiled with alcohol, not a trace of prussic acid or of oil of bitter almonds is found in the alcohol, but there has been dissolved a white crystalline solid substance, which is soluble in water, and to which it imparts a bitter taste. It is the glucoside amygdalin. When sweet almonds are crushed to a pulp, and ground up with four to six times their weight of water, a milky-looking fluid is prepared, which contains the substance emulsin. By the addition of alcohol, the emulsin is precipitated, and freed from oily matters. If to a solution of amygdalin in water a small quantity of emulsin be added, there is instantly recognised the smell of bitter almond oil and prussic acid.

When bitter almonds alone are crushed and mixed with water, the same change takes place, although, as previously mentioned, neither prussic acid nor bitter almond oil exist in the almonds, but only amygdalin, together with a little emulsin. Water is necessary to this reaction; and if an insufficiency is added, only a portion of the amygdalin is altered.

Everyone knows that mustard flour, when mixed with water, makes a mustard blister, which will cause excessive irritation if placed on the skin, and the very scent of it draws tears from the eyes. Many persons must have observed the fact that the ground mustard possesses these irritating properties only after it is moistened. It is easy to convince ourself of the fact by taking one of Rigollot's mustard leaves, which are carefully prepared dry and kept free from access of moisture; a few seconds in contact with warm water develops the pungent odour of mustard oil, of which there is not a trace in the dry mustard seed. By the action of the myrosin, which plays the same part as the diastase in starch, the potassium myronate enters into combination with water, which resolves it into allyl sulphocyanate or mustard oil, glucose, and acid potassium sulphate.

THE GENERAL CHARACTERS OF SOLUBLE FERMENTS.

1. They are all uncrystallisable albumenoid substances, coagulable by heat, and precipitable by alcohol. Though very soluble in water, they are incapable of diffusing through a vegetable or animal membrane, or of filtration under pressure through porous earthenware.

2. Their composition is very similar. The following figures show the composition of three important members of this class (Wurtz, *Dictionnaire de Chimie, Supplement*, p. 828):—

	Papaïn. (Wurtz.) Per cent.		Pancreatin. (Law.) Per cent.		Albumen-peptone. (Henninger.) Per cent.
Carbon....	52·48	..	52·75	..	52·28
Hydrogen..	7·24	..	7·51	..	7·03
Nitrogen ..	16·59	..	16·55	..	16·38

3. They manifest great chemical activity, or smallness of the relation of cause to effect. Thus one part of diastase can transform 2,000 times its weight of starch. One part of invertase can invert 5,000 times its weight of sugar.

4. Cessation of activity on coagulation. Diastase is incapable of saccharifying starch if heated to a temperature above 70° C., or 81°, when it becomes insoluble. Ptyalin loses its activity at 60° C.

5. Their chemical action is destroyed by contact with certain mineral substances. Thus borax destroys the activity of invertase, prevents the action of diastase on starch, of synaptase on amygdalin, and of myrosin on potassium myronate. (J. B. Dumas, *Comptes Rendus*, vol. 75, p. 925.)

6. They appear to combine with certain products of the changes they induce. Thus diastase retains dextrin in large proportions. Zymase, from the liver, retains more than 50 per cent. of glycogen. (Sugen and Kratschmer, *Jahresbericht der Thierchemie*, 1877, p. 360.) Invertase has been found to contain a large quantity of a gummy substance. (Barth. *Berichte, Deut. Chem. G.*, 1878, p. 474.) When treated with sulphuric acid, it yielded glucose. (Wurtz, *Dictionnaire, Supp.*, p. 828) Many of these bodies seem to combine energetically with mineral matters, as, for instance, with phosphate of lime, which is thus rendered soluble.

7. In the course of their action they undergo apparently no change in composition.

8. In all cases the changes they induce are accompanied by an absorption of heat, and the products have a smaller potential energy than the molecule of the original substance.

9. Organic substances, known as antiseptics or preventives of fermentation, are without action on zymases. For instance, phenol (carbolic acid), salicylic acid, chloroform, and prussic acid, have no action on diastase.

The reactions caused by one of these soluble ferments are not possessed by all the others, though many of the changes are common to several ferments. Thus, it has recently been discovered that the seeds of the vetch contain a diastatic ferment which acts very energetically on starch, producing sugar therefrom. The same substance has also an action like that of pepsin; it converts albumenoids into peptones. (Von Gorup Besanez, *Berichte Deut. Chem. G.*, vol. 7, p. 1478). Ptyalin, too, converts starch into sugar like diastase, and both ptyalin and diastase can liberate glucose from amygdalin and salicine. But no other substance, as far as I am aware, has been able to decompose the glucoside of black mustard except myrosin.

The Preparation of Diastase.—Diastase may be obtained from malt in an active state according to the process recently described by Mr. O'Sullivan at a meeting of the Chemical Society (*Chemical News*, November 14th, 1883). Malt is extracted with about twice its weight of cold water, and the liquid is separated by pressure in a filter press. The diastase is precipitated from the liquid extract by the addition of alcohol. Thus obtained, it is a white powder. Other methods have been proposed in which glycerine is used for the solution of the diastase, but the activity of the preparation is somewhat impaired by treatment with glycerine. The proportion of diastase in malt is about 1-500th, and this is more than enough to convert more than all the starch into maltose. If the starch extracted be 60 per cent. of the malt, and the diastase 0·2 per cent., this can convert 2,000 times its weight of starch, or more than six times that contained in the barley. Hence the reason why the proportion of malted to unmalted grain is one-fourth to one-seventh.

Somewhat clearer notions of the possible course of chemical change attending the saccharification of starch have been derived from the recent researches on papaïne of M. Wurtz. Albumenoid substances, when steeped in a solution of papaïne, retain a portion of the substance so obstinately that they may be washed with a large quantity of water without yielding any of the ferment. If, however, they are put into pure water at 40° C, the retained substances enter into solution as peptones, and, at the same time, papaïne is re-generated or liberated, which is then free to combine with another proportion of the albumenoids.

Pepsine behaves in quite a similar manner. (Wurtz, *Comptes Rendus*, vol. 93, p. 1104). It is rendered extremely probable that in the case of diastase a similar combination and decomposition results, since it has been proved that diastase removed from malt contains dextrin. The etherification of alcohol with a small quantity of acid, and the saccharification of starch likewise by a small proportion either of acid or of diastase, seem to be analogous chemical changes. Perhaps a more striking similarity exists in the formation of sulphuric acid in the lead chamber process, first devised by Chaptal, in which the oxides of nitrogen act as carriers of oxygen to sulphurous acid and water. In the presence of an inefficiency of water, nitro-sulphonic acid results, which, on contact with more water is decomposed into, sulphuric acid and nitric oxide. This decomposition seems to have some analogy with that which occurs when the combination of pepsine or of papaïne, with an albumenoid is put into pure water at 40°C. The chemistry of the process when sulphuric acid is employed for the purpose of converting starch into sugar is, so far as we aware, simply an addition of water to the molecule, which splits up the polysaccharide into molecules of maltose, or it may proceed further and by the same action convert the maltose into dextrose. In the same manner the action of acid on cane-sugar converts it into glucose commonly so-called, but which is in fact a mixture of two glucoses, one of which rotates a polarised ray of light to the right, the other rotates it to the left, hence the one is termed *dextrose*, the other *lævulose*. Now, as saccharose has a feeble right-handed rotation, which disappears during conversion into that which is left-handed, the change is called inversion. As there are two sugars present with opposite rotatory powers, it follows that the quantity of lævulose must be either larger in quantity than the dextrose, or else equal in quantity, but of greater rotatory power. This last is the true state of the case. The change of starch into maltose by means of diastase, the separation of glucose from glucosides, the inversion of cane-sugar, and the conversion of maltose into dextrose, are all brought about by the assimilation of water by the respective molecules of these substances, and the formations of molecules of a less complicated structure or constitution. As the word *hydrolysis* may fitly be employed to describe this action, the agents may be fitly termed *hydrolytics*, and by employing these terms, they are distinguished from ferments proper, while, at the same time, their action is not connected by phraseology with the phenomena of fermentation. What is the precise action of hydrolytics cannot at present be defined, but by collecting all the facts hitherto observed in the action of zymases, I have endeavoured to throw as much light on the matter as possible. In the case of sulphuric acid there is possibly a combination between the acid, and the carbo-hydrate which is decomposed by water, and re-formed from a fresh molecule of the carbo-hydrate.

Alcoholic Fermentation.

When a saccharine solution is exposed to the air at a temperature just comfortably warm, 68° to 70° Fahr., there ensues, after the lapse of some hours, a considerable disturbance in the liquid, which is made evident to the eye by a slow effervescence and an accumulation of froth upon the surface. If many gallons of liquid are under observation, and if yeast has been added, the disturbance becomes tumultuous from the disengagement of carbonic acid gas, and, at the same time, a strong vinous odour is perceptible in the gas. Yeast, which is so active in introducing this change, is a sort of viscous deposit which is found in vats or barrels, containing wine-must or beer-wort which has undergone fermentation. If the limpid juice of grapes be left to itself, it soon becomes turbid, and commences apparently to enter into a condition of spontaneous ebullition; at the same time, heat is generated so largely as to be sometimes perceptible to the touch. A saccharified solution of starch, whether obtained from potatoes or an infusion of barley or malt, goes through the same phase as a solution of sugar, or the expressed juice of the grape. At a certain period the effervescence slackens, and, finally, when it ceases altogether, it is found that the sugar is in great part, or even completely, replaced in the liquid by alcohol.

Vinous or alcoholic fermentation is the principal change observed during the process of wine-making, beer-brewing, and the production of alcoholic liquors and spirits generally.

In order to induce fermentative change in a saccharine fluid for the purpose of making beer or spirits, it is usual to add a small portion of yeast, leaven, or barm, by which the process is very much hastened, and carried out with regularity. The words used to denote the fermentative agent all signify a raising or bearing up of the substance fermented, that is to say, they refer to the "working" and frothing which is so remarkable. A knowledge of the fermentative process, and the technical application of this process, is historically traceable to the earliest times, and the course of inquiry into the nature and action of yeast has occupied scientific thought for something like two centuries.

Yeast both rises to the surface and subsides to the bottom of a fermenting liquid. The scum and dregs of this process were first examined by the microscope in the latter part of the 17th century, by Leuvenhock, who found that they consisted of minute particles of a definite shape, ranging in size from $\frac{1}{2000}$ to $\frac{1}{7000}$ of an inch in length. Cagniard de la Tour, and Schwann, in 1835, a century later, made the remarkable discovery that these particles were living, growing, and multiplying, their multiplication taking place at a prodigious rate, by a process of budding. An Italian chemist, Fabroni, discovered the nature of oval yeast particles to be that of cells, composed of a special variety of cellulose, and containing fluid matter, consisting of the elements carbon, hydrogen, oxygen, and nitrogen, in the form of an albuminous substance.

Van Helmont, a Dutch chemist, so far back as the commencement of the 16th century, recognised the gas evolved during fermentation as identical with such as is found in caves, wells, and cellars. Lavoisier examined the change produced in sugar by fermentation, and proved that its whole weight of the sugar is represented by the sum of the weights of the alcohol and of the carbonic acid produced. In accordance with this fact we say that the sugar is resolved into alcohol and carbonic acid. The part that the yeast plays in this change was undetermined until the year 1845, when Von Helmholtz discovered that it is the living yeast cell, or at any rate something inside the cell, which is the active ferment, for when a thin membrane, such as bladder, separates the yeast from the solution of sugar, no fermentation takes place in the vessel containing the sugar, but only in that containing the yeast, although there is a free communication for the liquids through the pores of the membrane. Dumas has proved this most completely by more recent researches; and he has shown, moreover, that fermentative changes cannot be communicated from one liquid to another by means of a neutral fluid. It is evident, then, that the live yeast cells are alone concerned in the change, and not the fluid particles which are in contact with them. It is a well-established fact, which no one now can call in question, that the chemical and physical phenomena already mentioned, namely, the resolution of sugar into carbonic acid and alcohol, and the upheaval or foaming of the mass, are intimately connected in some way or other with the life of a minute cellular fungus. When the life of the cells is destroyed by poison, the act of fermentation ceases. When the life of the cells is active by reason of a genial warmth, the presence of an abundance of mineral food, albuminous matter, and plenty of sugar, then fermentation is briskly carried on. By the addition of a very small quantity of yeast to mash or wort, a multitude of living cells are introduced into a liquid medium adapted in the highest degree to their nutrition, and they are thus capable of vegetating with most extraordinary rapidity. Pasteur has recorded an observation of the rapidity of growth of the wine ferment at even such a low temperature as 12° or 13° C. = 55° F.

"On October, 12th, 1861, at 10 o'clock in the morning, we crushed some grapes, without filtering the juice that ran from them; afterwards, at different times during the day, we examined the juice under the microscope, until at last, although not before 7 o'clock in the evening, we detected a couple of cells. From that time we kept these contiguous cells constantly in view. At 7.10 we saw them separate and remove to some little distance from each other. Between 7 and 7.30 we saw on each side of those cells, a very minute bud originate and grow little by little. These buds developed very near the point of contact, where the disjunction had just taken place. By 7.45 the buds had increased greatly in size. By 8 they attained the size of the mother cells; by 9 each cell of each couple had put forth a new bud. We did not follow the multiplication of the cells any further, having seen that in the course of two hours two cellules had furnished eight, including the two mother-cells." This increase is really nothing like so rapid as it would have been at a temperature of 77° to 86° F. (25° or 30° C).

The process of budding usually commences by a distortion of the cell at one side, which is followed by the cell-wall protruding; the protuberance increasing in size, becomes more or less rounded in shape; then a sort of strangulation process commences, which causes the cell-walls of the protuberance to meet, and at last the bud becomes detached. Sometimes a cell gives rise to several protuberances at once. An inaccurate discription of the mode of propagation of yeast has been given by certain writers, in consequence of which it is believed that the yeast cells burst, and that the contents, which are of a granular nature, attach themselves to mature cells and there grow. This, according to Pasteur, is never the case, though it is true that the yeast cells, under some abnormal circumstances of very rare occurrence, do occasionally burst. Their propagation, however, does not depend upon their bursting.

If we examine a speck of brewer's yeast under the microscope, with a magnifying power of from 400 to 600 diameters, we observe that certain of the oval cells are more or less elongated, while others are more nearly spherical in shape, and they are all isolated. In many of them there are apparently vacant spaces which are lighter or darker than the surrounding parts of the cell according as the object or the object-glass is slightly shifted. Granulations, too, are seen in the cells, and they present altogether a somewhat shrivelled appearance. Such cells are suffering from deficient nutrition an insufficiency of food; they are, in fact, half starved. If they be transferred to some fresh wort, and placed in shallow saucers so that they are freely exposed to the air, their appearance will be greatly improved. They will be seen to have filled out and become fatter, while the vacuoles or vacant spaces have disappeared, the granulations are scarcely visible, and the distended cell-walls are difficult to see, they are nearly all budding, and the buds are at different stages of development. The characters of the two conditions of yeast, as described by Pasteur, may be shortly summed up as follows:—

Old Cells. — Isolation and granulation; shrinking of the protoplasm to the cell-wall and creation of vacuoles; shrivelled appearance.

Revived Cells. — Cells distended; appear transparent to a greater degree; budding and growth of buds until detachment; interior gelatinous matter contains fine granulations not easily seen, but appearing at a certain distance brilliant.

Brewers are acquainted with two varieties of yeast and two kinds of fermentation, namely, that which occurs at a high temperature, and the yeast of which rises to the surface of the liquid is called a "high fermentation;" that which, on the contrary, is conducted at a low temperature, and the yeast of which is below the surface of the liquid, is called a "low fermentation." With all our brewers and distillers high fermentation is in universal favour, it is so much more rapid in its action, and generally saves both time and space. To adopt the process of low fermentation in a London brewery, would probably necessitate a large outlay for the extension of premises for the storing of beer while undergoing the prolonged process. This mode of fermentation is in operation at the Tottenham lager beer brewery, which has been specially built for the process. Both the high and low yeasts are the products of careful cultivation extending through past ages, the original and parent form of which was probably some variety of fungus growing upon either the hop or grape vine. Wheat is the cultivated product of some cereal, the original form of which has been lost, and in the case of these yeasts evolution has endowed them with new properties.*

The following is a description of the properties of these two varieties of the yeast fungus, which is termed *Saccharomyces cerevisiæ*:—

Low Yeast.—This may be appropriately termed German beer yeast, since it is almost entirely used in the brewing of lager beer.

The cellules are round or oval in their greatest diameter. It ferments wort at temperatures as low as (6° to 10° C.) 43° to 50° F.; under such cold wort other yeast is quite inactive. It never rises to the surface, even when the temperature increases to (20° C.) 68° F., and the fermentation becomes tumultuous. Its budding is less branched than is the case with high yeast.

High Yeast.—The cells are rather larger than those of the low ferment, and present a more globular appearance. Its budding is very rapid and more branched in form. It rises to the surface of liquids during fermentation, forming a head sometimes 6 ft. in height. It developes at (16° to 20° C.) 60° to 68° F.; at low temperatures it is quite inactive. When active fermentation takes place, in round or oval vats, the yeast rises upwards from the bottom at the circumference, and travels over towards the centre. The smell of acetic ether is generally perceptible in the gas which escapes.

* Even the yeast from different breweries ferments differently. Mr. Edward Purser informs me that yeast from Bass's brewery, at Burton-on-Trent, is extraordinarily active when transferred to Guinness's fermenting vats in Dublin, but in time its action becomes tranquil, being modified by the surrounding circumstances, and, probably by some difference in nutrition.

Rees has shown that high and low yeast may be obtained by cultivation under favourable conditions from opposite varieties, and he considers, therefore, that they belong to the same species, *Saccharomyces cerevisiæ*.

A second high yeast was discovered accidentally by M. Pasteur, which produces a beer with a special flavour resembling that of wine. The cellules are oval and indisposed to branching, in this resembling low yeast, but they rise to the surface like the preceding variety.

As fermentation is a process of great importance to the brewer and distiller, and one which is liable to miscarry unless great attention is paid to details in its management, I propose to state the conditions by which uniformity in the results are likely to be secured. These are—

1. A saccharine solution of a suitable strength containing a certain proportion of phosphoric acid free or combined, salts of potash and magnesia, and a sufficiency of nitrogenous substances as nutriment.

2. A pure yeast in a healthy state.

3. A suitable temperature.

4. Perfect cleanliness in the fermenting tuns.

5. Due proportion of yeast to sugar in the solution.

With regard to the proper strength of solution, it has been shown by Helmholtz that fermentation is only active and complete in solutions sufficiently diluted with water. If the proportion of water to sugar be less than four parts to one, the solution is too strong, and after a certain time the alcohol resulting from so large a proportion of sugar precipitates the albuminous matters in solution, and destroys the fermenting power of the yeast. An excess of sugar acts likewise in another way; it diminishes the amount of water in the interior of the yeast cell to a quantity below that which is necessary for its vital functions. If the sugar solution be too dilute, the irregularity in the fermentation and its slowness are apt to cause a secondary fermentation, which converts alcohol into acetic acid. This entails a double disadvantage; there is a loss of alcohol and an objectionable acidity which, beyond a certain point, has a retarding effect upon fermentation, notwithstanding the fact that yeast is always acid.

1. As yeast is a plant of low organisation, it is necessary to supply it with the mineral, and organic material such as will contribute to the formation of fresh tissues during reproduction and development. To ascertain what these are, we must turn to chemical analysis for our knowledge. According to Schlossberger (*Ann. der Chemie und Pharmacie*, vol. 51, p. 199) purified yeast contains:—

	High Yeast.	Low Yeast.
Carbon....	49·9 per cent.	48·0 per cent.
Hydrogen..	6·5 "	6·5 "
Nitrogen..	12·1 "	9·8 "
Oxygen ..	31·4 "	35·7 "
Ash......	2·5 "	3·5 "

Wagner's analysis:—

	High Yeast.	Low Yeast.
Carbon....	49·8 per cent.	44·4 per cent.
Hydrogen..	6·8 "	6·0 "
Nitrogen..	9·2 "	9·0 "

Schlossberger found the albumenoid cell-contents of the yeast to contain:—

Carbon.................	55·5 per cent.
Hydrogen	7 "
Nitrogen	13·9 "

Nægeli has examined the proximate constituents of yeast in a most careful manner (Mayers *Lehrbuch der Gährungs-Chemie*, p. 113). The sample was a low yeast, containing 8 per cent. of nitrogen, and it consisted of:—

Cellulose, gum, and cell membrane	37 per cent.
Albumenoids..............	45 "
Peptones	2 "
Fat	5 "
Extractives (leucine, cholesterine, dextrin, glycerine, succinic acid	4 "
Ash......................	7 "

It will be seen that nitrogen is a very important element, and nitrogenous matters must be a necessary form of nutriment for yeast.

This fact is now recognised, and it has been proposed by Birne, that in the fermentation of solutions containing a deficiency of such material, leguminous seeds, such as beans, should be steamed, and the mash so prepared be added to that about to undergo fermentation. The reason for this proposal lies in the fact that the leguminosæ are rich in a nitrogenous substance called asparagin, which has been found to be an excellent nutritive material for the yeast plant. Its composition is $C_4 H_8 N_2 O_3$, it is closely related to malic acid, as likewise is aspartic acid—

$$C_2 H_3 (OH)(CO OH)^2.$$

It is a well-known fact that yeast can derive its nitrogen and carbon from ammonia salts of organic acids, as for instance, ammonium tartrate. Pasteur's solution, which on exposure to air will undergo spontaneous fermentation by the nutrition of germs which fall into the liquid, is composed of sugar 10 grams.; tartrate of ammonia 1·0 gram.; yeast ashes of phosphate of ammonia 0·1 gram. (*Ann. de Chemie et Physique*, 3 vol. 58.)

The inorganic constituents of yeast, as shown by an analysis of the ash, were determined by me some fifteen years since to be very pure phosphate of potash, containing no trace of soda or other base, and soluble silica in small proportion. The analysis was made upon the ash yielded by 14 lbs. of compressed yeast from Messrs. Whitbread's brewery. The exact figures of my own analyses I cannot quote, but other chemists give figures in which 50 to 59 per cent. of phosphoric acid is combined with 29 to 39 per cent. of potash, 4 per cent. of magnesia, and 2 per cent. of lime. It is impossible to ferment sugar properly, unless these salts are present in the liquid in sufficient quantity. One might as well try to grow corn in the air, or feed a horse on water, as cultivate yeast without mineral nutriment, consisting of the phosphates of potash and magnesium.

2. The use of pure and healthy yeast is a condition of the very highest importance, but one which has been too much neglected, both by brewers and distillers.

There are several kinds of yeast which produce alcohol during the fermentation of wine or beer; they are named as follows:—

1.	Saccharomyces	Cerevisiæ	(Mayen)
2.	,,	Ellipsoideus	(Rees).
3.	,,	Conglomeratus	(Rees).
4.	,,	Exiginus	(Rees).
5.	,,	Pastorianus	(Rees).
6.	,,	Minor	(Engel).
7.	,,	Mycoderma	(Rees).

The species No. 6 is found in fermenting dough. No. 7 only acts as an alcoholic ferment under special conditions.

Where yeast becomes foul, it is because of the presence of more minute organisms, such as the *Bacterium termo*, which can oxidise alcohol into acetic acid; the *Bacillus amylobacter*, and the *Bacillus subtilis*, which yield lactic and butyric acids from even cellulose, starch and sugar. Certain forms of mould also produce foul yeast, as *Mucor mucedo*, *Mucor stolonifer*, and *Penicillium glaucum*. While the three last common forms of mouldiness can be readily seen, the presence of the former, which are named *bacteria*, or rod-like organisms, cannot be recognised without the aid of a powerful microscope capable of magnifying 500 diameters, at least. Yeast-cells may be diseased without being putrid, and they may be unhealthy without being diseased. The foul or diseased yeast is that which is mixed with minute organisms which it would be incorrect to describe as parasitic in character, but which thrive in fluids in which the *saccharomyces* developes. They are small rod-like or thread-like bodies, organisms very much smaller in size than the yeast-cells, and more difficult to observe, so that a magnifying power of not less than 400 diameters, with glasses capable of the best definition, are necessary. It is better to employ objectives with a magnifying power of 750 diameters. Were these disease organisms absent, acetous fermentation could not take place.

There are two customs practised with regard to the fermentation process; the first is the change of yeast of one brewery for that of another, the second, the mixing of several kinds of yeast, that is to say, the produce from different breweries, which is adopted by distillers. When the brewer finds his beer is being spoilt, and the fermentation process is getting troublesome, he sends to another brewery for some fresh yeast. Such a state of things as necessitates this arrangement is always found to coincide with a swarm of the thread-like organisms among the yeast-cells and in the beer. Sometimes they are found in the finings, and are therefore introduced after the chief fermentation process is over. The foreign organisms, smaller than yeast-cells, have much less vitality, and can therefore be made to perish by a treatment which is not injurious to the larger fungus. Pasteur has devised three methods of purifying yeast; they are the following:—

1. Growing yeast in water containing 10 per cent. of sugar. The operation to be conducted in shallow basins.

2. Growing yeast in wort containing an addition of 1½ per cent. of tartaric acid and 2 to 3 per cent. of alcohol.

3. Purifying successive growths of yeast by addition to the wort of a 10 per cent. solution of carbolic acid, in the proportion of one part of the solution to every hundred of wort. (Pasteur, *Studies on Fermentation*, p. 232.)

These methods are said to be impracticable on a large scale, but the following process of purification is deserving of attention.

Washing the yeast with an aqueous solution of salicylic acid, containing not more than one part of the substance in 10,000 of water, and not less than one in 20,000. (J. Bersch, *Gährungs Chemie für Praktiker.)*

The growth of the smaller organisms is checked, if not altogether stopped, by the action of disinfectants, but the yeast continues to develop with great rapidity, and soon greatly outnumbers the others. The purification of yeast by cultivation in pure sugar, and not in an infusion of malt or grain or a potato mash, is dependent upon a fact observed by Mayer, namely, the absolute necessity for inorganic nutriment, consisting of phosphoric acid and potash, while the yeast is in the saccharine solution, and the exhaustion of the plant if this be omitted.

The yeast may become unhealthy even when not diseased, by being grown for too long a time in a liquid deficient in mineral food; fermentation is thus languid, and those objectionable organisms, the filamentous ferments, may gain the race in the production of alcohol or acid. There is no doubt that in all fermentations artificially carried on, there are two processes at work, that which is alcoholic and that which is acid; and the result is favourable or unfavourable as the one or the other is the more rapid.

In a mash made from grain the necessary mineral food is always present, but it is doubtful whether there is always sufficient in a mash made of potatoes; indeed, in this latter case, it depends very much upon how the mash is made.

The reason why a distiller uses a mixture of yeast of different growths is, because he gains greater uniformity in the results from a given weight of the material; for where one growth may be deficient in mineral nutriment, the cells old and languid, another may be contaminated with disease ferments, while other two kinds may be perfectly healthy and vigorous. The law of the survival of the fittest then comes into play, and the most healthy cells increase with such rapidity, that the others are soon found to be in a very small minority.

3. The third condition is a suitable temperature to which yeast may be exposed without injury. Yeast may be subjected to a temperature of 32° F., provided the rise of temperature subsequent to this is gradual. If carefully dried, it will withstand heating to 212° F. Damp yeast loses its activity at or about 128° F. The most advantageous temperature for fermentation lies between 77° and 86° F. These conditions are easily stated, but not so easily maintained, because a large amount of heat is evolved during fermentation which escapes if the quantity of liquid is not very large, but the tuns hold many thousand gallons of mash and the increase in temperature is greater than the cooling power of the surrounding air. This fact may be observed in the record of some experiments carried out by Donovan; the quantity of fluid under examination is not stated, nor is the temperature of the atmosphere recorded, but we have the course of the fermentation indicated by the original gravity of the wort, and its decrease by the resolution of the sugar into alcohol and carbonic acid :—

Time.	Temperature.	Specific gravity of wort.
1st morning	70° F.	1·050
,, evening	70° F.	1·050
2nd morning	72° F.	1·046
,, evening	76° F.	1·032
3rd morning	80° F.	1·022
,, evening	84° F.	1 012
4th morning	88° F.	1·007
,, evening	88° F.	1·005
5th morning	88° F.	1·003
,, evening	88° F.	1·001

The course of a fermentation depends much upon the weather lasting from three to nine days, but the rise of temperature as here indicated is as much as 18° F. It is an advantage for fermenting tuns to be made of iron, with an outer jacket of wood; in this way the outside air is less liable to affect the temperature of the liquid, and, should the mash become too warm, cold water may be made to circulate inside the jacket, or steam, as circumstances require. Another plan for regulating the temperature of fermentation is to have the tuns enclosed in a wooden chamber, and above the surface of the liquid for coils of pipes to be placed, through which may circulate a refrigerating mixture for reduction of temperature, or steam for an increase. It is not, however, so necessary, as a rule, to hasten fermentation by warmth, because the initial temperature of the wort can be easily adjusted.

4. Cleanliness of the fermenting vessels is obviously of importance, because otherwise other ferments than the alcoholic may easily cling to the sides, and so induce an acid fermentation; this is particularly the case with the *Bacterium termo*. On this account

it is of importance to have the fermenting vessels constructed of some material which is easily cleansed. The best form of fermenting tun, when not made of metal, is that which is made of oak, rendered perfectly impervious to liquids by the staves being soaked in melted paraffin or in a shellac varnish. (J. Bersch. *Gährungs Chemie für Praktiker.*)

Melsens (*Comptes Rendus*, vol. 70, p. 629) has made some observations on beer yeast, and arrived at the following conclusions, which are indicative of the extraordinary vitality of this organism :—

1. Fermentation can proceed among melting ice, that is to say, at a temperature too low for the germination of grain.

2. Yeast immersed in water enclosed in strong vessels, is capable of resisting compression caused by the effort to expand when the water is frozen, even when the expansive force is equal to a pressure of 8,000 atmospheres.

3. The energy of the ferment is diminished, but life is not destroyed by a degree of cold more intense than any artificially produced (1870), or about—100° C.

4. Alcoholic fermentation is suspended when the temperature is kept for some time at 45° C. (120° F.)

5. Alcoholic fermentation is arrested when it proceeds in closed vessels, and when the pressure of the evolved carbonic acid exceeds 25 atmospheres the yeast is killed.

Some remarkable experiments were made by the late M. Dumas on fermentation. *(a)* He has shown that it takes exactly twice as long to ferment cane-sugar as grape-sugar, in point of fact, the process of inverting the cane-sugar requires as much time as the conversion of the glucose into alcohol. *(b)* When the proportion of yeast to glucose was 20 to 1, the fermentation was just as rapid as when five times as great, or 100 to 1; in other words, under identical circumstances, yeast being in excess, the duration of fermentation is proportional to the quantity of sugar. The regularity of the reaction upon the sugar is caused by the great multitude of cells taking part in the fermentation. With a magnifying power of 550 diameters, there were counted 60 to 77 distinct cells in each apparent square millimètre, which means 19,800 cells per actual square millimètre, or 2,772,000 per cubic millimètre, so that, in introducing 10 cubic centimètres of yeast paste into 150 cubic centimètres of water, there were really employed twenty seven thousand seven hundred and seventy-two millions of cells. (*Annales de Chemie et de Physique*, 5, vol. 3, p. 57.)

Some idea of the magnitude of this number may be conveyed in the statement that every second of a man's life, if he lived for about 900 years, would not out-number these yeast-cells.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

Report on Electric Lighting. By Prof. George Forbes.

The following is the first of a series of reports on the Exhibition which it is proposed to publish in the *Journal* :—

The electric light at the Health Exhibition this year resembles very much that of last year at the Fisheries Exhibition in the same place. But to the critical eye there is a vast improvement; last year a gigantic system was installed in haste, and there was not the means to estimate properly the extent to which the lighting would be carried. The experience then gained has gone far to smooth away the preliminary difficulties. The engine-shed has been enlarged, and the plant laid down according to a more intelligible scheme, and all the arrangements have a more systematic basis. The result is correspondingly satisfactory, and serves as the best connecting link between the isolated installations, which have hitherto been most common, and the centralised stations for large supply, which it is expected will soon be generally demanded. The most evident improvement is in the general arrangement of the engine-shed; but experience has also done much in guiding many companies to sounder views as to the dimensions of cables and other all-important details.

To begin with the engine-shed, steam-power is supplied chiefly by Davey-Paxman engines, three of these engines being employed to drive two long countershafts in one line; these are 60ft. and 45ft. in length respectively. From these a vast number of dynamos of various kinds are driven. There are also three special engines by the same makers working the dynamos of the Hammond Company, the Gülcher Company, and the Jablochkoff Company respectively. A Hodgson rotary engine and a "Tower" spherical engine are also at work each upon a "Victoria" dynamo of the Brush Company.

A gas-engine is also shown close by, driving another "Victoria" dynamo, to illustrate Mr. Dowson's system of generating gas for the purposes of motive power.

One of Lautensach and Bittner's gigantic thermopiles has also been placed in the engine-shed, but it does not seem to have been put in operation up to the present date.

Nearly the whole length of the building is occupied on one side by two large Davey-Paxman pairs of horizontal engines, and the six boilers required for this duty. These boilers also supply steam to the two rotary engines mentioned above.

These six boilers are all connected together. One main water-pipe runs along the whole length of the six, and the pumps are so connected, that if one fails, the others act and supply through the main. The pumps are by Mumford, of Colchester. There is a throttle-valve attached for the feed of each boiler. Each boiler has an independent safety-valve and stop-valve. The exhaust steam is carried away by the funnels of these boilers. The steam pipes to the two engines are connected with all the boilers.

Each of the two large engines indicate about 350 horse-power. The one which drives the 60-ft. countershaft has a 19-in. cylinder and 32-in. stroke. It is mounted on girders instead of being upon a solid bed-plate. This is for convenience of export. The cylinders are connected to the girders by strong brackets, which give great rigidity. The main valve is in a separate case to the cut-off valve, and this involves the use of less pressure to move the main valve. The cut-off can be varied from 0 up to $\frac{3}{4}$. There is a cylinder on each side of the driving wheel, and one governor acts upon both. The governor is supplied with a spring, to vary the action of gravity, so that the speed may be increased. It is not driven by belts, but by toothed-wheel gearing. The efficiency of one of these governors was shown on a recent occasion here, when the 21-in. link leather belt broke when in full action, and the speed changed by barely a revolution a minute. Schönheyder's lubricator is used in this engine. There are two driving pulleys 12 ft. diameter and 16 in. wide. The engine runs at 72 revolutions, and the pressure of steam has been 85 lbs. These driving wheels have each a 15-in. belt of linked leather driving a pair of 39-in. pulleys on the long countershaft, the distance between centres being 31 ft.

The second large double-cylinder engine drives a countershaft of 45 ft. length. This engine resembles the first, but it has an $18\frac{1}{2}$-in. cylinder, with a 32-in. stroke. It has only one driving-pulley, 12 ft. diameter and 24 in. wide. The 19-in. linked leather belt which broke on this work has been replaced by another, 24-in. wide.

The third engine, of Messrs. Davey and Paxman, is a fixed horizontal compound engine, in use by the Hammond Company to drive the Ferranti 1,000-lighter alternate current machine, a 40-lighter Brush machine, and a Ferranti 200-incandescent lighter. It has a single gridiron valve and a cut-off valve. The exhaust valve is in the same case as the slide valve of the low-pressure cylinder; the latter cuts off at $\frac{1}{2}$-stroke. The high-pressure cylinder has a diameter of piston of 15 in. and a stroke of 2 ft., and the low-pressure 22-in. with a 2-ft. stroke. This engine has indicated up to 220 horse-power, with a pressure of 120 lbs. It drives two pulleys, one 10 ft. diameter and 16 in. wide for the large Ferranti machine; the other a smaller one for the other two dynamos. This engine is fed by two boilers called a 50 and a 16 horse-power boiler respectively. These have each a donkey pump and injector.

The fourth engine is a compound one used for seven Fülcher dynamos. It resembles the last, but the diameters of the high and low pressure cylinders are $12\frac{1}{4}$ and $20\frac{1}{2}$ in., and the stroke 2 ft. It runs at 100 revolutions. With its attached boiler it can indicate 130 horse-power. The driving wheel is 8 ft. 6 in. by 16 in.

Another semifixed compound engine on the top of its boiler works the Jablochkoff dynamos. It has no special features of interest.

The first large engine described is assisted in driving the principal countershaft by a 25 horse-power engine, working, it is said, up to 100 horse-power. Altogether over 1,100 horse-power is developed in the engine-shed.

The main countershaft, 60 feet long, drives two secondary countershafts, one of them driving six Gramme machines of the British Electric Light Company, viz., two A's, one D, and three E's; the other driving ten double Edison machines. It also drives the following dynamos direct:—One Bürgin, four Pilsen Joel, one Siemens alternate current with exciter (small), and two Paterson and Cooper's "Phœnix" machines, all these on one side of the countershaft, and on the other side one huge Siemens direct machine for 420 ampères and 80 volts, a Clerk machine with Siemens exciter (for the "Sun" lamps), two large low resistance Siemens alternate current machines with exciter, and another Siemens direct current dynamo. An Elphinstone and Vincent 400 lighter machine is also in place and at work.

The second countershaft, 45 feet long, drives three Hochhausen dynamos, one Brush (23 arcs), one Oppermann with exciter, and one Gerard.

A great deal of interest attaches to the large machine exhibited by the Hammond Company. This is a 1,000 incandescent lamp alternate current machine by Ferranti. It resembles his well-known type of machine in many respects, but is conspicuous for the perfecting of details of construction, and for some novelties which are introduced. It is fed by a large quantity of Siemens direct current dynamos, attached to the same shaft as the alternate current machine. The shaft has a large bearing on each side of the Ferranti armature, of the fly-wheel, and of the Siemens armature, and has, in addition, a thrust bearing. These bearings are lubricated under pressure, the oil being collected in a reservoir, filtered, and pumped up to a supply reservoir. In the other types of Ferranti machine it has been found that, to prevent abrasion, the collecting rings must be oiled, and the resistance thus introduced is in many cases equal to the total resistance of the armature. In the present type of machine the terminal wires are attached to rings on the shaft which rotate within hollow rings, the intermediate space being filled with mercury to complete the electrical contact. This arrangement seems to work admirably. This device was patented by me in 1883. It has been said that the direct and alternate machines are on the same shaft. This is not strictly so, for the shaft of the Siemens machine is driven from that of the Ferranti machine through a leather ring clamped to each of the shafts. The Siemens machine gives 30 ampères and 120 volts, and works through the two sets of 24 Ferranti field magnets, each set of 24 being connected in parallel. The Ferranti machine gives 400 volts at 600 revolutions. It supplies Woodhouse and Rawson lamps in the Aquarium refreshment bar and the dining-room in the conservatory.

Another large machine deserving special attention is the Siemens machine, exhibited by the water companies. It is called a B 2 dynamo. It is designed to give 420 ampères current, with 80 volts electromotive force, and is used for the fountain illuminations. On the armatures there are ribs of copper from end to end, held bound by strong metal bands enclosing them. These bands have their greatest width radial, to prevent local currents being developed, and are in pairs; and two pairs go to each terminal commutator. There are about twenty arms to the commutator. There are two pairs of brushes, each pair being side by side. The width of each brush is 4 inches. The position of the brushes is adjusted by a worm-wheel. The machine is compound wound, the series winding goes through the four arms of the field magnets in parallel, and is of wire about $\frac{1}{4}$ inch diameter; the shunt winding goes round all four arms in succession, and is of No. 12 wire. The mechanical and constructive details of this machine are worthy of close inspection.

A machine shown by the Brush Company shows the enormous improvement which can be introduced by recognising, and so dispensing with, the local currents in the mass of iron constituting the armature. In this machine the armature is built upon a coil of hoop-iron, with H pieces let in during the winding to support the coils. A very great gain is said to have been obtained by this alteration.

The Hopkinson-Edison type of machine, manufactured by the Edison Company at New York, is exhibited by the Edison-Swan Company.

Of other machines mention may be made of the cheap classes of direct current and alternate current machines shown by Oppermann. The Gerard Company also show some small and cheap machines; among these is a very small compact laboratory machine, suitable to work with a treadle, which works four incandescent lamps.

The Victoria dynamos are on the model of the Schuckert machines, which, as turned out at Nürnberg, have acquired so high a reputation. In the Victoria, however, there are four poles, and the resulting pairs of coils on the armature are in parallel, so that there are only two brushes.

The Gramme, Hochhausen, Gülcher, Jablochkoff, Bürgin, Phœnix, and other machines, require no special notice here.

In the Consolidated Company's exhibit their secondary batteries are charged by a compact Parker-Elwell machine, with an 8-in. armature, giving 25 to 30 ampères and 130 volts; when run for a short time it can give 60 ampères without injury.

Having thus passed in review the dynamos at the Exhibition, it becomes a matter of interest to learn the size of cables used by different firms, and the current carried by them. In the following table the name of the company or firm, or other distinguishing mark, is given in the first column. The number of cables in parallel, or sections, is given in the second. The size of wire is in the third, thus 7/16 means 7 wires of No. 16 in a cable. The current in ampères fills the fourth, and the fifth gives the ampères in volts:—

The total illumination is over 5,000 incandescent lamps, besides some 300 arc lamps. It is worthy of remark that Sir F. Bolton's fountain display uses up from 120 to 180 horse-power in the illuminations. As this Exhibition is to a great extent illustrative of what can be done on a large scale, the nature of the lighting is worthy of record. The following facts have accordingly been compiled for the purpose.

Arc Lighting.

The small corridor and the south promenade and vegetarian room are lighted by 11 Ball lamps with 1 Ball dynamo; the electric machinery room by 6 Werner and 6 Cardew lamps, fed by 1 Brush machine; the west corridor and the south annexe by 8 Clark Bowman lamps with 1 Phœnix dynamo; Old London by 5 Lea lamps with 1 Gramme dynamo; the south central avenue and part of the east and west central gallery are lighted by 60 Jablochkoff candles with 3 machines, and there is a fourth spare one; in the west central gallery, 7 Brockie lamps and 1 Gramme dynamo; west and east annexes, 23 Brush lamps and 1 dynamo; east corridor, west and east quadrants, east arcade, and Du-Val dining-room, 40 lamps and 1 Brush dynamo by the Hammond Company; west gallery, 39 Pilsen lamps, 3 Schuckert dynamos; central gallery, 29 lamps, and 1 machine by Hochhausen; central fountain by 1 lamp and machine by Crompton, 10 lamps and 1 machine by Clerk, the latter being also distributed in the cascades and water pavilion garden. The Clerk machine is designed for 3 circuits of 10 lamps each. The Queen's-gate entrance has a Fox lamp and Oppermann machine; the masthead has 6 lamps on 1 machine by Hochhausen, and the conservatory has 4 lamps on 1 machine by Siemens.

Incandescent Lighting.

Ten Edison machines light the following spaces:—Entrance vestibule, 23 Swan lamps and 107 Edison lamps; the arts gallery, 172 Swan and 122 Edison; Bertram and Roberts' dining-rooms, 64 Swan and 264 Edison; cheap dining-room, 31 Swan and 115 Edison; literary superintendent's room, 20 Edison. The south gallery, 2 Siemens alternate machines with 2 exciters—1,063 Swan lamps; dairies, 2 Gülcher machines, 370 Crookes lamps; Old London, 1 Gramme and exciter, and 30 lamps by Mackie; east central gallery, 340 Gatehouse lamps and 1 Elphinstone Vincent dynamo; water company pavilion, 1 Oppermann alternate current machine with exciter, and 234 Woodhouse and Rawson lamps; Prince of Wales pavilion, 1 Siemens with exciter, 180 Swan lamps, and 1 Siemens with exciter to 40 Woodhouse and Rawson 25 volt and 10 candle power, besides 10 of 50 volts and 20 candle power; the aquarium, west arcade, and west dining-rooms and tea-rooms, 1 Ferranti alternate current dynamo with Siemens exciter, and 909 Woodhouse and Rawson lamps; refreshment bar, 1 Phœnix dynamo and 40 half Bernstein lamps of 25 candle power; cocoa tavern, 1 Victoria dynamo, and 100 Victoria lamps of 100 volts and 20 candles; Chinese restaurant, 204 Crookes 50 volt lamps, which with 300 more are fed by 6 Gülcher machines; Indian Court, 38 Bernstein lamps on a Hochhausen machine. Nineteen of these are series on two parallels. Doulton's pavilion has 24 Gerard lamps of 50 candles on 2 Gerard machines.

The only secondary batteries in regular action are those of the Consolidated Company in the machinery in motion gallery. The plates are made of corrugated strips of lead coiled into a disc and pressed into a square form.

Twice the lighting has failed up to this date (August 14). Once a driving belt gave way, and once a boiler-feeding valve stuck, and the boilers being all connected together the steam escaped. It may be said that the boilers being connected in parallel, and one of them short circuiting the mains, the whole of them were burnt up or run dry).

Mr. W. D. Gooch has superintended all the arrangements. Everything seems to be as well arranged as is possible with so great a mixture of systems in use. This is the most extensive application of electric lighting hitherto seen in this country.

BRITISH ASSOCIATION.

Sir Frederick Bramwell's Address to the Mechanical Science Section.

After alluding to the formation of Section H, Sir Frederick Bramwell said—At our jubilee meeting at York, I called the attention of the Section to the fact that in 1831, when the Association first met in that city, they arrived there laboriously by the stage-coach, and that practically the Manchester and Liverpool, the Stockton and Darlington, and some few others, were the only railways then in existence. I also called their attention to the fact that in 1831 there were but very few steamers. I find the total registered in the United Kingdom in that year was only 447. If under this condition of things, the proposition had been made in 1832 at Oxford, as it was made in 1882 at Southampton, that the next meeting but one of the Association should take place in Montreal, the extreme probability is that the proposer would have been safely lodged in a lunatic asylum, for suggesting that that which might have involved a six-weeks' voyage out, and a four-weeks' voyage back, could ever be seriously entertained.

. . . . . .

There are those I know who object that Section G deals too little with pure science, too much with its applications. It may be, as the members of Section G might retort, that it is possible to attend so much to pure science as to get into the unchecked region of scientific speculation. . . . I think all men, even although they be followers of science in its purest and most abstract form, will concur in the propriety of Section G dealing with engineering subjects generally as well as with abstract mechanical science. Once admitting this, I may ask—certain what the answer must be—whether there is any body of men who more appreciate and make greater use of the applications of pure science than do the members of this Section. Surely every one must agree that we engineers are those who make the greatest practical use, not only of the science of mechanics, but of the researches and discoveries of the members of the other Sections of this Association.

Section A (Mathematical and Physical Science).—The connection between this Section and Section G is most intimate. With any ordinary man I should have referred, in proof of this intimate connection, to the fact that the President of A this year is a member of the Council of the Institution of Civil Engineers; but when I remind you that it is Sir William Thomson who fills this double office, you will see that no deduction such as I have hinted at can be drawn from his dual functions, because the remarkable extent and versatility of his attainments qualify him for so many offices, that the mere fact of his holding some one double position is no certain evidence of the intimate connection between the two. But setting aside this fact of the occupancy of the chair of A by a civil engineer, let us remember that the accomplished engineer of the present day must be one well grounded in thermal science, in electrical science, and, for some branches of his profession, in the sciences relating to the production of light, in optical science and in acoustics; while in other branches, meteorological science, photometrical science, and tidal laws are all important. Without a knowledge of thermal laws, the engineer engaged in the construction of heat motors, whether they be the steam-engine, the gas-engine, or the hot air-engine, or engines depending upon the expansion and contraction under changes of temperature of fluids or of solids, will find himself groping in the dark; he will not even understand the value of his own experiments, and, therefore will be unable to deduce laws from them; and if he make any progress at all, it will not guide him with certainty to further development, and it may be that he will waste time and money in the endeavour to obtain results which a knowledge of thermal science would have shown him were impossible. Furnished, however, with this knowledge, the engineer starting with the mechanical equivalent of heat, knowing the utmost that is to be attained, and starting with the knowledge of the calorific effect of different fuels, is enabled to compare the results that he obtains with the maximum, and to ascertain how far the one falls short of the other; he sees, even at the present day, that the difference is deplorably large, but he further sees, in the case of the steam-engine, that which the pure scientist would not so readily appreciate, and that is, how a great part of this loss is due to the inability of materials to resist temperature and pressure beyond certain comparatively low limits; and he thus perceives that unless some hitherto wholly unsuspected, and apparently impossible, improvement in these respects should be made, practically speaking, the maximum of useful effect must be far below that which pure science would say was possible. Nevertheless, he knows that within the practical limits great improvements can be made; he can draw up a debtor and creditor account, as Dr. Russell and myself have done, and as has been done by Mr. William Anderson, the engineer, in the admirable lecture he gave at the Institution of Civil Engineers in December last on the "Generation of Steam and the Thermodynamic principles involved." Furnished with such an account, the engineer is able to say, in the language of commerce, I am debtor to the fuel for so many heat units, how, on the credit side of my account, do I discharge that debt? Usefully I have done so much work, converted that much heat into energy. Uselessly I have raised the air needed for combustion from the temperature of the atmosphere to that of the gases escaping by the chimney; and he sets himself to consider whether some portion of the heat cannot be abstracted from these gases and be transmitted to the incoming air. As was first pointed out by Mr. Anderson, he will have to say a portion of the heat has been converted into energy in displacing the atmosphere, and that, so far as the gaseous products of the coal are concerned, must, I fear, be put up with. He will say, I have allowed more air than was needed for combustion to pass through the fuel, and I did it to prevent another source of loss—the waste which occurs when the combustion is imperfect; and he will begin to direct his attention to the use of gaseous or of liquid fuel, or of solid fuel reduced to fine dust, as by Crampton's process, as in these conditions the supply may be made continuous and uniform, and the introduction of air may be easily regulated with the greatest nicety. He will say, I am obliged to put among my credits—loss of heat by convection and radiation, loss by carrying particles of water over with the steam, loss by condensation with the cylinder, loss by strangulation in valves and passages, loss by excessive friction or by leakage; and he will as steadily apply himself to the extinction or the diminution of all such causes of loss, as a prudent Chancellor of the Exchequer would watch and cut down every unproductive and unnecessary expenditure. It is due to the guidance of such considerations as these that the scientific engineer has been enabled to bring down the consumption of fuel in the steam-engine, even in marine engines such as those which propelled the ship that brought us here, to less than one-half of that which it was but a few years back. It is true that the daily consumption may not have been reduced, that it may have been even greater; but if so, it arises from this, that the travelling public will have high speed, and at present the engineer, in his capacity of naval architect, has not seen how—notwithstanding the great improvements that have been made in the forms of vessels—to obtain high speed without a large expenditure of power. I anticipate, from the application of thermal science to practical engineering, that great results are before us in those heat motors, such as the gas-engine, where the heat is developed in the engine itself. Passing away from heat motors, and considering heat as applied to metallurgy, from the time of the hot blast to the regenerative furnace, it is due to the application of science by the engineer that the economy of the hot blast was originated, and that it has been developed by the labours of Lowthian Bell, Cowper, and Cochrane. Equally due to this application are the results obtained in the regenerative furnace, in the dust furnace of Crampton, and in the employment of liquid fuel, and also in operations connected with the rarer metals, the oxygen furnace and the atmospheric gas furnace, and, in its incipient stage, the electrical furnace. To a right knowledge of the laws of heat, and to their application by the engineer, must be attributed the success that has attended the air-refrigerating machines, by the aid of which fresh meat is at the end of a long voyage delivered in a perfect condition; and to this application we owe the economic distillation of sea water by repeated ebullitions and condensations at successively decreasing temperatures, thus converting the brine that caused the Ancient Mariner to exclaim, "Water, water everywhere, nor any drop to drink," into the purest of potable waters, and thereby rendering the sailor independent of fresh-water stowage.

Sir Frederick Bramwell then proceeded to refer to the application, by the engineer, of electrical science, and to several other of the subjects dealt with in Section A. He then treated of the relations of mechanical science to the other sections, and concluded with these words:—

I trust I have now established the proposition with which I set out, viz., that not only is Section G the section of mechanical science, but it is emphatically the section of all others that applies in engineering to the uses of man the several sciences appertaining to the other sections; an application most important in the progress of the world, and an application not to be lightly regarded, even by the strictest votaries of pure science, for it would be vain to hope that pure science would continue to be pursued if from time to time its discoveries were not brought into practical use.

Under ordinary circumstances I should have closed my address at this point, but there is a subject which at this, the first meeting of Section G after the meeting at Southport, must be touched upon. It is one of so sad a character that I have avoided all allusion to it until the very last moment, but now I am compelled to grapple with it.

In the course of this address I have had occasion to mention several names of eminent men, many of them happily still with us, some of them passed away; but I doubt not you have been struck by the absence of one name, which of all others demands mention when considering physical science, and still more does it come vividly before us when considering the application of science to industrial purposes. I am sure I need not tell you this name, which I can hardly trust myself to speak, is that of our dear friend William Siemens, whose contributions to science, and whose ability in the application of science, have for years enriched the transactions of this Section, and of Sections A and B, for in him were combined the mechanic, the physicist, and the chemist.

But a brief year has elapsed since he quitted the presidential chair of the Association, and, with us at Southport, was taking his accustomed part in the work of this and of other sections, apparently in good health, and with a reasonable prospect of being further useful to science for many valuable years to come. But it was not to be; he is lost to us, and in losing him we are deprived of a man whose electrical work has been second to none, whose thermic work has been second to none, and whose enlarged views justified him in embarking in scientific speculations of the grandest and most profound character. Whether or not his theory of the conservation of the energy of the sun shall prove to be correct, it cannot be denied that it was a bold and original conception, and one thoroughly well reasoned out from first to last.

I feel that were I to attempt anything like the barest summary of his discoveries and inventions, I should set myself a task which could not have been fulfilled had I devoted the whole of the time I had at my command to the purpose. I had, indeed, thought of making his work the subject of my address, but I felt that his loss was so recent that I could not trust myself to attempt it. There is no need for me to dwell further upon this most painful topic. He was known to you all, he was honoured and loved by you all, and by every member of this Association he had so faithfully served, and over which he had so ably presided; and he enjoyed the respect and esteem of the best intelligence of England, the land of his adoption; of the Continent, his birthplace; and of Canada, and of the United States, whose populations are always ready to appreciate scientific talent and the resulting industrial progress. It is not too much to say that few more gifted men have ever lived, and that with all his ability and talent he combined a simplicity, a modesty, and an affectionate disposition that endeared him to all.

I am sorry to conclude my address to you in this mournful strain. I have endeavoured to confine my allusions to our dear friend within the narrowest limits, but if I have overstepped these I trust you will forgive me, remembering that "out of the fulness of the heart the mouth speaketh."

WOOD INDUSTRIES OF RUSSIA.

Few countries, says the *Times*, can show a better utilisation of forest products than Russia, and particularly in the furnishing of industrial employment to the peasantry. Carriage and cart building forms an important item in woodwork, giving occupation to at least 530 villages, particularly in the governments of Nijni Novgorod, Viatka, Kazan, Moscow, Riasan, Vladimir, Jaroslav, Tula, and Kalug. The annual production in the government of Moscow is 116,000 roubles, the wheels alone in that of Ekaterinburg amounting to the value of 145,000 roubles per annum. It is a singular fact, however, that a vehicle is rarely, if ever, finished on the spot where it was begun, one village providing the spokes, another the boxes, while a third will make the body. The manufacture of wooden spoons is on a large scale, about 126,000,000 being turned out every year. The same subdivision of labour is seen in this case, one workman cutting the wood into lengths, another shaping the spoon in the rough, a third hollowing it out, and a fourth varnishing it. The spoons are usually made of birch and poplar, or boxwood for the most expensive, the average price per 1,000 being from six to eight roubles. Some 3,200 cubic fathoms of wood are annually cut up into spoons, one cubic fathom making about 4,000. They are exported in great numbers *viâ* Irbit to Khiva, and *viâ* Astrakhan to Persia. The government of Kazan is noted for producing the majority of the "donga" or yokes, which are made of elm and willow. Of these, a family that includes three workmen will produce from 700 to 1,000 in the course of the winter. The frames, however, which are made of birch and maple, come from Kaluga, and are sent to market at Kursk. The alder tree yields the dye with which the harness is stained. Combs for weavers are a specialty of a place called Jegorieffalow, in the government of Riazan, and are produced at the rate of 500,000 a year, the reeds being bought in the south, and the metal work at Moscow. The spinning-wheels, however, all come from the government of Jaroslav. A place called Swenigrod, in Moscow government, supplies veneered and inlaid furniture and parquets; while Viatka, Kostroma, Vladimir, and Novgorod make the lacquered furniture peculiar to the empire. Tula provides concertinas to the amount of 250,000 per annum; and in Viatka government are also made organs and violins. In the same locality are grown great numbers of lime trees, the bark of which is turned into bast for matting and sacks, as also for making bast shoes, to the extent of 100 millions per annum. The best matting, known as "schangskaia," is imported to England, and to supply these industries, over half a million lime trees are annually cut down in Viatka. Paper-making is beginning to employ a considerable amount of wood, while of grosser industries, the annual production of tar is 2,000,000 poods (one pood equals 36 lbs.); of birch oil, 4,000,000 poods; pitch, 150,000; turpentine oil, 60,000; and charcoal, 8,000,000.

Obituary.

Sir Robert Richard Torrens, K.C.M.G.—Sir Robert Torrens died on Sunday, 31st ult., at Falmouth, after a short illness. He was the eldest son of the late Colonel Robert Torrens (some time M.P. for Boston, by his marriage with Charity, daughter of Mr. Richard Chute, of Roxburgh, county Kerry), and was born at Cork in 1814. He was educated at Trinity College, Dublin, and in 1841 was appointed Collector of Customs in South Australia. In 1852 he became Treasurer, and subsequently Chief Secretary of that colony. He was nominated a Knight Commander of the Order of St. Michael and St. George in 1872. He was also a magistrate for Devon, and M.P. for Cambridge, from 1868 till 1874. He became a member of the Society of Arts in 1872, and was occasionally a speaker at its meetings.

General Notes.

Gold-miners in New South Wales.—The number of miners engaged in gold-mining during the year, according to the returns furnished by the Mining Registrars, is 6,750. Of these, 5,742 are Europeans and 1,008 are Chinese. Taking the output of gold divided by the number of miners as indicating the average earnings of the miners, we find that each miner earned 18·34 ozs. of gold, valued at £67 18s. 6·53d., for the year.

Petroleum in Venezuela.—According to the *Corps Gras Industriels*, the portion of Venezuela comprised between the Rio Zulia, the Rio Cattamubo, and the Cordilleras has numerous asphalte mines and sources of petroleum. Special reference is made to a locality about four miles from the confluence of the Rivers Tara and Sardinartre, where jets of petroleum mixed with boiling water are thrown up. It is said that the rate of discharge is four gallons per minute. Venezuela petroleum has a density of 0·83. It is of interest to know that beyond the confluence of the rivers spoken of, the stream is navigable at all seasons for vessels of 40 to 50 tons burthen.

Vienna and Teplitz Exhibitions.—An Exhibition has been held at Vienna, organised for the express purpose of displaying the progress made in the application of machinery to manufautures on a small scale, in contrast with the extensive mechanical arrangements which are usually associated with modern industrial progress. The Hoffmeister motors for use in connection with electric power are spoken of in the *Metallarbeiter* as calling for special notice. The maximum force of the motors exhibited appear to be three horse-power. Up to about 20 years ago this branch of industry was comparatively neglected, and the very comprehensive display now organised deserves special notice. The Teplitz Exhibition, though local in its character, embraces subjects of general interest, and amongst them are various objects which illustrate the progress made by Austria in more than one branch of the metal industry.

CANTOR LECTURES.

FERMENTATION AND DISTILLATION.

By Professor W. N. Hartley.

Lecture III.—Delivered Monday, May 26th.

Distillation and the Products Therefrom.

One of the most delicate tests for alcohol consists in adding to liquid to be examined a little iodine solution and a small quantity of solution of potash; on gently warming, a yellow turbidity is seen, and frequently a crystallised substance separates out on standing. This is iodoform, which is insoluble in water, and is capable of being easily and well crystallised; the crystals are readily recognised by the microscope, and such is the delicacy of the reaction, that one part of alcohol in 300,000 of water may be detected with ease. By fractional distillation, the alcohol is concentrated in water, and by performing the concentration in an improved manner, less than $\frac{1}{1000000}$ of alcohol added to water has been proved to be present. This reaction M. Müntz has applied to the examination of river, rain, and sea water, and to the examination of the soil. (*Comptes Rendus*, vol. xcii., p. 499). All kinds of water, except that from springs, contain a substance capable of giving the iodoform reaction. This body is more volatile than water. It is absent from water specially purified, and it does not occur in very pure spring water. Alcohol, in fact, pre-exists in rain and snow water, both in town and country. The quantity in the River Seine is about $\frac{1}{1000000}$th, and the same amount is found in rain. This amounts to one gramme per cubic metre. Snow and sea water contain quantities not very different. This diffusion of alcohol in water is explained without difficulty. The surface of the globe and ocean depths contain organic matter in abundance, which is incessantly undergoing decomposition. Organisms of minute size, which execute this work of disintegrating organic matter, are nearly all capable of producing alcohol in greater or less quantity. M. Berthelot has observed (*Ann. Chimie et de Physique*, series 3, vol. l., p. 322) the production of alcohol from many different substances under the influence of various fermentative agents. There must be, it will be admitted, a continuous production of alcohol during the decay of vegetable matter freely exposed to the air and the organisms contained therein, especially when the vegetable matter contains starch, glucose, or glucosides. Even cellulose is known to undergo fermentation. If this be the case, alcohol should be found in the soil in notable quantities. Experiment has confirmed this view, by proving that poor soils contain sufficient alcohol to give a distinct reaction when only 100 or 200 grammes are used for the test; but rich soils, or soils rich in organic matter, contain large quantities of alcohol, so that it is indeed possible to extract this substance, and verify its essential properties. It is only necessary to consider that, though the alcohol is formed in the soil, it will obey the law of vapour tension, become vaporised and diffused in the atmosphere, from which it is washed out by the fall of rain.

The Dublin water supply is brought in closed pipes from the Wicklow Mountains to within five miles of the city, whence it is delivered from a reservoir in pipes at high pressure. Such water gives evidence of the presence of alcohol.

The third distinct order of our subject deals with the separation of the alcohol from water, after its preparation by the process of fermentation. The boiling point of water at the ordinary standard pressures of the atmosphere, equal to 30 inches of mercury, is 100° C. or 212° F., that of alcohol 78·5° C. or 173·1° F. At the sea level the pressure of the atmosphere may frequently vary between 28·5 inches and 30·5 inches; the boiling points of water corresponding to these temperatures are 210° F. and 213° F. Indeed, changes in the weather may cause the boiling point of water to vary as much as 5° F. in our climate. These alterations in pressure would cause corresponding changes in the boiling point of alcohol. If we gradually raise the temperature of alcoholic fluids to a point when vapours are freely formed, it is observed that though there is a continuous absorption of heat, yet the liquid does not increase in temperature. The heat which is absorbed during the first period is doing work of a different character from that employed subsequently. There are two phases in the process, and two different kinds of worked performed by the heat employed in boiling even a kettle of water.

The first phase is indicated by a rise of temperature from 60° F. to 212°; the second phase by a change of state, from that of a liquid at 212° to a vapour at the same temperature. The quantities of heat required by different liquids in these changes varies greatly, but the variation is greatest when they pass through the second phase. Thus one pound of steam at 212°, if converted into water at 212°, will give up heat sufficient to raise 996 pounds of water from 60° to 61° F. The heat rendered up by one pound of alcohol vapour at 173° during condensation to liquid at 173° will heat 374·9 pounds of water from 60° to 61°. These figures are sufficient to show that a small quantity of steam will boil a large quantity of alcohol. Stills of improved construction depend upon this principle.

The simplest form of distilling apparatus consists of a close vessel connected with a tube immersed in water; the tube is open, and as the vapours expand and pass into the tube, they are cooled down sufficiently to assume the liquid state, their heat being rendered up to the water. It is necessary, then, to have a large body of water to begin with, or else for the water to be continually changed. An ordinary still and worm consists of a boiling vessel with a large head for the accumulation of the bulky vapour, connected with a coiled tube immersed in a tub holding a large body of water, which is continually being changed. The coils of the tube are largest at the upper part of the worm tub, where the vapours are the most bulky. The change of water is effected in this way. A stream of cold water is conducted down to the bottom of the tube, which being there distributed, displaces the water at the top, this latter having condensed, alcohol vapour has become warm. As the liquid below gradually makes its way upwards, it comes in contact with successive coils of tube, each one being hotter than the other, until the top coil is reached, which is at a temperature differing but little from that at which the liquid is being distilled. The more perfect forms of stills are so designed as to take advantage of the latent heat of the vapours to raise the temperature of the liquid to be distilled. How this is carried into practice, I will presently explain.

When a mixture of alcohol and water is distilled, the liquid will not boil constantly at 173° until all the alcohol has passed over, but will rise in temperature gradually throughout the distillation until 212° has been reached. The distillate, if separated into fractions boiling between fixed points, consists of a series of mixtures of alcohol and water in definite proportions. The mixtures richest in alcohol come over first, that is to say, at the lowest temperature.

The latent heat of the vapour of a liquid with a high boiling point, can be made to boil a liquid with a lower boiling point; for instance, steam at 212° can boil alcohol at 173°, and alcohol at 173° in turn can boil ether at 94·8°. With a simple still, strong alcohol can be obtained from wash by repeated distillation only. Woulffe realised the fact that this wasteful and tedious process could be dispensed with, by connecting together a number of rectifying chambers in such a manner that the vapour driven off from the chamber nearest the fire should be condensed in the second, and by the heat given out by its condensation, cause the more volatile portions of the liquid of the second to distil into the third chamber, and those of the third into the fourth, and so on, until a sufficient degree of concentration is attained. Adam put this principle of rectification into practice, and it is well illustrated by a description of the working of Laugier's still. In this arrangement another process, that of dephlegmation, is put in operation, which is exactly the reverse of rectification.

It consists in partially cooling the vapours, whereby they are separated into an alcoholic and an aqueous portion; the former passes on to another cooler, only the latter being condensed. Laugier's apparatus consists of separate parts connected by the necessary pipes; these are 1st, a worm tub; 2nd, a dephlegmator; 3rd, a rectifier; 4th, a still. The rectifier is warmed by the waste heat in the flue, the still only is heated by a direct fire. The wash passes first into the worm tub, where it absorbs all the heat given off in the condensation of the alcoholic vapours, thence it passes into the dephlegmator, where it becomes heated to near its boiling point by the condensation of water vapour only; it next passes into the rectifier, where it is boiled by the aid of steam from the still; the alcohol in the steam becoming concentrated in the liquid, is boiled off; finally, the liquid in the rectifier is run into the still, from which vessel it is periodically discharged. The general arrangement, as shown in the diagram, is effective in separating the two liquids, and the former goes upwards and the latter downwards. It is not adapted to distilling mash of different kinds, nor for yielding alcohol of the highest strength at one operation. The first apparatus to fulfil these conditions was devised by Mr. Coffey, a Dublin man. Although a variety of apparatus for distilling have been constructed by Savalle, Siemens Brothers, and others, yet some form or modification of Coffey's still is most commonly used in this country. It is constructed largely of wood and sheet copper; the wood being a bad conductor, prevents loss of heat, but it is liable in turn to give rise to leakage, and requires frequent renewal. The wash is raised by a pump to the top of a column, the upper half of which is a condenser, and the lower a dephlegmator; by means of a zigzag copper tube, the wash passes downwards, and upwards again, to the top of a second column, into which it is discharged, where it undergoes a process of distillation, by means of steam rectification, on a series of perforated shelves connected with each other by over-flow pipes. Such stills may be built of any size, and I have seen them of such dimensions that the pumps of each still were capable of passing 8,000 gallons of wash per hour.

It is a well-known fact that spirit from different sources differs in character. Ethyl alcohol, apparently of the greatest purity, may contain small quantities of other alcohols which give a flavour and odour; thus alcohol from the marc of grapes contains propyl alcohol as well as other alcohols, rum from molasses contains butyl alcohol, while spirit from potatoes contains amyl alcohol. In addition to these bodies a number of ethers may be present; thus acetic ether, which is a product of fermentation, is, under certain circumstances attending fermentation, occasionally present in considerable quantities. There is a very simple and easy method of detecting all such impurities, well known to practical men, which consists in pouring a little spirit upon the hands, allowing it to evaporate, and smelling the residue; or moistening blotting-paper, and examining it in the same way. The senses of smell and taste are exceedingly acute in most persons, and the facility with which minute traces of impurities may be detected is remarkable. I have examined large quantities of strong alcohol, and by a method more delicate than any other, and I believe it to be one of the purest commercial products. The worst specimens examined were those which were intended for drink. The method of examination depends upon the fact that those rays in the spectra of metals which lie beyond the most extreme of the visible region, and therefore are called the ultra-violet rays, are extremely sensitive to the absorptive power of certain organic substances. I have recently examined some kinds of spirit by this process, which consists in causing the rays emitted by an electric spark passed between two points of metal to traverse a vessel with sides of rock crystal containing the liquid, and afterwards to pass through a slit and a prism and lens of quartz, and receiving the rays on a photographic plate.

Compounds of carbon and hydrogen, or of those with oxygen, may be divided into two classes—those which exert an absorptive action at one end of the spectrum only, and those which exert a selective absorption, in which rays are selected from the centre of the spectrum. Bodies of the latter kind give rise to what are called "absorption bands."

Bodies of the constitution or chemical structure of the alcohols and sugars increase in absorptive power with the number of carbon atoms in the molecule, or, in other words, in the case of alcohols with rise in boiling point, while bodies of the nature of benzene, and others of the aromatic series, have a greatly increased absorptive power dependent upon the imtimate linking of the carbon atoms, as it has been expressed, or as I would prefer to say, by the greater condensation of the carbon in the compound. Accordingly, the spectra do not show variations with the number of carbon atoms, or increase in the boiling point, and, furthermore, the absorption is not general but selective.

Some colourless bodies which display such selective absorption are the examples of benzene derivatives given on the next page.

In the preparation of alcoholic beverages, we may add essential oils or aromatic substances to pure spirit, and distil, and this is the manner in which gin is prepared; but in making whiskey, especially by the old process, certain details must be attended to, beginning with the preparation and drying of the malt, and in turn the fermentation and distillation. Of course there may be, and doubtless are, persons who consider anything which can be sold for whiskey as whiskey, but truly there are only two liquids to which this name strictly belongs. Beverages sold by the name, however, may be made in the following six different ways :—

1st. Prepared by flavouring a potato spirit not defuselised.

2nd. Prepared by flavouring a silent spirit.

3rd. Prepared by flavouring a purified corn spirit.

4th. Prepared by distilling malted grain other than barley; such a liquid is potheen, which is prepared from wheat.

5th. Prepared by the distillation of a mash of barley, or of barley and oats mixed with malt dried over a fire of coke or anthracite.

6th. Prepared by distilling a wash prepared entirely from barley malt dried over a fire of peat.

Silent spirit is alcohol of such purity that it does not betray its origin, whatever that may be.

Irish whiskey is generally of the character of No. 5, while Scotch whiskey belongs to No. 6. Such varieties of spirit are distilled in pot stills, and are fit to drink only after keeping for two years and a half. Other liquids sold under the name of Scotch and Irish whiskies may be anything, from diluted and flavoured potato spirit containing fusel oil to a good corn spirit made from a mixture of barley and maize with malt, which is blended with a malt whiskey of strong flavour. I once had a specimen placed before me, which it is my conviction was nothing more than potato spirit flavoured with wood creosote.

The difference between malt dried with peat and with anthracite is, that while the former yields up in the smoke the volatile aromatic substances which occur in the vegetation growing on or in the peat, as well as such as are produced by incomplete combustion, otherwise dry distillation, the malt dried with anthracite is free from such substances. This may be considered by some as a disadvantage, since the only aromatic bodies present are those contained in the malt, which are really very small in amount, but such whisky has a mild flavour which is much appreciated. When plants containing aromatic bodies are present in the turf, those which are very stable substances are volatilised by the heat, and condensed upon the malted grain; during the process of fermentation, they become dissolved in the alcohol, and are distilled off therewith, and the liquid afterwards keeps them in solution. Sometimes they become converted into ethers, and their etherification is in progress for some considerable period of time during the maturity of whiskey.

I have examined several samples of Highland malt whiskey, with the object of detecting the presence of aromatic substances. The following example illustrates the mode of examination. About 300 cubic centimetres were fractionally distilled. The boiling points

Examples of Benzene Derivatives, otherwise called Aromatic Substances.

Name.	Composition.	Source.
Benzene	C_6H_6	Coal-tar, benzoic acid.
Cymene	$C_6H_4 \begin{cases} CH_3 \\ C_3H_7 \end{cases}$	Oils of Roman cumin, lemon, thyme, and nutmeg.
Benzoic Aldehyde	C_6H_5 COH	Oil of bitter almonds.
Cinnamic Aldehyde	$C_6H_5 \begin{cases} C_2H_2 \\ COH \end{cases}$	Oils of cinnamon and cassia.
Salicylic Aldehyde	$C_6H_4 \begin{cases} OH \\ COH \end{cases}$	Oil of meadow sweet.
Vanillin	$C_6H_3 \begin{cases} OCH_3 \\ OH \\ COH \end{cases}$	Vanilla pod and sugar-cane.
Anethol	$C_6H_4 \begin{cases} OCH_3 \\ C_3H_5 \end{cases}$	Oils of aniseed and fennel.
Thymol	$C_6H_3 \begin{cases} CH_3 \\ C_3H_7 \\ OH \end{cases}$	Oil of thyme.
Eugenol	$C_6H_3 \begin{cases} OCH_3 \\ C_3H_5 \\ OH \end{cases}$	Oils of bay, cloves, and pimento.

of the several fractions are here given; they each measured about 38 cubic centimetres, and were eight in number:—

	Boiling Point.	
1st fraction	78°	The boiling point was constant. These fractions consisted almost of pure ethyl alcohol, a little ethyl-acetate was noticed in the first two. No. 3 possessed a slight odour of butyl alcohol; but No. 4 had no distinctive odour or flavour
2nd ,,	78°	
3rd ,,	78°	
4th ,,	78°	
5th ,,	78° to 80°	Amylic compounds were recognised in both of these fractions. In No. 6 some aromatic body was present.
6th ,,	80° to 95°	
7th ,,	95° to 99°	These were practically the same, and contained large amounts of water. An aromatic substance was present in No. 7.
8th ,,	99°	

The 6th fraction had an odour suggesting the presence of some aromatic substance, its boiling point is 80° to 95°. When submitted to the action of the ultra-violet rays, a series of photographs were taken after the rays had passed through various thicknesses of liquid, ranging from 5 millimètres to 1 millimètre. Distinct evidence of the presence of an aromatic body was obtained, the spectrum yielded being one characteristic of such substances.

The spectra were four inches in length, and the rays extended from the blue to the extreme of the ultra-violet region. The linear measurements of the prism spectra were reduced to measurements of the wave-lengths of the transmitted and absorbed rays.

Fraction No, 7, boiling point 95° to 97°, was submitted to a similar examination.

I hope at some future period to be able to give some further information concerning the aromatic substances to be found in whiskey.

I cannot conclude this course of lectures without thanking my hearers for the very close attention with which you have listened

me. In describing the scientific principles involved in carrying out the operations of the brewery and distillery, I have given you the latest information, obtained from various sources; I have drawn inferences therefrom, and thrown out suggestions which I hope may prove useful. Those whose business renders it necessary that they should have a practical knowledge of the processes described will, I trust, pardon all shortcomings, since the subject is one which is hardly capable of satisfactory treatment in a course of lectures so few in number. It is not without reason that scientific men are sometimes considered to be too dogmatic; but as I hold in the highest respect all practical knowledge, knowing how long it has successfully dealt with operations carried out on a large scale, how laboriously it has been acquired, being the accumulated outcome of years of continuous work, I trust that I have not created the impression of imparting knowledge in a dogmatic spirit. I am of opinion that practical knowledge should be guided by theory, but that while both go hand in hand, the latter should be subservient to the former. It should be borne in mind that a scientific reason can be given for every detail in every operation. Those who carry out large operations, and are not acquainted with the scientific laws which govern these details, have but an imperfect knowledge of their business, and are powerless to control the results in certain emergencies. Having had some experience in superintending extensive operations, I am in a position to appreciate how frequently the conditions of an experiment involving chemical change are modified when dealing with large masses of material, and how operations easy of performance in a small way, become expensive and cumbrous, if not altogether impracticable, on a large scale.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON HOUSE DRAINS AND DRAINAGE APPLIANCES. BY W. K. BURTON.

The portion of the Exhibition which has been allotted to the demonstration of the various kinds of drains and drainage appliances, and of the manner of fixing and using these, is one which is out of the beaten track of the casual visitor. Moreover, the general aspect of the appliances is, perhaps, not particularly inviting, and for these reasons one sees but few people walking through the South Annexe, except such as take more or less technical interest in the exhibits.

There is, however, much which should be instructive even to the casual visitor, as the various appliances tend to show in what direction the improvements in the means of draining houses are tending. A few words on the subject may not be out of place before we enter particularly into description of some of the exhibits.

When improvement in house drainage work first came to be seriously considered some thirty or forty years ago, the tendency which showed itself was one towards a reduction in the size of drains. This was quite contrary to former practice, when nothing was so commendable in a house drain as that it should be so large that a man could walk upright in it. For such elongated cesspools as these drains were, there were substituted pipe drains of sizes from twelve inches diameter downwards. An attempt was generally also made to secure a sharper fall than had been given to the old brick culverts. Still there was much left to be desired. Pipes were better than brick drains, but not very much better in many cases, where the laying of them, not only as regarded workmanship but direction and fall, was left to the sweet will of the particular workman employed. Probably in not one case in a hundred was the direction of the drains considered as part of the design of the house, but after the foundations were in, the pipes were laid in whatever was considered the best position by the particular workman who laid them. This latter generally chose to lay them *under* the house, and had a knack of making them wind and curve about in a truly marvellous manner. No record was kept of where they had been laid, and if, after some years, there was a suspicion of "something wrong with the drains," there was no means of telling where to get at them, nor even if the knowledge could be obtained, any means of doing so without considerable damage to the house.

The tendency of modern house sanitation is the very reverse of this. It may be summed up in a very few words. The object attempted to be attained, in these days, is the laying of all pipes in straight lines between manholes, so that every foot of pipe which has been laid may be examined by simply lifting one or more iron covers.

We see, in the section of the Exhibition referred to, two excellent examples of the means which are used to secure this state of affairs. Two exhibitors have built manholes of the kind mentioned. Those manholes—of which it will be understood there is one at each end of every straight length of pipe drain—have the drains running along their floors in the form of channels constructed of half pipes. By holding a small mirror at a certain angle in the channel, it is easy to see right through the pipe as one sees through a gun barrel, and to judge of its condition. It will be seen that wherever the drain takes a bend, or wherever there is one pipe junctioning into another, there must be such a manhole. This would appear to involve a great number of these, and it may surprise some to know that most houses of the nature of those in the best streets in London, may be drained as described with three or even only two manholes.

The manhole next the sewer has always a trap in it to keep the sewer-gas back, and is generally termed a disconnecting chamber.

Messrs. Houghton and Co., of 21, Sloane-terrace, show a disconnecting chamber with Field's trap, Angell's cover (which is hinged, and shuts down air-tight with a key), and a channel pipe of the nature made by Baily and Co., the Pottery, Fulham, who have themselves an exhibit of channel pipes of all shapes.

Mr. H. King, of Clarence-place, High-street, Kensington, shows a disconnecting chamber which differs from the last mentioned only in the fact that the trap used is Buchan's, and the cover Botting's. This cover has neither hinges nor key, but makes a joint by means of a rubber ring fitted into a groove in the cover, which is made somewhat heavy. The ring is pressed by the weight of the cover on to a sharp ridge running round the inside of the frame.

Mr. W. P. Buchan deserves somewhat more than a passing notice, as, if I am not mistaken, he was the first to suggest the method of through ventilation to be afterwards described, which is now universally adopted, and who invented the trap which bears his name and which is designed to secure this through ventilation. Mr. Buchan has received the sincere flattery of many who have imitated his trap with great exactness.

Passing on to the question of drains themselves, the most interesting thing to be noticed is the various ways of making the joints which must of necessity be used to connect one pipe with another.

It is almost unnecessary to say here that the material most used in the manufacture of pipe drains at the present day is stoneware or fire clay. The pipes are, as a rule, two feet long, and in ordinary work the joints are made with either clay, mortar, or Portland cement. Of the first two materials I may at once say that they are not suitable. A perfectly sound joint can be made with Portland cement, but there is the drawback that considerable skill is required to make it, and that when made it will not yield in the very least, so that the smallest settlement in the ground results in the breaking of one or more pipes.

Various methods of jointing have been invented to overcome these difficulties, the one which has had the greatest popularity, and so far as I can judge, has deserved the most, being that known as Stanford's patent. Samples of pipes with Stanford's patent joint are exhibited by Mr. Henry Ough, 16, Austin-friars, E.C.

The pipes used are the ordinary socket pipes, but in the socket there is a ring of a black pitchy composition, whilst on the other end of the pipes there is a ring on the outside. Both these rings are turned accurately to fit each other, each forming a portion of a sphere, the result being in fact a ball and socket joint of a kind. To fit the pipes, it is only necessary to moisten the collars with oil, tallow, or a mixture of resin and tallow, and to gently work one into another. The nature of the joint allows of a little play, without any breakage; but perhaps the greatest advantage of the arrangement is that when it is used there is no possibility of there occurring the defect which so often is discovered when pipes are jointed with cement, and which consists in a piece of this material sticking up into the inside of the pipe, and forming the means of causing a stoppage.

Although, as I have said, stoneware pipes are still the most generally used for house drains, there is at present a growing tendency to substitute cast-iron for stoneware in those cases where it is unavoidable to bring the drains under the house. The iron pipes are in longer lengths than the stoneware the joints can be made more securely water and gas-tight by caulking them with lead, and there is less chance of breakage through any settlement of ground.

The North British Plumbing Company, 4, Upper Baker-street, N.W., exhibit a set of specially heavy cast-iron pipes, prepared for draining purposes. These include all necessary connections, traps, &c., and all are coated with a composition which prevents the possibility of their rusting.

Before leaving the subject of drains, I must mention two exhibits showing methods of testing, to discover whether a really sound piece of work has been made or not.

Messrs. Watts & Co., of Broad Weir Works, Bristol, exhibit the "Asphyxiator," a revolving fan arrangement which may be used to pump volumes of smoke into drains; any leakage will, of course, be detected by the smoke issuing from it.

Mr. Charles Hawksley, of 30, Great George-street, S.W., shows an arrangement which, if far more complicated than that for the smoke test, is also far more searching. By means of a small hand air-pump, air is forced into the drain, which has to be previously stopped at all untrapped openings. A glass U tube, filled with water, and fixed at each end of the drain, serves to show whether any pressure in the drain is secured by the pumping, and if it is, whether it falls or not by leakage when pumping has ceased.

Having said so much on the drains themselves, I must at least make passing remark on the methods used in these days to ventilate such drains. The acme of ventilation would be gained could we have a brisk current of fresh air through every foot of drain-pipe which was laid. We may be unable to secure quite this, as short branches must often be left unventilated; but in a good modern system of drainage, there will be movement of air through all but very small portions of the drains.

This is usually managed in the following manner:—The disconnecting chamber, already described, is left open to the air either by fixing a grating over it, or by carrying from some more convenient point in the open air, to the disconnecting chamber a large pipe. From the upper end of the drain, or of each of several branches of it, there is carried a pipe to a point clear of the house. This pipe is usually four inches diameter, and often forms the soil-pipe. The wind blowing across this pipe tends to cause air to flow up it, and, consequently, air is drawn in at the ventilator of the disconnecting chamber, which ventilator is, therefore, usually termed the air inlet. The most perfect ventilation is gained by leaving the air inlet quite open by having a grating as mentioned; as, however, there can be no certainty that there will not be occasional reversals of the current, the air issuing in such cases from the inlet, this arrangement is objectionable where the opening must of necessity be placed in a very confined situation near windows, as for example, in one of the narrow front areas so common in London houses.

In such cases, it is the practice of at least some sanitary engineers to affix to the air inlet what is termed a mica flap or valve, which is simply a light sheet of mica, so hinged that it will open to incoming air, but will close against issuing air.

Both the disconnecting chambers exhibited are fitted with mica flaps made by Mr. Francis Botting, of 6, Baker-street, and as this particular make differs from others, and has, in my opinion, some advantage over them, I shall give a brief description of it.

In most mica flaps, the position of the mica is such that when there is *no* air current, the flap is completely closed. The consequence is that some force is necessary to open it and to keep it open, and thus the air current is greatly impeded. In Mr. Botting's valve the mica is so hung that it is normally *open*, some slight force being required to *close* it. As a consequence, no opposition is offered to the incoming air.

The modern method of disconnection of baths, sinks, basins, &c., from house drains, is now so well known, that it requires mention only here. The custom is to cause all such appliances to discharge through syphon traps over gullies in the open air. The only point requiring explanation is the necessity for a trap or a pipe which is to discharge into the open air, as, at first sight, it would appear that complete disconnection is secured without it. Certainly a complete immunity from sewer or drain gas is secured, but something more than this is necessary. It has to be borne in mind that the discharge pipe, even from a bath or washhand basin, and far more from a sink, becomes more or less foul. Any air blowing through it into the house will, therefore, have a disagreeable smell, and the use of the syphon trap is to prevent the possibility of such air blowing in.

There are numerous exhibits of gullies suitable for receiving the discharge of waste pipes. I may mention as particularly deserving notice one by Messrs. R. Houghton and Co., which is fitted with a movable top piece, with branches for receiving the discharge pipes, and another by Messrs. Broad and Co., which is very well shaped, and has an arrangement for gaining access to the drains.

Mr. King's exhibit, already mentioned, shows very clearly not only the disconnecting chamber, but the whole arrangement of ventilation, disconnection of discharge pipes, &c., already mentioned.

---

*REPORT OF SCREW GAUGE COMMITTEE OF THE BRITISH ASSOCIATION.**

1. Since the presentation of its first report on a gauge for small screws at the meeting of the Association held in 1882 at Southampton, this Committee has further examined into the recommendations there made, with the result that they have now to propose some important modifications, the general effect of which will, it is felt, be to materially facilitate the introduction of the system.

2. The want of unanimity on the part of the Committee, referred to in Paragraph 7 of that Report, arose mainly on the question as to whether the inch or millimetre should be taken as a unit of measurement. It is evident that if either is rigidly adhered to, and in any way employed in the nomenclature of the screws, as, for example, in specifying the diameter, pitch, or threads per inch or per mm., the same dimensions could not be expressed in whole numbers in the other unit, and thus a material obstacle would be at once introduced to its adoption.

3. It should be pointed out, however, that it has hitherto been the common practice to designate such small screws as the Committee alone is considering, not by any specific dimension, but by a number, which, as a rule, is arbitrarily chosen, and does not of itself form a guide to the size of the screw. Considering then, that the unit of measurement is only indirectly connected with the subject of a screw gauge, the Committee has felt that the two units might be reconciled so far as relates to such a subject, and that thus one important difficulty would be removed.

4. The manner in which the series of screws adopted lately by Swiss manufacturers is correlated has been sufficiently explained in the previous report, and very full explanations are given in the two

* Second Report of the Committee, consisting of Sir Joseph Whitworth, Sir William Thomson, Sir Frederick Bramwell, Mr. A. Stroh, Mr. Beck, Mr. W. H. Preece, Mr. E. Crompton, Mr. E. Rigg (Secretary), Mr. A. Le Neve Foster, Mr. Latimer Clark, Mr. H. Trueman Wood, and Mr. Buckney, appointed for the purpose of determining a gauge for the manufacture of the various small screws used in telegraphic and electrical apparatus, in clockwork, and for other analogous purposes. (For First Report, see *Journal*, vol. 32, p. 115.)

original pamphlets to which reference is there made.* The diameter (D) is related to the pitch (P) by the formula $D = 6 P^{\frac{6}{5}}$, (1) all measurements being in millimetres, and P having successively the values 1 (or $0{\cdot}9^0$) mm.; $0{\cdot}9^1$ mm.; $0{\cdot}9^2$ mm.; $0{\cdot}9^3$ mm. . . . $0{\cdot}9^n$ mm.

Thus n, the index, becomes a convenient designating number for the screw, and the formula (1) may be expressed $D = 6 (0{\cdot}9^n)^{\frac{6}{5}}$, where $P = 0{\cdot}9^n$.

5. The pitch of any screw can be at once ascertained from its designating number by raising 0·9 to the power indicated by that number; and from this pitch the diameter is directly deducible by the formula (1), so that the number (n) given in the first column of the table, by which a screw is known, is intimately related to its dimensions.

PROPOSED SMALL SCREW GAUGE.

Number.	Nominal Dimensions in Thousandths of an inch.			Absolute Dimensions in Millimetres.	
	Diameter.	Pitch.	Threads per inch.	Diameter.	Pitch.
I.	II.	III.	IV.	V.	VI.
25	10	2·8	353	0·25	0·072
24	11	3·1	317	0·29	0·080
23	13	3·5	285	0·33	0·089
22	15	3·9	259	0·37	0·098
21	17	4·3	231	0·42	0·11
20	19	4·7	212	0·48	0·12
19	21	5·5	181	0·54	0·14
18	24	5·9	169	0·62	0·15
17	27	6·7	149	0·70	0·17
16	31	7·5	134	0·79	0·19
15	35	8·3	121	0·90	0·21
14	39	9·1	110	1·0	0·23
13	44	9·8	101	1·2	0·25
12	51	11·0	90·7	1·3	0·28
11	59	12·2	81·9	1·5	0·31
10	67	13·8	72·6	1·7	0·35
9	75	15·4	65·1	1·9	0·39
8	86	16·9	59·1	2·2	0·43
7	98	18·9	52·9	2·5	0·48
6	110	20·9	47·9	2·8	0·53
5	126	23·2	43·0	3·2	0·59
4	142	26·0	38·5	3·6	0·66
3	161	28·7	34·8	4·1	0·73
2	185	31·9	31·4	4·7	0·81
1	209	35·4	28·2	5·3	0·90
0	236	39·4	25·4	6·0	1·00

6. It is evident that, by takingthe exact successive powers of 0·9 for the pitch, complex numbers would soon be arrived at. Such dimensions would, however, involve a degree of accuracy which is hardly attainable in practice, and it may be shown that, with two significant figures employed throughout to express the pitch, the degree of accuracy likely to be attained in screws of the kind under consideration is reached. Relying on this fact, the series of pitches given in Column VI.* is arrived at for screws ranging from ·236-in. to the smallest in use, 0·01-in. in diameter, in place of the mathematically exact series obtained by raising 0·9 to successively higher powers.† And this is the series which the Committee recommends for adoption.

7. Viewing the numbers thus obtained in the first place merely as a graduated series of pitches, and ignoring the unit of measurement, it may be admitted that the series of powers of 0·9 from which they are deduced is perhaps as good a one as can be suggested for the purpose, and it is found to very closely correspond with experience. Thus Column VI., which gives the nearest approximation to this series that is practically required, is well adapted for such a system of screws. It is to be observed that in selecting a series of pitches there are three simple alternatives to choose from: (1) to have a constant arithmetical difference between successive pitches, in which case either the pitches of small screws would differ by too great an amount, or those of the larger screws by too small an amount; or (2) to divide the entire range into sets, in each of which the differences are constant. The third alternative is to take successive powers of some other simple fraction, for example 0·8, but such a series would not so well correspond with the screws most generally employed.

8. Accepting this series, it may, however, be urged that it should be based on some aliquot part of an inch rather than on the millimetre. But any advantages to be gained by such a modification are inappreciable. For an examination of the numbers at once shows that they are, for the most part, awkward fractions of a millimetre, and the metric system of measurement thus enjoys no advantage in this respect over that based on the inch. From the point of view of interchangeability, however, of screws to be manufactured in this country and on the Continent, it is essential that the same basis of measurement of the pitch be everywhere adopted; because, having agreed upon only two significant figures on one basis, terminable decimals are obtained, but such terminable decimals could not be accurately expressed by two significant figures on the other basis of measurement.

9. Again, it is to be remembered that the use of metric measurement to designate the pitch need not inconvenience English manufacturers who are desirous of cutting the screws in their lathes. For, as has recently been pointed out by Mr. Bosanquet,‡

* *Systématique des vis Horlogères*, by Prof. M. Thury, Geneva, 1878. *Notice sur le Système des vis de la Filière Suisse*, Geneva, 1880, by the same author.

* It may be incidentally pointed out here that this series comprises two screws, with pitches of 1 mm. and 0·25 mm., which would be serviceable for micrometers.

† Sir Joseph Whitworth's gauge, in general use, ends at ¼-in., where this commences.

‡ *Phil. Mag.* (Fifth Series), vol. xv., pp. 217, 438.

it is easy to cut a thread whose pitch differs from one millimetre by an amount which may for all ordinary purposes be neglected ($\frac{1}{55300}$th), with a guide-screw based on the inch by the addition of a wheel of 127 teeth, and thus the series here recommended could, on the rare occasions that it became necessary, be originated on any screw-cutting lathe provided with the requisite wheels. But the Committee do not consider it needful to specially contemplate facility in the originating of the threads, as the screws under consideration are made in a plate or by the aid of dies; and manufacturers on a large scale would be provided with a special lathe for the purpose.

10. Whether the inch or millimetre is adopted as a unit of measurement, the series of pitches for these small screws becomes an ideal rarely attained in practice, for with screws tapped in a plate, or even with dies, the exact pitch aimed at will often not be attained; neither is it safe to assume that two screws, tapped in corresponding holes in different plates, will have precisely the same number of threads per inch. This is especially the case with the smaller screws, as may be proved by accurately measuring the pitches of several tapped in holes that are nominally alike.

11. The fact here stated affords a reason against extending the practice of designating screws by their number of threads per inch, already sometimes resorted to in the case of large screws, to the screws now under discussion. It is found that screws, nominally alike, frequently differ in this respect by as much as five or even ten threads in the inch, nor need this occasion surprise when it is remembered that the screw-plates employed must expand to varying extents in the hardening, that the hole is often not more than three or four threads deep, and that the pressure applied by hand must vary considerably. Such a nomenclature would thus involve the use of inconveniently high numbers to express a minute degree of accuracy but seldom attained, while they convey but little real information, since mere examination would not enable any one to distinguish between, say, a screw of 169 and 181 threads per inch.

12. The series of diameters must next be considered. Before the formula $D = 6\,P^{\frac{6}{5}}$ was adopted, it was ascertained by the minute examination of about 140 small screws that the series very closely corresponds with those recognised as good in the trade, and the screws made in the new plates, known as *Filières Suisses*, which the Committee have had an opportunity of examining, appear to them to be well proportioned in this respect. The series of diameters, like the pitches, are expressed by two significant figures in each case, as the values for D deduced from the formula (1) are necessarily indeterminate in most cases. These diameter are given in millimetres in Column V., and their nearest equivalent in thousandths of an inch in Column II. As the Committee considers that these screws are well-proportioned as regards pitch and diameter, and approves the formula (1) being taken as a basis, it is led to recommend this series of diameters being adopted in conjunction with the pitches already discussed. It has been suggested to the Committee that the introduction of such a system into general use in this country might be facilitated by punching against each hole in the screw-plate, side by side with the designating number, as given in Column I., the approximate diameter of the screw made in it, as expressed in thousandths of an inch (Column II.), as these numbers would convey a meaning to English workmen more definite that the numbers in Column I. or V. The Committee sees no serious objection to such a course; but it should be remembered that screws have hitherto always been recognised by a number seldom higher than twenty-five, and it may be questioned whether any substantial advantage is gained by substituting such high figures as are involved in the expression of the diameters.

13. It will be seen that the series here recommended gives twenty-six screws for the range from $\frac{1}{4}$-inch to the smallest in use. Comparing this number with those of two of the best systems commonly met with —namely, the Latard (Perrelet et Martin) and Bourgeaux plates, we find that—

For a range of 21 sizes of watch screws on the Latard plate, this gives 15
For a range of 23 sizes of watch screws on the Bourgeaux plate, this gives 17
For a range of 36 sizes of clock screws on the Latard plate, this gives 23

The entire series is thus less than that of well-established plates, and cannot, therefore, be considered greater than the requirements of practice demand; while the fact that the watchmakers (who probably require the most extensive assortment of screws) in Switzerland have accepted it, confirms the Committee in its opinion that the series is not deficient in this respect.

14. It remains to consider the form of thread. There are so many practical points to be taken into consideration in discussing such a question that it becomes specially useless to rely much on theory for guidance, and the divergence observable among the forms adopted by different manufacturers is thus very great.

The most important points to be borne in mind in its selection are—

(1) The threads must be easily cut with the class of screw-cutting tackle ordinarily met with in workshops.

(2) The strength of the threads on the male and female screws must be so correlated that the liability of either to strip is a minimum.

(3) The resistance of the core to torsional stress when force is applied in rotating the screw must be a maximum.

(4) The friction should be as small as possible, in order to reduce wear.

15. In regard to the first of the above conditions, it is to be observed that very many of the screws considered by the Committee are usually made by

means of a plate in which are round tapped holes. Such a hole forms a thread by causing the metal to "flow" from a space towards a thread, and its action is obviously of quite a different character from the cutting action of dies or of a chasing tool. In the case of plates with notched holes the cutting and squeezing actions are combined.

16. As bearing on the second condition, it is evident that, as the strength of the threads depends so essentially on the materials of which the screw and nut are made, and these are very varied, no precise and invariable rule is attainable. If strength were the only point to be considered, a purely triangular form without any rounding would be the best, contact being assumed to take place over the entire surface. But in practice it is impossible to secure such perfect contact, and it becomes needful to round off the crests from all the threads; and this rounding is the more necessary as the screws are smaller, and irregularities in the manufacture becomes relatively more marked. This modification is also necessary in view of condition (1) already considered.

17. The third point—namely, the resistance of the core to torsional stress—is determined primarily by the depth of thread. If the sectional area of the ring cut away is less than that of the core, the probability of the latter breaking across may be regarded as approximately equal to that of the threads stripping; but it is impossible to maintain a constant ratio, as such a condition would require the thread to be so fine, in the case of small screws, that there would be no sufficient hold in the nut. Thus in the very smallest screws (those below ·030 in. in diameter) the ratio $\frac{\text{area of core}}{\text{sectional area of thread}}$ is less than 1, and it gradually increases till a proportion of between 2 and 3 is attained.

18. Condition (4) is evidently best satisfied by a square thread. Such a form is, however, impracticable in the case of the small screws under consideration, but it is obviously approximated to according as the angle of a triangular thread is made less and the rounding greater.

19. The angles that have been adopted in practice show, as might be expected, considerable variation. On the one hand an angle of 60° is rarely exceeded, the thread being thus derived from the equilateral triangle, and, on the other hand, 45° may be taken as the lower limit.

20. The depth of a thread is evidently a function both of its angle and of the amount of rounding at the top and bottom. It may conveniently be expressed as a fraction of the pitch (taken as unity). In the case of the small screws in general use the mean value of the depth thus expressed is found to be 0·563, the maximum being 0·771, and the minimum 0·311. It is evident that any increase in the depth beyond what is essential will materially and needlessly increase the difficulty of manufacture when a screw-plate is used; at the same time the depth must not be too much reduced, on account of the greater tendency of the thread to strip. It is further important that the additional torsion involved in cutting a deep thread, which materially increases the risk of tearing the metal across, should not be lost sight of.

21. The Committee, after comparing together a large number of different forms of thread, some of which are in actual use, while others have only been suggested, were much tempted to recommend the Whitworth thread for adoption by the British Association, because it is so well known in this country, and experience has proved indisputably that it is excellent when employed for engineers' bolts, &c. But, as appears from sections 16 and 18, in the case of small screws the tendency should rather be to increase the rounding on account of the difficulties of manufacture, and the depth of the Whitworth thread is 0·64 of the pitch, which is considerably in excess of 0·563, the average adopted in practice. The Whitworth thread is, moreover, characterised by a greater angle than is usual in small screws.

22. The advisability of modifying the form of thread of small screws, as compared with those of greater diameter, is fully recognised by the Swiss Committee, their thread for the former having an angle of 47½°, while that for the latter is 53°, nearly the same as that of the Whitworth thread. In the case of small screws made in the *Filière Suisse* the crest of each thread is rounded off with a radius equal to $\frac{1}{6}$th the pitch, and the hollow with $\frac{1}{5}$th the pitch. The actual depth is 0·60 the pitch, somewhat less than in the Whitworth thread.

23. While approving the general form of thread here described, this Committee could not but feel that the difference in the roundings ($\frac{1}{6}$th at top and $\frac{1}{5}$th at the bottom) was unnecessary. Looking, moreover, to the fact that very many of the screws of the sizes now under consideration are for electrical and telegraphic instruments, and, therefore, may be of brass, and that, with such dimensions, it is impossible for the eye to ascertain whether a given screw satisfies the required conditions in regard to such small differences between the crest and hollow of the thread, the Committee feels that an equal rounding ($\frac{2}{11}$ths of the pitch) at the top and bottom would be preferable. This would maintain the angle of thread and the depth the same—namely, 47½° and $\frac{3}{5}$ths of the pitch respectively.

24. Having now discussed the three main points that require to be considered in any system of screws—namely, the pitches, diameters, and form of thread, it seems desirable to enumerate briefly the recommendations at which the Committee has arrived. These are:—

(1) That the series of diameters for screws from $\frac{1}{100}$th inch to $\frac{1}{4}$th inch be that given in millimetres in Column V., the nearest thousandths of an inch being given in Column II.; these diameters being the series calculated by making P, in the formula $D = 6P^{\frac{6}{5}}$, have in succession the following values:—

1 (or $0{\cdot}9^9$) mm.; $0{\cdot}9^1$ mm.; $0{\cdot}9^2$ mm.; $0{\cdot}9^3$ mm.; . . . . . $0{\cdot}9^n$ mm.

Only two significant figures are taken to represent the diameters.

(2) That the pitches of these screws be the above gradually decreasing series, each pitch being $\frac{9}{10}$ths of its predecessor, but that only two significant figures be used in their expression. The series thus obtained is given in Column VI.

(3) That in view of the desirability of securing a system of small screws, international in its character, English manufacturers of screws, screw-plates, &c., adopt the exact pitches given in millimetres in Column VI., which, as we explained in par. 9, can, if required, be originated on an English lathe. Further, in view of the fact that small screws and screw-plates, while nominally alike, will not unfrequently differ considerably as regards their number of threads per inch, the practice of designating such screws by their number of threads per inch should not be adopted. For reference, however, the approximate number of threads per inch, as calculated from the pitch given in Column VI., are given in Column IV.

(4) That the designating numbers given in Column I., being the indices of the powers to which 0·9 is raised to obtain the pitch, be punched against each hole in the screw-plate, and that, if thought desirable, its diameter in thousandths of an inch (Column II.) might be punched side by side with this number.

25. In his *Systématique des vis Horlogères*, Prof. Thury has done for the small screws used by watch, clock, and scientific instrument makers what was done forty years ago by Sir J. Whitworth for the larger screws used by engineers; and, like the admirable system introduced by the latter, the scheme here advocated is based on the data obtained by measuring the several dimensions of many screws accepted by practical men as being well-proportioned.

26. The Committee has had an opportunity of examining both screws and screw-plates (for the smaller screws) made on this system, which it is convinced will satisfy all the demands of practice. The Committee can, therefore, confidently recommend its adoption by the British Association, subject to the slight modification discussed in par. 23; and it feels that an important incidental advantage would be the support it would at once receive on the Continent, and the consequent increased rapidity with which it might be expected to come into general use; for it cannot be doubted that its recognition by so important a body as the British Association would have considerable influence in establishing the system abroad.

[The recommendation for the appointment of this Committee having failed to reach the Committee of Recommendations at Southport in time to allow of its sanction by the General Committee, the Council at their meeting on November 6th, 1883, requested the Committee to continue their labours, and undertook to recommend to the General Committee at Montreal that this report be printed among the Reports.]

THE SUPERGA RAILWAY.

The new railway to the Superga from Turin, opened to the public a few months since, cannot fail to be regarded by all engineers with great interest. To the general public it has already proved a great attraction, and few visitors to the Exhibition leave Turin without having made a pilgrimage to the Superga by the "Ferrovia Funicolare."

The Church of the Superga was built in fulfilment of a vow made to the Virgin by the Duke Vittorio Amedeo II. of Savoy at the siege of Turin in 1706, and having gained the victory over the French its construction was decreed, and it was built from designs of the celebrated architect, Juvara. The crypts contain the tombs of the princes of the House of Savoy. The church is built on a hill about five miles to the east of Turin, at a height of 678 metres above the level of the sea.

The railway to the Superga cannot be regarded as a mere cable line, where the rope has to be of sufficient strength to haul the dead weight of the cars and their freights up hill, as is the case with the Vesuvius funicular railway, the Highgate steep gradient tramway (recently opened), or with the various wire rope railways that are being worked in America and elsewhere. This line, on the other hand, is the first practical application of a system invented by an Italian engineer, Signor Tommaso Agudio, by which the power of a fixed engine is transmitted to the mechanism of a driving car or "locomotore" by means of an endless steel rope running at a high speed, and in the present case five times as fast as the train. In this way a far lighter rope can be used than would be the case were the trains merely hauled up. The first experiments of this system were made by Signor Agudio as far back as 1863 and 1864, on the incline of Dusino on the line between Turin and Alexandria, and afterwards on the French side of the Mont Cenis near Lanslebourg in 1874 and 1875, and notwithstanding the favourable results obtained, no further application of the system was made until the present time. On the experimental line just mentioned, an incline of 38 to 100 (1 in 2·53) and 1,300 metres in length (over three-quarters of a mile) was successfully worked.

Finally, in March, 1883, a concession was granted by the Italian Government to the Municipality of Turin for the construction and working of a cable line, on the Agudio system, from the hamlet of Sassi at the foot of the hill to the Superga, together with a subvention of 900,000 Italian lire (£36,000), which concession was transferred to a limited liability company formed in Turin, who, in addition to the Government subvention of 900,000 lire, will receive from the city of Turin a further subsidy of 300,000 lire (£12,000), and, amongst other conditions, the Municipality, after a certain number of years, are to have a share in the receipts from the working of the line.

The principal feature in this system of railway is a steel wire rope, which is made endless by careful splicing, this rope being driven at a high speed by a stationary engine.

The endless rope in the present case passes from the Sassi terminus, situated at the foot of the hill, and about three miles by steam tramway from the Piazza Castello (which is the centre of the tramway system of Turin), and up the hill to the Superga station, where it passes over a large terminal pulley 4 metres in diameter (13 ft. 4 in.). At the lower or Sassi end the rope passes round the driving pulley fixed on the main shaft of the engine, suitable apparatus for its proper tension being provided, which will be described afterwards.

The lower portion of the loop of endless rope, which is driven in an upward direction by the engine, is supported in its passage up hill by a sufficient number of grooved pulleys fixed at about the level of the rails to keep it from touching the ground, and at a distance of 52 centimetres (21 ft.) outside the left-hand rail of the track; on curves guiding pulleys are used, and are placed horizontally, and instead of a groove, have a flange on their lower side; the bearings being constructed in such a way as to protect the axles from dust and rain.

The upper portion of the loop, or down line, is carried at a height of about 4 metres above the level of the rails by 35 grooved pulleys, of which 15, 2·30 millimetres in diameter (7 ft. 8 in.) are placed with vertical or slightly inclined axis, in order to guide the rope round curves, whilst the remaining 20, which are 1 metre (3 ft. 3 in.) in diameter, serve to support the rope on the straight parts of the line. As only the lower part of the loop of endless rope is used for driving the trams, the return, or upper part, no longer requires to be carried parallel to the line of rails, and the 35 supporting pulleys, which are securely carried on brick pillars, are placed where it has been found most convenient, sometimes on the right and sometimes on the left-hand side of the track.

The slack in the rope is taken up by a gravitation car to which the terminal pulley at the lower end of the line is fixed, the car being held back against the pull of the rope by a counter weight. The weight now used is 1,300 kilogrammes (26 cwt.) The length of ways upon which the car travels is about 15 metres, and whilst the rope is running it is in constant oscillation, moving irregularly through a space of about $1\frac{1}{2}$ metres (4 ft. 10 in.) The down hill or upper portion of the loop passes over this pulley, which is 4 metres in diameter (13 ft. 4 in.), and from thence, at the level of the ground, round another pulley of similar diameter fixed at about 20 yards further up the line than the driving pulley (which is placed in the middle), back over this, making two turns over these two pulleys before proceeding on its journey uphill, the object of the additional pulley being to prevent the slipping of the rope on the driving pulley, as would be the case were it in contact with only a small portion of the circumference, instead of being so with the whole. The second pulley is fixed upon a slide carriage, which, by means of screws, can be adjusted so as to take up any permanent lengthening of the rope. The driving pulley is also 4 metres (13 ft. 4 in.) in diameter, and has several grooves in case an extra turn of the rope should be found necessary.

The cable is 22 millimetres ($\frac{15}{16}$ in.) in diameter, composed of six strands each of eight wires of crucible steel, 2 millimetres ($\frac{1}{16}$ in.) diameter, wound round a hemp core. The breaking strain is given at 135 kilogrammes per square metre, or about $85\frac{3}{4}$ tons per square mile, but the actual strain upon the rope does not exceed 25 kilogrammes per square millimetre, or $15\frac{3}{4}$ tons per square mile. The weight of the rope is $1\frac{1}{3}$ kilogrammes per metre run (about 1 lb. per foot).

The stationary engine was constructed by Messrs Sulzer, of Winterthur, and is of 300 nominal horse-power. It consists of two horizontal cylinders, the valve gear being on a plan introduced by the firm, the engines can be worked with or without the condensor. Steam is supplied from four boilers of the Cornish type,

The terminus at Sassi being 223 metres above the level of the sea, whilst that of the Superga is 642 metres, the difference of level between the two extremities of the line is 419 metres, and its length being 3,150 metres (or about 2,000 metres less than the old carriage road), the mean gradient is 13·30 per 100 (1 in 7·51). The minimum gradient is 7 per 100 (1 in 14·30), whilst the maximum gradient is 20 in 100, or 1 in 5. The minimum radius of the curves is 300 metres.

The line is of the ordinary 4 ft. $8\frac{1}{3}$ in. guage, in order that the cars may be used on the steam tramway to Turin.

The rails are of the Vignoles type, weighing 18 kilogrammes per metre (36 lbs. per yard) and are fixed upon longitudnal sleepers, which are connected by cross sleepers of iron, to which is firmly bolted another longitudinal sleeper which carries a double rack with teeth placed vertically, into which the pinions of the driving car work.

In order to secure the permanent way from slipping, two piles, $1\frac{1}{2}$ metres in length, are driven on the lower side of each cross sleeper.

The width of the line at formation level is 4·20 metres (14 ft.), whilst that of the tunnels is 4·50 metres (15 ft.). The first tunnel is 67 metres in length, and situated at 783 metres from the lower terminus; whilst the second is 61 metres long, and at 1,799 metres from the same place.

The central rack is formed of a bar of steel 11 centimetres ($4\frac{3}{8}$ in.) in depth by 12 millimetres ($\frac{1}{2}$ in.) thick, bent in such a way as to form a double row of teeth, in which the pinions carried on the lower ends of the vertical shafts of the "locomotore" or driving - car, can work. This driving - car or "Locomotore Agudio," which is the most important feature in this system, consists of a metallic frame-work supported by four wheels which run on the rails, and which are completely independent of the mechanism of the "locomotore" which they carry.

The frame carries two horizontal axles; at the left hand end of each (looking up the line) are fixed a grooved pulley 2·30 metres in diameter (7 ft. 8 in.) The driving cable passing under the front pulley and over it to the hind one, and back underneath again, sets them in motion, transmitting its speed to them, which is converted into power by the mechanism. This hind axle carries near each end a bevel wheel, which can be thrown in and out of gear by a friction clutch. These wheels gear into other bevel wheels fixed at the uppermost end of two vertical shafts, one on each side of the central rack, and carry at their lower ends the pinions which gear into it.

It will be readily seen that whilst the rope is running, the driving pulleys on the horizontal shaft will transmit their motion by means of the bevel gearing to the pinions working in the rack, and that the speed of the car, as compared with that of the rope, will depend upon the ratio between the diameter of the driving pulley on the "locomotore," which is the receiver of motion, and the pinion, and which in the present case is as 5 to 1. The bevel wheels have 28 teeth, and the pinions 23.

The front axle, on the other hand, carries the two bevel wheels near the centre, so that when in gear with the horizontal ones on the vertical axles, a reversed motion is given to the car, whilst the cable is constantly running in the same direction. Thus the train can be stopped by throwing both sets of bevel wheels out of gear, driven uphill by throwing the hind bevel wheels into gear, reversed by throwing these out of gear and putting into gear the front pair. This is only used for backing the train at the stations and for starting it, as the downhill journey is accomplished by gravitation, when both sets of bevel gearing are disconnected, and the speed of the train is controlled by the brakes.

The right ends of the horizontal axles also carry pulleys over which a brake strap passes, the tightening up of which serves to check the speed going down hill, and for pulling up the train when going slowly. The most powerful brakes, however, are those which act upon the hind vertical axles, and consist of wooden blocks which, by means of suitable screw gearing, can be brought to bear upon a cylindrical projection cast upon the lower side of the horizontal bevel wheels. The blocks wear rapidly, but can be easily replaced. As a further precaution, a means of gripping the central longitudinal sleeper is provided, consisting of a pair of jaws which can be tightened up by a screw, and this takes a tight hold of the sleeper and effectually stops the train.

In going up hill, four pawls—a pair on each side of the central rack—are brought into play, and in the case of the breaking of the rope, would act as a ratchet and stop its running down hill.

The train at present is composed of two carriages, capable of containing 60 persons each; and the "locomotore," both for ascent and descent, is always on the down hill side of the train.

The carriages are not only provided with powerful brakes, which not only act upon the wheels, but also with a means of gripping the central sleeper, as is the case with the "locomotore."

Communication between the conductors of the train is constantly kept up with the driver of the stationary engine by a simple system of telegraphy, so that it is possible for those in charge of the train to give instructions to increase or slacken speed, or to stop the rope at any moment. Between Turin and Sassi the carriages of the Superga Railway are drawn by the locomotives of the Turin and Gassino Steam Tramway, which is laid on the provincial road, the railway being connected with it by means of a siding, and in this way passengers from Turin have not to change carriages.

The arrangement of the points and crossings is highly ingenious, a portion of the central sleeper with rack being lowered into a trench by means of cams, in order to allow the wheels of the carriage to pass from one line to the other.

The coutractors for the construction of the line were Messrs. Delvecchino and Perini, and great credit is given to Mr. E. Perini, the representative of the firm, for the manner in which he has worked out all the details, and overcome a host of difficulties which could not fail to have arisen in an undertaking of this nature.

The greater part of the material for the construction and working of this line was made in Italy, the Railway Plant Works of Savigliana supplying the central rack, metallic sleepers, girders for bridges, &c., the carriages and trucks. The two "locomotori" were made at the workshops of the Alta Italia Railway, with the exception of certain portions of special mechanism which were executed by the Royal Arsenal of Turin, and by Messrs. Enrico, engineers. The pullies, bearings, &c., were supplied by the foundry of Messrs. Colla.

The number of persons employed for working this line are 44, composed as follows:—1 engineer and traffic manager, 2 station masters, 2 ticket clerks, 2 guards, 2 brakesmen, 3 drivers, and 2 assistant drivers for "locomotori," 2 engineers, and 2 stokers for stationary engine, 1 oiler and linesman, 2 pointsmen, 1 head platelayer with 4 assistants, 1 ganger, and 10 labourers for maintenance of line.

No experiments have yet been made as to the cost of working, consumption of fuel, &c.

It is evident, however, that the Agudio system is especially adapted for very mountainous countries, where the gradients for a locomotive line would be too heavy, and where abundant water power might be availed of for motive power.

An official report states that during the month of May 13,880,000 kilo. (about 12,553 tons) of coal were imported from Germany into Italy by the St. Gothard line. This is the largest monthly export of coal from Germany to Italy that has yet occurred.

CANTOR LECTURES.

THE BUILDING OF TOWN HOUSES. THEIR ARRANGEMENT, ASPECT, DESIGN, AND GENERAL PLANNING.

By Robert W. Edis, F.S.A.

[The right of reproducing these lectures is reserved.]

Lecture I.—Delivered Monday, Feb. 18, 1884.

In accepting the invitation of the Council of this Society to give three of the Cantor Lectures of this season, and in choosing as my subject "The Building of Town Houses," it seemed to me that I might, from the experience gained during the past five and twenty years in my professional career as an architect, give some information and suggestions on the various points which should be specially observed and insisted upon in any building wherein sound construction, healthy arrangement, common-sense treatment of the rooms, and practical knowledge in their general fitting up, are all-important, where health, cleanliness, and comfort, and economy of service and labour are considered necessary. I use this phrase advisedly, for day by day, and year by year, I see in London, and other large towns, hosts of houses erected of the flimsiest construction, built with the most trashy materials, and finished without the slightest regard to the laws of health, comfort, or ordinary artistic character, externally or internally.

The speculative builders—and under this term I mean not only the host of small men who help to raise, fungus-like, the streets of flimsily-built cottages and fourth and fifth rate houses which disgrace our suburbs, and form the houses of the bulk of our working classes, but also those larger capitalists who have carried out, in the last twenty years, the innumerable streets, squares, and terraces in our more fashionable quarters, and whose erections, certainly from an art point of view, are, to a large extent, equally to be condemned—have too long had their way without control of any kind, save that which is provided for under the Metropolitan Building and other local Acts, and which simply permit of the district surveyors insisting upon certain thicknesses of walls, but gives them no power to reject inferior materials, or to prevent the too often scamping and utterly unsound work, the utter disregard of all known sanitary laws, or the commonest precautions to insure health and comfort.

It is surely time that every house erected in the great centres of habitation should have some systematic supervision, so that ordinary precautions shall be insisted upon to secure proper sanitation, to prevent the use of grossly inferior materials, and to prevent these plague-spots being formed in our midst; for it must be borne in mind that every house built under the system I have condemned, not only tends to the individual discomfort of the special occupier, but adds materially to the unhealthiness of a neighbourhood.

Within the last few months, the Metropolitan Board of Works have recognised the necessity of seeing that all buildings of which the drawings are submitted for their approval are so supervised, and have a special officer whose duty it is to see that the specifications are properly carried out, and that sound and proper materials are used; but their supervision can only be extremely limited, as it only applies to buildings carried out on their own property.

In all towns there are, I am aware, certain local Acts which, to a limited extent, insist upon a minimum amount of cubical contents, and a minimum height in the various rooms, and require certain minimum superficial contents in the back areas—which often form the only ventilation and lighting spaces for all back rooms—and that some sort of sanitary arrangement shall be carried out, so far as drains, &c., are concerned, but these requirements are too often over-ridden by the cunning and rascality of the speculative builder. As I have written elsewhere, "the Metropolitan Building Act is practically useless for any real sanitary purpose; it leaves all questions of drainage, proper arrangement of sinks, cisterns, and supply and service pipes, ventilation and heating, lighting, and general protection from building on improper and damp foundations unrestricted." It takes no note of inside construction, as regards soundness and character of timber and joiners' work, or of the proper making up of plaster, or of the strength of lead pipes, the thickness of lead work on the roofs, and in no way troubles itself so long as the mere ordinary requirements as to thickness of walls, depth of fire-place openings and recesses, &c., are carried out.

In the building of new and the rebuilding of old houses, it is essential that proper regard shall be had to the rapid growth of the sanitary science, and not only to comply with, but "anticipate as far as possible, its many requirements, and especially those of them which will, I believe, in a few years be considered by the population at large as absolutely necessary for habitable dwellings, not only as regards the actual sanitary fittings and appliances of the houses themselves, but also as regards their actual construction from the foundation upwards, and also more especially as regards the light and air spaces with which they are surrounded." *

If Government cannot take up the matter, and provide for such competent inspectors as may be necessary, who shall certify that every new house erected is built of sound materials, is properly drained and ventilated, and in fact is a healthy habitation, surely it would answer the purpose of a private company to take up the question on a large scale, and for some moderate fee, if required, make a proper inspection of any building, and certify as to its general soundness, the general character of materials used, and its fitness for human occupation.

I believe that most common-sense people would be glad to pay a small fee for some such searching inspection and certificate, and I am quite certain that if the public were to decline taking any house that was not certified as properly built with sound and proper materials, and in which the ordinary known laws of sanitation were not well and sufficiently carried out, we should see a great deal less of the scamping class of buildings, which are now daily rising around us.

It has been my lot to inspect numerous houses of the so-called better class of speculative builders' houses. I have in many cases found the walls very badly built with inferior materials, porous bricks and wretched mortar externally covered over with Portland cement to hide their deficiencies, with masses of cement mouldings overlaying their general faces, stuck on to flimsy brick or stone cores; cast cement ballustrading, party walls honeycombed with flues roughly pargetted, as the internal lining of plaster is called, and in many cases the plugging for joiners' work of all kind driven in to within a few inches of the smoke flues, so as to render them absolutely dangerous from fire; the stone floors in basement showing unmistakeably the dampness of the subsoil, laid on a few inches of bad concrete, the fittings of most inferior character; the inside walls and ceilings covered with plaster of such thickness as to invite shrinkage and cracking; the timbering insufficient in strength, so as to cause the floors to shake with the mere walking across them; to say nothing of the trashiness of the so-called internal decoration, in the shape of plaster cornices and centre flowers, all put up to attract the ignorant into a belief that the rooms are well and expensively finished; the drains unventilated, and laid on made up ground, so that the joints soon become leaky and unsound; the cisterns placed in the darkest and most inaccessible places, so that it is almost impossible to get at them to clean them out; the various lead pipes buried in the plaster work of the walls, and carried here, there, and everywhere, without protection from frost or means of access for examination and repair; the floors showing wide gaping spaces between each board, owing to unseasoned wood being used, through which dust and filth collects between the ceiling and floor, impossible to clean out, and, I need scarcely say, engendering stuffiness and unhealthiness everywhere.

The unfortunate tenant sees the house carefully painted and papered, and, from want of knowledge, imagines that the house is everything he can wish, and only finds out, after he has signed an agreement or lease, the wretched whited sepulchre that he has taken, which if it be not indeed a means of bringing illness or death to any of his belongings, is a certain cause for continual expenditure in repairs and making good the defective work, which, in taking it, it never occurred to him he would have to pay, thus adding materially to his annual rent, as well as to the general discomfort of every one in the house.

Practically, there is no real supervision of a vast proportion of the houses we live in;

* Report by Rowland Plumbe, F.R.I.B.A., to the Artisans' Labourers' and General Dwellings Company.

perhaps one per cent. of the houses erected are designed and superintended by a competent architect, the other ninety-nine being left to the tender mercies of the speculative builder, who is controlled only in a very limited degree, in the great centres of population, by certain Acts which provide for main drainage, water, and gas supply. Moreover, even if a competent architect be employed, the Jack-in-office ignorance of some of the officials of local vestries, or estate agents, bind him with red tape, or fence him about with difficulties and requirements which act prejudiciously, not only to the individual lessee, but to the whole of the surrounding district. I have the misfortune at this moment to be dealing with one of these Jacks-in-office, who insists on a building being faced with materials which time and experience have shown to be utterly unsuited to the London atmosphere. I can only hope that within a few years a law will be passed, enforcing the ground landlord to enfranchise, on terms equitable alike to himself and the building owner, so as to prevent as far as possible any really unfair interference which is based on supreme ignorance or power of brief authority. In the case I name there is no remedy; the agreement provides for drawings to be approved by the landlord or his agent; the agent, a man of no architectural or building knowledge, declines to recognise the fact that he is receiving for his employer, as ground rent, nearly four times the amount of the rental hitherto paid as gross rental, and that the unfortunate building owner is spending many thousands of pounds which, unless the law is altered, will revert to his master or his heirs in some sixty or seventy years, and insists on a certain character of facing being carried out, utterly at variance with all the experience of past years, and opposed to all advance either of art or construction.

All such legal restraints on the part of property owners, or on the part of local vestries, which are based merely on caprice or ignorance, must, in the nature of things, be swept away; the common sense of the people, their necessities and requirements—based on higher knowledge and greater desire to have the individual homes put in order and arranged, so that each house may in itself form an integral portion of a well-arranged and sanitarily constructed whole, by which the community will be equally benefited—will, by-and-by, insist on a new order of things, so that the monopoly of sites in crowded towns shall not be vested in the hands of a few individuals, without the lessees having the right of the equitable redemption of the ground rentals, whereby at least the buildings on which they have spent enormous sums of money shall remain theirs for ever, by payment of such sums which may fairly be demanded for their enfranchisement.

The present system of leasehold tenure in England generally is as iniquitous as it is unjust, leading in many instances to inferior work, overcrowding, and general badness of building, and, by the narrowmindedness and ignorance of grasping agents, to the setting aside of all modern improvements in building and construction.

If our towns are to be reconstructed and added to on healthy and proper principles, each house must be properly constructed, and certain fixed rules insisted upon, as regards proper general health arrangement and sanitation; for "the same rule," to quote Dr. Richardson, "applies to accumulation of health as to the accumulation of wealth." "Take care of the pennies," says the financier, "the pounds will take care of themselves." "Take care of the houses," says the sanitarian, "the towns will take care of themselves." It follows, therefore, that so far as common-sense laws can be applied to the rebuilding of the houses of closely packed communities, they should be on some general and uniform system, so far as laws of health are concerned, which all must follow. But this only applies to sanitation; so far as general arrangement is concerned, the wants of the individual must necessarily be consulted; and so far as the artistic improvement of our towns is concerned, I am strongly of opinion that the greater the variety of designs, the greater will be the artistic character and general picturesqueness of our streets.

We do not want whole rows of houses which, in bad sham plaster decoration, shall imitate the feeble monotony of the Rue de Rivoli in Paris, or which shall, by the censorship of some body of specialists or local official, crowd our cities and towns with pseudo Italian palaces, or Gothic town-halls, as ill-suited to our climate as they are opposed to all true principles of common sense, construction, and design.

To sacrifice internal comfort, light, and ventilation to some special order of fenestration, Greek, Roman, or Italian, or to the cramped and narrow lines of a mediæval fortress, or building of bygone ages, seems to me to convey nothing but poverty of thought, or narrow-minded conventionalism, equally opposed to all true principles of architecture as it is to the wants and requirements of the people of the 19th century.

Comfort and convenience of arrangement, ample light and ventilation everywhere; protection from damp and miasma, impure and unhealthy smells; warmth, freedom from draught; pure air, pure water, general cleanliness, and attention to all laws of sanitation, are first of all to be considered in every house. The architect or artist can so fashion the external clothing of a good framework as to make it agreeable in its outline and general constructive decoration; but the elevation should be subservient to the plan and constructional requirements necessary to provide all these desiderata, and should not be made the paramount feature in the design of a new house, or in the rebuilding of an old one.

I have lately been reading a powerfully written article by Dr. Richardson, in which he sets forth, in vigorous but not exaggerated language, the various communicable diseases which are "promoted or introduced by the errors of construction in the dwellings of our communities;" and I have been much struck by the number of preventable ills which he associates with bad ventilation, damp, bad drainage, impure water supplies, want of light and through draught, uncleanliness and foulness, or stuffiness of modern dwellings; and as, in the course of my remarks, I shall have occasion to specially allude to the means by which all these evils may be at least ameliorated, if not got rid of altogether, I hope you will permit me briefly to refer to and quote some of his remarks, for I cannot too strongly impress upon you, that the sole object of these lectures is rather to treat the houses we live in from a general health point of view and common-sense treatment of plan, design, and fittings, rather than from any mere personal opinion so far as regards particular type of architecture to be adopted in internal planning or external design.

If my teaching is to be of any service to the public at large, it must be based on broad general facts rather than on individual theories as to artistic design, or any special views as to any particular mode of treatment in any of the matters I may bring before your notice. If the various views that I shall lay before you in exposing the innumerable evils of which I shall have to complain in general house construction meet with your approval, I have no fear of the results artistically, for I shall condemn, in the strongest manner, all the innumerable shams which help to make our houses unhealthy and unartistic, and to recommend the simplest and, as far as possible, the most common-sense mode of external decoration, which will at least do away with the dull monotony of sham plaster fronts and ill-constructed openings, which may be called by the ignorant palatial or quaint, terms synonymous and equally foolish when applied to ordinary street architecture.

To begin with, typhus, typhoid, relapsing and scarlet fevers are mainly due to foul air, impure smell, or water, or closely packed and unventilated rooms, while the poisons thrown off by these diseases are retained in the walls and flooring, if badly constructed; while impure air arising from dust and dirt accumulations, and bad sanitation, tend to other illnesses in a minor degree, such as dyspepsia, nervousness, and depression, "during the presence of which conditions (to quote Dr. Richardson) a person is neither well nor ill." Another of our worst English diseases, "pulmonary consumption, or consumption of the lungs, has been largely promoted by the presence of unchanged and impure air in the dwelling house," while "neuralgic and miasmatic diseases" are brought about by the same causes, assisted by atmospheric moisture or damp, so often to be found in houses built either upon clay or in moist situations, where the ordinary precautions of covering the whole surface area with concrete or some other damp preventive has not been carried out.

Dampness, which is so often to be found in the basements of town houses in conjunction with impurity of air brought about by bad ventilation or imperfect sanitary arrangements, or general closeness and stuffiness of rooms in which dirt and dust are perforce allowed to accumulate, is more or less directly the cause of all the malarious diseases—ague, neuralgia, and rheumatism—and here the speculative builder comes in, with venom certain and incurable, with soft spongy bricks which absorb a large amount of water, with mortar composed of road drift or scrapings, foul and unhealthy; with damp and unseasoned timber, ingredients in the plague spots which warmth of fires bring out in vapour, and wherein moisture seems ever present, dimming the mirrors or condensing on painted walls, or absorbed in paper or distemper; which, on every damp day, becomes a visible barometer, marking plainly the change of temperature.

In badly constructed and ill arranged houses, how often do we hear the inhabitants complain of what is technically called "draught," which means sudden and irregular change of temperature; unpleasant as it is in itself, it is most insidious and dangerous in its results, bringing about colds, chills, and general "disturbance in the circulation of the organs of the body."

It is unnecessary to dwell further upon the numerous ills which we have it in our power to lessen, or altogether get rid of, by attention to the general construction of the houses we live in. I can only insist generally with Dr. Richardson, that "the intention and object of domestic sanitation is so to construct houses for human beings, or if the houses be constructed, so to improve them, that the various diseases and ailments incident to bad construction may be removed to the fullest possible extent. The diseases need not be looked upon as necessities of existence, but may be recognised as results of ignorance, or as accidents which, though they may not spring from sheer and wanton ignorance are removeable by accurate foreseeing and all providing knowledge."

In towns, where, for the most part, all houses are built in groups, either in streets, terraces, or squares, and rarely detached, owing to the value of building area and frontage, the general aspect is naturally fixed by the location of the building, and the laying out of the street or terrace of which the particular house already forms or is to form a part; and, therefore, it is of the utmost importance as far as possible to secure as much light and sun as can be obtained by the slightly varied aspect which is given by semi-octagonal or circular-projecting windows with side lights, more especially where the plotting of the site lies more or less due north and south.

All these bay-windows and projections find little favour with the local authorities, who, as far as possible, do all they can to prevent their being carried out, whether it be from the fanciful objection that they tend to stop proper circulation of air in the street, or from the still more ridiculous objection of their interfering with the ordinary frontage line. Nothing can be more miserable and unartistic, nothing more insulting to good taste, than the dreary monotony and vulgarity of most London streets, old and new, whether they be of the commonplace character of Gower, Wimpole, and Harley-streets, with stockbrick facing—with here and there what are called red dressings to the windows—or the meretricious and tasteless vulgarity of the never-ending rows of cemented fronts in the new districts of Bayswater, Tyburnia, and South Kensington, in which the design of each front is made up of plaster cornices, bad in design and construction, plaster architraves, and unmeaning pediments filled in with cast plaster ornament of the meanest and most tasteless description. The eye is wearied with the everlasting sameness, and is almost thankful when one of the occupiers suddenly causes his house to be painted externally bright red or yellow, for the relief from the sickly glare and sham of the cement or stone-painted frontages. How much more artistic and picturesque could our streets be made if broken up with bays and gables, cutting up the sky-line, like the streets in many of the old towns in Germany and Belgium; and how much more cheerful and healthy would be the rooms wherein these bays are thrown out, and through which sun, air, and light can be obtained in more ample quantity, than by means of the two or three parallelogram-shaped openings which generally form the windows in most London fronts. Anyway, there is an old adage, which is more or less true, that "where the sun does not enter, sickness in some sort or way is sure to obtain." We do not get too much sun in smoke-covered towns; and surely every possible allowance, consistent of course with what is due to the comfort and enjoyment of our neighbours, should be made for flat-sided projections, by which more sun and light can be given to our homes.

Fancy being on the south side of a street, where the windows face due north, and into which, for nearly the whole of the year, the sun can never shine, save very occasionally in thin slantwise streaks. Were it not for the generally disagreeable views that are obtainable from the backs of town houses, I should be often inclined to advise that all the best rooms in such a case should be placed at the back, with projecting bays, which the authorities who rule over street frontages cannot interfere with, and so to obtain, as far as is practicable, considering the close packing of the building area of all towns, some glimpse and use of the sun during all hours of the day.

Why, too, cannot the backs of our houses be made more decent, if only by means of glazed bricks varied occasionally with bands of colour When we see the backs of some of the grand stucco-covered palaces of our western suburbs, we are apt to think of the old rhyme which, written on some piece of modern church or chapel architecture, says that—

> "They built the front, upon my word,
> As fine as any abbey;
> And thinking they might cheat the Lord,
> They made the back part shabby."

Of course I know glazed bricks are more expensive than the common stocks, but the extra expense would be amply repaid by the extra light and better air, for the glaze naturally makes the brick not absorbent, and every shower of rain would wash the walls, so faced, clean.

The laying out of streets and squares in towns has very little changed in the last few hundred years, owing more or less to the value of the frontage, and the necessity of providing for some general street line beyond which the main front walls should not project; but there is no sound reason why flat bays, so arranged that they do not look into each other, should not be permitted in every house; the general picturesqueness of the streets would be materially improved, without, in my opinion, interfering in any way with the proper circulation of air, which must, in the nature of things, be duly considered in the laying out of new streets, and which must be maintained in all old thoroughfares.

Why should we not have every new house in such places as Berkeley or Grosvenor-squares built with projecting oriels and bays, and high pitched gables; the gables would add materially to the light and comfort—not to say anything of the artistic character—of the rooms, while the latter would surely be preferable to the generally miserable so-called dormers, which are, as a rule, set back behind the balconies or parapets, in the attics of most town houses; these, I am told often, are quite good enough for servants, a selfish, cruel, if not a suicidal opinion; for if we are to have servants in health, and fitted to carry out their daily occupations, with comfort to themselves, and justice to their employers, their rooms should be just as light, airy, and cheerful as any others in the house. Let the sun call them in the morning if you can, and give a greeting in a light cheery manner to the commencement of their daily labour. In addition to the manifest improvement to the elevation and rooms of the house, all these irregularities tend to promote movement in the air, to give light and shade, and thus to help towards health in the building, and pleasure in our walks abroad.

Rules that have long since been found to be useless, and practically detrimental, not to say preventive of any improvement in the building of town houses, so far as their frontages are concerned, seem to be tied up with musty red tape in the musty heads of vestry officialism. The old machine goes on with its everlasting and monotonous click, worn out, effete, useless, and absurd—there it is, and will, I suppose, remain so, until some general common-sense order of the day turns it figuratively into the dust yard of oblivion, and a new *régime* and a new order of things arises, from which we may hope for practical common sense in all matters pertaining to the building of new, or to the rebuilding of old houses, instead of the stupid bumbledom of most modern Board and Vestry officials; and we may be thankful that at least one large owner of land in this City—I mean the Duke of Westminster—sets a good example on his own property, by encouraging in every way in his power, a departure from the old fogeydom of street design, for "fresh fields and pastures new," in which projections and gables are asked for rather than decried, and modern improvements in building construction and materials are not only permitted but encouraged.

All town houses must necessarily be influenced by local conditions, and in speaking in any way of aspect, these conditions must materially influence all questions of general aspect; but I cannot too strongly urge the desirability of bettering, as far as practicable, special local conditions, by a far more common-sense view of projections and arrangements for providing sunlight and air, than generally obtains with many of those who, unfortunately, are the critics, as well as the judges, of what they presume is necessary for modern requirements.

In speaking upon the next part of my subject, that of design, I desire to recognise and appreciate, in the largest possible sense, the varieties of taste which must necessarily prevail in an age where, as a rule, precedent and fashion are all predominant. I have no wish to force any particular period of architecture upon you, or to ask you to agree in any of my remarks; it must necessarily be more or less eclectic if, as wise men, you desire to embody as far as is consistent with your building all that is good in past, and to incorporate therein the improvements in materials and general building appliances of the present; but I do insist that the external design, properly considered, that is, the general elevation of the street front, should and must be subservient to the internal requirements;

and that the light, air, ventilation, and common-sense requirements of the house must in no way be sacrificed to the external design, for no beauty of mere architectural effect will compensate for discomfort and bad internal arrangement.

I live in a square, in which a certain portion of the houses have been carried out in semi-classic sort of treatment, in which the comfort of the bedrooms has been, to a large extent, sacrificed to meet the requirements of the external design, in which the windows are inconveniently placed and altogether insufficient, owing to their having to be adapted to the classic elevation. All this sacrifice of internal comfort and convenience to external effect is inconsistent with common-sense and ordinary requirements of health, and any architect who sacrifices comfort, utility, and internal arrangement to mere external effect is unworthy of being trusted for a moment. A good plan will make a good elevation; but an elevation in which specific rules which might be fitting for a Greek temple or a mediæval fortress are insisted on, is in no way suitable to an ordinary house, in which the first essentials are lofty and well-arranged windows, and proper light and air space.

Gothic tracery and pointed openings are not suited to ordinary sash windows, and it surely is inconsistent with modern street design to attempt anything in which one or other of the so-called five orders of classic architecture has to be worked into a house in which the frontage is perhaps 18 or 20 ft. at most. When it was attempted in the beginning of this century in the terraces of Regent's-park, generally two or more houses were embraced in the design, a manifest inconvenience and absurdity when one owner wants to paint his front red and the other yellow.

I have already condemned, as strongly as words can do, the vulgarity and unartistic pretentiousness of the host of modern buildings erected in our fashionable suburbs in imitation of Italian palaces or Roman temples, with sham plaster columns running up the whole height, gigantic pediments, and unmeaning and unnecessary cornices, such as can be seen in the terraces of Regent's-park, the confines of Belgravia and Tyburnia, and other quarters, where the fashionable speculative builder of the day has imitated—in plaster—temples and palaces utterly at variance with the requirements of ordinary houses. The fashion of the day is running into modern Dutch, or so-called Queen Anne, and inasmuch as this style admits of ample fenestration, and does not limit the size of light openings, and relies for its piquancy and character on honest red brick instead of sham plaster and vulgar imitation, we may be thankful for small mercies, and be content with a revival of a 16th and 17th century Renaissance school of architecture, which gives us at least colour and picturesqueness in our London streets.

I go so far as to say that the man who builds a red brick house in a town, where want of colour tends to make everything glaring or, where smoke-covered, gloomy, is a benefactor to his species; and I go still further in saying that to a great extent the materials used should, in a manner, be those which are peculiar to the country and locality. Granite is natural to Aberdeen, and used rightly, is a godsend to the place; stone of various kinds is indigenous to certain localities, and naturally suggests itself to the particular neighbourhoods. I should hardly suggest the desirability of putting up a red brick house in an Aberdeen street, although I think Aberdonians might well obtain more warmth and colour in a naturally cold quarter, by judicious use of red and rose-coloured granite mixed with their sparkling grey, which is charming when the sun causes it to light up and glisten, but cold in the extreme when made dead and dark by mist and rain.

We have plenty of good brick clay; we can obtain readily first-class red bricks and terra cotta, and both these materials are more lasting and more suitable to London smoke and the deleterious action of London atmosphere than almost any stone which exists. We have only to take a walk through London, and see the manner in which even the best qualities of stone have become disintegrated by the action of smoke and other impurities which abound in a London atmosphere, and to understand the difference between it and burnt clay, either in brick or terra cotta, to realise that any materials such as terra cotta, glazed faience or brick, are impervious by the nature of their composition to the action of smoke and other impurities, are more suitable than stone for ordinary buildings in our cities and towns.

Glazed and coloured brick, and faience, and terra cotta, admit of almost any variety of design; they give picturesqueness, warmth and colour where they are wanted.

I should like to see London streets made picturesque and beautiful in colour with terra cotta and glazed faience, which every shower shower of rain would cleanse and improve, and should like to see every stucco-fronted building decaying and unlet. As a rule, this sort of work is not only imitation of stone, bad in taste, bad in construction, and unfit to last any time, but glosses over inferior building, and covers a multitude of sins which it would be well for the occupiers, from a mere common sense and sanitary point of view, to lay bare.

We do not want pseudo-Italian palaces, or bad copies of French street architecture, with forced arrangement of fenestration and cutting up of wall space, utterly at variance with home requirements; nor do we want so-called mediæval structures, in which light, ventilation, and air are sacrificed to narrow Gothic or pointed-headed windows and doorways.

So far as I can judge, it seems to me that the so-called Elizabethan or later Renaissance of this country is infinitely more charming and more suitable to every-day wants and requirements than any other style, Greek, Roman, or Gothic; anyway, we want to express in our external work a sense of comfort and utility, and to provide ample light and air space for the rooms, of which the front wall is only the external casing; and any style which combines these desiderata will commend itself to common-sense people, in place of those external architectural styles which have nothing in common with English taste, or English home life.

Classic design, based on rules which were charming in the temples of Athens or Herculaneum, or the monumental buildings of Italy, are not fitted to street architecture; everything is sacrificed to the symmetry and proportion of the elevation, and the arrangement of the interior is left, more or less, to go as it will.

It is not in any way a part of the purpose of these lectures to enter into the various features of architectural design in other countries, or I might enlarge upon the beauty and vigour of the Venetian Gothic, or on the richness of Italian Renaissance, the charm of much of the work of Palladio in Vicenza, or the magnificence of the Florentine and Genoese Palaces; but all the work in these special schools was done at first hand by great masters in their art, and were more or less suitable to the luxury and splendour of the age; but any mere copyism of any of these styles in the cities and towns of this country seems to me utterly opposed to the condition and requirements of English life.

Good architectural effect may be perfectly well obtainable with a good common-sense plan, and there is no possible excuse for a design, whether classic, Gothic, or Queen Anne, which does not first of all recognise the internal necessities and conveniences, and which is not subordinate to a great extent to everyday internal requirements of a well-arranged and comfortable house. While I advocate first of all that the elevation or design should be made subservient to the plan, I do not see the necessity of following the types of various schools of French, Italian, or 13th, 14th, or 15th century Gothic buildings; and when I see the pretentiousness of imitation of either of these schools, I am bound to confess that it suggests nothing but an ignorant conceit, which would not for a moment have been carried out by the great architects whose works we admire, had they had all the modern improvements which increased knowledge and higher skill in invention have brought about.

In our monumental buildings, and even in our ordinary street fronts, architecture should be much more intimately allied with the sister arts of sculpture and painting. Even a porch in which the ornament is modelled with care by an artist, or the corbel of a projecting bay, will redeem an otherwise bad design from commonplaceness; a proper regard for proportion and arrangement of outline in the most simple building shows the work of a true artist, much more than the overlaying of his work with useless ornament or carving, or the overcrowding of parts with feeble enrichment stuck on balustrading and pediments. In house design, it seems to me, that first of all the design should convey some expression of the comfort and general planning of the building, and that its fenestration should show, above all, proper regard to the lighting and ventilation of the rooms, and generally bear the characteristics of the material with which it is carried out, and with English rather than foreign features.

I know of only two or three instances in which Portland cement has been rightly treated in street fronts, in which the architect, the late Mr. Owen Jones, relied upon general effect by incised lines or ornament, carefully avoiding projecting strings and cornices, which might seem suggestive of stone or sham construction. In street frontages, it is desirable, as far as possible, to do away with the sameness and monotony of long lines of façades, in which there are no breaks in the sky line or picturesque cutting up of the roofs, except those not very pretty features in the shape of chimney cowls, which offer themselves in every form of ugliness that zinc workers can conceive, over the whole of the London area.

If importance is wanted in an elevation, let it be got by good sculpture in such portions of the building as are nearest the eye line; a porch properly treated with good modelled decoration, either in figure or relief ornament, can be made as imposing as you like, while balcony fronts can be of good wrought iron, like some of those in the old picturesque towns of Spain and Germany, instead of lumpy and heavy with ballustrading, which not only shuts out light from the rooms, but suggests an element of danger by their utterly false and generally insufficient construction; but I confess to a feeling of astonishment when I see friezes and cornices of buildings in narrow streets, some forty or fifty feet from the street level, covered with elaborate carving and enrichment which it is impossible even to look at without craning the neck, and which can only be appreciated by the servants who inhabit the attics over the way. There is no possible reason why street frontages should not be made picturesque and beautiful instead of tame and ugly, and the commonest of fronts can often be redeemed by some good bit of detail and decoration in the shape of red brick, terra cotta, or glazed faience. If the public will only remember that plaster or cement is generally used to gloss over bad and inferior brickwork, and decline to take houses in which all this bad and false surface covering is used, even speculative builders would be forced to conform to the requirements which higher artistic education and knowledge are gradually insisting upon. Picturesque fronts, with projecting oriels or bays and gabled roofs, need cost no more than some of these wretched travesties of Italian or French architecture, with so-called Mansard roofs and cramped dormer lights, and would give grace and charm, and colour, where now commonplaceness, vulgarity, and bad taste reign supreme.

Too often the first principles of proportion are lost sight of, owing to the want of proper culture of the eye, and details which might be well suited to a Genoese or Roman palace are stuck on to a narrow street frontage. As was well said by the late Sir Gilbert Scott, in a paper read by him some twenty years ago before the Architectural Association—

"It is ridiculous to suppose that such an art as architecture is to be learned without the most careful study of its existing proportions, or that originality is likely to be developed upon a basis of ignorance; and it is equally unlikely that excellence will be attained solely through the medium of knowledge, without the most zealous and careful training of the eye to the most delicate and scrupulous perception of the right and the wrong in form and proportion. The want of this is the most crying sin in modern architecture, especially, I fear, in this country. . . . As the greatest of moralists has said, 'Keep thy heart with all diligence, for out of it are the issues of life,' so we may say to the architect, 'Keep thine eye with all diligence, for out of it are the issues of art.'"

There is no need why London street architecture should not embody every modern improvement, and be carried out in a commonsense and picturesque style, suitable for everyday wants, and in conformity with all the various scientific principles of sanitation which the nineteenth century has produced, "instead of rescusitating old forms and old features, which our forefathers would have gladly changed" had they had the knowledge or benefit of modern improvements. I have no desire to see any one uniform style of building, but whatever style is taken up by the individual owner—presuming always that he is not to be stopped by the caprice or ignorance of some local board official or agent to his ground landlord—it is first of all essential that it should be made to adapt itself to the internal requirements, and that there be ample light, and common-sense treatment of the window spaces, so that they be arranged in the rooms in proper places, and not thrust into corners, or raised so high from the floors as to be prison-like, to suit the external design; and whether Greek, Italian, Queen Anne, or any date or period of so-called Gothic art, it must be governed by present wants, and every sanitary and modern invention which may make the individual house more comfortable, more healthy, and more convenient for the purposes for which it is required, and thus to assist to the general good by providing buildings which are not only soundly constructed, and in conformity with all the known laws of hygiene and sanitation, but picturesque and pleasant in their elevations, adding thus to the pleasures of those, the greater part of whose lives are necessarily spent in the towns in which they have to carry on their daily avocations.

Renaissance, whether German, Italian, or French, freely or simply treated, and all the later phases of the Jacobean and English Elizabethan periods, are capable of being successfully adapted to present home life and modern requirements.

So far as my experience goes, the public generally are unaware of the real advantages and merits of terra cotta for facing street fronts. Some few may recall the excellence and beauty of the terra cotta work in the lovely cloisters at the Certosa, near Pavia, and in innumerable or ecclesiastical and domestic buildings in other parts of Northern Italy and Germany, although I believe casts of parts of some of the more important buildings have been taken for the Museum at South Kensington, and for the Crystal Palace at Sydenham; but few are really cognisant of its great superiority as a building material in crowded towns over ordinary brick or stone. In the first place, when properly burnt, it is absolutely impervious to smoke, and is unaffected by acid fumes of any description; it is about half the weight of the lightest building stones, and its resistance, when burnt in solid blocks in compression, is nearly one-third greater than that of Portland stone; it is not absorbent—a great desideratum when damp has to be considered—it is easily moulded into any shape, for strings, cornices, or window-sills and architraves, can be easily modelled for figure or other enrichment, and last, but not least, in these days of high taxes and increasing School Board rates, is cheaper in London than almost any description of really good building stone. It can be got in good warm yellow or red colour, and, when glazed, can be produced in almost any tones of soft browns, greens, reds or yellows—and its strength, durability, and imperviousness to all the destructive influences of town atmospheres, to my mind, recommends it as the building material most adapted for facing street frontages.

Within the last two or three years, Mr. Holroyd, of Leeds, has materially improved the glazing of terra cotta and fire clay, and, under the name of "Burmantofts Faience," is producing most excellent material for external and internal work, for which almost any colour of glazed ware can be readily obtained at a price very little in excess of good Bath stone—and when it be remembered that this material mellows with age, is washed clean by every shower of rain, and practically shuts out all damp from the walls in which it is used for facing purposes, it will, I feel sure, commend itself to those who desire to have beauty of colour combined with sound and truthful material, and an important element of healthy construction in our London houses. It should be used in small blocks, so as to avoid the unevenness which is caused by the unequal shrinkage of the material in burning, and which in string courses, cornices, or even ordinary facing, would occur if large blocks were used.

Let me say a few words about iron railings. To what disastrous order of things we owe the prison-like bars and straight lines of the ordinary front railings in our streets, I am at a loss to understand; but surely nothing can be more hideous or more unartistic. We must have these iron enclosures to our areas, first of all, to avoid the shutting out of light and air to our basements, and next for the sake of security; but surely they need not be made in never ending rows of perfectly straight bars, with spear like heads, suggesting nothing but dread of impalement should one be so unfortunate as to fall from one of the usually badly constructed balconies which, in festival times, are generally shored up to ensure the safety of those who, once or twice in a lifetime, crowd them for the purpose of looking at a Lord Mayor's show, or other similar interesting fête. Wrought ironwork, if worth anything at all except for prison bars or girders, is meant to be wrought and twisted into endless form and shape. Why cannot we redeem the general want of taste in London streets by something like good design in balcony fronts or area railings. They may be made just as secure, and just as useful, if made ornamental in form, like the beautiful ironwork of the old towns in Spain, Italy, and Germany, which can be seen in the humblest street front as well as in the princely palaces; or like the English work of the last century, some few specimens of which remain in some of the older squares and streets of London, instead of being mean, ugly, and commonplace.

I have recently had some wrought ironwork done for me by a young artist smith in London, which can hold its own, in skill of handicraft and application of artistic treatment in the right spirit to the material, with much of the olden work, and at a cost very little in excess of the usual trashy railing which is reproduced in endless monotony, to the disfigurement of all our streets and squares.

It is in these small matters that the taste of a people is shown, and it is by these minor features of design in the necessities of street architecture that picturesqueness and grace are to be obtained.

I do not suggest expensive and flowing ornament; with delicately wrought foliage or flowers but if only we could see a few good wrought-iron panels of simple character interspersed here and there amid the upright bars, we should admit, I think, that it is by these small matters that the ultimate improvement in London façades may be obtained. The same remarks might apply with equal justice to street lamps. What can be more hideous than the vulgar cast-iron posts that are stuck up at intervals throughout our streets; but until the gas which is said to illuminate them be something better than the noxious compound which it is at present, we can hardly expect better or more artistic setting of the feeble glimmering of gas-light which it encloses.

It would seem as if the sense of sight, and the love of the beautiful, when applied to ordinary everyday matters, are not appreciable elements in the ordinary English character, or it would be impossible to believe that, year by year, we should be content to accept and pay for things which are not only vulgar and commonplace, but unartistic and detrimental to any real improvement in our street architecture. If art were costly, I could understand that a so-called nation of shopkeepers would object to any change; but when, annually, enormous grants out of public funds to which we all individually contribute are applied to the improvement of artistic training by means of so-called schools of art, and the fact that good design is practically no more costly than bad design, I marvel much that, long suffering as we are, we put up with ills which are curable, and with vulgarities which are disgraceful to any educated nation.

I must ask you, as time warns me that I must conclude, to allow me to deviate from my syllabus so far as to include the remarks I may have to address to you on general planning in my next lecture, as this practically is intimately associated with the items of sanitation, light, heating, and ventilation which are specially set forth in the syllabus.

Let me close this lecture by a quotation from one delivered over a quarter of a century ago, by a writer who was then one of the greatest of living word painters:—

"If you build well and artistically you will talk to all who pass by, and all those little sympathies, those freaks of fancy, those jests in stone, those workings out of problems in caprice, will occupy mind after mind of utterly countless multitudes, long after you are gone. You have not, like authors, to plead for a hearing, or to fear oblivion. Do but build large enough, and boldly enough, and all the world will hear you; they cannot choose but look."

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON SANITARY APPLIANCES. BY W. K. BURTON.

Sanitary appliances, as distinguished from actual drains and drain attachments, are, for the most part, to be found in the East Annexe, and are grouped under the heading "Class XXIII." The position given to these is better than that given to the drains, and the exhibits, although for the most part they consist of water-closets, fixed basins, urinals, and so forth, are more attractive, as gilding and brilliant colouring have been by no means spared on them.

I shall first notice an appliance which might possibly have found its best place among the drainage arrangements, but which has been exhibited in Class XXIII. I refer to Rogers Field's flushing tank, exhibited by Messrs. Bowes, Scott, and Read, of Broadway-chambers, Westminster, S.W.

Mr. Field has possibly done more to bring house drainage to its present state of perfection than has any other man, and this invention of his is one particularly worthy of notice. Its object is to secure the periodical passage of a large volume of water through the drains of a house, so as to ensure their being thoroughly flushed. The manner in which this is brought about is simplicity in itself. The tank has attached to it a large syphon which, from a peculiarity in its construction, will start with a very small dribble of water. All that is necessary is to fix the flushing tank over the extreme upper end of the drain, and to supply it with a dribble of water which may be so regulated as to fill it once a-day, twice a-day, or once in two or three days, or just as often as may be desired. When the tank has thus been slowly filled up the syphon starts, and the whole contents are quickly emptied, sending a great flush of water down the drain. The tank may be supplied in various ways besides that mentioned; for example, by the discharge of a bath or other appliances.

Coming to the subject of water-closets, I may say that the number of those shown is legion, and that the chief impression produced by looking at the whole of those exhibited is one of wonder at the closeness with which one maker has, for the most part, imitated another.

The object which is attempted to be gained with all closets of modern design, is the complete clearing away of all soil immediately the water flush is applied, the best closet being that which retains the least trace of such deposit in any of its parts.

The old pan closet, now condemned by all sanitary authorities, was an excellent example of how to construct an apparatus *not* to do what had been mentioned.

Closets of modern construction may be divided into two great classes, the valve closet and the wash-out closet, although there are several which fall half-way between the two.

In the valve closet, the basin is closed at its lower end by a valve which opens when the handle is raised, the water-flush being admitted at the same moment. The soil is carried from the basin through a trap into the soil pipe, after which the valve is closed. The water, however, continues to run for some time after the handle has been allowed to fall, so that the basin fills partly full of water and remains partly filled until the closet is again used.

The wash-out closet consists merely of a basin and trap, the outgo from the basin to the trap being sometimes at the back of the former, sometimes at the side; in one case at least in the front and in several cases at the bottom.

The two matters chiefly to be attended to in designing a wash-out closet are (1st) that the soil shall drop into water, not on to the sides of the basin, and (2nd) that the whole apparatus can be thoroughly flushed by the two gallons of water which the water companies allow to be used.

So many valve closets, excellent in every particular, are exhibited, that it would be invidious to select any one as an example.

Concerning the wash-out closets, we might perhaps mention that of Bostel as exhibiting great excellence of design and of general finish. It is exhibited by the Hygienic and Sanitary Engineering Company, Limited, 23 and 24, Charing-cross, London.

As an example of a closet lying half-way between a valve and wash-out apparatus, we may take Pearson's "twin basin." This closet consists of a large basin divided into two compartments. These are kept filled with water by a self-acting arrangement. The soil falls into one of them, but at the bottom of the other there is a large plug closing the outgo; on raising this plug the whole of the contents of both basins are discharged into the soil pipe.

Various plumbing and other appliances are exhibited by Messrs. Dent and Hellyer, of 21, Newcastle-street, Strand. This firm deserves great praise, as having brought out many of the best sanitary fittings that are to be had. We may specially mention among those exhibited the **V** or anti-**D** trap. This trap is intended particularly for fixing under closets, and has the same self-cleansing properties as the syphon trap, whilst it is not so likely to be untrapped by a great rush of water as that appliance is. A novelty is shown by the firm in the shape o a movable grease-trap for fixing under sinks upstairs. Where, as is frequently the case in restaurants, &c., the kitchen is at the top of the house, great inconvenience is often experienced through the choking with grease of the necessarily long pipes which pass from the sinks to the nearest gully in the open air. To collect this grease before it reaches the discharge pipe, Mr. Hellyer has invented the movable grease trap, which is placed immediately under the sink, but can be readily uncoupled from the pipe and carried to the nearest convenient place for the depositing of the grease.

Du Bois' traps and bends, exhibited by Messrs. George Farmiloe and Son, 34, St. John-street, E.C., deserve notice. These consist of syphon traps and bends of various sizes, to all appearance similar to other traps and bends, but unlike them in being neither cast nor made up from two pieces soldered together, but being in fact "drawn," presumably by hydraulic power. They are of the most ductile lead, and can be worked by the plumber more easily than other traps can.

Dry earth closets are now generally admitted to be the best appliances to use when closets may be out of doors, as in the case of cottages, country houses, &c. There are several exhibits of such, the most noticeable being that of the "Moule's Patent Earth Closet Co., Limited," of 5A, Garrick-street, London, W.C.

There is not space here to describe the various baths, fixed hand basins, urinals, and so forth, which are to be seen on all sides. Suffice it to say that the visitor will see many of these objects, all more or less conveniently and handsomely fitted, some of them being, in fact, works of art in themselves.

The Sanitary and Insanitary Houses.

In the grounds of the Exhibition there have been erected two houses, each with drainage systems, the one intended to illustrate the defective condition of affairs only too commonly met with, the other intended to illustrate a system as perfect as modern sanitary science can make it. The buildings are at present in a somewhat unfinished state, but they are quite far enough advanced to illustrate what is intended.*

Taking first the "insanitary" house, we find on the first floor a closet of the very worst form, namely, the pan closet. In this there is under the basin (in ordinary circumstances the only part of the apparatus visible) a huge cast-iron container, which becomes a receptacle for filth which accumulates there and evolves noxious gases, which escape every time the handle is raised and the water seal between the "container" and the basin is thus removed; or, for the matter of that, escape more or less at all times, because the container is by no means perfectly air-tight. This closet is situated in the very middle of the house, so that no means of ventilating it can be got. Under it there is the objectionable **D**-trap, which, as well as the container, acts as a receptacle for soil—as a miniature cesspool in fact.

Beside the closet there is a sink, and this, instead of discharging into the open air, is connected directly with the **D**-trap already mentioned, the discharge pipe giving ready egress to the gasses generated in this same.

The soil pipe taking the discharge from the closet is made up of portions of lead and of light iron pipes,

* They have been completed since this was written.

the junction between the two being made by smearing a little red lead putty round the part. There is no ventilation whatever. The drain leading from the soil pipe is laid in the sinuous manner already mentioned in the article on house drains and drainage appliances, and is left exposed at several places, to show that the joints are innocent of any material to prevent the free egress of sewer gas. The closet on the ground floor is little better than that upstairs. It is of the kind known as the "long hopper," and is supplied with a miserable dribble of water from a "stool-cock."

On the ground floor there is, besides the closet, a scullery sink placed in the most unsuitable position that could readily have been found. This discharges by a straight iron pipe into a built pit below, usually dignified by the name of a grease trap. The only protection against the gases generated from this pit, and rising from the drain and sewer, is a "bell-trap." The portion of this apparatus which forms the slight seal which at any time exists, is removeable, and as a matter of fact is usually removed, to facilitate the flow of water down the discharge pipe, by the servant who may use the sink. In the floor under the sink there is over the cesspit a similar trap for sweeping the dirt off the floor into.

The waste pipes of the cisterns are connected directly with the drains.

It might be supposed that the state of affairs represented in this model house is a sort of caricature of what is to be seen anywhere. I can assure the reader that this is far from being the case. That in fact the state of affairs represented is one such as is to be found in probably nearly fifty per cent. of houses in London. The committee who arranged the house might have shown a much worse state of affairs than they have, without in the least overstepping the bounds of truth.

In contrast to the house jnst described stands the other one. In this latter the closets are placed against the outside wall so that they can be properly ventilated. The one upstairs is a valve closet, that on the ground floor a wash-out. Both forms have already been described.

The soil pipe is a sound lead pipe fixed outside the house, and carried full size to a point clear of the roof.

The sinks, and so forth, discharge through syphon-traps over a gully in the open air. The cisterns overflow into the open air by pipes simply projecting through the outer walls of the house.

The various branch drains run as curved channel pipes along the bottom of a manhole and branch into each other. From the manhole a perfeectly straight iron pipe runs from the back to the front of the house, where there is a disconnecting chamber, such as we have already described when treating of drains and drainage appliances. This is provided with channel pipe, disconnecting trap, air inlet, and cast-iron cover.

On the whole, the *simplicity* of the good arrangement, as compared with the bad, is very noticeable.

EDINBURGH FORESTRY EXHIBITION.

No. II.

The Executive Committee of the Exhibition prepared a classification, but practical difficulties were found in the way of carrying it out in its entirety, and the geographical principle was adopted, by which the exhibits of each couutry were brought together. The heads of the Classification were as follows:—Class I, practical forestry, including implements and tools, models and plans, machinery, fencing materials, &c. Class II., forest produce, raw and manufactured, including woods of all kinds, cooperage, turnery, basket and wicker work, tanning and dyeing substances, gums, oils, drugs, &c. Class III., scientific forestry, including botanical specimens, parasites, forest fauna injurious to woods, preservative processes, fossil plants, &c. Class IV., ornamental forestry, including growing specimens of rare and ornamental trees and shrubs, rustic work, dried specimens. Class V., illustrations of forestry, including paintings, photographs and drawings. Class VI., forest literature and history. Class VII., essays and reports. Class VIII., loan collections. Class IX., economic condition of foresters and woodmen; with a Tenth Class of miscellaneous, to include articles bearing on the objects of the Exhibition, but not coming within any of the previous classes.

Although this classification was not carried out, it represents fairly well the objects exhibited by the different countries. The contents of the Exhibition might also be broadly divided into (1) *Forest*, including the trees, trunks, branches and leaves, seed and cones, monstrosities, &c., the tools used by foresters, transplanting machines, protective materials, and forest animals; (2) *Wood*, in the rough and made up, including curiosities, furniture, and useful articles, as well as materials obtained direct from wood, such as paper from pulp. In the first of these divisions may be mentioned the four bamboos from Burmah, grouped at the corners of the central transept to reach to the roof of the dome. These are 150 feet in length. The Californian Redwood Company exhibited a section of *Sequoia sempervirens*, 13 feet in diameter. The tree from which it was cut was 295 feet high, and from counting the rings, it is computed that it was 2,000 years old; 6,250 cubic feet, or 75,000 feet board measure, were cut out of this tree. There is also a complete chamber formed of the bark of a tree exhibited by the Company. The bark, which is of varying thickness, is raised 12 feet high, and the interior, the floor of which is formed by a section 13 feet in diameter, will accommodate forty persons. Tools were also well represented. Transplanting machines, capable of removing trees 30 feet high, and from two to ten tons in weight, were exhibited. The Queen lent heads of red deer from Windsor and Balmoral; the Prince of Wales and the Duke of Edinburgh a large number of forest animals and sporting trophies.

In the second division there is a considerable display of furniture, casks, tubs, &c. Among the curiosities are an arm chair made from a pile taken from one of the piers of the old bridge, Rochester, in 1822. The old bridge was in progress in 1360, and finished in 1392, so that the pile from which the chair was made had been nearly 500 years under water.

Returning to the geographical arrrangement, it will be well to begin with the British department.

The first collection to be seen by the visitor is that contributed by the War-office. Here are shown specimens of the various woods used in the Royal Arsenal, such as oak, teak, ash, mahogany, &c. There is also a case of the timber employed in making charcoal for gunpowder, and the charcoal made from it. Stocks for rifles in the rough blocks, and chiefly cut out of close-grained walnut, are displayed; and the Royal Small Arms Factory contributes lances in various stages of manufacture.

Captain Mackenzie, conservator for Epping Forest, shows a collection of numerous specimens of freaks of nature, in extraordinary self-grafting of branches, interlacing of roots, and peculiar contortions of trunks, also plans for lodges which have been erected in the forest for the accommodation of workmen. The far famed Burnham Beeches are represented in large photographs and specimens of their wood. The Commissioners of Woods and Forests exhibit a specially interesting collection of objects and information connected with Dean Forest and Highmeadow Woods, Gloucestershire; New Forest and Crown Woods, in Hampshire; and Windsor Parks and Woods. The extent of the forests under the management of the Commissioners are as follows:—Dean Forest and Highmeadow Woods, 19,500 acres; Windsor Forest, 10,000 acres; New Forest, 18,750 acres; Bere Woods, 1,434 acres; Alice Holt Wood, 1,887 acres; Woolmer Forest, 1,870 acres; Parkhurst, Isle of Wight, 1,152 acres; making a total of 54,593 acres. Oak is still regarded as the main crop, but the mixed plantations consist chiefly of ash, birch, beech, Spanish chestnut, elm, lime, horn-bean, larch, cluster pine, spruce, the Corsican pine, and the Himalayan deodar. From the Dean Forest are specimens showing comparison of growth between transplanted and non-transplanted oak trees, and a record of comparative growth kept since 1809. The injury to timber from the careless tearing of the branches, or from leaving dead branches attached to the trunk is exhibited in different tabled specimens, also sections show the inroads of blight and canker, of grubs, and of ants. From the New Forest are sections of oak and other timber of ages from 10 up to 200 years, showing the varying growth of timber under varying circumstances, and in different kinds of soil, also sections showing the progress of disease in timber, and the result of checking it by excising the diseased portion at an early age of the tree. From Windsor Forest was sent the root of an elm tree taken out of a drain by means of a tool for removing obstructions in drains, also a number of logs of wood showing the effects of cutting off branches close to, and at a distance away from, the main stem. Forest tools were sent from all of the forests.

The Scottish Arboricultural Society occupies, with its important exhibit, the northern division of the western transept, and a large portion of space in the nave. The exhibits here are arranged according to the classification alluded to at the commencement of this article. Under Practical Forestry are shown meteorological instruments, dendirometers, axes, and other tools, models of bridges, embankments, &c., specimens of fencing, gates, &c., and a large number of specimens of forest produce. Here is a silver fir railway sleeper which had been in use for seven years, and is still sound; the Baltic timber sleepers laid at the same time were worn out a year before. A large number of seeds and cones are exhibited. Under the head of Scientific Forestry are dried specimens of the forest flora, fossil plants, and photographs of rare and remarkable trees. The Duke of Buccleuch sent photographs of representative trees growing on the Eskdale Estate. Among these is "The Duke," 60 feet high, containing 232 cubic feet, and "four oaks" from one root, 56 feet high, and containing 317 cubic feet. A sycamore at Hagg-on Esk, a favourite tree of the late Duke's, is 90 feet high, containing 803 feet. There are also two spruce firs of 140 years of age, each 124 feet high. The Society also shows sections of timber exhibiting the various diseases to which different trees are liable, sections showing the effects of injudicious pruning, the injuries caused by squirrels, curious growths, some of which bear fanciful resemblances to human figures. The description of there exhibits occupies thirteen pages of the catalogue.

BAVARIAN BEER.

Consul Horstmann, of Nuremburg, says that breweries were in existence in Bavaria previous to the founding of the City of Munich, by Henry the Lion in 1158, but up to the 15th century, the principal drinks of the inhabitants were mead, a fermented mixture of water, honey, and various fragrant herbs, and Bavarian wines. One of the first breweries established in Bavaria was at Weihenstephan in the year 1146, by the Bishop of Freising. In 1370, there were but three breweries in Munich, which number in the course of two centuries had increased to fifty-three. In the 16th century wheat beer was introduced into Munich from Bohemia, and threatened in the beginning to supersede the brown beer; but the opinion soon began to be held that white beer was not wholesome, and, moreover, it was contended that the consumption of wheat for that purpose would soon drain the country of that cereal, and there would be none left for other purposes. Different measures were taken to restrict the brewing of white beer, all of which proved failures, and eventually the Duke of Bavaria took to himself the sole right of brewing it, and thus was established the royal white brewery which exists to the present day. In 1881, there were 5,482 breweries in Bavaria, or rather more than one to every thousand inhabitants. In Munich the smaller breweries have been gradually swallowed up by the larger establishments, and there are now twenty-nine breweries in the city, the largest of them using about 364,000 bushels of malt, and producing about 7,000,000 gallons of beer annually. Most of the beer produced in Bavaria is consumed in the country itself, only about seven per cent. being exported, the principal cities taking part in this export being Munich, Kulmbach, Nuremburg, and Erlangen. In the making of this beer two methods are in general use, the one by a process of infusion, the other by a process of decoction. The object of the mashing is not only to extract the sugar and the dextrin which is contained in the malt, but also to produce sugar and dextrin from the existing starch, with the help of the so-called diastase of the malt, and a temperature of 167° Fahrenheit. The process of infusion and of decoction differ from each other in the manner in which the temperature of the mash is raised to the proper degree for producing sugar. In the first-named process the mash is brought up to the proper temperature without any part of it reaching the boiling point. In the process of decoction, which is the one universally practised in Bavaria, the mash is brought up to the required temperature by putting a part of it in the kettle and heating it to the boiling point, and then conducting it back to the rest of the mash, so that the whole reaches a temperature of 125° Fahrenheit. A part is then put a second time in the kettle and boiled, and again returned to the rest of the mash, so that it reaches a temperature of 167° Fahrenheit. The proper temperature is generally reached by twice boiling a part of the mash, although in some few breweries it may be done in three successive boilings. This process takes more time, and requires greater attention, than the heating of the whole to a certain temperature, but better results are obtained by it. It produces a beer richer in dextrin, while by the method of infusion a beer is produced containing less dextrin but more alcohol. The Bavarian winter beer contains about 4 per cent., and the summer beer 4·5 per cent. of alcohol, while porter contains from 6 to 7 per cent., and ale 6 to 9 per cent. of acholol. The malt used for Bavarian beer is obtained partly from Bavaria itself and partly from Hungary, and the hops are mostly of Bavarian growth, these being universally acknowledged as the best Consul Horstmann says that Bavaria takes the lead of all nations in the consumption of beer, the average annual consumption being 260 quarts per head of population, compared with 125 in England, 165 in Belgium, and 45 in the United States, and he estimates that at Munich the annual consumption reaches the enormous figure of 470 quarts to each person, or about one quart and a third daily.

FIG ÇULTIVATION IN SICILY.

There are several varieties of the fig tree in Sicily, some yielding a large, others a small fruit, and this fruit varies in its degree of sweetness, also in colour from white to black. The fruit of some varieties ripens sooner than that of others. The trees grow equally well in poor and rich soil, and bear abundantly when planted on the mountain side and in the valleys. Consul Woodcock, of Catania, says that the favourite varieties of Sicilian figs are the *Sangiovannaro*, the *Sottuno*, the *Melinciano*, and the *Ottalo*. The *Ottalo* has smooth leaves, the peduncle of the flower and fruit is longer and the fruit is sweeter than that of the other varieties. The *Ottalo* fig is considered to be the best for drying. The fig is propagated from the suckers that spring up from the roots, cuttings from the tree being also used, and these are set in the months of February and March. In orchards the distance maintained between the trees is about twenty-six feet. The fig is long-lived, as it is constantly being renewed by shoots that spring up from the roots taking the place of the main trunk when it becomes old and decayed. The soil is worked in the spring, and also in the November following. The best varieties in Sicily are grafted, and also budded upon the stock of the wild fig, this operation being performed also upon healthy trees of the best varieties, and the time chosen for it in March, or when the trees are in blossom in June. Great care is exercised in the cultivation of the tree to remove all dead and diseased branches, and to avoid too much cutting and pruning. The fruit is dried in the following manner. It is gathered when partially ripe, that is when the fruit is more green than ripe, and immediately plunged into boiling water, and allowed to remain only a very few minutes. It is then placed in a spot sheltered from the sun, and the next morning, at sunrise, spread upon a platform in order that it may be flooded with sunlight, care being taken not to place it upon the ground on account of its dampness. While drying, shallow willow-work baskets are used for holding the fruit, and these are never placed upon the ground, but kept in an erect position. At sundown the fruit is covered to protect it from the night dews or unexpected showers of rain, and this operation is continued for several days until the fruit becomes thoroughly dry. When dry it is placed in layers in small boxes or baskets, these layers being arranged very neatly and artistically, the fruit being pressed down firmly by hand until the box or basket is full, when they are securely covered and kept in a dry place ready for shipment.

CORRECTION.—SUPERGA RAILWAY.—Page 1021, column 8, line 19, for "21 ft." read 21 *inches*; line 28, for "millimetres," read *metres*. Column 2, line 9, for "square metres," read *square millimetres;* line 10, for "square miles," read *square inches;* line 12, for "square miles," read *square inches.*

TOBACCO MONOPOLY IN SPAIN.

Tobacco is a monopoly of the Government in Spain, and its cultivation in the Peninsula is prohibited. Consul Reed, of Madrid, states that nearly, if not quite, all of the tobacco consumed in the Peninsula is imported from Cuba, Porto Rico, and the United States. It is brought in the leaf and manufactured at the Government factories, in which a vast number of persons are employed, chiefly women and girls. The largest factory is at Seville, and gives employment to about 2,000 people. According to the statistical returns of the Director-General of Monopolies, the amount of tobacco manufactured during the year 1883, amounted to about 18,182 tons, of which 3,008 were made into cigars, and 2,231 into cigarettes. The remainder was used for smoking and cigarette tobacco. Tobacco is divided into classes, and is furnished to the Government by contract for a certain time, generally one to three years, and large fortunes are frequently made by the contractors. In awarding these contracts the following is the system employed. Due notice is always given in the *Gaçeta de Madrid*, that a public auction will be held on a certain day to supply the Government with a certain amount of Cuban, Porto Rican, or American tobacco. On the day named tenders are deposited with the Commission consisting of the Director-General of Monopolies, who is president, two other persons, and one or two secretaries. For the tenders to be in due form the persons presenting them must be Spanish subjects paying Government and municipal taxes; whenever a foreigner, as is often the case, desires to tender, he must do so through a Spanish subject. The tender must be accompanied by a document, duly signed by the proper authorities, stating that the applicant has paid his taxes, together with a receipt from the *caja general de depositos* that he has deposited the necessary sum, ranging in amount from £7,000 to £30,000 (according to the quantity to be furnished), as a guarantee to the Government for the fulfilment of the contract. If the applicant obtains the contract, the amount remains on deposit, but if unsuccessful, it is returned next day, less 2 per cent., which is retained by the *caja general de depositos*, or in other words, the Government. The tenders are handed to the Commission a few minutes before the hour named for the auction, and there are usually from five to seven tenders for each contract. At the hour named the *subasta* (auction) commences, and the tenders, in the order in which they have been deposited, are handed one by one by the President of the Commission to the Government Notary, who opens and reads them aloud to the public. After all have been read, the President awards the contract to the lowest bidder, provided the tender is found to be in due form. Very explicit directions are always given in the *Gaçeta de Madrid* announcing the *subasta*, as to the manner in which tenders should be made out, and if a tender should vary in the slightest degree from these directions, there is always someone to protest, and it is rejected. The Government have established in all the cities and towns a species of wooden booths, called *estancos*, for the sale of tobacco, cigars, and cigarettes, and it is only at these places that they can be bought.

General Notes.

Iron and Steel Institute. — The autumn meeting of this institute will take place in the City of Chester, on September 23rd, and three following days. The following papers and subjects for discussion are announced:—"On the Geology of Cheshire," by Aubrey Strahan; "On Improvements in the Siemens Regenerative Gas Furnace," by Frederick Siemens; "On Recent Improvements in the Method of the Manufacture of Open-Hearth Steel," by James Riley; "On a New Form of Regenerative Furnace," by F. W. Dick; "On the Manufacture of Crucible Steel," by Henry Seebohm; "On the Recovery of By-products from Coal, more especially in connection with the Cooking and Iron Industries," by Watson Smith; "On the Most Recent Results obtained in Germany in Utilising the By-products from Otto and other Coke Ovens," by Dr. C. Otto; "On the North-Eastern Steel Company's Works at Middlesbrough, and their Products," by Arthur Cooper; "On the Spectroscopic Examination of the Vapours Evolved on Heating Iron, &c., at Atmospheric Pressure," by John Parry. Eaton Hall and Hawarden Castle will be visited, as well as a considerable number of works.

Nuremberg Metal Exhibition of 1885.—This international display of precious metals and alloys, organised by the Bavarian Industrial Museum, promises to be of remarkable interest. The Government has decided upon giving medals of gold and silver. Free entry will be granted to all works which are again exported, and a lottery will take place in which the prizes will consist of objects which have been exhibited. A guarantee fund of £5,000 has already been arranged, and the various German Consulates in other countries will assist in the work. It is stated in the *Metallarbeiter* that Indian metal work, as well as Persian and Kabyle specimens, will be exhibited. In America, Spain, and Portugal the idea has been warmly taken up, and the participation of Japan is considered certain. France, Italy, Belgium, and Austria have been applying for space in an encouraging manner. As to Germany itself, it would seem that the old metal-working towns, Hanau, Pforzheim, Stuttgart, Gmünd, &c., will be represented in a special manner. The historical department will be of great interest. The light will partially be obtained from above, the objects shown being thus exhibited under specially favourable circumstances.

CANTOR LECTURES.

THE BUILDING OF TOWN HOUSES. THEIR ARRANGEMENT, ASPECT, DESIGN, AND GENERAL PLANNING.

By Robert W. Edis, F.S.A.

[The right of reproducing these lectures is reserved.]

Lecture II.—Delivered Monday, Feb. 25, 1884.

Planning, Sanitation, Lighting, Heating, and Ventilation.

On the general planning of a house depends, to a great degree, the comfort and health of the occupiers thereof, beyond which the cost of keeping it in order may be considerably increased or decreased by the attention, or want of attention, to the numerous small details which make all the difference between a good and a bad plan.

If a great amount of passage space with stone flooring, to be daily subject to broom and holystone, abounds, you want a certain number of hours' work daily out of one servant to keep it clean; if the general fittings are so arranged that there are inviting places for dust and dirt to accumulate under, and for all manner of filth to lodge above, another servant's time is tolerably taken up for some hours in keeping them clean and sweet; if chimneys smoke and will not draw, there is not only waste of time in lighting the fires, and relighting them, perhaps, several times in a day, but a good deal of temper lost, with possible friction, between the master or mistress, and the maid; if ranges will not burn, or burn too much, and will not heat the water, and will persist in adding to the miseries of the house by emitting, and, owing to the want of proper arrangement of swing doors, and sufficient fresh air and ventilation, perfuming the whole house, at inconvenient hours, with stray whiffs of cooking; or, as is often the case, with whole gales of disagreeable smells of cooking meat or vegetables, the owner or occupier, who may come back, weary and worn, from a day of worry and hard work in his particular occupation, is inclined to flee the house, to go to his club, in fact, anywhere rather than submit to the filthy and sickening forerunner of his dinner which meets him on his crossing the threshhold of his house.

How many of us know the nausea and annoyance which these ante-prandial stenches bring upon us, which, unsubstantial as they are in reality, oft-times destroy all appetite for the real food of which these preliminary whiffs and gales are the unpleasant forerunners in so many of our town houses. Or, what is more annoying and unpleasant than to find that, directly the street door is opened, it is like putting the match to a series of small blasting holes in a mine, and, one after another, we hear door after door bang, bang, all over the house, and the rattle of small arms, in the shape of blinds, picture frames, and other articles hung on the walls, going off along the whole passage and staircase line, damaging the walls, and irritating our nerves, until the cause of offence is taken away by shutting the street door; or, perhaps, after nightfall, when we open the front door, we are met in the face with a great rush of foul and heated air arising from the gaslight in the hall, where no ventilation exists to modify or do away with this common evil.

The staircases are often causes of trouble and evil, especially to weak-chested and short-winded people; they are often so badly designed, and pushed into the narrowest possible spaces, that the riser of each step is perhaps seven inches high or more, and the flights are so steep and long, without rest or break, that in our journey upwards to the second floor, where our bed or dressing-room is provided, we are apt to feel very much like a man out of condition who has suddenly been called upon to clamber up a steep hill, without the benefit of the pure air which the out-of-door exercise generally brings; or perhaps some dull, foggy morning in winter, when the frost has been a little more severe than usual, and has therefore kept down the smoke and fog, we are met, in our half-awakening to the darkness and cold of the early morning, by the not very pleasant information that one of the water pipes has burst, and is flooding the house; and we, if our knowledge carries us so far, have to turn out of a warm and comfortable bed, and hastily robed in a dressing-gown, to find our way through a narrow trap-door, in which we may possibly stick for a few minutes, to grope our miserable way through the dusty and sooty roof to some inaccessible corner therein to the cistern, to turn up the ball-cock or shut off the water—if such a provision has been provided—by means of the stop-cock, and half-drenched, thoroughly cold and miserable, and probably as black as a sweep, to finish up with stepping between the ceiling joists, and breaking through the thin lath and plaster, to find ourselves suspended between "the devil and the deep blue sea"—in other words, the inside of our roof and the servants' attic, and all for want of a proper arrangement of the water cisterns, proper casing-in of pipes, and a proper gangway and access to both.

In all probability, during our compulsory travel through hitherto perhaps unknown regions, we shall have seriously damaged our nether limbs by tumbling over the naked bell wires, which the modern builder delights to carry inside the roof, generally without cover or support, and shall then find that some of our bells will not ring, or what is perhaps worse, and is not an exaggerated fact, that when we pull one of the levers or bell cords, we set going a whole band of jingling bells, which suggest to those below an idea that the house is on fire, or that everybody in the house has gone mad.

Occasionally perhaps, in the middle of the day, the cisterns run out, and there is no water anywhere, and the cook is scared to death for fear of being blown up by a bursting boiler, and every sink, closet, and lavatory is rendered not only useless but absolutely foul and unhealthy. Someone has to go for the turncock, who, of course, has just started on his rounds, and when he comes, someone has to give him a shilling for the pleasant information that it "can't be expected that a hundred gallon cistern is sufficient for the use of the house;" or "that the fittings are all wrong, or worn out, or not the right kind," and then—"the deluge"—for the plumber comes in, and a really pleasant chatty gentleman he generally is, but we find his society palls upon us after a time, and his bill for the various little jobs makes him absolutely loathsome. Or in summer time, our own or our neighbours' dustbin emits most unfragrant smells, which, coming up from the front area, necessitate all the front windows of the house being closed, and we are thus almost asphyxiated inside with unventilated rooms, or nauseated with the foul stench which finds its way all over the house, and when the dustman who hails "ahoy," from a distant part of a neighbouring street, like the approach to a strange ship at sea, is brought to an anchor opposite your house, you are forced to give him a fee or a drink before he will empty your dustbin, as he says it has got some refuse or other in it which the dust contractor is not bound to remove, and he will not do it without the usual blackmail. Or, perhaps, the housekeeper informs you, in the blandest way, that the scullery drain is stopped up, and "she is quite sure that the maid has done nothing at all to cause it;" and when you have it opened up—as the builder has not thought it necessary to put in any grease trap—you find the pipe furred and foul with rancid filth enough to brew a whole hospital-full of ailments.

Or, again, you are hospitably inclined, perhaps, and invite your friends to dinner, or the modern crush called an "at home," and your rooms soon become so hot and suffocating for want of proper ventilation that they are almost unbearable, and you and your guests get nausea and headache, or if the windows be open, worse still, cold and neuralgia.

I might go on for hours enlarging upon the ills which, I am quite sure, many of you who live in the ordinary unsanitary and unhealthy houses erected in the last fifty years, suffer from ills that are curable or to be considerably alleviated, by a little knowledge, and by the application of some little of that forethought and common sense which most of you use in your various daily avocations.

My object this evening is to attempt, first of all, to give you some few suggestions as to the proper planning of your houses, and to include therein some general simple rules for at least avoiding many of the manifold ills and disagreeables to which I have briefly alluded.

In my former lecture I urged the desirability, not to say the necessity, of some enforced system of supervision over the building of all new houses, whatever their class or size, as in so many cases many people are, more or less, obliged to live in certain districts, and, practically, have to take what they can get in the way of houses, and to take them, more or less, on trust, they themselves not being competent to know whether the house is really fitted for healthy habitation; and are naturally not inclined, even if the landlord will permit it, to have it pulled about and thoroughly examined, and then if they do not like what they find, to make it good after, for all this entails expense which they ought not to incur. They may, perhaps, think that the rooms are sufficient in number, and the arrangements convenient; they are told that the drainage is perfect, the water supply ample, that hot and cold water is laid on to the top of the house, and that there is gas in every room; but how is it possible for the mere outsider and non-professional man to know whether the cisterns are properly placed, the drains laid properly and ventilated, and the various pipes about the house so placed as to be readily laid bare for inspection; or whether the roof is sound, the timbering sufficient, and the walls built with materials that will not let through damp and rain; or whether the chimneys smoke, or the range is sufficient and suitable, and not too expensive in cost of fuel; and the hundred and one matters that make all the difference in the way of comfort and health between a well and badly built tenement.

It is not fair to ask the incoming tenant to pay for professional advice, unless it be that he knows what he is about to take, and is prepared to add to his yearly rental for the term for which he takes the house, by sinking a certain sum of money in making good the manifold defects, and, in fact, doing the landlord's work for, perhaps, his own present comfort, but for the ultimate advantage of the landlord, who, if the house be taken on lease, not only accepts, without thanks or return of any kind, all the improvements which have been made, but still further mulcts the unfortunate lessee by a heavy claim for dilapidations, and for generally doing up the house with paint and paper for the benefit of the next tenant, who, perhaps, continues the same expenditure, and thus, eventually, the bad and rotten structure has become, by the outlay of different tenants, a tolerably decent habitation.

All this sort of robbery—for it is nothing else—demands Government interference; the tenant should have the right to recover for all work done which can be shown to have been absolutely necessary for the healthy enjoyment of the house which he is compelled to take on trust; and if some law enforcing this could be passed, we should have less bad building and fewer unsanitary houses; when I say unsanitary, I mean not only from bad drainage, but from improper and unsound fitttngs, bad ventilation—usually none at all—and the generally scamping nature of the work.

I am glad to find that Sanitary Aid Committees are being formed in various parts of London, in connection with the Mansion House Council, for the purpose of bringing to the notice of the officers of health, in the various metropolitan vestries, all houses which contain in themselves nuisances, which are not only dangerous to the individual occupiers, but to the community at large, and of endeavouring to insist upon the proper carrying out of the Nuisance Removal Acts, Metropolis Loca Management, and the Artisans' and Labourers' Dwellings Acts, for the improvements of houses which are in a faulty condition.

They are publishing information as to what these Acts can enforce, and bringing them before the occupiers with a view of aiding them in forcing their landlords to comply with the various requirements of these Acts, so that they, the tenants, may, if they wish, insist upon certain sanitary rules being complied with; but all the Acts are fenced about with difficulties which, in ordinary cases, are very difficult to overcome, and when, as is often the case, the vestryman is a large owner of small property, it is somewhat difficult to make him act as an impartial judge on matters which must manifestly affect his own pocket.

A Bill has lately, I believe, been introduced by Mr. Monckton, M.P., into the House of Commons, and which I hope will become law, to provide for a much better and more systematic supervision of all new buildings, whereby a tolerably sound construction may be ensured; for instance, that the foundations be dry, and a proper damp course inserted, that the drains shall be laid of adequate size, and to a proper fall, properly ventilated and cut off from the main sewer, and that there shall be no direct communication between the house and the drains; that all closets and slop sinks, &c., shall be in proper situations, and properly ventilated, and not opening direct into the house from the top of the principal staircase, as is often the case in many houses built fifty years ago; and, in fact, to carry out some general scheme of sanitary arrangement such as I have shadowed forth in my former lecture. But I fear much that the question of the appointment of the inspectors under the Act (if it becomes law)—which is to be vested in the various local vestries or boards, subject to confirmation by the Local Government Board—will be a rock on which there will be much foundering of good intentions.

Inspectors qualified for all this sort of work must be men of position and standing, with ample general knowledge of all the details which make up the sanitary wellbeing and construction of the house, able to hold their own against all official Bumbledom and bullying; men *sans peur* and *sans réprôche*, anxious to carry out their duties conscientiously, and not to fence them about by narrow-mindedness or faintheartedness; able to look at their work from a broad, not a narrow and dogmatic point of view, by which their authority may be either rendered widely useful and beneficial, or otherwise merely irritating and senseless by petty spite and jealousies; and competent to seek out real abuses and to condemn them, and to insist upon their removal, whether the property belongs to their masters or to mere outsiders.

Such men can only be obtained at good salaries, and must not be men who are paid a few pounds a week, as is the case with the usual so-called sanitary inspectors. As having had the honour of being once, for a brief period, a member of a vestry which has earned for itself a somewhat unenviable notoriety in the metropolis, I unhesitatingly assert that I believe, with proper businesslike control and management, ample funds might be saved from the present rates sufficient to pay a staff of such competent inspectors as I have named; but unless this be done, it can hardly be expected that the community at large—which is already somewhat too heavily taxed, and on which such preposterously heavy and grossly unfair rates as the present School Board rates are continually increasing—will consent to any additional burden being thrown upon them; and if the expense is to be thrown, as is proposed, upon the owners of property, it can hardly be expected that they (the owners) will be prepared to accept a Bill—which will manifestly reduce their annual receipts from the property considerably—with any amount of satisfaction or assistance.

Good planning means not merely the arrangement of a certain number of rooms on a certain number of floors, but careful and close attention to the general domestic requirements and arrangements of the ordinary householder, and to all smaller details which make up the comfort and convenience of the house. It means that every foot of space shall properly be laid out, that there shall be no dark corners, and no inaccessible places in which cisterns or lumber are stored, that every room, closet, and staircase, shall have ample light and ventilation, and that staircases shall be conveniently arranged, easy of going, with broad landings, and of sufficient width to allow of passing easily.

Each room has to be considered, and its relative proportion and position in the plan. The dining-room, or general eating-room of a house, should be so arranged that, although above the kitchen level, it is not at any unreasonable distance, whereby an extra amount of carriage of dishes and service is required, and, as a necessary sequence, smell of food all over the house, and likelihood of the hot meats becoming warm or cold, of risk of accident and breakage in carriage, and discomfort in the meeting of servants passing and repassing.

If it be possible in an ordinary town house of the first or second class, the dining-room should be placed at the back, as it is rarely used except at meal times, and good outlook is not necessary; besides which, in summer-time, when it is sometimes pleasant to have windows open, if the room face a much used thoroughfare, there is all the unpleasantness of noise of traffic, and constant inrush of dust; whereas, if placed at the back, provided always the light area into which the room looks be of sufficient size, and lined with glazed bricks, with some slight variation in coloured lines or panels, with window boxes, filled with sweet smelling flowers or shrubs, there is freedom from noise and dust, and the comfort and quiet of the room is considerably enhanced.

Next the dining-room, should, if possible, in every house, be arranged a small service-room, with a light service lift from the basement, by which a considerable saving of labour will be gained, better service, and if, in this room, a small hot plate be fitted up, heated by gas, the plates can be brought in hot instead of half cold, as is so frequently the case. This lift should be taken down in the basement to a small china closet or pantry, close to the kitchen, but quite separate, so that it may not be made a funnel or shaft up which the smell of the kitchen can ascend. If, however, the kitchen be really properly ventilated, with plenty of fresh air inlets and extract shaft over the fire-place—that is, immediately over the cooking portion of the kitchen—there should be no risk of smell, even if a serving hatch is made direct into the kitchen; but it is better, if possible, to separate the two by a small lobby. If this special service room cannot be provided, a small lift may easily be arranged in the buffet, or at one end of the dining-room, and this need be only of the lightest description, so as to be easily workable by a maid servant. To the lift, a speaking tube or electric bell, or both, should be attached, and these will not only be found convenient at meal times, but in sudden emergencies, when unbidden and unexpected guests arrive and stay to dinner or luncheon, will give an easy means of communication between the mistress and the cook. It is well to get a service room on the ground floor, next to the dining-room if possible, as this can be fitted up with sink and cupboards, all useful for washing up and storing away glass and china, and thus avoiding the risk of carrying up and down stairs. Naturally, the servant, man or woman, is anxious to save him or herself as many journeys from the basement as possible, and thus frequently he or she is inclined to overcrowd the trays, to the imminent risk of everything upon them.

As a rule, a dining-room must have a central light over the table, but this should not be of such a size as to impede the view from either end, or to cause an amount of heat on the heads of those who are sitting round it. A small light, with a shade made to throw its rays direct upon the table, with—if gas be used—side brackets next the sideboard, and on either side of the mantelpiece, so as to distribute the light all over the room, and light up the pictures or whatever else is upon the walls, is infinitely better than a great blaze over the table, neither pleasant or comfortable to those who have to face its glare, and oft-times unpleasant heat. Nothing is so unpleasant in a dining-room as the heat, which too often in our London rooms, when we have a dinner party, makes the room stuffy, close, and most unbearable, taking away from the enjoyment of the dinner itself, and helping to faintness and headaches, and to spoil the best appointed and best cooked dinner in the world.

To avoid all this, it is essential that pure fresh air shall be introduced and distributed over the room, to take the place of that which necessarily becomes foul and tainted by fumes of cooked meats, gas, and the straining of the cubical contents of air supply by a larger amount than usual of people using the room.

If there be no means of providing fresh air, and no means of extracting foul air, it follows that in a very short time the good air originally contained in the room will become tainted, and after a time heated and foul, as the only ordinary means of obviating these evils are by opening the doors or windows for fresh air inlet, and of trusting to the fireplace opening for extracting a certain amount of foul air which, remember, is always drawn down in waves over your heads, and is more or less breathed, in its passage to the fire pump, by every one in the room.

Stand on a chair in an ordinary London room, about an hour after the room has been lit up, and the dinner commenced, and you will then obtain for youselves some practical knowledge of the suffocating and foul nature of the upper stratum of air in the room, and will not wonder that faintness, nausea, and headache, are often necessary portions of a dinner party in an improperly ventilated room.

All this can be cured by providing in, say, each corner of the room a tube, adjusted in proportion to the size and height of the room, for the access of fresh air through gratings from the outside wall; and the current and amount of air injected, so to speak, into the room, can be easily adjusted by an ordinary butterfly valve, and all dust and soot, and other impurities kept back by a piece of fine silk or wet sponge. These tubes are often put in much too small, and the size of the outside grating is not considered; in all cases the size of the tube should be proportioned to the cubical contents of the rooms, and the external grating should be, practically, twice the area of that of the tube, as the ironwork of the grating, as a rule, diminishes its usefulness in ventilating area by about half.

If it be not possible to arrange for an extract shaft in the ceiling, a large-sized ventilator may be put in the flue over the fireplace, provided always it be fitted with talc flaps to prevent all back draught; but even the introduction of fresh air alone by some such means as those I have named will make a difference in a few minutes of many degrees in the temperature of the room.

In ordinary houses nothing has struck me as so wanting in thought as the general arrangement of the staircase. As a rule you enter from the front door into a narrow passageway, with perhaps an internal screen, with folding-doors which are rarely shut, and immediately opposite is the main staircase of the house, so that anyone, on entering, not only commands the absolute thoroughfare of the house, but sees everybody who goes up or comes down, by which the privacy of the house is materially interfered with, and the whole house is made subject to sudden draughts of cold air, which are driven up the well hole, as it is called, by the opening of the street door.

There is no reason why the ordinary narrow entrance should not be increased two or three feet, so as to make a moderate sized hall, in which you may have a fireplace, which will help to supply warm fresh air all over the house, and by a little care in planning, the first flight of stairs at least may be screened from view.

There are now very many good ventilating grates which can be so arranged as to provide, with communication from the outside, warmed fresh air, and if one of these, of sufficient size, be placed in the hall, it will not only help to ventiltae it, and to lessen the evils of heated and foul air generated by the gaslight, but can be made the means of introducing warmed fresh air all over the house.

The staircase itself, whether it be of wood or stone, should never rise more than 6½ inches to each step, and, if possible, a landing or resting place should be arranged every twelve or fifteen steps. In ordinary London houses the half-landing is sufficient, but all winders are fatal to a good staircase.

In the hall it is essential to have proper ventilation; if you shut the screen or inner hall doors, as a rule, the air becomes ventilated and heated by the gas lights, and the staircase and passages are fed with foul instead of fresh air. It is essential, therefore, that a proper supply of fresh air should be brought in independent of the door, and this can be done by means of a proper ventilating grate, or if there is no fireplace, by a simple ventilating letter box, or by some such arrangement as that which I have suggested for the dining-room; in fact, in every room throughout the house fresh air should be brought in, either warmed over hot water coils, or direct through tubes communicating with the outside, or through some of the best of the now numerous ventilating grates, which are made so as to feed the house and to mix with and counteract the evils caused by overcrowding, or by the products of combustion of gas or oil lamps.

The library may be arranged as a comfortable and quiet apartment at the back, while the front space may be devoted to the morning or general reception-room, in which all the cheerfulness which the outlook into a London street can be obtained; but do not sacrifice the entrance and hall entirely to these rooms. Give an extra foot or two to the passage-way of the house, and you will not only make it more imposing and important, but will add materially to its comfort and convenience when you receive guests, and to its healthiness, by providing a larger shaft for air circulation.

The basements of London houses are generally so badly arranged and ventilated that they add materially to the stuffiness of the houses; for, as a matter of course, all foul air is apt to fly upwards, and if the basement be foul, heated, and unhealthy, it forms the practical reservoir from which the whole house derives a large amount of its general temperature and tone, and too much care cannot, therefore, be taken in its proper sanitary arrangement. Above all, in new houses it is important that the whole surface of the ground shall be covered with concrete, and that proper damp courses shall be inserted in the walls to keep down all damp, with air bricks for ventilation under all wood floors. The basements should be, in every sense, kept dry and sweet, and all passage floors made absolutely damp proof, and the latter can best be done by putting down Portland cement concrete six or eight inches thick, finished off to a fair surface so as to form an even floor, and not, as is so often done, finished with a thin layer or covering of finer cement over the concrete bed, which by-and-bye is sure to peel off and leave a rugged and uneven floor.

The scullery should, as a rule, form part of the kitchen, where the kitchen is not used for servants' meals and sitting-room, and not be shut off, or, if so, by a low glass screen. It is merely a washing-up place, and should be under the immediate supervision of the cook, and not, as is so often the case, a small, dark, unpleasant, and ill-ventilated hole, in which unpleasant smells are supposed to be allowed. It should be as fresh and as sweet as any other portion of the basement, and although used for the washing-up and general dirty work of a kitchen, it should not be allowed to remain dirty, or to be a place in which dirty pots, unwashed and greasy plates, and vegetable refuse are left for hours to breed foulness and unhealthiness everywhere.

Line the whole of the scullery walls, and, as far as possible, those of the kitchen also, with glazed tiles, so that there be no absorption and retention of the smells which must necessarily accrue with the ordinary work of this portion of the house; bring in fresh air, provide means for extraction of foul, but do not make a pestilential corner in which all the impurities of the house are to be confined, the smell of which may find its way over the whole house.

I cannot too strongly advocate the finishing of all the walls in a London basement, so far as the working portion of it, together with the passages, are concerned, with glazed tiles; they are cleanly, absolutely nonabsorbent, reflect and give light, are easily washed, and tend to make the house sweet and healthy. The pantries and larders should be so arranged that they have continued ingress of fresh air, and should in all cases be lined with glazed tiles or bricks, so that the evils arising from the contents should not be allowed to be absorbed in the distempered walls, and to render them stuffy and unhealthy.

They can easily be made fresh by bringing in outside air, by means of external gratings and tubes, and everything should be done to provide a constant draught and sweeping out of the foul air which is naturally engendered by hanging game and uncooked meat. The shelves should be of slate, or, better still, of polished marble, so as to be absolutely non-absorbent and easily cleaned.

As in all town houses where space is limited, a large portion of the back offices derive their light and air from the small enclosed areas at the back, it is of the utmost importance that these areas should be lined with glazed bricks, to keep them as light and as sweet as possible, and as the air at the bottom is likely to become stagnant and vitiated, a direct current should be ensured up all these small light areas, by means of a large induct shaft built under the basement floor from the front area, so as to provide for constant circulation and change of air; this can be done at a very trifling cost, as the shaft may be formed of, say, glazed drain pipes 18 inches diameter, covered at each end with large open gratings made to lift up, so that the shaft may occasionally be cleared out.

In every basement a comfortable room for servants should be provided; some small sitting-room, fitted up with book shelves and cupboards, and if possible facing the street, so that the workers of the house may have some sort of spare room in which they may be at rest from their ordinary duties; for if you want good servants you must treat them as ordinary beings like yourselves; and it is hardly fair to leave them for all hours in the heated and not always pleasant atmosphere of the working rooms.

I cannot too strongly insist upon the necessity of making those about us as comfortable as possible; for I am quite sure that if we provide comfort and health for them, they will be much more capable of doing their daily work fairly, and acting well by us. Remember always that a large proportion of their lives is spent absolutely underground, and that it is essential that they should have at least one room which shall be cheerful, well ventilated, and as pleasant as we can make it. Put yourselves in their places, and do as you would be done by, and, so far as my experience teaches me, I am morally certain that the master or mistress who treats his servants as he would treat his equals, by providing well-lighted apartments for them to live and sleep in, will be more certain of keeping good servants, and of obtaining good work from them; if they are to be mewed up in ill-ventilated, uncomfortable, and unhealthy chambers for the greater part of their daily lives, you can hardly expect their work to be properly done; the atmosphere in which they live will enervate them, and bring on lassitude, and ennui, which will absolutely make them comparatively useless.

The kitchen department should, as far as is consistent with proper and quick service, be shut off from the staircase of the basement, as this naturally acts as a funnel up which all smells ascend, so that when the door at the top, which opens into the hall, is open, they escape and permeate the whole house; a swing door can generally be arranged at the bottom of these stairs, closed with one of those patent American valve springs which close the door at once without allowing it to bang.

In every house, if possible, a small coal and luggage lift should be provided; in a new house, where a back staircase is provided, it may run up in the well hole; and in any old house it may often be arranged outside the back wall, with openings on to the various staircase landings.

If attention be paid to these smaller details in house planning, I believe that in many cases the cost of a servant may be saved, for every one knows the daily labour in winter time of carrying up heavy scuttles of coals and wood, and the great addition to the work of the house by having constant journeys from the basement to the second and third floors.

The wine cellars may well be arranged in the centre of the house, as these should be kept always to a certain equable temperature, if good wine is not to be spoilt; but under all circumstances a certain amount of ventilation should be provided.

Too much care cannot possibly be taken in providing all the necessary conveniences in the way of store closets, conveniently arranged near to the kitchen, so as to reduce to a minimum the service and labour expenditure in the house; and in every case proper ventilation is easily obtainable by a little forethought on the part of the architect or builder, so that each closet and cupboard may be kept sweet and airy; there should be no dark corners in which dust and filth may be allowed to accumulate, but ample light and ventilation everywhere. It is so easy to provide for a large fresh air drain or channel from back to front, such as I have named, of every new house, out of which separate ducts may be taken to every cupboard or closet; and this main air shaft or duct should be continued into the back area, or lighting space for the back rooms, so that a constant draught shall be caused, and the air not allowed for a moment to stagnate.

The back areas are often of necessity made small; and if unprovided by some arrangement such as I have described, by which a constant current and change of air is enforced, the lower portion becomes absolutely foul and unwholesome, and any air drawn from it for ventilation is practically worse than useles.

In Professor Kerr's book on the planning of country houses, he lays great stress on comfort as an essential element in every well-planned house. Now this means good constructive care in the arrangement of the different portions of the house; all proper and requisite conveniences, light, warmth, and good ventilation everywhere; freedom from damp and smells, no smoky chimneys, and no badly-constructed floors, through which noise from above or below may be readily heard. If these essentials are not properly looked after, the finest design, the most useful decoration, the most graceful art, all go for nothing, for common-sense people are so apt to appreciate the mere material comfort and convenience of the house much more than the art work in the external elevation, or in the internal decoration of their rooms.

The basement of a house should be made perfectly impervious to damp, for if the lower storey be damp and unhealthy, it follows that the whole house is made more or less uninhabitable. If the lower floor be made perfectly damp-proof, and the walls be lined with glazed tiles or some other impervious material, the floors made dry, and thorough draught be provided from back to front, the healthiness of the whole house will be considerably increased.

I do not propose to enter upon the question of drains or sewage ventilation, as this subject has been treated by many more able lecturers than myself in these rooms, who have made it their special study, and I would only propose very briefly to refer to it. I can only insist upon every closet being thoroughly ventilated, upon all sink wastes being cut off from the main sewer, and upon all drains which must perforce be carried through the house being laid and bedded in concrete, with manholes at each end, to sweep them clean from end to end if necessary, for proper traps cutting off all drains directly from the main sewer. That all sink wastes empty clear over proper traps, and to avoid everywhere any connection with the main drains, whereby sewer gas can in any way be brought into the house.

All closets and bath-rooms should, if possible, be lined with tiles or some equally non-absorbent material, for unless this is done, they soon become stuffy and unpleasant.

To show the present unsanitary condition of many London houses, I may be allowed for a moment to draw attention to the report of the London Sanitary Association, as reported in the *Architect* of this week. The society has examined in the past twelve months over 400 houses. In nine of these the drains were found entirely stopped up, without any connection with the sewers; in 79, or 20 per cent., the soil pipes were found to be leaky, allowing sewer gas, and in some instances liquid sewage, to escape into the houses; in 93, or 23 per cent., the overflow pipes from the cisterns led direct into the drains and soil pipes, allowing sewer gas to percolate everywhere into the house; and if we may judge of the general run of houses by these few examples, we must have but small belief in the care or common sense of the ordinary householder.

This shows, practically, how little regard we have for the healthy and sanitary condition of our homes, and a want of common sense which is not only wicked to ourselves and our own immediate belongings, but to the community. As I said of the small matters which in my opinion marked the taste of the people, so I say that this want of common sense and individual care in little things which pertain to the general well-being of the house, marks the want of sense of the people in matters which make up the sanitary or unsanitary state of their dwellings.

The drawing-rooms of the house should naturally be made as cheerful as possible, and doors arranged so as to allow for the proper circulation of your guests when the rooms are crowded.

The arrangement of windows and fire-places should be carefully studied, so as to allow of sufficient wall space for furniture, and in these rooms bay and recessed windows and cozy nooks will help to make them more liveable and comfortable, whether for the ordinary occupants, or on such occasions when you receive your friends.

In my next lecture I shall have something more to say about the fitting up of these rooms, as so much depends upon the manner in which this is done; whether they be made cheery and pleasant, or cold and formal.

As a rule, I think two fire-places are a mistake, unless the rooms be absolutely divided by doors or portières, as when only one fire is alight, there is a tendency for it to act as a pump, and to draw down smoke through the other.

If the room be very long, a small coil of pipes, taken off the hot-water service, may generally be arranged under the back window, over which fresh air may enter for ventilation.

I need not again refer to this part of my subject, as what I have said in a former part of this lecture on ventilation will apply to every room in the house, for whether it be a living or bedroom, to my mind it is essential that fresh air shall be brought into it quite independent of opening doors or windows.

It is no part of the intention of these lectures to advertise the wares of any particular inventor, but I have been much struck by the manifest advantages of the "Griffin grate," which seems to me to solve, to a great extent, the difficulties of heating, ventilating, and smoke consumption at the same time; but of course this only applies to the months in which fires are necessary, and must not do away with other modes of bringing in fresh air when fires are not wanted. The grate I have named seems to provide for a continuous circulation and renewal of warmed fresh air, not, as is so often the case, polluted by contact with hot iron; and it is said to be economical in consumption of fuel, and to consume its own smoke, as far as practicable, without mechanical means. To my mind it has one disadvantage; its general ugliness of design, but this is a fault which its inventor can do away with by getting any good designer to work out a decent-looking front suitable to the mechanical arrangements of the grate; otherwise its advantages are manifest, for it not only provides for ingress of fresh air, but withdraws a large amount of foul air from the room, for the purpose of keeping the fire in a high state of combustion.

I cannot, of course, pretend in a short lecture of this kind to give any elaborate idea of the planning of every room. Street houses are more or less, by the limited nature of the ground on which they stand, bound to be very similar in plan; but they can all be materially improved by a careful study of the wants and requirements of the ordinary householder, and by a proper regard and attention to all the smaller conveniences which practically render the house comfortable or the reverse.

In every house, on every floor, means should be provided of through ventilation from back to front, so as to enable them practically to be swept clean at some time in the day, by a current of air from back to front.

As a general rule, London bedrooms are often very badly arranged; either the wall space is planned that the bed must be placed immediately opposite the light, or in a thorough draught between the door and fire-place. I am inclined to think that the modern system of arrangement in French bedrooms might with advantage be more frequently carried out in town houses, and that the rooms might be made suitable for the double purpose of private sitting as well as bedrooms. In a house in which there are several grown-up sons and daughters, it will be evident that some such arrangement will commend itself, so that each may have a private working-room for writing or studying, apart from the general living-rooms of the house. The bedroom may often, therefore, be divided up so as to form at one end—that farthest from the window—recesses for bed and washing-closet, which can be screened off in the daytime by a curtain, and the rest of the room fitted up as a sitting-room wherein the occupant may receive his or her own more intimate friends if need be.

The dressing-rooms are often made much too small. They should be of sufficient size to hold a bed if requisite, so that it may be used on occasions when, let us say, the master of the house comes home late, and does not want to disturb the wife of his bosom in the small hours of the morning; or when sickness is in the house, the room can be used for a nurse; or if the master of the house be a professional man, afflicted occasionally with sleeplessness, he would often like to take up his work instead of tossing about for hours, or lying restless and tortured with all the troubles which seemingly come in upon him on such occasions, like bad dreams in the quiet hours of the night, and become more vivid and intense as the wakefulness increases; whereas if he could take up some of that professional or other work on which his thoughts are conjuring up all kinds of troubles and difficulties, the reality would soon drive away the nightmare, and after a time sound and refreshing sleep might be induced, instead of the oft-times unrefreshing and unsatisfactory rest which comes after hours of utter wakefulness, and utter weariness of the brain and nerve.

I am quite sure that we might, with advantage, study the arrangements of our neighbours across the Channel, and provide bed recesses and washing closets self-contained within the rooms, but so arranged as to be capable of being shut off in the daytime, and leaving the room cheery and pleasant for working purposes; for in these days, when the lady part of the community as well as the men take up a certain amount of the work of the world, irrespective of the daily duties in the house, the comfortable privacy of a separate room would often be acceptable and pleasant.

The nurseries of a house should be cheerful, well lighted, and well ventilated, and made opening into each other, so that at night time the door may be left open, and the air space made as large as possible. A small pantry or scullery should be fitted up on the same floor, with sink and ample closets or cupboards for crockery and toys, and, if possible, a water-closet and bath-room close adjoining.

Of the servants' rooms, which are as a rule arranged on the top floor, I have already spoken; I can only add that they should be made as healthy and convenient as any other rooms in the house, well lighted, and being in part in the roof, care should be taken in all new houses to protect them from undue heat and cold by means of boarding and slates, by over laying the former with battens, on which the slates are hung, so that, as far as practicable, the rooms may not be rendered hot and close in summer, or icy cold in winter.

All these precautions can easily be taken in the building of a new house without any great additional cost, and will amply repay the extra outlay by the increased comfort and healthiness of the house.

Somewhere on the top floor a box-room should be provided, lighted from the roof, and this should be boarded all round, so as to prevent the damage which is often caused in plastered rooms by the boxes being placed roughly against the walls.

A cistern room with top light is also essential in every well-found house, boarded in to keep it as clean and free from dust and filth, which would be sure to foul the water; top-lighted, so as to enable the cisterns to be examined and frequently cleaned out, and out of this room access might be made to the outside of the roofs, as, with the occasional snow-storms which we have in London, it is necessary that a proper means of getting out to the roofs so as to cleanse them from snow, which, if left to melt, in all probability would cause the rain-water heads to be choked with half-thawed snow, and the gutters to be filled to such an extent as to cause the top water to overflow, and spoil the ceilings of the house.

I should like to see tiles used more frequently in London houses, where they are designed with high-pitched roofs and gables, so as to give colour to the usual sombreness and dulness of London streets. They are not only more cheerful in colour, but render the house much warmer than slates. As far as practicable, all water pipes, hot and cold, should be run up together, properly labelled and easily to be got at, in a chase or recess which should be cased over and screwed up, so as easily to be got at. The hot-water pipes, if properly felted in, would contain a sufficient amount of heat, long after the kitchen fire is out, to keep the space, even if next to an outside wall, well above freezing point.

The bell wires should all be laid in zinc tubing, the gas pipes always iron, and not what is called composition, and in no case should any pipe of any kind be rendered inaccessible by being buried in some remote corner, or in the plaster work of the rooms. The ordinary plumber and gasfitter takes no heed of how his pipes go, and what happens to them after he has fixed them in their places; his anxiety seems to be to carry them by the shortest possible way to the points at which they are to be used, and unless carefully looked after, you may be tolerably certain that they will be so hidden away that, in case of accident, you will have to pull up half the floors of your house, or knock about a good many of your walls, to discover any leakage, especially if it be in a gas pipe.

Fire risk rarely enters the head of any builder, and he is content to leave the upper floors to be cut off by the burning of the wooden attic stairs, and allow the occupants to be slowly grilled or suffocated, that is, so far as any means of escape shall have been provided by him. In all high street houses ready access should be made at various points in the attic storey to the roof, and iron ladders fixed against the party walls, so as to enable the occupants to get readily away. This has its objections, of course, as enabling thieves to pass from an empty house to any of those in the same block; but good trapdoors, well bolted and lined with iron, would practically keep them out, or at least they would make noise enough in their attempt to open them to make themselves heard when the house was occupied by the family, and in their absence, I take it that the valuables of the house would be put away in safety; and these light-fingered gentry are not, as a rule, disposed to run any large amount of risk in making raid for the purpose of carting away wardrobes, bedsteads, and other bulky furniture.

Speaking tubes should be put up in every house, or at all events one communicating on every floor, for it is quite easy to establish a simple code of signals by which one whistle calls the downstairs servants, and two for those on the nursery floors. In this manner the constant running up and downstairs to answer bells, and then to bring what is wanted perhaps up many flights of stairs, is avoided.

There are innumerable other little things which tend to increase the comfort and convenience of the house, but which it is impossible to even refer to in the time at my disposal. Suffice it, that in building a house, not only is it necessary to study the planning and design externally and internally, but a good architect or builder will take care to fit it up with all the improvements which modern skill and ingenuity have given to his hand; and if this be done, not only will the comfort, convenience, cleanliness, and healthiness of the house be materially enhanced, but the value will be so considerably raised as to render it a matter of interest to the owner to see all these smaller details properly attended to.

But, after all, every man's house is his castle, and all these views of mine as to art, science, and sanitation may be worthless; the glitter and shine of the world to so many has more charms than the reality. In the pomp and show of their surroundings many men pride themselves; their dinners are splendid and luxurious, their reception-rooms laden with the rich things of the earth, and the show and the glitter express the affectation and the imitation of others dwelling in the midst or on the confines of higher ranges of society, and in all else there is little care or thought.

As Emerson says truly, in one of his essays, "Take off all the roofs from street to street, and we shall seldom find the temple of any higher God than prudence. The progress of domestic living has been in cleanliness, in ventilation, in health, in decorum, in countless means and acts of comfort, in the concentration of all the utilities of every clime in each house. . . . The houses of the rich are confectioners' shops, where we get sweetmeats and wine; the houses of the poor are imitations of these to the extent of their ability." Avoid all such imitations; let our houses be fitted for everyday wants, for everyday requirements; let them above all be clean, be comfortable, be healthy; let there be no unfound skeletons, no tangles that are not unravelled; open up the doors, let light and air in upon the skeletons, search them out; make the houses you live in pure from end to end, and depend upon it you will have less disease of mind or body, less worry, less enervation, unless you agree with the Scriptural statement that "Ahithophel set his house in order and hanged himself." One would have expected him to have hanged himself because his house was not set in order.

Remember always that the healthiness, the comfort, and the pleasant and artistic arrangement of your houses, means the healthiness, the teaching, and the bodily and mental health of your children; the seeds of illness may be sown broadcast in your children, and the life may fail when you should be garnering the fruit.

I pray you do not treat my views as Utopian and absurd, and be not content with Hamlet's advice, so far as the ordering of your houses is concerned, to—

> "Rather bear the ills we have
> Than fly to others that we know not of."

Let me close this portion of my lectures by a quotation from Dr. Richardson's eloquent opening address at the Brighton Health Congress, in 1881, on the seed-time of health.

"By a few rules, in short, which all prudent and wise people may carry out in their own houses, the accidental perils of the seed-time may be kept from the homestead as easily as from the prison house. Let every man and wife be their own sanitarians, and make their house a centre of sanitation. Let the sun keep out the damp; separate the house from the earth beneath; connect the house with the air above; once, nay twice, a year hold the Jewish passover, and allow no leaven of disease to remain in any corner or crevice; let the house cleanse itself of all impurities as they are produced; and all the good that science can render you is at your absolute command."

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON HOUSE DRAINS AND DRAINAGE APPLIANCES. BY W. K. BURTON.

(*Continued from page* 1016.)

The Birmingham Sanitary Association, 28, Upper-priory, Birmingham, show—amongst many other appliances—"Potts' Patent Edinburgh Air-Chambered Sewer Trap." This is an arrangement to take the place of the manhole bottom with channel pipe and trap, which was described at the beginning of this article. The chief peculiarity of the appliance consists in a transverse partition dividing the chamber into two equal portions. The object of this partition is to prevent any sewer air which may pass the disconnecting trap from being drawn through the house drains by the air current which, as has been explained, passes along them. The sewer-gas escapes into the open air at one side of the division, whilst fresh air for the ventilation of the drains is drawn in at the other.

Messrs. Banner Brothers and Co., of 11, Billiter-square, London, E.C., have a large and interesting exhibit. In the "Banner system" it is usual to ventilate the drain by an inlet and outlet, as already described. The soil pipe is, however, trapped at the foot by one of Banner's patent ventilating traps, which, besides keeping back any drain gas, has provision for an inlet of fresh air, a constant current being (it is claimed) ensured by the use of a patent ventilating cowl applied to the top of the soil pipe ventilator. No traps are fixed under the closets.

Amongst the numerous appliances exhibited by Messrs. Banner Brothers, perhaps the most ingenious is their patent water-closet. I have heard this apparatus described as "a beautified pan closet," and in general appearance it has something of the aspect of this most objectionable of closets, but in reality it has none of the drawbacks possessed by the old "container" apparatus. Every part is open for inspection, and all parts are self-cleansing.

The London Sanitary Protection Association, of 1, Adam-street, Adelphi, have exhibits of "Defective Plumbing removed from London Houses," by direction of their engineers.

There are to be seen pipes of various sizes, which have served for closets, urinals, &c., and which are some of them completely stopped, others so nearly so that there is a water way of perhaps only a quarter the diameter of the pipe. There is one sample of a ventilating pipe completely choked with a bird's nest, and there are several old D-traps, more or less eaten away by sewer-gas, in one case half the trap being entirely gone. Perhaps the most interesting sample of these horrors is one which shows that in spite of all that is being said and done by sanitary reformers there are still some plumbers who cannot or will not get themselves out of the old grooves of work. This is a closet D-trap, with four or five pipes from sink, cistern, drip-tray, &c., branching into the sides of it, one entering considerably above the water line. This arrangement had been fixed in a house only a few months before the time at which the Health Exhibition opened.

THE NATIONAL "FOOD COLLECTION." BY W. STEPHEN MITCHELL.

In the southern gallery of the Exhibition, a prominent and central position is assigned to a part of the "Food Collection" of the Science and Art Department, the nucleus of which, when first formed in 1857, was located in the South Kensington Museum, and in its more developed form was removed, in 1874, to the Bethnal-green Museum.

The object of the collection, as stated in the first edition of the handbook, is "to represent the chemical composition of the various substances used as food, and, secondly, to illustrate the natural sources from which the various kinds of food have been obtained."

Since the removal to Bethnal-green, it is only the first part of the scheme, the "representation of the chemical composition of foods," which has been maintained, though, situated as the collection now is in the Exhibition, it has surroundings of a character somewhat similar to those which originally formed the second portion.

The plan adopted for representing the chemical composition of foods was what is called "displayed analysis," a suggestion made by Mr. Thomas Twining, of Twickenham, in 1856.

The term "displayed analysis" was used to indicate that actual weighed quantities of food components are displayed, instead of their quantities being stated in figures.

In analysing foods, there are two kinds of analysis that may be made, either that which is called "proximate," which ascertains the quantity of albumen, starch, fat, cellulose, and other compounds in a food; or that which is called "ultimate," in which their "proximate principles" or compounds are further analysed to ascertain the quantities of the chemical elements, carbon, hydrogen, nitrogen, and so on, which they contain.

Why both are required will be referred to further on, together with the explanation why the ultimate analyses are given "reckoned as starch." It is the proximate principles only that are shown, in the "displayed analysis" of foods. The ultimate analyses are given in figures. The distinctive feature of the scheme is this series of displayed analyses, since analyses in figures are given in many books. Keeping in consideration the popular requirements for the success of this "visual teaching," and that the chemist obtains his results in grains (437·5 of which go to the avoirdupois ounce) or in grams, while the public is in the habit of looking at food weights in lbs. and ozs., it was arranged that the proportions given should be as if a whole pound of each food had been analysed. The larger quantities were arrived at from the smaller by the simple process of multiplication. As foods themselves, and in many cases their "proximate principles," cannot be kept from disintegration in a museum, models are substituted, and materials having the appearance of the "proximate" principles are used. Looking at rice for example, there is to be seen a lb. of rice, and there by the side 2 oz. 147 grs. of water, 1 oz. 87 grs. of fibrin, 12 oz. 70 grs. of starch, 35 grs. of fat, 63 grs. of cellulose, and 35 grs. of mineral matter. The figures relating to the ultimate analysis are given thus, "for one part of flesh formers in rice, there are ten parts of heat givers, reckoned as starch."

In this way it was hoped that the public would be familiarised with the idea of looking at their foods as being what they essentially are, apart from their flavours and odours being a source of pleasure, just so many different forms of conveying to the blood for distribution those elements, in proper proportions, which according to changing requirements each person needs. As many provincial art collections have sprung from the influence of South Kensington, so it was hoped that provincial museums would have copies of the type "Food Collection." A "travelling collection," with this end in view, was formed, but very few applications have been made for it. Such were the intentions with which the collection was originated, and such was the plan adopted for the proposed popular teaching. Throughout the many modifications it has undergone, and the important changes in the designations "heat givers," "force producers," and "flesh formers," the main features have not been departed from. The collection has not, however, developed equally throughout, and while analyses of vegetables and fruits of many kinds are given, there are only two of fish, mackerel and cod, none of birds, and but few of animal foods.

Looking at the scheme as a whole, it seems evident that it was supposed that those who would consult the collection possess some knowledge of a portion of organic chemistry, not such a wide organic chemistry as we have now, but such a knowledge as, when the plan was proposed, there was good reason to believe was gradually spreading in a popular form. At the time of the formation of the collection, which is more than a quarter of a century ago, the interest taken by the reading public in such a subject was greater than at present. Prout's contribution to the celebrated "Bridgewater Treatises" had not passed into the stage of being merely of historic interest, and Liebig's "Familiar Letters on Chemistry" were much in fashion. His writings captivated. Eloquent in richness of historic knowledge, comprehensive in grasp of the many bearings the new chemistry might have, clear in stating facts without using unexplained technicalities, simple in the sequence of ideas which it was no fatigue to follow, and grand in the vast problem of life dealt with, he irresistibly carried minds of many kinds along with him. There was, too, the additional attraction of novelty. The subject was novel, there were novelties in the successive editions to which he constantly added, and it was in itself a novelty to have the writings of a German chemist simultaneously brought out in English, which at his own wish was done by his pupils Gregory, Lyon Playfair, and Blyth.

The "Food Collection" was practically a series of illustrations of those parts of the "Familiar Letters" and "Animal Chemistry," which referred to the food of man. Far different in scope from such books as Sir Thos. Elyot's "Castel of Health," Henry Butte's "Dyet's Dry," Tobias Venner's "Via Recta ad Vitam Longam," or Dr. Arbuthnot's Essay, his works, which dealt with the chemistry of foods, were kept strictly to chemistry. Digestion and the moral effects of different foods on different constitutions were but incidentally alluded to. The mechanical and physical outcomes of the chemical separations and unions of the component elements of food were the theme. His keynote was, "all vital activity arises from the mutual action of the oxygen of the atmoshpere and the elements of the food." The older writers could not have dreamed of approaching the subject of the actions of foods by such a road as this; or if any of them, from seeing Mayow's forgotten account of his experiments, had their day dreams, they remained mere dreams. Looking at the course of events as they actually followed one another, we know that it was not till 1752 that Black arrived at the explanation of what carbonic acid is, not till 1772 did Rutherford separate nitrogen; it was 1774 before oxygen was known as a separate air, and it was not till after Cavendish in 1784 had shown that water is a chemical combination of hydrogen and oxygen, that the generalisations of oxidations was made by Lavoisier; not till the interaction of these elements and compounds was known could Thénard have opened up the chemistry of organised beings. Liebig, from attending his lectures in Paris in 1823, saw as from a newly-discovered coast hill a whole country of illimitable extent inviting exploration. All was fresh for those who should push forward first. He was both original in his own work, and in the generalisations he based on that work, combined with the work of others; and even his popular expositions have the indefinable charm of individuality. Now he is but little read, probably because it is known that some of his inferences have had to be modified, and on many points he is "out of date."

The practical result is that the "Food Collection," which was a carefully worked out illustration of some of his work, remains to many little more than an elaborate set of calculations, seeming to offer no more interest in daily life than a chemical history of the stones of which a town is built, or of the granites or porphyries which adorn it.

In considering the collection, and what practical use it may be, this cannot be lost sight of without the risk of mistaking its real purport, that it is confined to showing, with the greatest accuracy attainable, what is the chemical composition of foods. If to any student it appears an unintelligible collection, that is because he is not possessed of that part of chemical knowledge requisite for understanding it. If to any it appears practically useless, that is because there is not possessed that knowledge requisite for using it. It was, at the time of forming the collection, supposed that such knowledge was possessed or would be easily obtained from reading Liebig, and the plan has not been altered. Therefore, it is that in the handbook which reproduces the tables of analysis for people to have for reference at home, while definitions are given of the sense in which the terms "force producers," "heat givers," and "flesh formers," are used in connection with the collection; still some knowledge of the basis of organic chemistry, obtained from some other source, is pre-supposed, and, as the *Times* of January 19th, 1877, pointed out, "students rather than the general public" were in view.

The kind of knowledge pre-supposed can be briefly indicated, and it will be seen that though, in most text-books, organic chemistry comes after inorganic chemistry, it in no way follows that inorganic must be "read up" before proceeding to organic, so far as to be able to understand the meaning of the collection.

This was early found as one food after another was analysed. They all contain compounds of carbon, hydrogen, and oxygen; some also contain compounds of these and nitrogen. Liebig divided food compounds into two great groups, those which contain nitrogen, and those without nitrogen. This distinction into nitrogenous and non-nitrogenous compounds is retained, as it is based on fact, though their relative functions are understood differently from what they were in the earlier period of Liebig's writing. Nitrogenous compounds also contain sulphur, though the special function of this, if it have any at all, is not known. There are other elements also present with these in small quantities. About the functions of most of these we are still ignorant.

As we at present understand the chemistry of food, the interest centres on the amounts of nitrogenous and non-nitrogenous compounds as it did present at the time of the appearance of Liebig's "Animal Chemistry," 1841. He then wrote "The supply of heat lost by cooling is effected by the mutual action of the elements of the food and the inspired oxygen which combine together. . . . . . It matters nothing what intermediate forms the food may assume, what changes it may undergo in the body; the last change is uniformly in conversion of its carbon into carbonic acid and of its hydrogen into water." He had drawn the inference that the production of heat in the body was effected by the process of oxidation independent of any force production manifested by the action of muscles. This he assigned to another cause. The destruction of muscle tissue. "It is obvious that the work performed consists in the waste or consumption of bodily parts." It is difficult to picture to the mind the kind of changes Liebig supposed took place when he speaks of work performed consisting "in the waste of the substances of muscle or nerve." This, however, is of only historic interest, for in 1866 Professor Frankland, in a lecture at the Royal Institution, "On the Origin of Muscular Power," showed, as the result of calculations based on observations alluded to further on, that the oxidation of carbon into carbonic acid, and hydrogen into water, not only supplies heat to the body, but also the source of muscular power, and since then the disentegration theory of muscle tissue has been modified. This is the most important of Liebig's generalisations that further research showed to be incorrcct. [The nomenclature used in the collection was modified about 1868 or 1869 in accordance with the newly adopted view.] The importance of the oxidation of carbon and hydrogen was not only as great as Liebig took it to be, but greater; not merely keeping up warmth, but also supplying muscular power. The title flesh formers is still retained as a fitting name for the nitrogenous compounds, since muscle is not formed without them, though they are also heat givers and force producers, as the carbon and hydrogen in them appears to be available, as if they were carbon compounds, especially when carbon compounds are not present in sufficient quantity. Experience proves that in severe hard work they are of great importance.

Liebig, besides pointing out oxidation of foods as "the first condition of animal life," applied himself to ascertain the relations between the quantities of oxygen inspired, the quantities of carbon and hydrogen taken in as food, and the consequent quantities of water and of carbonic acid formed. He here laid the foundation of the study of the quantities of the elements used as food, as distinct from the former rough calculations in dietaries of the weights of meat, bread, vegetables, &c., consumed. In the hands of subsequent observers following his lines, the subject has attained considerable exactness.

His own inquiries into the quantities of different kinds of food, consumed by different classes of people, were numerous. For accuracy, he relied much on the known quantities served out to troops as rations. He then reduced the values of different compounds to some convenient standard of comparison. For example, "The fat of butter and that of flesh contain carbon and hydrogen very nearly in the same relative proportion as starch and the various sugars. These differ from fat chiefly in containing more oxygen. It is easy in our calculations, by adding oxygen, to convert a given amount of fat into starch. In this way we find 10 parts of fat are equivalent to 24 of starch. In like manner, by deducting a certain amount of water, we can reduce milk-sugar to its equivalent of starch, and by thus reducing all the non-nitrogenous elements of food to their equivalent value as expressed by starch, we can compare them."

In ways such as this, he could readily compare the total amount of carbon and hydrogen taken in in a day, in a form available for use. The form has to be considered, since carbon, hydrogen, and the other elements of food are not available in the form of elements, but only as compounds. This method of comparison is still used.

Some foods contain so large a per-centage of water that they are of small value as food. This is especially the case with fruits. For example, apples contain 83 per cent., gooseberries 86, peaches 85, onions 91; of other vegetables celery contains 93 per cent., cucumbers 96, and rhubarb 95. So a pound of any of these would contain very little carbon, hydrogen, or nitrogen. Taking Liebig's method of comparing food values, is is seen that sixteen pounds of cabbage would furnish only as much "nourishment" as a quarter of a pound of meat. Not only was the amount of water found to be very different in different foods, but the amount of carbon, hydrogen, and nitrogen varied. Liebig pointed out, having reference probably to the old theory of transmutation, that if the requisite amounts of carbon, hydrogen, and nitrogen are not present in the foods taken, these amounts cannot be in the body to do the work they have to do.

Hence the practical need of determining these two things with accuracy.

1. The amounts that are needed.

2. The foods—and the quantities of the foods from which the amounts can be obtained.

The two lines of inquiry are quite distinct. For example, if the knowledge of the composition of turnips were of no use in regard to the food of man, it still would be of use for cattle feeding. The knowledge of the composition of any particular food may lead to its more general adoption or disuse. In England potatoes are far more largely used than oatmeal. Yet potatoes have but 17 per cent. of carbon compounds, while oatmeal has 73. Since Liebig led the way, so much has been done, that it is the results of many hundreds of analyses of different samples of different foods which are given in "Tables of Analyses." Owing to variations in conditions of growth, they vary somewhat, and figures selected represent the mean of the many analyses made.

In the national food collection the proportions of the carbon compounds present are stated not only in their actual quantities, but also reckoned out to their equivalent values expressed as starch, on Liebig's plan.

As to the second consideration, the quantities needed, Liebig pointed out how these varied according to temperature, but remarkable advance has been made on his conclusions with regard to the variation in amounts needed in relation to work done.

Investigations have been carried on by two distinct methods.

1. The one that which Liebig first adopted has been to note the different quantities of food eaten by people taken in groups according to their occupation, and the amount of work they do. The most exact of these inquiries have been on large numbers of men dieted uniformly under control, soldiers, inmates of workhouses and prisons, while the most varied, but necessarily not so exact, have been such as Dr. Edward Smith's enquiries made for the Privy Council during 1863 and 1864, on the diets of "distressed operatives," and "the food of the poor labouring classes of England." The quantities of food taken are then calculated out into the amounts of carbon, hydrogen, and nitrogen they contain, and with analyses of foods, ready at hand, this is merely a matter of arithmetic.

Such results can be of value when the averages are based on a wide number of observations. Some margin must be allowed for the variation of the compositions of the foods they eat according to localities and season.

One advantage of this method is that the returns can be obtained without any apparatus, and without the collector having any training in experimenral research. This may be called the "method of intakes."

2. The other method is just the reverse, taking the body's expenditure instead of its income as the basis. This method requires apparatus for collecting the carbonic acid gas, the water, and the urea given off. Some experiments Dr. Edward Smith made on himself were on the relative amount of carbonic acid given off during various degrees of exertion Pettenkoffer carried out experiments on a watchmaker, who worked for three days in a case, the amount of food and oxygen admitted to him, and the amount of carbonic acid gas and water, &c., given off, being accurately weighed. The work he did during the three days was varied, so as to ascertain the relation between work, and the amount of oxidation that took place. The celebrated ascent of the Faulhorn by Professors Fick and Wislecenus, and other observations by others, have been made with the same end in view. The conclusions arrived at, not all at once, but by correcting and checking one observation with another, have been:—

(1.) That the amount of carbonic acid given off (that is, the carbon oxidised), and of the water formed (the amount of the hydrogen oxidised), varies with the amount of work done.

(2.) That, reckoning the amount of hydrogen into its equivalent of carbon (taken at three times), the average quantity of carbon oxidised in the twenty-four hours is 4,900 grains.

(3.) That the quantity of nitrogen used during the same period is 300 grains.

(4.) That by the first of the two methods it is found the amount of nitrogen has to be increased considerably when hard work is done. The chemico-physiological explanation of this is still a matter of uncertainty.

These facts being known, the practical problem in a dieting which shall supply amounts of carbon, hydrogen, and nitrogen in proportion to work done, but not in such unnecessary quantities as to lead to the overstorage of fat or to energy which will manifest itself in insubordination or wanton mischief, is to select foods in such proportions that neither the nitrogen nor the carbon shall be in excess or deficient. The tables of some public dietaries are drawn up with this end in view, and examples of some (showing only weighed quantities of carbon and nitrogen) are exhibited in a case at the end of the series.

The aim of the collection is to enable people at home to regulate their diet as the public dietaries are regulated. They must first know their wants, and the analyses already prepared, show how the wants can be most efficiently supplied.

The last edition of the hand-book expresses that, after going over the subject the reader will be in a position so to adjust the proportion of the several articles of food to one another, so as to construct useful dietaries in which there will be no marked excess of carbon over nitrogen, or of nitrogen over carbon, that is, no marked excess beyond the quantities respectively required for each element. The nearest approach to working this out are the tables of Dr. E. Smith, given in his report alluded to above.

It is for the information of hard-working artisans and labourers that the work-power of various foods is expressed in foot-pounds. Assuming a pound of any food to be duly digested, assimilated and oxidised in the body, there is a maximum of muscular power which it can produce. It does not necessarily follow that it will produce that amount, since digestive power of assimilation or some personal defect may interefere with its doing so. But it is of use to know that not more than a certain amount can be obtained, and it is, therefore, useless to expect to obtain for example as much power from a pound of potatoes as from a pound of peas, or from an ounce of tea as from an ounce of cocoa. The standard of measurement—the foot-pound, that is one pound raised one foot—is a convenient one, and it is not unfamiliar to engineer mechanics. The calculations are based on the thermo-dynamic experiments of Prof. Frankland, made in 1866.

The acquisition of a knowledge of the chemical composition of foods is not a mere fad, as, if rightly applied, it may have very useful results. For example, when in 1872, five hundred miles of rails on the Great Western Railway were shifted in a fortnight, 3,000 men were employed, working double time. The men, as usual, carried their own supplies of bacon, bread, cheese, cocoa, &c., but in addition to this the company made arrangements for a supply of oatmeal and sugar. Oatmeal has 16 per cent. of nitrogen compounds, and 73 of carbon compounds. Temporary fire-places were built along the line, a cook was provided for each gang of twenty-men, and a pound and a-half of oatmeal, with half a pound of sugar, was served out, well cooked, to each man, during each twenty-four hours. The men not only liked this form of taking extra nitrogen and carbon, but during the whole of the work no case of illness occurred in spite of the severity of the labour.

It is well-known that when the British navvy is matched against those of other nations on a hard-working job, he generally does more real hard work than they can get through. A contractor, for some railway work in Sicily, found progress retarded by the relatively small amount of work the Sicilians did. It struck him they did not eat meat enough, as in their thriftiness they would not spend the money for it. He adopted the plan of partly paying them in what was really needed for the work, more nitrogen and carbon in a compact form, and as meat was obtainable, he paid partly in meat, instead of money that might have been spent in other ways. The result was a marked increase in the amount of work they did, which came very nearly up to the average of the British.

EXPORT ASSOCIATIONS ON THE CONTINENT.

While the marked development of British export trade within a certain period has been mainly due to the activity of private enterprise, the efforts now being made by various continental nations to extend their trans-oceanic commerce, are in a certain degree promoted by associations, in which the needful financial and industrial resources are combined. Thus, according to the *Journal de Roubaix*, an export company has been formed at Brussels, with a capital of £100,000, for the purpose of encouraging trade in Belgian products by undertaking financial responsibilities, and by exploring distant markets in the interests of Belgian industry. Similar organisations are said to be in contemplation as regards French export trade, but the suggestion is made by the journal in question that manufacturers should unite in forming small groups, the members of which make different classes of goods, and that such combinations should undertake the execution of the projects referred to.

Past experience has not been uniformly favourable to schemes of this description, which seem (according to the *Economiste Français*) to have been tried in Germany under apparently favourable circumstances.

An association was formed at Stuttgart in 1853, with a capital of about £20,000, of which a quarter was furnished by the State. It paid during the first three years of its existence dividends at the rate of 4 per cent., and was liquidated about 1868, there being not much more than half of the original capital available for distribution amongst the shareholders. A fresh effort was made in 1881, and an export sample collection has been organised, to which 500 members have contributed. An extensive export association was formed at Berlin in 1878, which has 3,000 members, and has recently opened an export bank, with a capital of £12,500. A financial organisation, on a much more extensive scale is also spoken of, the capital of which would be £2,500,000, and which is to some extent originated by Prince Bismarck. An Austrian society, founded in 1871, has arrived at satisfactory results, principally in Persia, India, and South Africa. In connection with this association and others of a similar kind, an information office has been opened at Vienna, for giving exporters all needful information as to the wants of foreign countries, rates of freight, and other matters of utility.

THE PRECIOUS METALS IN MEXICO.

In 1808, the population of Mexico consisted of six millions; it rose in 1856 to 7,829,000, and is now estimated to exceed twelve millions. The greater part of the inhabitants belong to the indigenous race of Mexican Indians, who retain their original dialects, although Spanish is the official language of the country.

The state of Chihuahua is considered the richest in the Mexican Republic. It is divided into twenty cantons, in which there are 127 mining districts; and in these districts 575 mines have been worked since the Spanish conquest.

Indeed, the greater portion of the gold and silver mines that are now in action were also worked at the time of the Spanish conquest. While the country was under Spanish rule, that is to say from 1537 to 1821, the mines produced gold to the amount of £13,753,682, and silver to the amount of £417,253,940. Since that period, and up to 1880, the mines produced gold to the amount of £180,131,662. The total value of the gold and silver produced between 1537 and 1880 is £621,022,042, the average annual production being to the value of £1,812,000. Compared with this, California, Nevada, Colorado, Utah, Dakota, Montana, Idaho, Oregon, Washington, New Mexico, and Arizona, have produced the precious metals from 1848 to 1882, of a total average value of £13,560,000; and a large portion of this was obtained from territory which formerly belonged to Mexico.

It has been found necessary to abandon mines, even when yielding more than nine troy pounds of silver to the ton of ore, on account of the difficulty of transport and want of labour; but with systematic mining and economical methods of reducing the metal, added to the necessary capital and improved means of communication, Mexico would regain the foremost position among countries producing the precious metals which she held up to 1848. The completion of the central railway, which traverses the state of Chihuahua, will contribute towards bringing about this result. It has often been said that there is no coal in Mexico, and that this want will prove an obstacle to the development of the natural resources. This, however, is not the case, as the Government has published an official list of localities where coal deposits exist. Petroleum is also found in large quantities.

PRIZES OF THE SOCIETE D'ENCOURAGEMENT.

The Société d'Encouragement pour l'Industrie Nationale, founded in 1801, and declared of public utility by a decree of 21st April, 1824, has determined the subjects for the competition of 1886. The large medal, bearing the image of Jean Goujon, will be devoted to Architecture and the Fine Arts. The following have been the recipients of this prize:—1870 (Commerce), M. F. de Lesseps; 1870 (Chemistry), M. H. Sainte Claire Deville; 1872 (Agriculture), M. Boussingault; 1873 (Physics), Sir Charles Wheatstone; 1875 (Commerce), Mr. Jacques Siegfried; 1876 (Mechanics), M. H. Giffard; 1877 (Chemistry), Mr. Walter Weldon; 1880 (Fine Arts), M. Charles Garnier.

The Grand Prix of the Marquis of Argenteuil (12,000 fr. = £480) for the inventor or discoverer of the improvement most useful to French industry, especially for those objects in which France has not obtained superiority over foreign countries, either as regards the quality, or the cost of production, of the articles manufactured. This prize has been successively awarded, in 1846, to M. Vicat; in 1852, to M. Thoreul; in 1858, to M. Heilmann; in 1864, to M. Soral; in 1870, to M. Champonnois; and in 1880, to M. Poitcoin.

Mechanical Art.—1,000 fr. (£40) for the utilisation of the power absorbed by brakes.

Chemistry.—3,000 fr. (£120) for the manufacture of black diamond; and 4,000 fr. (£160) for the artificial production of fatty substances and wax.

Agriculture.—1,000 fr. (£40) for the bringing into cultivation of waste land by fruit trees.

Further information may be obtained at, and descriptions should be addressed to, the offices, 6, Place Saint-Germain des Prés, Paris.

The first lecture of a new course of lectures on Fuel will be given at the Evening Class Department of King's College, London, on October 6, from 7 to 8 p.m., by Mr. W. G. McMillan, Demonstrator in Metallurgy. This course is intended to include the subjects required for the City and Guilds of London examination in Fuel.

General Notes.

Australian Coal Production.—In 1829 the quantity of coal raised in New South Wales was 780 tons, valued at £394; in 1857 the quantity was 210,434 tons, valued at £148,158; in 1858 the coal exports of New South Wales amounted to 216,397 tons, valued at £162,162; in 1883 the quantity was 2,521,247 tons, valued at £1,201,941. The total quantity exported during the twenty-six years, 1858-83, was 27,095,302 tons, valued at £13,536,823.

Proposed Technical School at Elbeuf.—The *Jacquard* calls attention to the efforts now being made by the Industrial Association at Elbeuf to establish a technical school which would be on a level with the institutions of a like description at Bradford and Leeds. The scheme has been drawn up in a very detailed form, and embraces a three years' course of study. There will be eight professors, with a competent body of technical assistants. The general expenses would amount to £2,000 a-year, and the necessary machinery and appliances would cost £8,000, the erection of a suitable building being estimated at about £3,000 more.

THE LIBRARY.

The following works have been added to the Library since the last announcement:—

Amos, Sheldon, M.A.—A Systematic View of the Science of Jurisprudence. (London: Longman, Green, and Co., 1872.) Purchased.

Brereton, William H.—The Truth about Opium. (London: W. H. Allen and Co., 1882.) Presented by the Author.

Britten, F. J.—The Watch and Clockmakers, Hand-book, Dictionary and Guide. (London: W. Kent and Co., 1884.) Presented by the Author.

Browne, Lennox.—Science and Singing. (London: Chappell and Co., 1884.) Presented by the Author.

Burt, Major T. Seymour, F.R.S.—The Æneid, Georgics, and Eclogues of Virgil. Three vols. (London: Effingham Wilson, 1883.) Presented by the Translator.

Eastlake, Charles L.—Notes on the Principal Pictures in the Old Pinakothek at Munich. (London: Longmans and Co., 1884.) Presented by the Publishers.

Ewing, R. M.—The School and College Handbook of Agriculture. (London: W. Swan Sonnenschein, and Co., 1884.) Presented by the Publishers.

Godard, John George. — George Birkbeck, the Pioneer of Popular Education. A Memoir and a Review. (London: Bemrose and Sons, 1884.) Purchased.

Greenwood, William Henry.—Steel and Iron. (London: Cassell and Co., Limited, 1884.) Presented by the Publishers.

Holland, Thomas Erskine, D.C.L.—The Elements of Jurisprudence. (Oxford: Clarendon Press, 1882.) Presented by the Author.

Holtzapffel, John Jacob.—Turnery and Mechanical Manipulation. Vol. V. (London: Holtzapffel and Co., 1884.) Presented by the Author.

Jagnaux, Raoul. — Traité pratique d'analyses chimiques et d'essais industriels. (Paris: Octave Doin, 1884.)

Local Government Board.—Twelfth Annual Report, 1882-3. (London: Eyre and Spottiswoode, 1883.) Presented by the Medical Officer.

McLaren, Walter S. B., M.A.—Spinning Woollen and Worsted. (London: Cassell and Co., Limited, 1884.) Presented by the Publishers.

Ormerod, Eleanor A.—Guide to the Methods of Insect Life. (London: Simpkin, Marshall and Co., 1884.) Presented by the Author.

Perry, John, M.E.—Practical Mechanics. (London: Cassell and Co., Limited, 1883.) Presented by the Publishers.

Pollock, Frederick, M.A., LL.D. — Essays in Jurisprudence and Ethics. (London: Macmillan and Co., 1882.) Purchased.

Scribner, G. Hilton.—Where did Life Begin? (New York: Charles Scribner's Sons, 1883.) Presented by the Author.

Smith, Robert H. — Cutting Tools Worked by Hand and Machine. (London: Cassell, Petter, Galpin and Co., 1882.) Presented by the Publishers.

Solly, Rev. Henry.—Re-housing of the Industrial Classes. (London: W. Swan Sonnenschein and Co., 1884.) Presented by the Publishers.

Springinühl, Dr. Ferd.—Italiens Weine und die concentration des Mostes im vacuum. (Frankfurt-a-M.: James Weller, 1884.) Presented by the Author.

Thompson, Silvanus P., D.Sc.—Dynamo-Electric Machinery. (London: E. & F. N. Spon, 1884.) Presented by the Author.

Wallace, Roger W.—The Patents, Designs, and Trade-marks Act, 1883, with Introductory Chapter, Explanatory Notes, Notes on Decided Cases, &c. (London: William Maxwell and Son, 1884.) Presented by the Author.

Watt, Alexander.—The Art of Soap Making. (London: Crosby Lockwood and Co., 1884.) Presented by the Publishers.

Wharton, C. J.—Electricity as a Motive Power, by Count Th. du Moncel and Frank Geraldy, translated and edited with additions by C. J. W. (London: E. and F. N. Spon, 1883.) Presented by the Editor.

Winchell, Alexander, LL.D. — World-Life or Comparative Geology. (Chicago: S. C. Griggs and Co., 1884.) Presented by Messrs. Trübner and Co.

Journal of the Society of Arts.

CANTOR LECTURES.

THE BUILDING OF TOWN HOUSES. THEIR ARRANGEMENT, ASPECT, DESIGN, AND GENERAL PLANNING.

By Robert W. Edis, F.S.A.

[The right of reproducing these lectures is reserved.]

Lecture III.—Delivered March 3rd, 1884.

Fittings, Planned Furniture, Constructive Decoration.

In my former lectures I have endeavoured to point out, in the brief space of time at my disposal, some few of the evils which so many of us have to endure in modern-built houses, and to suggest means for their removal or amelioration.

I have sought to show that good design in external elevation, and picturesqueness of treatment, are not incompatible with good internal arrangement, or with the comfort, sanitation, and common-sense treatment of the house. I have done my best to expose the barbarisms and vulgarities of so-called speculative building ; to point out the inconsistencies and lowering influences of having our streets and squares carried out in one dreary "dead level of unimaginative uniformity;" and in this my third, and last address, I hope to offer to those who are furnishing old, and to those who are building new houses, some suggestions which may commend themselves as worthy of carrying out, and as tending to the better ordering, greater comfort, and more artistic homeliness of the rooms we live in.

In the early portion of this century, to quote Mr. Redgrave, R.A., in his pleasant little book, "The Manual of Design" :—

"While our architects were content to put columns that supported nothing, roofs that covered nothing, and parapets and balustrades that protected nothing ; to contrive sham attics to hide the construction of ugly roofs, to make us peep through the scroll-work of a frieze, or the channels of a triglyph, instead of a window, or to make the pedestal of a statue into a chimney pot, how was it likely to fare with furniture which became a sort of toy architecture? Was it to be wondered at that all constructive shams were increased tenfold when used as ornament? Was it surprising that Grecian stone altars formed our sideboards, Roman temples our cabinets, sarcophagi our cellarets and wine coolers, or that our harpsichords stood on lyres instead of legs; that constructive truth, in short, was wholly and entirely disregarded, in order that some favourite type might be reproduced? Was it to be wondered at, moreover, that men broke loose from these dead shams, and getting sick of these classicalities, entirely deserted constructive truth and symmetrical arrangement ; went mad first after Rococoism, and then, in our own days, after picturesque naturalism, and that the very revolution of taste produced the wildest contradictory faults."

While I want to see our homes artistic, that is to say with decoration and furniture good in design and taste, and harmonious in colour, and not overlaid with trashy decoration, or fitted with useless lumber, I hold that true art in the house means the practical rendering, in good taste and pleasant guise, of all the absolute necessities and requirements of modern life, and all domestic art is bad which ignores the purposes to which the furniture, decoration, or general belongings of a house are to be put. Comfort, utility, and good sense should go hand-in-hand with the internal finishing of every house.

Men take pride in the building of their houses, and spare no pains or expense in seeking to make them comfortable and convenient internally, and artistic and beautiful in their external design ; but they seem so often to forget that the true and healthy decoration and artistic furnishing of the building should be considered and thought out as part and portion of the whole fabric, that they cannot properly be separated, and although, to a certain extent, eclecticism may, and must, prevail in the smaller items of moveable furniture, and in the numerous necessary articles which make up the comfort of the various rooms, the general scheme of decoration and fitting up their houses should form a "part of an harmonious whole, in companionship with other art." That, in fact, as Mr. Ruskin wrote in one of his eloquent lectures, in one of his early books, "The Two Paths:"—

"The only essential distinction between decorative and other art is the being fitted for a fixed place, and in that place related, either in subordination or in command to the effect of other pieces of art; and all the greatest art which the world has produced is thus fitted for a place and subordinated for a purpose."

We build our houses ample and luxurious, and having built the outside shell, are apt in our pride to say:—

"I built my soul a lovely palace house,
Wherein at ease for aye to dwell,
I said, O! soul make merry and carouse,
Dear soul, for all is well."

And often in the furnishing and fitting up of our individual palace, we cram it with heavy, useless, and unartistic things, which suggest another verse in the same poem:—

"But in dark corners of her palace stood
Uncertain shapes; and unawares,
On white-eyed phantoms, weeping tears of blood,
And horrible nightmares!"

The "horrible nightmares" being emphasized in the motley crowd of ofttimes hideous lumber brought in to fill our rooms, without thought of how they will harmonise with the palace we have reared, or accord with the comfort and necessities of our home life.

In recent times, in the ordinary furniture of our houses, we have brought in, it is true, a new order of things, and to a certain extent gone back to the designs of Chippendale and others, and have made the designer and manufacturer work up to the improved taste of the people; but it seems to me we are yet labouring somewhat in the dark, and do not exercise that forethought and common sense in the fitting up of our houses, which combined would, I believe, add so materially not only to our comfort, but to the general sanitation of the houses we live in.

We are still content to look upon the furnishing of our rooms as more or less the purchasing of various ready made goods, which can be stored and used for a while, and removed as occasion may require; and in doing this are apt to get furniture and fittings which, like ready-made clothing, are often misfits, and in part only answer the purpose for which they are bought; and are not inclined to consider with any amount of care the requirements of the various rooms, and to construct our fittings to suit those requirements, and to make them not only useful and ornamental, but part and portion of the rooms we live in, in harmony and keeping with the general design, and carrying out those views which are considered necessary for proper sanitation in all well ordered buildings. In fact, we complete our buildings without thought as to their internal fitting up, and when the rooms are painted, papered, and whitewashed, we treat the filling of them with furniture as something quite apart; and as a consequence, the care and thought bestowed in their design and decoration is often materially marred by the character of the furniture with which we fill them. More than this, by this want of thought, there is often much increased expense in the building which, by a proper and due regard for its final fitting up and completeness for occupation, might have been avoided; for instance, window recesses, which can be well fitted with box or ottoman seats, answering the double purpose of comfortable resting places, and store places for papers, clothes, and other household goods, are finished with panelled and moulded wooden backs and skirtings altogether unnecessary.

Recesses in rooms, which naturally suggest themselves as proper places for fitted cupboards, are completed with mouldings and skirtings which have to be removed, or increase the expense of the fitting by the labour and time involved in "scribing," as it is called, the fitting to the mouldings, which are not only not wanted, but are absolutely in the way. Window shutters and fittings are often so arranged that when the necessary blinds or curtain poles are fitted to them, the shutters will not open; and when cupboards are provided by the builders, they are practically useless, or so arranged, that their tops form dust traps and spaces for lodgment of dirt and filth, which lies for months before it is cleaned away, and of necessity helps to make the rooms stuffy and unhealthy.

If there is any truth that all fittings and materials which "catch dust, keep dusty, hide dust," and on being "swept or shaken, yield clouds of dust," are bad, then I will ask any of my readers to take an early opportunity of inspecting the tops of their bookcases, or wardrobes, cupboards, or other heavy furniture with which their rooms are filled, and I fancy they will be somewhat startled by what they will see, and believe that a great deal of these moveable fittings, while filling up the wall space, and difficult to move even at the periodical autumn and spring cleanings, should be got rid of, if possible, as not only unhealthy, but absolutely uncleanly; for it must be remembered that a certain amount of this dust and dirt gets disturbed by every draught and inrush of air from open windows, and mixes itself with the air we breathe, and falls upon and pollutes everything in the room, carpets, curtains, clothes, and coverings of all kinds.

Most people require now-a-days that there shall be some other means of ventilating their rooms beyond merely opening doors and windows, and all this work should be constructed and arranged as part of the furniture and fittings of the house; that is to say, in all newly-built houses, any arrangement for bringing in fresh air behind grates or through tubes should not require the cutting away and making good, and therefore double expense, usual wherever any system of ventilation is attempted to be carried out; the tubes, instead of being after-thoughts, should be properly arranged and thought out, and form part of the decorative construction of the rooms, or they will prove anything but artistic additions, and will tend to damage the general pleasant and harmonious effect of the rooms.

Everyone now-a-days hangs pictures on the walls, or divides the wall spaces by mouldings which form picture or chair rails. As a rule the builder has taken no thought of these requirements; the walls have to be cut about and plugged to ensure the proper fixing of the mouldings or rods.

Most people have a certain number of books, which they want to arrange in some convenient place in the library of the house; either moveable bookcases have to be provided for these, or if recesses be fitted up, there is a good deal of extra expense and damage caused by cutting away the walls, cornice, and skirting; and finishings, which have all cost money, have to be cut away or covered up; so that practically double expense is incurred.

I hold that the architect should consider all these matters in the general planning of his rooms, that in fact, as far as possible, the question of planning furniture and fitting up recesses, window and other openings, should form part of his original design; and that in many rooms of the houses, constructed and useful furniture may be designed to suit the different requirements of the various rooms, which, if thought out in the planning of the house, would not only save money being spent in finishings, which would then be unnecessary, but would provide a large amount of the heavy furniture of the house, such as wardrobes, bookcases, buffets, boxseats, and other usefu fittings, at considerably less cost than the bought goods, and in accord and harmony with the design of the house.

Most people are alive to the necessity of proper drain sanitation, and in taking a house, every common-sense person bargains that the drains and sanitary arrangements shall all be perfect; but the builder rarely thinks how easily he might ensure constant flushing and cleaning out of the house drains, by collecting the waste water from rain-water pipes, baths, and cisterns, or even housemaids' sinks where generally fairly clean water is carried away. All this is allowed to waste and filter slowly, perhaps, over open traps, into the various drain outlets. At the cost of a few pounds one or more of the many flushing tanks now invented might be placed in the front or back area or both, into which the waste water from baths, housemaids sinks, cisterns, and rain-water pipes might easily be collected; and, these tanks being automatic, would, as they were filled, continually let loose a great body of water, back and front, so as to sweep clean, two or three times in the day at least, the whole of the main house drain, and thus the water now wasted would be made useful for sound sanitary purposes. I do not say these flushing tanks are necessary where the general drainage is really sound, but I do say that they would be found constructive fittings which would materially tend, without difficulty or expense, to the daily scouring out of the drains, and to the better sanitation of the house.

Whenever a bath is provided, it is generally left open, and forms a receptacle for dirt and dust, which is not always cleaned out when the bath is filled. I suggest that the bath be slightly lowered into the floor, and fitted with a hinged top, about seat high from the floor, so as to keep the bath clear of dirt, and when not in use, make it answer as a table or seat. A bath-room is often fitted up with cupboards for linen, and if the hot-water cistern be placed in the room on the floor level, or sufficiently high for use, the linen cupboard, with lattice shelves, might easily be fitted over it, with closed doors of course, by which the linen would always be kept properly aired; and if the room be lined with tiles, as I suggested in my former lecture, there would be no fear of damp or moisture from steam condensing on the walls.

The bath should be formed in a recess, with tile lining all round and overhead, and the recess might then be fitted with cupboards over, and drawers and useful shelves at one end, so as to provide storage room for a large amount of spare clothing and linen, for which it is often so difficult to find room.

In the bedrooms, which I hold should, more or less, in all town houses, be arranged so as to form sitting as well as sleeping rooms, why cannot we have, say, one side of the room fitted up with wardrobe drawers, bookshelves, boot, and medicine cupboards, all designed as part of the internal finishing of the room, carried up to the ceiling line, with top cupboards for store places for clothing which is not immediately required. If some such fitting as this were arranged on the fireplace side of the room, where generally the chimney breast projects, leaving deep recesses on either side, the mantelpiece might form a central feature, simply designed with ornamental tiles next the iron grates, and enclosed in plain wood mouldings with wide shelf for ornaments; a good looking-glass let into a panel over, so as to lighten up the room, and be used for dressing purposes, with shelves on either side for books or dressing paraphernalia; the fire opening enclosed with a glazed faïence or marble fender, and the woodwork finished in general keeping with the other work in the room; the skirting of the room made to run round the fitting as a base, and the ceiling cornice carried round and enframing the whole. Such a fitting as this might have the ends formed into hanging closets for dresses, with long looking-glass panels let in; and in other parts arranged with drawers, boot cupboards, enclosed trays and shelves for linen, and in fact be made to take the place of the usual so-called suite of furniture consisting of wardrobe, chest of drawers, and dressing table; and the whole might be carried out in plain deal stained and varnished, or painted and varnished, to match the other woodwork; the top portion, above the glass over the mantle, being coved out so as to meet the face of the projecting side cupboards, and covered with gold stamped leather paper, or decorated with stencil work, so that the whole should be harmonious and pretty in design, as well as essentially useful in every part. Such fittings, or fitments, as they have been called, could be designed to suit the requirements of the various rooms, large or small, as the case may be, and would not only increase the pleasantness and comfort of the room, but would do away with a number of the usual moveable pieces of furniture under and over which dirt and dust collect, and which cannot be moved by the maid for the purpose of cleaning behind and below.

Expense would be saved, to begin with, in the room; the skirting board and cornice on this side of the room would be omitted from the first cost, and in the usually somewhat cramped areas of the rooms of London houses, the wall and floor space taken up by the usual pieces of furniture would all be lessened, and the room made practically more comfortable and convenient, so that by arranging the bed recess at one end, the whole of the general area would be left clear to be fitted up as a living room with a central carpet, and outside space next the walls and fitting, either painted, stained, or finished with parquet.

I am quiet sure all such arrangements as these would materially add to the comfort and convenience of every room, and by avoiding all dust traps, narrow spaces between walls and furniture—which always exist when the furniture is moveable and placed next the skirting—wherein fluff and dirt can collect—the room would be made healthier in every way.

I am aware that I may be met with the objection that all this kind of constructed furniture cannot be carried out when a tenant only occupies a house for a limited term of years, that is to say, on a yearly agreement, or on the ordinary leased tenure of seven, fourteen, or twenty-one years, inasmuch as the fittings, arranged as I have suggested, if absolutely fixed to the walls, become more or less the property of the landlord at the end of the term; but even supposing they are not made to unscrew and take to pieces, and that—as in all probability if this was done so as to leave them as tenants' and not landlord's fixtures—when taken down they would not fit in any other house. I believe that, as a general rule, an incoming tenant would be glad to take them over at a fair valuation, after allowing for depreciation for wear and tear; and when you remember that the depreciation of furniture, except in special cases of art work, may be taken at something between five and ten per cent. per annum, it follows that at the end of a term of twenty-one years' lease, the special fittings will have paid for themselves to a great extent; and you would have to incur no more cost in providing some such similar arrangement in another house as you would have to do in buying new furniture in place of much of the old, which, as a rule, would not be found any more suitable either to the new house, or the enlarged views and increased requirements which you would probably have at the end of such a term.

I may be wrong, but I believe a house fitted up as I suggest would, to most common people, command a higher rental, and that thus a fair and ample per-centage on the preliminary outlay might be secured; but even if this were not so, surely the increased comfort and health of the occupants of the various rooms must be taken into consideration, and what you might lose directly you would gain indirectly.

The question of constructional and decorative improvements, as between landlords and tenants, will, in all probability, undergo a material change in the next ten years, and be made the subject, as they undoubtedly should be, of legislative consideration; for the present iniquitous system by which the landlord reaps practically all the advantages of alterations and improvements, which are absolutely necessary to make the usual badly built houses fit for decent comfortable and healthy occupation, cannot, in the nature of things, be much longer maintained; and as year by year legislation is seeking to improve the position of the tenant in all questions of holding of land and farm buildings, I cannot but believe the present unfair arrangement of leaseholds and ground-rents in house property, will, 'ere long, be fairly met, by which I am morally certain a much better character of building will be ensured in our cities and towns.

In most houses it is common to have the store places for clothes and other household goods practically self-contained in every room, and therefore we put therein furniture sufficient for our requirements; but we all know how soon our drawers and wardrobes get overcrowded, and the nuisance and annoyance it often is to have to take out coat after coat, or dress after dress, until we reach the particular one we want, which may be stowed away at the bottom of the drawers or chest; and it, surely, must appeal to ordinary common-sense to utilise in every way, with constructive fittings as far as possible, all spaces which, as a rule, are practically useless. Why not, therefore, in the window recesses of every bedroom, provide fixed Ottoman boxes, which can be used as seats as well as store places, and if covered with stuffed tops, may thus not only be made useful but ornamental; while in the sitting-rooms they might be used for store places for papers and magazines until bound up, and thus avoid the littering of our rooms, or the storing away of all such things in inaccessible places where they are never dusted, and only help to breed dirt and disease.

While we may delight in collecting artistic and valuable pieces of furniture as we may collect pictures, engravings, or china, we do not want to make our rooms into curiosity shops or museums, and must have a certain amount of absolutely useful furniture in every room.

If we watch the progress of the art of furniture in all ages, we find that while it gradually became more luxurious and elaborate in its finishing, the artists who designed them always bore in mind, to a great extent, the necessity for the various pieces being made useful, and it was not until the Rococo period of the last century, that mere show, caprice, and elaboration formed the chief elements in furniture design. The old coffers, cabinets, doubled-bodied presses or *armoires*, credences, and buffets of the sixteenth century, while elaborate and luxurious, were generally adapted for the requirements of the people; and to-day, when the requirements and the general comfort of our surroundings, as well as the healthiness and well-being of the people, are daily becoming more thought of, we may fairly insist that the fitting up and arrangement of the interiors of our houses should be just as much considered as the external elevation, or the mere decoration of our walls.

If instead of the usual heavy and ugly valences, which so many people still insist upon placing over their windows, as a top finish to the curtains, we were to provide framed recesses, constructed with the architraves or mouldings which run round the window openings, with slightly arched heads, leaving room for a slight iron rod to be fixed behind and out of sight, with space for the proper and easy running of the curtain, we should, to my mind, have not only a much more artistic but certainly a much more healthy and less expensive arrangement; and these arched heads would form part of the constructive finishing at no more cost than the framed and panelled window linings and architraves, and if carried up to the ceiling with the cornice returned round, would leave no spaces for the accumulation of dirt and dust, such as are now provided by the projecting boxed linings and heavy valences, fringes, and poles which the modern upholsterer provides. Let me not be misunderstood in this remark; I do not mean that the modern upholsterer provides these, to my mind, expensive and utterly unhealthy arrangements for the sake of increasing his bill; he does it often to suit the taste—or rather want of taste—of his employer, and in ignorance of the better effect and artistic character of the simpler and more constructive fittings such as I have suggested, and practically from the fact, which I have always so strenuously sought to condemn, that the furniture is treated entirely as a separate art in the household, and is not in any way considered, as it should be, as forming part of the general design of the internal constructive fittings of every house.

It is impossible to lay down any particular rules for the design of these constructive fittings, nor would I if I could; they must be made to suit the various rooms and requirements of the individual owner; but I do say that the use of properly designed and arranged constructive furniture should enter much more largely than it does at present into every home, and that if considered in the planning, and carried out in the finishing of the house, more comfort and better arrangement of the rooms might be combined with considerable saving of cost and infinitely better artistic character of the general fittings of the building.

In the dressing-rooms, where as a rule in town houses the space is very limited, every one knows how difficult it is to provide room for all the articles of furniture required. All such constructional fittings such as I have named would add materially to the healthiness and convenience of the room, and comfort of the occupants.

As I said here, in one of the series of lectures which I gave four years ago, the bedrooms and dressing-rooms should be clear of everything, as far as practicable, that can collect or hold dust in any form; should be bright and cheerful, pleasantly furnished, not with the everlasting heavy mahogany wardrobes and dingy-looking chests of drawers, but with light and cheerful furniture of good and simple design, in which everything should be carefully arranged and studied for use not show. We do not want heavy and unnecessary hangings and furniture, which hold dust, keep dust, and are necessarily unhealthy, for if we are to secure healthy and refreshing rest and sleep, it is of the highest importance that nothing shall take away from or taint the pure air which is necessary during the hours of sleep, so that our waking may not find us feverish and nauseated by the continual inhaling of the impure air, which all such dirt and dust traps tend to create.

Let the whole floors be painted or stained, or, better still, finished with parquet flooring, which is almost non-absorbing, and which can be cleaned by a damp cloth every day, and rugs or simple homespun carpets laid down beside the bed and elsewhere where required, so as to be easily taken up and shaken every day without trouble; and if you do away with all resting-places for dirt and dust on the tops of wardrobes and hanging-closets, and behind and under chests of drawers and other heavy furniture, there will naturally be much less labour required in cleaning and purifying the rooms.

The nurseries of the house, the rooms in which our little ones spend so much of the early portion of their lives, should naturally be made healthy and beautiful, fitted with cupboards and cheerful light furniture, with no holes and corners in which broken toys and damaged picture-books may be stored away; the wall spaces utilised with planned furniture, divided as far as possible for each child, with the floor space left as open as possible for exercise and play. Nothing should interfere in these rooms with ample light and sunshine, for, as plants turn towards the sun and light, so children grow up more healthy where care is taken to avoid darkness and dinginess; and on the careful and proper fitting of their rooms depend their bodily as well as mental health. Want of light and sunshine means everywhere "stunted bodies, imperfectly formed blood, feeble limbs, dull senses and torpid minds." As Miss Nightingale says in her "Notes on Nursing," "Where there is sun there is thought, all physiology goes to confirm this; where there is a shady side of deep valleys, there is cretinism. Where are cellars and the unsunned sides of narrow streets, there is degeneracy and weakness of the human race, mind and body equally degenerating. Put the pale withering plant and the human being into the sun, and, if not too far gone, each will recover health and spirit."

In all the upper rooms of a house, which may be used as nurseries, I would, where practicable, construct semi-octagonal projecting bays, so as to provide for the greatest possible light and sunshine; and if this cannot be arranged, the windows should be as widely splayed inside as possible, and no light or sunshine shut out by heavy curtains or venetian blinds; and here too, as in the best rooms of the house, should be thick plate instead of the miserably thin glass which is considered sufficient in the upper portions of so many houses. The thick glass gives truer light, is less penetrated by sound, and helps to retain the warmth of the room after the fires have gone out, and the house is left to cool in the long night hours. For ventilation, some such pleasant arrangement as that originally designed by Mrs. Priestley, and which may be made part of the constructive fitting of the windows, may be carried out. This consists of a double glass lining, or practically a small glass case fitted into a window, a little way from the external light surface, with folding glass doors to open in front, but with the top left open, so that the lower sash may be raised, and, without draught, admit fresh air into the inner case, which escapes at the top, and finds its way upwards into the room, and helps to keep the room pure and sweet. The case may be filled with flowers, and the top covered in with thin gauze or silk, so as to prevent blacks and other impurities being drawn into the room, and the air passing over the plants or ferns is filtered and purified, the plants absorbing to a large extent all the "ammoniacal and carboniferous impurities," with which the air of large towns is materially laden, while the charm and colour of the delicate fern foliage and growing flowers adds to the pleasant aspect of the room.

All these you may say are small matters, but they make up half the evils and half the troubles of life, and are certainly well worth considering in rooms in which our children live and sleep.

Apropos of nurseries, as I wrote in an article in "Our Homes," "it is possible that there may be some sort of sentiment existing which makes mothers desire to keep for all time the long disused toys belonging to their children in early life. I have seen boxes and cupboards half filled with broken toys and other useless lumber, which only serve as resting places for all kinds of impurities, seldom disturbed and rarely cleaned out; while, in our hospitals and amongst our poorer neighbours, there are hundreds of children who would be delighted with these no longer required toys and belongings of our own childhood. Clear out all such lumber, and give all that is fit for anything—old picture-books, old toys, old clothing, to those who will heartily appreciate them; and while conferring a pleasure on these little ones of our poorer neighbours, who cannot possibly obtain in any other way such things as toys and picture-books, you will be clearing away things which are now only lying useless in some out of the way corner or cupboard, and adding to the comfort and cleanliness of your own house. How many thousands of poor children are there who would be benefited and amused, and whose lives might be made more cheerful and more happy, by the contents of many a box or cupboard of toys and books which are no longer required. Every housewife knows how old books, old papers, old clothes, old linen, accumulate in the course of a few months. Instead of these being periodically cleaned out and given away, they are often carefully stowed away, in the most out of the way places, practically as useless, and help to make the rooms and house generally stuffy and unhealthy, when they might be the means of giving health and pleasure to others who have no means of purchasing them for themselves."

We are so apt to think that the commonest of furniture, so long as it is fairly strong, is good enough for our nurseries; surely this is a cruel and unwise thought, for our little ones should, above all, be brought up amongst beautiful things and graceful influences; let the fittings and surroundings, and the decoration of their rooms all help to inform and impress upon their minds something of grace and beauty, of form and colour, and assist in the early teaching of their sense of sight; surround them with pretty objects, teach them method and tidiness by having everything about them showing tidiness and method; teach them to love nature, to appreciate good form and colour; let them see how nature "restricts her true ornaments, the flowers, to the most salient and culminating points of plants, and sprinkles them sparingly, contrasted with the foliage; that art itself is nature," and that, as Shakespeare tell us—

> "Nature is made better by no mean,
> But nature makes that mean; so o'er that art,
> Which you say adds to nature, is an art
> That nature makes."

There is one other piece of fitted furniture which I think might be much more largely brought into use into London houses, where, as far as practicable, it is desirable to save labour and service, and that is the so-called lavatory. I cannot see why every bed and dressing-room should not be fitted with a tip-up basin arranged in one angle of the room, next the window, and with hot and cold water laid on, and covered with a hinged top, so as to fold down and cover basin, soap trays, and other washing requirements, the front fitted as a cupboard, and all made to match the other woodwork in the rooms; the waste-pipe might be taken into one of the flushing tanks I have named, or otherwise effectually cut off from the sewer, so that there need be no fear of foul air finding its way into the rooms, and thus the comfort and convenience of the room would be still provided for, and the expense and bother of moveable basins and ewers done away with.

In the reception rooms of a house much expense might be saved by making the mantel-pieces much more important features than they are at present; if instead of the usual cheap and trashy marble mantle, with its heavy and vulgar trusses supporting nothing, we were to have simply designed wood mantels filled in with marble slips or painted tiles next the fire grates, with recessed looking-glass over, and cupboards and shelves at the sides made for holding ornaments, or guns, or books, cigars, or whatever else might be required in the particular room for which it was designed, how much more artistic would be the effect of the room, while at the same time a useful piece of furniture would be provided.

I do not mean that we should perforce buy one of the present ready-made fashionable so-called over-mantels, with their spindly turned ballusters and velvet-covered recesses, which are generally too large or too small for the ornaments we have, and which require fresh purchases to be made of ornaments we do not want, in order that they may be filled. But I would have the mantel-piece an important object in the room. We gather round the fire in winter, and have it always before our eyes, why, therefore, should it be formed with the usual tasteless marble framework which we are so accustomed to see in many modern town houses. In the smaller bed and dressing-rooms it may be made useful as a dressing table, and so save the expense of moveable table and looking-glass.

In the dining-room of the house, if possible, a recess should be arranged and fitted up with a handsome buffet, in place of the modern expensive and, oftentimes, very useless sideboard. It can be made to hold china and glass, with glass cupboards above, and to include a light lift from the basement, with store places for wine and decanters; can be fitted with drawers and shelves for prints or photographs, and, at a comparatively moderate cost, be made an useful as well as ornamental feature in the room, answering several purposes; or the back of the recess might be panelled with centre glass reflecting the end windows and the table, and adding thus to the picturesqueness of the room.

This glass panel could be made, if necessary, to slide, and form a serving hatch from the usual small back room in most second and third rate houses; but all this sort of work, I am aware, means time, thought, and design.

Now, as a rule, the owner is not prepared to give the necessary time or thought to any such arrangement, even if he have the knowledge to enable him to make the design; besides which he does not know, unless he be an architect or an artist, how the finished work will look; whereas he can see for himself in any good upholsterer's shop a variety of made-up sideboards; and thus he prefers to buy the ready-made goods, and to get the best fit he possibly can for his money.

This practically applies to all questions of fitted furniture, but so far as the fitments I have described for bed and dressing-rooms, he may, if he will, see various designs of these, applied to different shaped rooms, in the show-rooms of Messrs. Jackson and Graham, in Oxford-street, who have shown a willingness to depart from the ancient upholsterer traditions, and in the belief that my views are fairly sound, and at all events worth a trial, in questions of fitted and planned furniture, to carry out various designs I have made, expressing, so far as it was possible in the made-up spaces in a large show-room, the views I have advocated.

I should weary you were I to enlarge more upon this portion of my subject. What I have said as regards the constructive fitting up of our bedrooms and sitting-rooms, applies with equal force to every room in the house, that is to say, in the offices, in the hall, in the lobbies, in the landings. But it is useless advocating any such doctrines, if you are content to buy ready-made furniture without regard to its suitability or general fitness for your rooms.

As a matter of course, all the smaller items of furniture, and carpets, curtains, and small general fittings must be taken from store, and arranged in their places about the house; with these matters I have nothing to do in this address, they will be good or bad, artistic or common-place, as the taste of the individual purchaser may direct. But in these he may now-a-days, when taste in design has so materially improved all furniture, crockery, silver, pottery, and glass, safely trust to the numbers of excellent manufacturers who are supplying their various specialities to the public. And as the taste of the public and the sense of sight becomes more educated, and the common-sense of the people insists, first of all, that comfort and fitness are essential elements in all those fittings of the house which are not absolutely luxuries or ornaments, we may rest assured that there will be gradual artistic improvement in all the trades which are specially cognate to art; and we shall, when this knowledge and common sense is applied to our everyday surroundings as it is to our daily work, no longer be content to change and follow a mere fashion and order of the day, and to live in dread of the time when a new fashion, a new caprice, or a new fancy shall compel us to a change which is to be condemned on every ground artistic and common sense.

I cannot understand why so many common-sense people are content to stock their houses with all kinds of unsuitable ready-made furniture. I am told that some people buy ready-made clothing, and perhaps in the smaller things they get very well fitted, but I fancy in dress, most sensible people choose their own cloth and colours, and have their clothing made to suit them, and adapted to particular seasons and purposes. Why not apply the same common sense and thought to the furnishing of a house? It is all very well to say that almost any kind and character of fittings can be bought nowadays, but so far as my experience goes, most of the furniture offered to us is made after some particular fashion, good, bad, or indifferent, without reference to its suitability for the place each piece may have to occupy, with all kinds of expensive and unnecessary trimmings in the shape of carving, notching, or constructed ornament, and without regard or thought to its providing inaccessible ledges and resting-places for dirt and filth of all sorts.

I unhesitating assert that greater comfort, greater convenience, greater economy of space, greater artistic character, and considerable saving in cost, may be effected by more thought and less hurry in the furnishing of both old and new houses.

It seems to me that we cannot leave old grooves in the finishing of our houses, and modern builders are content to ignore, to a large extent, all modern improvements. We still have locks and door and window furniture which are a disgrace to a civilised community; composition handles, trumpery finishings, unwieldy sashes with no means of lifting them; boxing shutters which are either never shut, or if they are, necessitate the moving of every piece of furniture in the windows, and which practically often will not shut at all, owing to the arrangement of curtains or window blinds. We accept the same miserable arrangement of lighting, of bell wires, and of the hundred and one small matters which make up the comfort or discomfort of the house. Either those who run up our houses prefer to keep in the old grooves, or do not take the trouble to ascertain and adopt the many inventions which have been brought out in the last twenty years. To do so involves extra trouble, and perhaps a trifling additional expense; but if the public are content to accept the old order of things, the builders perhaps can hardly be blamed for not providing the new. In the present day there are innumerable small fittings which should be insisted upon in every house, many of them—especially in such small matters as locks, door springs, sash fastenings, and shutter bars—the invention of our ever-progressing and ready-witted brethren across the Atlantic, but all to be obtained at almost the same cost as the old inferior and should-be obsolete fittings to which we have been so long accustomed.

I have no intention of advertising these special wares, and do not, therefore, allude to them in detail, but anyone who has visited the various exhibitions of building appliances which have been held during the past few years, will, no doubt, have noticed for themselves the various articles to which I especially refer, and which, if used, will materially add to the comfort of the dwelling. Where plate-glass is used for glazing, shutters are rarely required and where they are fitted are rarely used; but if they are wanted, surely we might adopt some of the more modern systems of light wooden revolving instead of the old-fashioned lifting and folding shutters, which are often as inconvenient as they are ugly; but this means thought and anxiety to make everything about the house as good, as convenient, and as practicable as possible, elements which I fear do not enter into the heads of the ordinary speculative builder, whose sole anxiety is to run up in the cheapest possible way a given number of houses, and to get rid of them entirely, or to let them on lease to the unfortunate househunter, who has then to provide for himself all the modern improvements which ought, to my mind, to have been provided for him.

What can be worse, in most houses, than the wretchedly constructed decoration, plaster cornices, and centre flowers of the paltriest design, and the cheapest of cast enrichments. What can be worse than the trashy mouldings, the heavy skirting boards, or the cheap plaster decoration crowded everywhere for the sake of show and effect. What can be more vulgar or less artistic than the cast-iron staircase balustrading in imitation of wrought, which fences in our badly constructed stone staircases. What more dreary or monotonous than the everlasting rows of cement balustrading that form the parapets of our roofs, or the common-place imitations of stone or other construction which nearly every mere builder's house in London is bedaubed and bedizened with in Portland cement; or what more trumpery than the cast brass bell pulls, the flimsy gas-fittings, the composition door knobs, and finger plates; or what more terrible and heartrending to good servants than the polished steel fire grates with stuck-on ormolu, or cast brass ornaments, or the vulgarity of the "Brummagen" fenders with rows of turned ballusters, all involving endless labour in cleaning and polishing; yet, seemingly, all these shams and absurdities of false construction go on, like Tennyson's brook, "for ever." Let us hope that, with improved taste and better knowledge of the people, these may soon be delegated to that bourne from whence, let us hope, there is no return.

If ornamental ceilings are wanted, why not dispense with the old-fashioned lath and plaster, and use more extensively fibrous plaster, which can be modelled to any design, and be screwed to the joists. All this sort of work is infinitely better than the old system of lathing and daubing two or three coats of heavy plaster on to our walls and ceilings; for, owing to its strength and tenacity, it has no liability to crack, is virtually fireproof, is rapidly fixed, and can be decorated within a few weeks, and saves all the dirt and mess, which, unless great care is used, absolutely destroys all floors if they are required to be stained after, for the spots formed by the dropping lumps of wet plaster practically will show through any amount of stain or varnish: this canvas plaster is about one-quarter the weight of ordinary plaster. Both fibrous plaster and papier maché adapt themselves to the ornamentation of ceiling and walls, and can be successfully applied to many purposes in the building of a house, for instance, for skirtings, door architraves, and cornices, where wood or common plaster are now used.

I am no advocate for the copyism of any particular type of work, but I confess I should like to see London ceilings, especially in good houses, carried out somewhat after the manner of the delicately designed and beautifully modelled examples of the Brothers Adam, as carried out by them in the end of the last century. Nothing can be more graceful than some of these designs, with their modelled figure and flower enrichments, in very low relief, suggesting all the grace and beauty of delicate Greek ornament, with a treatment essentially fitted for large flat surfaces, and capable of the purest decoration in soft tones like Wedgwood ware.

All this kind of work can be done at comparatively small cost in canvas plaster, and when expense is an object can be repeated with reversible designs in all the principal rooms of a town house; and to a great extent some of this low relief decoration might legitimately be applied in the friezes of the various rooms, in the panels of doors, and in the saffits of staircases.

Messrs. Jeffreys and Co., of Islington, have made some charming leather papers, in low relief, tinted and gilt, adapted from the designs of old Spanish and Italian leathers, which are admirably adapted for wall and ceiling decoration, and would form a pleasant change to the generally perfectly flat surfaces; the ornament being in very slight rounded relief is not likely to hold dust or dirt, and can be cleansed easily with the ordinary feather brush.

The material known as "Lincrusta Walton" may fairly be used for wall surfaces, and some of the designs furnished by the company are very delicate and good.

Thin marble and onyx slabs, and coloured and glazed faïence, may also be introduced into London halls and staircases, as cleanly, healthy, and decorative; but with the knowledge that every house designer of the present day ought to have of the great increase of beautiful materials and useful inventions which are ready to his hand, there should be no difficulty, with proper care and thought, in improving the interiors of our houses, and making them artistically beautiful, as well as more cleanly and more healthy in their design and treatment.

But all this is hopeless if people are content to live under the present condition of things, to look at sanitation, comfort, and art in the house, as mere hap-hazard luxuries.

I can only hope that the views I have set forth in my three addresses may not at least be thought Utopian and impracticable by the bulk of my hearers, and that at least I may have scattered seed which, if it be good seed, shall find a resting-place in some of your minds, and in the progress of time germinate and bring forth good fruit.

In the best Renaissance houses, almost invariably the decoration, furniture, and fittings were designed by the architect, and were made more or less elaborate as the taste and luxury of the age required; and in many of the older towns in France, Italy, and Germany, there are still innumerable examples of the vigour and force of external design in the decoration, panelling, and furniture of the houses, showing the same characteristics as the building, and generally good and harmonious in composition. The fireplaces, ceilings, and panelling of many of our English houses still remain to show how intimately the design of the internal fittings was connected with that of the exterior, and I cannot see why the architects of the present day should not make the interiors, as regards decoration and fittings, as much a part of their study as the mere outside shell work which enframes the rooms; and I am quite certain the taste and knowledge of design which marks the work of every educated architect, fits him especially for the proper completion of the internal fittings, whether in furniture or decoration, and that it will be hopeless to expect truth and unity in any work wherein the construction is entrusted to one man, the decoration to another, and the furniture to another. The same master hand and mind should at least have the general control of the work from "find to finish," as a foxhunter would say; and I believe, if this system pertained now as it did in the best periods of art, we should have better and more satisfactory results in the interiors of our houses, with no material difference of cost to the client. If the architect be, as he should be, the chief or head builder, working in association with the sculptor, the painter, and the upholsterer, the art work of his building will, if he be himself an artist having delight in his work, speak more surely than any words, and we may then hope for better buildings, for higher art work; but he must be able to associate himself with those who can and will aid him in carrying out his thoughts, for, as Mr. Ruskin truly says:—

"Either his own work must be disgraced in the mass of collateral inferiority, or he must raise his fellow designers to correspondence of power. If he have genius, he will himself take the lead in the building he designs. . . . It rests with him either to repress what faculties his workmen have into cunning subordination to his own, or to rejoice in discovering even the powers that may rival him, and leading forth mind after mind into fellowship with his fancy and association with his fame."

And by the example thus set, and the higher knowledge thus created, by association with his fellow-workers in the world, he may help to foster a more healthy feeling of art in home life; and in teaching, with honest endeavour and loving thought, those who are associated with him, exercise an influence over all who come in contact with him, and help, in the progress of time, to provide for higher artistic excellence in all trades cognate to art, and to the carrying into all houses, to some slight degree, the grace and preciousness of beauty and refinement.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON METEOROLOGY IN ITS RELATION TO PUBLIC HEALTH. BY DR. MANN, F.R.C.S.

Several well-known makers of meteorological instruments have contributed to the collection contained in the annexe of the east corridor, and designed to illustrate the science of meteorology, so far as this bears upon matters affecting public health. Watson and Sons, Dring and Fage, Stanley, Denton, Negretti and Zambra, Casella and Hicks, are represented amongst these contributors. They all exhibit the well-known standard forms of instruments devised for meteorological investigations, in conditions of finish and excellence which seem to leave very little to desire, and which certainly do not invite invidious comparisons where all are so unexceptionably good. Instruments for measuring the pressure, temperature, moisture, and movements of the air, the radiation of the sun and earth, the amount of rainfall, the evaporation from the ground, and the generation of ozone, are shown in almost identical forms, and in very considerable numbers, by all these firms. Great ingenuity is also displayed in the attempt to cause all variations in such conditions to record themselves without the tedious and somewhat uncertain intervention of human eyes and hands. Permanent records are now made automatically, at all the leading meteorological stations, of the oscillations of the barometer, the daily march, and maximum and minimum rangings of the temperature, the occurrence and duration of sunshine, the direction and velocity of the wind, and the conversion of oxygen into ozone. These are all important factors in the health-sustaining conditions of meteorology, and therefore appropriate objects for study from the point of view which is taken up by this Exhibition. Several kinds of self-recording instruments are shown by various exhibitors, but not in operation, with the exception of an electrical anemometer set up by Negretti and Zambra, in which a hand upon a large clock-face-like dial may be seen making a spasmodic jump every time the wind has blown over the hundredth part of a mile. The various meteorological instruments in general use are, however, so well known, and have been so recently exhibited again and again, that no sufficiently good reason arises for attempting to repeat an already thrice told tale so far as they are concerned.

But there are some few amongst the instrumental fraternity, possessing a more or less direct application to physiological and sanitary science which call for, or admit, some special attention being drawn to them. Foremost amongst these stands the serviceable little instrument now well known as the clinical thermometer, of which specimens are shown by all the exhibitors. This instrument, as most people are aware, is a short mercurial thermometer, having a scale which extends only from 95° to 113° of Fahrenheit, and a column of mercury which expands under the application of heat, but remains stationary in the glass tube as a permanent register when the heat is withdrawn, to indicate the exact temperature to which it has been exposed. Mr. Casella first constructed a serviceable thermometer of this character, some few years ago, by the happy expedient of introducing a small quantity of air into a fine column of mercury, in such a way that it constitutes a gap in the continuity of the column, which on that account remains in the position into which it has been pressed by expansion under increments of heat when the temperature is once more lowered. When in use, the bulb of the thermometer is placed in the arm-pit, or some other convenient recess of the living body, and is allowed to remain in that position for a few minutes. A somewhat novel form of this instrument is exhibited by Mr. Hicks, in which what should be the bulb is a lengthened out cylindrical and very narrow receptacle of mercury, that takes up the full temperature of the surrounding parts with which it is placed in contact very quickly, and so effects a not inconsiderable saving of time to the observer. Other forms of the instrument have oval and ring-shaped tubes of small calibre in place of bulbs. A notable illustration of the refined care which it is thought worth while to devote to the perfecting of these serviceable instruments, is furnished in the circumstance, told by the Royal Meteorological Society in a digrammatic form, that whereas some eleven years ago about 1,200 of these clinical thermometers were examined annually, and certified as to their character, by the Observatory at Kew, as many as 8,500 are now passed through the ordeal in the same interval of time. The important fact that the construction of this useful instrument has been very materially improved within the last fourteen years is also diagrammaticably indicated.

The clinical thermometers of the best makers are graduated to the fifth part of a degree. A standard thermometer, with the more extended scale for air temperature, is exhibited by Mr. Hicks, in which the graduation is carried to the fiftieth of a degree of Fahrenheit. Mr. Denton furnishes another illustration of the careful work that is now given to meteorological instruments. Some fifty thermometers, which had been examined at Kew immediately after their construction, were inclosed under seal for twelve months, and then tested again, and the Kew certificate attached to them states that their readings had not in any way changed from alterations of internal capacity. All meteorologists will be aware that this constitutes a very severe test of excellent workmanship.

Negretti and Zambra construct their clinical thermometers with the column of mercury and the graduations of the scale brought into very prominent relief against a back-ground of white enamel; this is a great practical advantage where the varying length of a fine column has to be noted. Most of the eminent makers have recently introduced a further advantage in the same direction, by the ingenious plan of fashioning the glass tube which contains the mercury, so that it acts as a magnifying lens when the liquid column is looked at. Some very fine air temperature thermometers are here shown, in which sensitiveness is secured by giving the reservoir in one form the shape of a gridiron of light parallel bars, and in another that of a cork-screw like spiral. Mr. Watson exhibits in his case a curious form of what he terms a "balanced thermometer," in which the extremity of the stem travels along an arc-shaped scale, under the shifting of the position of the weight as the mercury expands into, or shrinks back from, the elongated stem of the tube, and so affords an indication of the varying temperature that can be at once read off by a rapid glance from the opposite side of a large room.

There is one of the self-recording instruments that appears in this department of the Exhibition which has hardly yet lost its claim to rank as a novelty; the beautiful piece of apparatus, namely, which has been contrived to register the occurrence and duration of sunshine. It essentially consists of a transparent globe of glass which acts as a burning lens, however the sunshine may fall upon it, and so leaves a charred track upon any combustible substance spread out at a proper distance from the opposite portion of the sphere. The attempt to get a permanent register of the occurrence of sunshine by this device was first made by Mr. J. F. Campbell, of Islay, something like thirty years ago, but in those early days the instrument was of a very rude form of construction. It consisted of a hollow sphere of glass, filled with water, and supported within a bowl of wood at such a a distance from it that, whenever the sun shone upon the globe, a charred track was branded in upon some portion of the wood. This instrument was brought into use by the Board of Health in London, in 1857, and a new bowl of wood was provided for the sunshine to burn every six months, the old one being laid up as the record of the burning capacity of the sunshine during the period it had been in use. The water-filled globe was, however, very soon superseded by a solid sphere of glass. The very beautiful and perfect form into which this originally rude instrument has developed, is shown in a case standing on the left-hand side of the annexe, where it is marked as the sunshine recorder exhibited by Mr. Lecky. The instrument has there assumed a form which was suggested by Professor Stokes, in 1880, and which has been well worked out by its exhibitor. It will be observed that a globe of glass, four inches in diameter, rests upon a pillar of brass, in such a way that sunshine falling upon it throws its burning focus upon a strip of cardboard carried in a concave brass frame. A four-inch sphere of glass forms a focus for parallel rays, just 0·89 of an inch away from its outer surface. The cardboard is, therefore, held at this distance away from, and concentric with, the surface of the sphere, whilst the sun is performing its diurnal march across the sky, and a charred track corresponding with its duration is left upon the card in the form which is exhibited in Mr. Leeky's case. The cardboard is blue tinted, and scored by white graduation lines which mark half-hourly progresses of the focal spot, and the carrier permits the strip which is to receive the focal mark to be inserted in grooves higher or lower in the frame, accordingly as the sun reaches a lower or higher noontide altitude in the sky at each particular season of the year. A fresh strip of cardboard is inserted in the carrier for each day. The ingenious way in which the grooves are arranged in the frame, so that six grooves permit a zone 48 degrees broad, corresponding with the highest summer and lowest winter noontide of the sun in the sky, to be brought into play, is well worth the visitor's notice. The simplicity with which this essential condition is secured without in any way interfering with the fixed stability of the instrument is a great triumph of constructive ingenuity. The instrument may be seen burning its track upon the cardboard, and accomplishing its appointed work on any sunny day in the typical climatological station of the Royal Meteorological Society, which has been established in the south-east corner of the open garden which intervenes between the Central Gallery and the Albert-hall.

The practical use to which this sunshine recorder is capable of being put, is well illustrated in some large wall-charts exhibited by the Royal Meteorological Society. In one of these, transverse red tracks indicate the prevalence of sunshine for every day for three years, extending from 1881 to 1883. The ruddy spaces in this chart which catch the eye, draw the attention to the times when sunniness was predominant at Apsley Guise, in Bedfordshire, the place where the records were made. Thus, for instance, the last week in March and the first week in April, 1881, are seen at a glance as having constituted a period of almost uninterrupted sunshine. It is not possible to overrate the importance, in a meteorological and sanitary sense, of having comparative records of sunniness at different stations and times, such as this instrument supplies. During the short period in which the instrument has been at work, Hastings has proved to be the South of England station most favoured by sunshine. Southbourne, a sea-cliff district, situate midway between Christchurch and Bournemouth, stands next. It will scarcely surprise the *habitués* of London to learn that its purlieus in the matter of sunshine fare the worst. It appears that during the last year, 1883, there were 1,825 hours of sunshine at Hastings, 1,647 at Southbourne, 1,504 at Marlborough, 1,484 at Kew, 1,368 at Croydon, 1,241 at Greenwich, 1,228 at Brixton, and only 974 in the City of London. The number of hours of possible sunshine at Kew, or in other words the number of hours during which the sun is there above the horizon in a year, is 4,380. Thus it may be roughly said that Hastings gets nearly one-half its possible hours of sunshine, and the City of London very little more than one-fifth.

It should be remarked that Negretti and Zambra exhibit the same form of sunshine-recorder that has here been described, and that Casella has sent a somewhat different form in which the carrier of the registering strips of cardboard is adjusted to the seasonal altitude of the sun for each day.

The Royal Meteorological Society indicates the mean temperatures of the months of January and July in London for one hundred years. The lowest mean for January occurred in 1795, and was 25·5° Fahrenheit. The highest mean for January 47°, in 1796. The lowest mean temperature for July was 55·5° in 1816, and the highest 68° in 1778 and 1859.

The Society also marks in a similar way the mean annual temperatures, and the lowest and highest temperature for several important and well-known places. The mean annual temperatures in this interesting series of records most worthy of note are for Ferozepore, in the Punjaub, 95°; Calcutta, 81°; Hongkong, 75°; Cairo, 71°; Rome, 60°; Constantinople, 58°; Pekin, 53°; St. Petersburg, 40°; Hammerfest, 35°; Fort Enterprise, 14°; Boothia Felix, which upon this ground should surely be rather marked as "infelix," 5°; and Melville Island, zero.

The highest temperatures recorded for the several stations are for Murzouk, in Fezzan, 135°; Bagdad, 120°; Cairo, 116°; Jerusalem, 102°; Greenwich, 97°; Moscow, 90°; Falkland Isles, 75°. The lowest recorded are, for Barbadoes, 72°; Singapore, 66°; Bombay, 53°; Jerusalem, 25°; Constantinople, 17°; Greenwich, —10°; Chicago, —30°; Moscow, —53°; Melville Island, —65°; Fort Reliance, —70°; and Werchsjansk, —81°, which outlandishly named, and hard to identify, place, so far seems to possess the unenviable distinction of being the coldest spot upon the earth; unless a station nearer home may be inclined to contest with it the frozen supremacy, upon the ground of an observation that has been made since these comparative records were drawn up. On the evening of the 13th of June last, in the Lecture Theatre of the Royal Institution of Great Britain, in Albemarle-street, a temperature of—252° Fahrenheit, with alcohol turned into a kind of viscid ice, and with oxygen gas congealed into a liquid, was recorded. In this instance, however, it must in meteorological fairness be said the result was brought about by human as well as by natural agency; the spell of boiling solid carbonic acid having been used in the final depression of the temperature. The event is, nevertheless, worthy of a passing mention in this place, as it is probably a record of the greatest cold that has ever yet been brought under the rigid examination of science.

Amongst the other illustrations submitted by the Royal Meteorological Society, is a chart drawn up by one of its Fellows, Mr. Edward Mawley, the author of the annual digests of "Weather observed in the neighbourhood of London," and showing in a graphic form the relation of low temperature to high rates of mortality. A black tracing, or so-called curve in his diagram, expressing the death-rate in London, is seen to rise, as a red tracing, expressing the temperature during the period of exceptional cold which prevailed from November, 1878, to October, 1879, is seen to fall. The highest monthly mortality, consisting of 2,085 deaths, appears to have immediately followed the greatest cold occurring in February. When the mean monthly temperature rose to 45°, the monthly death-rate fell to 1,600.

The Meteorological-office has covered the wall opposite to the one occupied by the Royal Meteorological Society with a series of large charts, some of which not inaptly illustrate the direction in which meteorological science is moving. The first of the series shows the eleven districts into which the British Islands are distributed for climatological purposes. The next five furnish a record of what are termed the weekly increments of accumulated temperature expressed in day-degrees. In reference to these charts some words of explanation are certainly needed. They are drawn up for five out of the eleven climatological districts. On looking at these maps the observer is perplexed by a series of red step-like squares sidling away from the left corner below to the right hand corner above, where, if he takes for his examination the one which relates to the South of England district, he will find that they mount up by weekly stages to a height which is marked as 3,200 day-degrees at the end of the year. This upward ascent is made from a transverse line which represents 42° of temperature according to Fahrenheit's scale, and which is distinguished upon the chart as the base-line. Below the base-line there is a somewhat similar display of diagonally descending blue steps. The explanation of this hieroglyphical record is, that it is an attempt to express what is ordinarily spoken of as mean temperature in a more exact and serviceable form. The transverse base-line is to be taken to represent the degree of temperature at which, according to De Candolle's researches, the growth of vegetable structures is started in European climates. The amount of the excess of temperature above this initial line is expressed in a quantity arbitrarily fixed, and termed a day-degree, in reference to the mechanical engineer's analogous unit of a foot-pound. The day-degree means a temperature of one degree Fahrenheit sustained throughout a period of twenty-four hours. An elaborate mathematical investigation has shown that the quantity of temperature which is so maintained may be ascertained by taking the difference, in degrees, of the highest and lowest temperature of twenty-four hours, and by multiplying that difference by a fixed co-efficient calculated out for each month. The red quadrangular space in each vertical column of the chart gives the accumulated temperature of seven days arithmetically calculated out in this way, and fused together into the day-degree equivalent for the week. The red space is thus the measure of the temperature for the week, which was available for the maintenance of vegetable growth. The next column towards the right shows the amount that was added to the first, in a similar way, in the second week, and so for the succeeding columns, until the 3,200 day-degrees indicated at the top of the last column on the right is reached for the sum-total attained at the end of the year. Three thousand two hundred such units of heat, uniformly maintained through twenty-four hours, were supplied during the year for the stimulation and maintenance of vegetable growth. The blue spaces below the base-line indicate, in a similar form, the degrees of heat maintained uniformly for the day, which were below the intensity required for the stimulation of vegetable growth, and which were furnished during the colder portions of the year. There are no blue spaces, it will be observed, for the portions of the year during which the temperature does not fall below 42°. The day-degree is thus, it will be understood, one degree Fahrenheit of either excess or defect of temperature above or below 42° that is continued for 24 hours, or the number of degrees that have been continued for any proportionally less number of hours.*

The charts thus require some little exertion of thought before they can be understood, but the information which they convey, when this thought has been given to them, is of a very valuable kind, and capable of being turned to good practical account. Thus, for instance, each particular crop grown under

* The foot-pounds of mechanical work, it will be remembered, may be expressed either as the number of pounds that have been raised one foot high, or as the number of feet that one pound has been raised. So the number of day-degrees of accumulated temperature may be expressed as the number of days one degree of increment of temperature has been maintained, or the number of degrees that have been maintained through one day. The full explanation of the process, by which the day-degrees of accumulated temperature may be calculated out, is given in a paper by Lieut.-Gen. Strachey, R.E., F.R.S., printed in the second appendix of the "Quarterly Weather Reports" for 1878.

cultivation for food purposes has its own base-line, at which productive assimilation of nutritive matters begins, and its own number of accumulated day-degrees of heat which corresponds with the occurrence of its harvest. By marking and comparing the relative march of accumulation of heat at different districts or stations, the time when harvest may be expected at each may consequently be anticipated and predicted.

The diagrams also show that there was about 1,500 hours of bright sunshine, and 28½ inches of rainfall in this district in the year, for which the register of accumulated temperature is given.

The remaining twelve charts from the Meteorological-office represent the temperature of the surface of the sea immediately surrounding the coast of the British Islands, for each month of the year. The temperatures are given from the lowest found in February, 27°, to the highest found in August, 64°; and they are expressed by a deep blue tint for the coldest, shading off gradually into lighter, and ultimately passing into deep red for the highest.

EDINBURGH FORESTRY EXHIBITION.

Part III.

Mention has already been made of the establishment, in 1862, of a department of Forest Conservancy for the whole of India, under Dr. Brandis as Inspector-General. The department now consists of an inspector-general, 10 conservators of forests, 51 deputy conservators, 34 assistant conservators, 22 sub-assistant conservators, and 113 rangers. The department includes British Burmah. There are separate establishments for the Governments of Madras and Bombay as follows:—Madras—2 conservators, 14 deputy conservators, 8 assistant conservators, 8 sub-assistant conservators, and 44 rangers; Bombay—3 conservators, 6 deputy conservators, 19 assistant conservators, 13 sub-assistant conservators, and 26 rangers. The area of reserved forests in India is about 46,000 square miles; that of the unreserved has not yet been determined; while there are large nurseries and plantations for the rearing of trees to be employed in reafforesting denuded districts.

The cost of the establishments in salaries, travelling allowances, contingent expenses, &c., is £190,000 per annum; and the net revenue, after deducting all charges for salaries, working expenses, &c., is over £300,000.

The trees chiefly cultivated in the different provinces are as follows:—Bengal—toon and teak; North-West Provinces—deodar, walnut, and horse-chesnut; Punjaub—deodar, sissu, kikar, ber, and mulberry; Bombay—teak; Burmah—teak; Assam—caoutchouc; Madras—teak, red sanderswood, casnarius, and eucalyptus; Coorg and Mysore—teak and sandalwood; Berar—teak and babool; Oudh—sal.

The Government of India has sent to this Exhibition an *Index Collection*, embracing no fewer than 1,064 different exhibits, which is divided into six sections:—First, gums and resins; second, dyes, tans, and mordants; third, fibres and fibre-yielding plants; fourth, oils, seeds, perfumery and soaps; fifth, medicinal products; and sixth, timbers—the latter alone numbering 800 different species.

Sir George Birdwood writes:—"We have an illustration in Northern Afghanistan of how misgovernment may convert a once fertile and wealthy country, such as Afghanistan was under the commercial rule of the Buddhists, into an inhospitable desert, and all India, within the solstitial line, would probably have, by this time, been reduced to the same condition, but for the English conquest of the Peninsula. When, about ten years ago, Mr. Griffin W. Vyse was executive engineer at Dheera Ghazee Khan in the Punjaub, he planted over a million timber trees along the frontier joining India to Afghanistan and Beloochistan, and scattered five tons of their seeds broadcast everywhere; and in 1877, at least fifty per cent. of these seeds had sprung up into flourishing young trees. Great zeal was also shown by Mr. E. E. Gladstone, who was an assistant commissioner in the Punjaub at this time, in encouraging the planting of trees along the base of the Sulieman range. The Punjaub Government have also formed a forest of trees several miles in extent at Chunza Munza, near Lahore; and the result of all this planting on our Indian north-west frontier is already being felt in the gradually increasing annual rainfall in the Southern Punjaub, Southern Afghanistan, Northern Beloochistan, and Northern Scinde."

India is very fully represented at this Exhibition, in fact the whole of the southern division of the central transept has been devoted to the display of the forestal productions of that great country, which have been arranged under the direction of Colonel Michael, C.S.I., the Commissioner from the Indian Government. The walls have been hung with more than a hundred maps, containing the results of the survey of the forests of India, executed under the direction of Major Bailey, R.E. When completed, these maps, done on a scale of four inches to the mile, will enable the forest officers not only to put their hand on every tree of importance, but they will form an important instrument in the hands of the conservators in the details of forest management. With the maps are hung large photographs of full-sized specimens of all the important trees of the Continent. Then there are pictures showing the woodmen at work in the forests, of elephants working in removing large logs, and of the rafts of teak, &c., being towed down the large rivers, such as Rangoon, to the sale yards. There is also a large collection of carved Indian work in the shape of cabinets, inlaid boxes, gong stands, doors, panels, furniture, book racks, and vases, contributed by the South Kensington Museum, the Museum of Science and Art, Edinburgh, Messrs. Proctor and Co., and others. There are many specimens of the tapestry and carpets of the Punjaub; but the bulk of the space in the courts is taken up with the collections having more direct reference to forestry. Each province sends a complete assortment of the woods found in the indigenous forests, together with sets of the implements employed in forest work by the natives. Some of them have been built up as trophies; all of them show the grain of the timber in its natural state, and also as polished.

In the island of Ceylon much injury has been caused to the dense woods and jungles by reckless clearings for coffee and other gardens; but forest reserves are now being formed, and a Department of Conservation has been organised to stop further devastation. Mr. J. Alexander sends complete collections of the products of the cocoanut and palmyra palms, and of cinchona barks with specimens of flowers.

Although the island of Singapore is remarkable for its luxurious vegetation, a large area of its indigenous forests has been sacrificed to the demands of the pepper and gambier planters, and the climate has consequently deteriorated. The Government of Singapore sends a collection of specimens of woods from the Malay Peninsula.

His Highness the Maharajah of Johore sends a complete representation of the forest products of the Singapore Straits Settlements and the Territory of Johore in the Malayan Peninsula, which form a special attraction of the Exhibition. The specimens of timber trees from the Johore forests number 350, and embrace teak, eaglewood, the sago palm, camphor, gambier, gutta-percha, which was originally discovered in the forests of Johore, rattans, &c. Of forest products there are the gum from the camphor tree, which fetches about £25 per lb. for the finest samples in the Chinese market; Dammar gum, from which a valuable varnish is manufactured; incence gums, gambier, caoutchouc, pepper, oils, seeds, and barks, tea, coffee, and cocoa. Methods of Malay forestry are illustrated by a complete set of native tools and implements, some of them very curious, and the rattan canes with which the natives build their houses and boats.

Of other Asiatic countries which are represented at the Exhibition, special mention must be made of the large display from Japan, which fills both divisions of the eastern annexe. A system of forestry has been practised in Japan for centuries, and when the Dutch first landed in that country they found that wherever a tree was cut down another had to be planted in its place. Now the forest laws have been codified, and a Forest Department established at Tokio, with sub-offices in each of the forty-four districts into which the Empire is divided. The German system of cropping has been introduced, and hard-wooded trees from Europe and other parts of the world have been acclimatised.

The Japanese exhibit is divided into six classes; in the first are drawings illustrating the mode of felling trees and transporting timber, tools, machines, and models; in the second, timber specimens with pressed leaves, and a chart illustrating the natural distribution of forest trees in Japan; in the third, gums and resins, lacquer juices, drugs, spices, fruits, barks, &c.; in the fourth, specimens of ornamental woods, fencing materials, &c.; in the fifth, wood-carving blocks for wood engravings, specimens of forest flora, insects, &c.; and the sixth, parasites, lichens, young shoots of trees introduced from foreign countries, and a chart illustrating the geological formation adapted to the growth of trees in Japan. On the centre tables are disposed blocks, slabs, and sections—many hundreds in number—of all the indigenous trees of Japan. Many are in the rough, others are planed smooth. The display of ninety-six cabinet-making woods of firm texture and beautifully figured has been greatly admired. Some of these are thus described—The *Magnolia Kobus*, white speckled with little brown spots; *Temstronia Japonica*, a rich purple; *Phellodendron aumsense*, with a yellow ground and brown curls and rolls; *Rus*, a deep orange; six varieties of maples, with the figures on as many different ground colours; the *Cryptomeria Japonica*, waved, curled, eryed on yellow and darker grounds; *Juniperis Chinensis*, with rich brown veins and curls on a red ground; *Podocarpus*, a wavy drab; *Fagus sylvatica*, like white marble streaked with the purest black; *Zelkowa Keaki*, wonderfully mottled and of the most varied figures.

Of the various British Colonies represented at the Exhibition, mention must be made of British Guiana, the Cape, British Columbia, Cyprus, Gambia, Guatemala, Honduras, Mauritius, New Zealand, St. Vincent, Sierra Leone, Tobago, &c. The Borneo Company also sends collections of timber and ornamental woods. The Government of Canada was merely represented by two maps showing the limits of its forest trees. The value of fir logs annually exported from British North America is nearly a million, of oak a quarter of a million, and other timber about £200,000; while the sawn fir from the same territory reaches nearly three millions sterling. New Brunswick shows a collection of native woods in rough and finished state, and loan collections of polished woods and forest leaves, as well as tools, &c. There are $17\frac{1}{2}$ million acres in the colony, two-thirds of which are said to be virgin forest, consisting of spruce and pine, black birch, maple, beech, ash, elm, and oak. As yet no system of conservation has been introduced, and a great part of the forest land has been acquired by the New Brunswick Land and Lumber Company.

Denmark, which next to the United Kingdom is the worst wooded country in Europe (see *ante* p. 995), was almost alone among European countries in exhibiting its forestal resources on this occasion. In 1805, effective measures were taken to institute a proper system of forest management. The total forest area is only 498,000 acres, of which 26 per cent. is under the crown, 9 per cent. belonging to public institutions, 29 entailed estates, and 36 per cent. freehold estates. From 1790 to 1880, the Crown forests have been increased by planting from 58,000 acres to 112,000 acres. The 435,300 acres of older woods consist of 60 per cent. of beech, 7 per cent. of oak, 6 per cent. of other hard wood, and 21 per cent. spruce and fir. Nearly the whole of the forests consist of large trees. Of the total yield of the forests, 19 per cent. is used for implements, furniture, buildings, &c., and 81 per cent. for firing. Denmark is, next to England, the country which consumes, per individual, the largest quantity of foreign wood in Europe. Of hard wood for implements, furniture, &c., it can export a portion, but it does not produce 10 per cent. of the spruce or fir wood it uses.

Most of the countries which exhibit send examples of forest literature, and the manufacturers of wood pulp for paper in England, France, Germany, Norway, Sweden, Denmark, and New Brunswick, show specimens of their products, models of pulping mills, and the paper made from the pulp.

The grounds adjoining the Exhibition buildings contain a large number of sheds for machinery, foresters' huts, and collections of growing trees, mostly conifers. In a remote corner is the Manitoba farm, shown by the Canadian Pacific Railway Company, which contains a pioneer's tent and his log home, with two rooms and a stable. Samples of wood, of fencing, of household furniture, and all the necessaries required by the settler are here exhibited.

RUSSIAN PRODUCTS AND INDUSTRIES.

The following particulars relating to the products and manufactures of Russia are extracted from a report, by the Belgian Consul at Moscow, on the late Industrial Exhibition held in that city.

Fuel.

Peat.—Vast peat deposits are met with in Poland, and in the governments of Moscow, Vladimir, Nijni-Novgorod, Riazan, Tambov, and Orel. The peat is found by analysis to contain as much as 45 per cent. of carbon.

Lignite, containing 40 per cent. of carbon, is met with to a considerable extent in the governments of Kiev and Cherson. The quantity extracted yearly amounts to 16,320 tons, but would be much greater if it were not for the distance between the deposits and the main roads.

Coal.—The production of the Polish basin, entirely consumed in the country, was 1,142,400 tons in 1880; it is capable of great extension on the completion of the railway between Dombrova and Ivangorod. The sub-Moscovite coalfield, in which there are twenty collieries, is only worked at present in the governments of Toula, Riazan, and Kalouga. The coal is not, as a rule, of good quality, as it readily crumbles when exposed to the air; it is not therefore capable of transport, but is consumed on the spot. The best, containing 71 per cent. of volatile matter, is found in the mines of Mouravina and Pobiedino, in the government of Riazan. The total production of the sub-Moscovite coalfield was 587,520 tons in 1880. In the Donetz basin, containing coal of great purity, there are more than 200 collieries. Anthracite, containing 90 to 94 per cent. of carbon, is worked to a considerable extent in the south-west of the basin, and in the government of Ekaterinoslav and the Don Cossack provinces. The production of the Donetz basin in 1880 was 1,403,520 tons, including 473,280 tons of anthracite. The coal of the Oural basin, worked only to the north, in the government of Perm, contains 69 per cent. of carbon. The production amounted, in 1880, to 114,240 tons. Although the Russian collieries generally are worked more and more actively every year, the development of the Donetz basin is still retarded by the insufficiency of means of transport, and the absence of markets in certain districts, where coal is found on the spot and sold at a lower rate, beside the effect of foreign competition at the principal seaports. According to official statistics, no less than 1,876,000 tons of coal—more than one-third of the total production of the empire—were exported during 1880.

Mineral Oil.

In 1860, the production of raw naphtha was 500,000 poods (8,000 tons), which increased to 3,500,000 poods (56,000 tons) in 1880, while the price per pood (36 lbs.) fell from 0·4 to 0·1 rouble (1s. 3d. to less than ½d.). The naphtha of Baku generally contains only from 25 to 35 per cent. of illuminating oil; so that, in 1860, no more than 10,000 poods (160 tons) of petroleum were produced; but in 1880 the figure rose to 7,000,000 poods (112,000 tons), the price per pood falling from 4·9 to 0·4 rouble (15s. 9d. to 1s. 3d.).

The residue from the distillation is used for firing the boilers of the steamers on the Volga and the Caspian Sea, and also for making gas; while from the tar left by the gas are obtained benzole, lubricating oil, anthracine, and asphalte.

The petroleum is sent by steamers from Baku, Astrakan, whence it is conveyed in flat-bottomed barges up the Volga to Tsaritsine. The working of naphtha is stopped during the winter months, on account of the interruption of the Volga navigation, so that large depots are necessary. The increase in the production of naphtha is due to various causes—the discovery of new springs, the discontinuance of State working, and the abolition of the tax on distillation per retort per day. When the railway between Baku and Batoum is finished, the petroleum can be sent without interruption to the various ports of the Black Sea.

Metals.

Iron.—The iron ores of the Moscow basins, which are generally brown peroxides, contain from 50 to 60 per cent. of metallic iron, with a small per-centage of sulphur, phosphorus, and manganese. They are worked in the governments of Nijni-Novgorod, Toula, Kalouga, and Riazan, while, in that of Vladimir, a carbonate of iron is found containing from 35 to 40 per cent. of iron with no sulphur or phosphorus whatever. Carbonates and peroxides are present in the south; and red hematites, containing from 59 to 67 per cent. of iron, in the Cherson district. Masses of magnetic iron are also found on the eastern slope of the Oural mountains. At Blogodatt, the ore contains from 52 to 58 per cent. of metallic iron, while those of Vissokaia and Magnitnaia contain from 63 to 69 per cent. At the Imperial Ironworks in the government of Perm, and those of Prince Demidoff, the ore is smelted with charcoal, but without flux, and yields a pig-iron of such excellent quality that it may be at once run into castings.

Copper.—The quantity of copper ore raised in 1880 amounted to 195,518 poods, or 128 tons. The rich ore in the government of Perm contains from 6 to 8 per cent. of copper, and the poor ores about 3 per cent.; while those in the governments of Oufa and Orenbourg do not exceed 3½ per cent. Only 195,500 poods, or 3,128 tons, of ingots were produced in 1880.

Zinc.—Ores containing from 8 to 14 per cent. of zinc are found at Bendzizi in the government of Petrokoff, and at Kousch in that of Keltzel, in Poland. The mines have not, however, been worked very actively, owing to their slight yield of metal. Since 1880, a deposit of blende has been worked in the government of Abo, in Finland.

Lead.—The production of lead in 1880 only amounted to 1,142 tons. In fact, lead ores are only worked for the copper, silver, and gold with which they are associated. Some specimens from Perm were found to contain 10 per cent. of lead, and 3 per cent. of copper, while 100 poods (1 ton 12 cwt.) of ore contains 1½ zolotnick (92½ troy grains) of silver; and 1½ lbs. of gold is extracted from a pood (36 lbs.) of silver. Lead ore is also met with in the North of Russia, in Finland, and in the government of Archangel. The largest mines are situated at Laghlin, in the Provinces of the Terek Cossacks, in the Caucasus.

Quicksilver.—In 1881, a deposit of cinnabar was discovered in the district of Bacmuth, in the government of Ekaterinoslav, which was found by analysis to contain 12 per cent. of mercury; and a Russian company has been formed for working it.

Silver.—The quantity of silver extracted from argentiferous lead ores at the Government works, near the Altaï mountains, in Siberia, was 616 poods (under 10 tons).

Platinum.—The platiniferous sand from the mines of Prince Demidoff, contain from 1½ to 2 zoltnicks (92½ to 123½ troy grains) per 100 poods (1 ton 12 cwts.) of sand; but the production in 1880 was only 179 poods (under 3 tons) for the whole of Russia. The manufacture of articles in platinum is a new branch of industry in this country.

Gold.—Traces of gold are found in Irkoutsk, about 20 ft. below the surface, where 100 poods (1 ton 12 cwt.) of sand yield 1½ zolotnick (92½ troy grains), while at 24 metres as much as 2½ zolotnicks (154 grains) are obtained from the same quantity. At another deposit, in Siberia, nuggets have been met with weighing from 70 to 90 zolotnicks (9 to 11½ troy ozs.). Auriferous sand, in strata of 45 to 90 centimetres (1 ft. 6 in. to 3 ft.) thickness, also exists in the Oural, the richest being those in the government of Orenbourg. In the government of Perm there are auriferous quartzites of great richness, 100 poods (1 ton 12 cwt.) of ore containing as much as 5 zolotnicks (308 grains). The quantity of gold obtained in 1856 was 1,733 poods (27¾ tons), and in 1880, 2,641 poods (42¼ tons), the total quantity from 1856 to 1880 inclusive being 47,852 poods (765½ tons).

Cast and Wrought Iron and Steel.

This branch of industry has greatly increased in importance of late years on account of the raising of import dues, the construction of numerous railways, and the orders and subventions of the Government. The country is, however, far from supplying its own demand; and large quantities of manufactured iron and steel are exported, notwithstanding the Customs' dues, which are almost prohibitive. The excellent quality of the Oural ores give the irons produced in that region a marked superiority over those of the rest of Russia. The Oural is, besides, the chief centre of the Russian iron trade. The nail trade has made great progress during the last few years. The works are, as a rule, well stocked with plant; and hand-made nails are now only produced at a few of the Oural works.

Machinery.

The workshops of the Imperial Technical School at Moscow were founded with the special object of giving pupils the means of practically studying construction; and all the railway companies have also their technical schools. At the end of 1880, the 21,240 versts (14,082 miles) of way were provided with 5,690 locomotives, 7,230 carriages, and 112,000 goods wagons. Most of the machines made in Russia are imitations of those in other countries. Many of the works are able to produce engines up to 30 horsepower, but not larger, while the prices are very high. The production of machines has greatly increased of late, owing to the subsidies and prizes given by the Government. The number of works increased from 155 with 46,025 hands in 1876, to 237 with 856,105 hands in 1880. The value of the locomotives made in 1880 was 7,099,953 roubles (£1,124,159); and that of those which were imported in the same year, 2,673,385 roubles (£423,286). The value of machines imported in 1880 is 18,748,939 roubles (£2,968,582); and that of parts only of machines, 21,355,786 roubles (£3,381,333).

There are 340 works where agricultural implements are made, to the value of 5,000,000 roubles (£791,666) annually; but these are not sufficient for the requirements of the country. In 1881, implements to the value of 4,487,861 roubles (£710,578) were imported free of duty.

Ceramic Ware and Glass.

Earthenware and Porcelain.—The raw materials for the manufacture of porcelain are imported from England and Finland, while clays for earthenware are found in the governments of Tchnernigov, Novgorod, Cherson, and Ekaterinoslav. The chief markets are Moscow, St. Petersburg, and the fair of Nijni-Novgorod. According to latest statistics, there are fifty-one potteries, employing 9,000 hands, for a production of over 3,000,000 roubles (£475,000).

Glass.—Crystal manufacturers try to imitate the productions of Baccarat, without, however, having succeeded up to the present time, as their wares are deficient in whiteness and purity. The raw materials are found on the spot, except soda, which is imported. The products are sold in Russia and in Eastern countries. There are only three manufactories of looking-glasses, as the want of trained workmen and foreign competition hinder the increase of this industry. In the process of silvering, nitrate of silver is substituted for mercury, thus effecting a great saving. Window glass is not made in large quantity, nor is it very good. A small quantity of coloured glass is made for church windows.

OLIVE CULTIVATION IN TURKEY.

Consul Heap, of Constantinople, in his last report, states that olives grown in Turkey receive little cultivation after the young trees reach maturity. At the end of the autumn, or early in winter, a trench of two to three feet in diameter, and from eighteen to twenty-seven inches in depth, is dug round each young tree, and filled with manure, more or less rich, according to the age and strength of the tree. The manure is well covered with soil, so as to prevent it being disturbed, and to keep it as long as possible in the position best fitted to feed the roots of the tree. The ground between the trees is generally neglected. The olive tree generally comes into full bearing about its twenty-fifth year when it has been grown from slips, but when grafted it yields abundantly between its eighth and twelfth year. In both cases it continues to produce largely, every alternate year, for about fifty or sixty years, and if cultivated it will continue to yield, though less largely, up to the age of one hundred years. Under ordinary circumstances a young healthy tree that has reached maturity will produce about eighty-two pounds of fruit in a poor year, and with careful cultivation the same tree will yield in a good year double that quantity. The trees vary in yield every alternate year. An acre will contain 120 trees, and each tree will yield an average of 100 pounds of fruit, so that the produce per acre will be about 12,000 pounds, and as it takes about sixty pounds of fruit to produce one gallon of oil, the yield per acre would be two hundred gallons. When olives are intended for pickling, a small portion is plucked while green to be pickled in that state, but the larger portion of the fruit intended for preserving is gathered when it has fully ripened and has turned black; in Turkey it is preferred in this state, and there is a very large consumption of black pickled olives. To preserve black olives for the table, the fruit is packed in casks or boxes with a large layer of common salt, three quarters of an inch thick at the bottom. On this is laid a layer of olives, about two and a-half to three inches in depth, upon which a light covering of salt is sprinkled, and so on until the cask or box is filled, the upper layer of salt being deeper than the others except the lower one. The staves of the cask are left loosely bound to allow the bitter water from the olives to drain off. In preserving green olives, the fruit after being washed is packed in cases in its natural state. The casks have a small hole bored in the bottom to allow the water to run off slowly. They are filled with olives to about three inches of the top, and the cask is then filled to the brim with fresh water once in twenty-four hours, until the bitter taste of the fruit has almost passed off. The hole in the bottom is then plugged, an aromatised pickle is poured on the fruit, and after the pickle has taken effect, a little oil is added, to soften the olives and reduce any bitterness that may remain in excess of what is required to give them piquancy or an agreeable flavour. In extracting the oil, the method practised in the interior of Turkey is the same as was employed in the earliest ages. The fruit is collected in a large receptacle near the mill where the crushing is done; this mill is simply a large circular shallow tank with an upright beam in the centre, which runs through a large stone and serves as a pivot around which the stone revolves. A horse harnessed to a horizontal pole attached to the stone sets it slowly and laboriously in motion. An improved apparatus has lately been introduced; this consists of two stones attached to the horizontal pole, and which are dragged round with it. When a sufficient quantity of the fruit has been thrown into a tank the machine is set in motion, and a man precedes the horse with an iron pole to push the olives under the stones. After a short time, about two gallons of water at boiling heat are poured in to assist the action of the stones, and more is added as required, until the mass acquires the consistency of a thick paste. The mass is then put into a large jar and conveyed to the press, where it is kneaded with more hot water into a square cloth of coarse material, which will bear the greatest power of the press without bursting. The paste is then formed into a square flat mass, the cloth being folded neatly over it, and tied with a string attached to each corner, and it is then replaced in the press. The press is turned down by means of a hand lever, and when more power is required, a rope is carried from the lever to an upright rotary beam at some distance, which is rapidly turned. The oil and water which are expressed run into a trough roughly hewn from wood. This trough is divided into two parts longitudinally by a partition, which comes up to about two inches below the level of its sides, so that when the oil and water run in together on one side of the partition, the oil coming to the surface floats over to the other side, while the water is conveyed away by a pipe, placed at the level at which it is desired to maintain the water within the trough. After the press has been screwed down as far as it will go, it is loosened, and hot water is poured upon the pile to wash off any oil that may remain on the cloths, and they are kneaded without being unfolded. More boiling water is poured upon each package, and they are again placed in the press, to be again removed and undergo for a third time the same process until no oil remains. The oil comes out a light green colour, and is poured into a large jar near the press whence, after depositing any water or dirt it may contain, it is poured into skins. It is next emptied into large earthenware jars four or five feet in height, where it remains for at least two months until all impurities are deposited.

Correspondence.

HOUSE DRAINS.

Seeing the utter uncertainty which exists as to the position and nature of "house drains" generally, would it not be well if, in any future legislation on the subject, a clause in the Act were inserted, compelling any person selling or letting a house to supply the purchaser or hirer with a proper plan of the drains?

W. E. Bartlett.

Westgate, Guisborough,
September 30, 1884.

As the albumen obtained from eggs costs too much to be regularly employed as a mucilage on a large scale, Herr Muth, of Carlsruhe, has substituted that from caseine, which is of the same composition. Though it is but little soluble in pure water, this caseine readily dissolves in water made slightly alkaline, and by preference ammoniacal.

General Notes.

The Swiss Cotton Industry.—According to the *Berliner Börsen Zeitung*, there are at present 1,809,303 spindles occupied in the Swiss cotton industry, the average for each establishment being 19,046. Two-thirds of these are for coarse numbers, (up to No. 60), and the others are making from No. 60 upwards. The annual production of coarse numbers is 16,800 tons, and that of fine numbers, 2,900 tons. Cotton weaving occupies 15,783 looms, of which 11,102 are engaged upon heavy tissues, calicoes, percales, &c., and 4,681 upon fine goods, muslins, jaconets, &c. The annual production of heavy goods is 7,457 tons, and of fine goods, 1,385 tons. The weaving of coloured goods employs 6,967 looms, using yarns to the extent of 3,264 tons annually.

Water-melon Oil. — Experiments have been made by M. Lidoff, with a view to defining the quantity of oil contained in the seeds of the *cucumis citrullus*, a water-melon plant extensively grown in the South of Russia. According to a description of the process in the *Corps Gras Industriels*, the seeds are dried at a temperature of 266° Fahrenheit, after which the oil is extracted in a Tharn apparatus. By this method there was obtained a quantity ranging from 24 to 25 per cent. of a lubricating oil, with a density at 64° Fahrenheit of 0·9298. It absorbs atmospheric oxygen very rapidly, an augmentation of about ¼ per cent. taking place within three days. M. Lidoff thinks water-melon oil suitable for culinary purposes, but fears that its extraction would be too costly to allow of its coming into general use.

Electric Telegraphy in Australia.—The extent of Electric Telegraph wire in New South Wales, in actual use during 1882, was 15,901 miles, 47 chains, 13 links; the number of stations was 345; the revenue for the year, £120,265 13s. 4d.; and the expenditure (exclusive of interest on cost of construction of lines), £142,534 13s. 6d. In 1883, the extent of electric telegraph wire in actual use was 17,272 miles, 41 chains, 35 links; the number of stations, 368; the revenue, £134,643 2s. 4d.; and the expenditure (exclusive of interest on cost of construction of lines), £163,328 16s. 11d. 2,107,288 telegrams, of the value of £165,276 14s. 10d., were transmitted from the Colony; and 2,102,044 telegrams, of the value of £159,095 2s. 1d., were issued in the Colony. The New South Wales receipts on local and intercolonial (exclusive of New Zealand) business were £122,891 0s. 7d.; on New Zealand business, £1,898 15s. 1d.; and on international business, £3,049, making the total receipts £127,838 15s. 8d.

CANTOR LECTURES.

RECENT IMPROVEMENTS IN PHOTO-MECHANICAL PRINTING METHODS.

By Thomas Bolas, F.C.S.

Lecture I.—Delivered January 28th, 1884.

New Developments of the Woodbury-type Process.

The printing press has been the main factor in bringing about that interdiffusion of thought, which has resulted in the widespread and complex civilisation of to-day; and it is especially of interest to note that the productions of the printing press have, even from the first, been permanent: that is to say, the ink used has been one made with a basis of lamp-black, the pigment which, of all others, seems best able to resist the continual breaking strain of time, while writings may be—and indeed often are—gone in the course of a few years.

The introduction of block printing into Europe, the discovery of a new world, and the construction of the camera obscura by Leonardo da Vinci, are events which mark the latter end of the 15th century, a period memorable in the history of our civilisation of to-day; the beginning, indeed, of that active fermentation of thought which has made the world what it now is.

When Leonardo da Vinci looked upon the wonderful nature-picture in his camera obscura, and dreamed of the possibility of fixing this shadow, it is difficult to imagine that his wildest thoughts could have led him to suppose the possibility of converting that shadow into a printing block, and making copies in the then new printing press.

The honour of first fixing the camera image belongs to Nicéphore Niépce, who, in or about 1816, first transferred and fixed the image of the camera upon paper, and not only this but Niépce actually made printing plates by photographic agency before the year 1827. Those pictures and printing plates, which represented landscapes or general views, were very imperfect it is true, but, some years before 1827, he made true camera pictures, which were fixed in the technical sense, that is to say, would bear subsequent exposure to light without disappearing, and he thus laid the foundation of those more perfect elaborations of his processes developed by Daguerre and by Talbot.

The perfection of united photography and printing is thus to make the shadow into a solid substance, and so to obtain a plate or block from which impressions can be taken on the printing machine, and in this direction much practical progress has been made since the time when it was my privilege last to address you.

One point to which allusion has just been made may perhaps be again mentioned. The printer, whether he work from type, from an engraved block, or from a printing surface obtained by the aid of photography, can select his pigment, and, as a matter of fact, he generally selects one of which the basis is lamp-black; consequently, exposure to light and air will not cause the print to fade. The photographer, who makes his pictures by a photo-chemical method, has to content himself with such a colouring material as he can get—generally metallic silver or a mixture of this metal with gold. The consequence is that the earlier photographs are now mostly faded, and one may safely say that not a single copy of Fox Talbot's "Pencil of Nature" can be said to have altogether survived the forty years or so which has elapsed since its publication. Notice the copy which is lying on the table, and see if you can find a single picture which shows no sign of fading. The first photo-mechanical process, however, which gave really good representations of scenes of nature, is the photoglyphic method of Talbot, and although the gradations of tone are not represented in quite the same degree of perfection as is the case with Talbot's pictures by his calotype or silver-printing process, we have the enormous advantage of permanency.

Here are some examples of Talbot's photoglyphic method, printed in ordinary carbon ink from the intaglio plate, and issued with the *Photographic News* in 1858. Where, indeed, will you find silver print a quarter of a century old which shows no sign of fading?

To unite the permanency of the press-print and its rapidity of production with the exactness of the camera picture is the aim of the photo-mechanical experimentalist; and let me now pass on to some of the advances made since the date of my last lectures.

During 1878, Dr. Eder, of Vienna, published a most comprehensive monograph upon the "Reactions of the Chromium Acids and the Chromates on Organic Bodies;" and, considering how largely progress in matters of actual practice is dependent upon sound theoretical knowledge, one is not likely to be wrong in attributing much of the recent progress to the labours of Dr. Eder. The series of articles in question will be found in the volume of the *Photographic News* for 1878. One of Dr. Eder's latest discoveries may be mentioned here. He finds that ferricyanide of potassium tends to make gelatine insoluble, and that exposure to light tends to restore solubility. Possibly useful methods of working may be founded upon this observation.

Great progress has been made during the past five years in the application of photography to lithography and type-block printing; indeed, at the time of my last lectures, it was the exception to find a London printer who made use of photo-transfers for litho work, or of photo-etched zinc blocks for type-printing; but now it would be difficult to find a large London printing house where these are not in regular use.

From the general to the particular, that is to say, to the special subject of this evening's lecture—printing by the Woodburytype method.

The old Woodburytype method, in which the mould is made by the hydraulic press, has not been improved to any notable extent, but new modes of working have been devised, in which the mould is made without the aid of the hydraulic press; indeed, more than this, for Mr. Woodbury has quite recently devised a method of working in which the gelatine relief is itself the printing surface, this gelatine being covered with a sheet of thin tinfoil, cemented down by means of india-rubber; but before describing this the newest and most successful modification, let me call your attention to some of the modes of making a printing mould from a relief without the help of the hydraulic press.

What is now going to be demonstrated will illustrate to you a process for moulding the relief, which was devised by M. Gustave Re. A compressible box, placed upon the bed of this small hand-press, is filled with plaster of Paris in a dry form, and a sheet of tinfoil having been laid over this, the gelatine relief is placed on the tinfoil, and pressure is applied. It is easy to understand that under these circumstances the tinfoil will be forced into all the details of the relief; but in order to produce a solid mould suitable for printing from, it is necessary to take means to cause the backing to consolidate itself together, and for this purpose some water is poured into an outer casing which surrounds the moulding box. Soon after the water has penetrated into the compressed powder, setting takes place, and as this is always accompanied by expansion, the metallic foil is still more closely compressed against the gelatine relief. It is scarcely necessary to say that the press is kept closely screwed up until the plaster has thoroughly set. It is my impression that no commercial use has been made of this ingenious method of moulding, but it, like many other processes, rests ready to hand for any person who may wish to make use of it or to improve it. Methods of making the printing mould by rolling pressure, instead of the direct pressure of the hydraulic press, have only been decidedly successful when extremely thin sheets of metal, such as tinfoil, has been used, as a thick plate of lead, or other soft metal, extends considerably in one direction, when under the action of the rolling press. Casting a printing mould from the relief in sulphur, or in what amounts to about the same thing, the so-called Spence metal, has been suggested, and Mr. Warnerke has carried the method into practice with success. By melting sulphur at a low temperature, and stirring in about one-sixth of its weight of black lead, a very good casting material is obtained, and this can be easily illustrated to you. Here is a relief which has been developed on a piece of thick glass, and warmed up to a temperature of nearly 50° Centigrade, and having placed a metal rim round the relief, the next step is to steadily pour over it the mixture of sulphur and black lead, so as to form a cast about an inch thick. When this is cold, Mr. Barker will separate it from the glass, and make a print from it by the usual Woodburytype method, that is to say, by pouring on to the mould a pigmented gelatinous solution, laying on a sheet of paper, and then pressing out the excess of the coloured gelatine solution by bringing down a rigid and truly flat slab of metal on the paper. When the gelatine has set, the cast in pigmented gelatine will prove to be a perfect picture, showing all the gradations of the original photograph by various thicknesses of the tinted gelatine.

It will interest you to see some casts which Mr. Barry has made in brass and iron from the Woodbury relief, and although these do not appear to possess that perfect evenness of surface which is an essential in printing by the Woodburytype process, they are likely to have considerable value for decorative purposes.

Now, as to Mr. Woodbury's new development of his process, which he calls stannotype. There are two stannotype processes—the old and the new; but the former can be summed up in a very few words, especially as it has been altogether eclipsed by the latter.

The gelatine relief is developed on a rigid support, such as a slab of plate glass, and when the relief is dry, a sheet of tinfoil is made to adhere to it, and at the same time to take a perfect impression of the details, by pressure under a rolling machine. The next step is to deposit copper by the electrotype method on the tinfoil, the thickness of the copper thus deposited amounting to about three or four times that of the original tinfoil. The copper backing is now washed and dried, after which a warm sheet of glass, covered on one side with a layer of resinous matter, is laid—coated side downwards—on the coppered plate, and by the application of a steady and prolonged pressure, the softened resinous matter is made to accommodate itself to all the inequalities of the electrotyped surface. The whole being now allowed to cool, the complex cast is removed from the gelatine relief, and this cast is used as the printing surface. If you have followed my remarks, it is needless to remind you that the cast consists of the tinfoil facing which was moulded directly against the gelatine original, then the backing or stiffening of electro-deposited copper, next the resinous cement, and finally the rigid plate of glass intended to give strength or body to the whole. Mr. Barker will make a print in a mould of this kind.

The new stannotype process necessitates the use of a transparency, as the original photograph, under which the gelatinous tissue is exposed; and as regards the preparation of the sensitive gelatine, its exposure and development, there is no need for me to say anything, as this matter was fully treated of in my previous lectures. Carbon transparencies made direct from the original negative are used, and the representative of Messrs. Woodbury, Treadaway and Co., who is about to demonstrate the whole process, has just developed such a transparency in hot water, and he will now proceed to intensify it by means of a solution of permanganate of potassium.

A sheet of gelatinous tissue, which has been exposed under a similar transparency, is now soaked in water until flaccid, and laid face downwards on a slab of glass, perfect contact being established by the use of the squeegee. The glass to which the tissue now adheres is next placed in hot water, where the paper backing is stripped off, and all that gelatine which has not been rendered insoluble by the action of light is washed away. In this way a negative relief is obtained on the glass, the high portions corresponding to the light shades of the original subject, and the low portions to the deep shadows. When dry, this gelatine relief itself forms the mould in which pictures are cast or moulded by the ordinary Woodbury method; but before the gelatine mould can be used to print from, its surface must be coated with tinfoil. To do this, a thin solution of india-rubber in benzole is run over the plate, and a sheet of tinfoil being laid on, intimate contact is established by passing the whole between rubber-coated rollers—in fact, an ordinary wringing machine.

All is now ready for the printing. Mr. Woodbury's assistant takes the mould, adjusts it on the bed of a small press, oils the face slightly by a pad of oiled flannel, pours on the gelatine solution charged with colouring matter, lays on a sheet of paper, and closes the press, taking care to leave it closed until the gelatine is thoroughly set, when he will strip off the print.

This, then, is the new stannotype process, as adapted to the requirements of the general photographer who may wish to make fifty prints or more from a negative.

Another application of the Woodburytype method is the so-called photo-filigrane process, in which the water mark of paper is imitated by rolling a Woodbury relief against the paper with a considerable degree of pressure, the paper being rendered more or less transparent according to the degree of pressure, or in other words, according to the thickness of the relief at any one particular point. In this way photographs of all kinds can be reproduced in water-mark form, and Mr. Barker will show you how very rapidly impressions of this kind can be made on the paper. The method in question is worked commercially by Messrs. Brown, Barnes, and Bell, of London and Liverpool, this firm having been good enough to send me the interesting specimens which are before you.

The Woodbury process is specially adapted for making transparencies to be exhibited by means of the optical lantern, and Mr. George Smith, who has been exceptionally successful in executing work of this kind, will now demonstrate to you the whole process of making slides by the Woodburytype method. Instead of laying a sheet of paper on the mould after flooding with gelatine, a glass plate is used, and the cast in tinted gelatine is thus made directly on the glass. Mr. Smith will use a hydraulic press of his own construction in making the relief, and those of you who have studied the construction of appliances of this kind will know how to admire the excellence of the design.

The translation of the Woodbury relief into a line or stipple, suited for lithographic or typographic printing, is a matter of considerable interest and importance, but it must be considered in another lecture.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

The Library.

A sub-committee was appointed in February last, to supervise the library and reading-room which it was decided to establish in connection with the Exhibition. The original intention was to collect together the exhibits comprised within the class of literature in the different groups; but, subsequently, a request was issued by the Executive Council to Government Departments, learned societies, authors, publishers, and others, for the loan or gift of works, reports, and papers dealing with the two subjects—Health and Education. A liberal response was made to this appeal, and the result is that about 5,000 volumes have been collected, arranged, and catalogued, and are available for use by any visitor to the Exhibition, in two rooms of the Royal Albert Hall. Additions are constantly being made, and besides the books, in the library proper are files of the daily papers, and English and foreign sanitary and educational journals. The library was opened to the public on Monday, the 16th of June, and is available for purposes of reference and study from 11 a.m. to 6 p.m. A visitor requiring a book fills up one of the application tickets which is supplied to him, and on returning the book he receives the ticket back.

The books have been arranged in accordance with the plan adopted in the Exhibition itself, the two main divisions being Health and Education. The catalogue thus gives an indication of the bibliography of these subjects.

I. Health —The first group contains Acts, Laws, and text-books, and includes manuals respecting sanitary law, laws of quarantine, vaccination, &c. Census reports follow, and chiefly relate to the British Islands and India. Of foreign countries there are only the Tenth Census of the United States, and those of Vienna and Buenos Ayres. The Guide Books to Health Resorts form an interesting group, and their description in the catalogue occupies eleven double-columned pages. Besides the numerous places in Great Britain which are described, there are guides to German, French, and other foreign watering places. Then follow medical and other treatises on health, of which there are a considerable number, and reports of Sanitary Commissions and Medical Officers of Health, &c. This is a large group, and includes works on vital statistics. The transactions, reports, &c., of societies and journals, include the publications of the Ladies' Sanitary Association, Manchester and Salford Sanitary Association, National Association for the Promotion of Social Science, Sanitary Institute, Society of Arts, and some medical societies, besides journals and transactions of German, Hungarian, and Italian Societies. Food includes cookery and the various questions connected with adulteration. The description of the books in this class occupy ten columns of the catalogue. There are a few works on Dress, and then follow books on the Dwelling House, with which is joined the literature of Water Supply and Drainage. The heading of Ambulance (in which are works on nursing and hospitals), completes the first division of the catalogue devoted to Health.

II. Education.—The first group in this division is devoted to works on pedagogy, examination papers, educational journals, reports on and history of education. In this class the various European countries are well represented; there are nineteen works in French, twelve in German, twenty-three in Hungarian, two in modern Greek, one in Dutch, twenty-seven in Italian, nine in Portuguese, one in Spanish, two in Russian, forty-eight in Swedish, and five in Norwegian. The description of this class occupies twelve pages of the catalogue. The next class contains books, English language and literature, especially prepared for school use. Works on domestic economy follow, then those on classical languages and literature, modern languages and literature, and works used in foreign schools for teaching the native languages and literature. After these classes we come to history and biography, theology, church history and liturgiology, and a few books on mental and moral philosophy and political economy. Mathematics, writing (including shorthand and book-keeping), drawing and painting, and music are well represented. The books on technical instruction in arts, manufactures, and trades, handbooks on industrial arts, form an important class. Then come the following classes—geography, astronomy, geology, and mineralogy; zoology, botany, and general natural history; chemistry, electricity, physics, &c.; and physical training, gymnastics, &c. The last class of all contains books of reference, such as dictionaries, encyclopædias, peerages, almanacs, calendars, catalogues, &c. The list of English and foreign medical, sanitary, literary, educational, and other journals, the current numbers of which can be seen in the reading-room, is a long one, commencing with the *Academy*, and ending with the *World*. It contains as many as 231 titles of newspapers, journals, &c. The hon. secretary of the Library Sub-Committee is Mr. J. L. Clifford Smith, and the librarian who has compiled the catalogue is Mr. Carl A. Thimm. Besides the books in the library, there are many educational works shown in the foreign section of the Educational Department in the Central Institution of the City and Guilds of London.

PRIME MOVERS AND BOILERS AT THE TURIN EXHIBITION.

By P. Le Neve Foster.

The progress that has been made in Italy during the last quarter of a century in mechanical industry is clearly demonstrated by the excellent show of prime movers at the Turin Exhibition. It has been too much the fashion to suppose that Italy could not compete with other nations in the construction of machinery; and although there may be little or no danger of immediate competition in her export trade, it is clear that England must use every effort to hold her own with regard to finding a market for her machinery in Italy. At the present time it is an undoubted fact that the imports to Italy of engines and machinery made in England are sensibly diminishing, and from the intelligent labour displayed during late years by Italians, affords reason for believing that before long in this respect she will be completely independent of other countries.

In 1861, at the first Italian National Exhibition, held at Florence, the largest of the seven steam-engines exhibited was that of Messrs. Ansaldo, of 32 horse-power. Three years ago, at the Milan Exhibition, the most powerful motor shown was that of 150 horse-power, by the "Società Veneta di Costruzione Mecchaniche;" whilst at the present Exhibition at Turin the power of some of the engines is from 200 to 250 nominal horse-power, and reaches, in the case of the fine engine of Messrs. Neville and Co., to 310 indicated horse-power, from diagrams taken when driving part of the machinery for the electric lighting of the grounds. Most of these engines, as regards workmanship, design, and price, can compete very favourably with those constructed in other countries.

Great attention has been paid of late years by Italian mechanical engineers to the economical use of steam, a matter of vital importance in a country like Italy, where fuel is relatively expensive. Hence we observe, in all the engines exhibited, that mere rule of thumb has been set aside, and that in designing them the utmost care has been bestowed on all the details, and more especially so to those parts relating to the distribution of steam to the cylinders.

The motive power to the gallery of machinery in motion is furnished by eight engines, supplied with steam from eight boilers of various types. The class of boiler most in favour in Italy is the "Cornish," but of late years, and as is seen at the present Exhibition, the "Ten-Brink" type is gaining ground. These boilers are fixed side by side in a boiler house specially constructed for the purpose.

The first boiler is of the Fairbairn type, with double flue, by Messrs. Miani and Venturi, of Milan. Its heating surface is 100 square metres (1,076 sq. ft.), and grate surface 2·40 square metres (25·83 sq. ft.). The working pressure is 5½ atmospheres (82½ lbs. the square inch).

The next boiler is of the Lancashire type, with double flue, by Messrs. Tosi and Co., of Legnano. The heating surface is 97 square metres (1044·23 sq. ft.), grate surface 2·75 square metres (29·60 sq. ft.). It is furnished with Sulzer water-heating tubes, and a grate adapted for burning small coal and dust, an advantage to be appreciated in Italy. The fire bars, instead of being fixed longitudinally, as is usually the case, are fixed across the furnace, to which air is supplied by a Körting blower.

The third boiler is one of the marine type, constructed by the "Società delle officine di Pietrarsa e Granali," of Naples. It is cylindrical, with "Fox's" corrugated furnaces. The diameter is 2·38 (7·80 ft.), and 4·55 m. in length (14·92 ft.) The tube plates contain 60 tubes. The heating surface is 89·59 square metres (967·77 sq. ft.), and grate surface 1·73 square metres (18·61 sq. ft.). The working pressure 6¼ atmospheres (97½ lbs. to square inch).

The fourth boiler is shown by Messrs. G. Rochette and Co., of Turin, and is of the "Ten-Brink" form, consisting of three cylindrical shells placed one above the other. The heating surface is 56 square metres (602·80 sq. ft.), and grate surface 0·87 square metres (9·36 sq. ft.)

The fifth boiler, also of the "Ten-Brink" form, is exhibited by the "Fonderia Fratte," of Salerno, and in which certain modifications have been introduced. This boiler has double flues, a heating surface of 65 square metres (709·67 sq. ft.), and grate surface 1·70 square metres (18·30 sq. ft.)

The largest boiler in the Exhibition is that shown by Messrs. Odero, of Sestri Ponente; it is of the "Ten-Brink" type, with double furnace, the heating surface being 111·60 square metres (1201·30 sq. ft.), and grate surface 2·30 square metres (21·85 sq. ft.) This boiler is fitted with an apparatus for consuming smoke.

Messrs. Cravero and Co., of Genoa, furnish two boilers of the Cornish type, with Sulzer water heaters. The first, with double flues, has a heating surface of 80 square metres (861·14 sq. ft.), and grate surface of 2 metres (21·52 sq. ft.), whilst the second, with a single flue, has 44 square metres (473·55 sq. ft.) of heating, and 1·12 square metres (12 sq. ft.) grate surface. This boiler is adapted for burning the "spent" bark from tanneries, and is supplied automatically with fuel from a hopper placed above the furnace.

A second group of eight locomotive boilers supply steam to the engines in the electrical department, and have been furnished by the administration of the Alta Italia railway.

The water for the condensors, for watering the grounds, and for general purposes, is pumped up from the River Po, by an engine of 40 nominal horse-power, constructed by Messrs. Cerimedo and Co., of the Elvetica works of Milan, who have recently furnished a similar pumping engine for the new water works at Venice. The engines, pumps, and boilers, are placed in a building at the river edge, near the mediæval castle, and the water is forced at the rate of 60 litres per second (13·20 gal.) to a vertical height of about 25 metres, through a length of 430 metres of cast-iron mains to an ornamental tank near the south entrance to the gallery of machinery in motion.

The boiler is of the MacNichol type, with a total heating surface of 60 square metres (645·85 sq. ft.), and 2·72 square metres grate surface (28·25 sq. ft.) The working pressure is 6 atmospheres (90 lbs. to sq. in.)

The engine is of the horizontal compound condensing type, the cylinders being placed parallel to each other, and are respectively 0·24 m. (9⅜ in.), and 0·44 m. (17⅜ in.) in diameter, with 0·50 m. (24 in.) stroke. The air pump is worked direct from the piston rod of the low pressure cylinder. The expansion gear is automatic. The crank shaft carries a pinion which gears into a spur wheel on another shaft placed at a lower level, the former making 80 revolutions per minute to 12 of the latter, from which the pumps are worked, and advantage this way is taken of high pressure of steam, rapid piston stroke, and a large degree of steam expansion, whilst the pump plungers move relatively slow with a minimum of reversals.

The pumps are of the Girard type. The four barrels are placed in pairs horizontally, with one plunger to each pair, actuated by a piston-rod with crosshead working in slides with connecting-rod from crank pin. They are 0·425 m. (16¾ in.) in diameter, with 0·70 m. (2 ft. 3½ in.) stroke. Between each barrel is a tank filled with water, inorder that the plunger glands shall always be submerged. The plungers, which are of cast-iron, are hollow, and their weight being equal to the quantity of water that they displace, friction is reduced to a minimum.

From the ornamental tank, the water is forced by another set of Girard pumps placed in a building near the entrance to the gallery of machinery in motion. Important modifications have been introduced in the design of these pumps by the makers, Messrs. Bosisio, Larini, Nathan, and Co., of Milan, and as a sample of Italian hydraulic machinery, is unrivalled in the Exhibition, and would do credit to the best constructors in England.

The pumps are four in number, placed in pairs, with one plunger to each pair, the glands being submerged in the same way as those just described. They are 0·60 m. in diameter (2 ft. 11⅝ in.), and their stroke can be varied from 0·70 (2 ft. 3½ in.), 0·85 (2 ft. 9½ in.) to one metre (3 ft. 3⅜ in.), by altering the position of a pin on disc, which is used instead of a crank, for actuating the connecting and plunger-rods. The main shaft carries a large spur wheel, and makes 9½ revolutions per minute, and is driven by a pinion on a counter shaft, connected by suitable gearing with the main shafting in the electrical department. Each pump is completely independant of the other, and can be put out of work without interfering with the action of the others; the valves are of india-rubber, and the chambers in which they work are easily accessible. The delivery of the pumps is 166 litres (35½ gals.) per second. The air vessel is of boiler plate and provided with an automatic regulator, by means of which the pressure is maintained constant, whilst, at the same time, the introduction of air into the mains is prevented.

The "Stabilimento Forlivese di Costruzioni Meccaniche" furnish a horizontal non-condensing engine of 20 horse-power with variable expansion; the valves are worked by excentrics. The expansion valve is on the Rieder plan, and controlled by the governor.

Messrs. Luciano and Co., of Turin, also exhibit a single cylinder non-condensing engine of 20 nominal horse-power, with variable expansion. The slide and expansion valves receive a reciprocating motion from a disc fixed at the end of a shaft driven at right angles to the crank shalf by mitre gearing. The expansion valve is tubular, working in a cylindrical chamber. The ports are spiral, and the governor is so coupled up to the valve spindle, that at the slightest change of speed, the latter is partially rotated and so shifts the tubular expansion slide at right angles to the direction of its motion, and by the relative position of the spiral ports of the valve and chamber, the amount of "cut off" is varied, and the admission of steam to the main slide is regulated.

The "Fonderia Fratte" of Salerno have furnished an engine of 100 nominal horse-power, which, as regards beauty of workmanship and design, is unrivalled in the whole Exhibition; it is of the horizontal "compound tandem" type, with cylinders 0·32 m. (12⅝ in.) and 0·49 m. (19¼ in.) in diameter, and 0·80 m. (2 ft. 7½ in.) stroke. They are fitted with equilibrium valves, those for the admission of steam, which are placed on the upper side of the cylinder, being actuated by excentrics fixed on a shaft driven at right angles to the crank shaft by bevel gearing, whilst the exhaust valves placed on the under side of the cylinders are worked by cams, and, by a special arrangement of levers, the degree of expansion in the higher pressure cylinder is controlled by the governor, whilst that in the low pressure one is regulated by hand.

Both cylinders and intermediate receiver are steam jacketted; the condensor and air pump are placed below the level of the flooring, the latter being worked by a rocking lever connected with the end of the piston-rod, which passes through a stuffing-box in the cover of the low-pressure cylinder.

All the principal parts of the engine are under the control of the engine-driver, who from a stand can handle the starting valves, injection cocks, feed to boiler, and the four drain cocks of the cylinder; the gauges showing the pressure in the boiler and cylinder, and vacuum in the conductor, together with a mercury gauge, being conveniently placed within sight, so that everything can be regulated from one place.

The fly-wheel is 4 m. (13 ft. 1½ in.) in diameter, with five grooves. The engine is furnished with automatic lubricators; a tubular "swan neck," revolving in bearing with the crank, conveys the oil from the lubricator to the pin, so that it can be kept oiled without stopping the engine. A speed indicator is placed at the end of the excentric shaft, and an ingenions arrangement is provided for taking indicator diagrams. The engine makes 70 revolutions per minute, with a working pressure of 5½ atmospheres (82½ lbs. per square inch).

Messrs. Cravero and Co., of Genoa, exhibit a horizontal compound condensing engine of the "tandem" form, of 40 nominal horse-power. The valves are controlled by an arrangement of levers worked from four excentrics fixed to a shaft driven at right angles to the crank shaft.

Another engine is also exhibited by Messrs. Luciano, of Turin, of the horizontal compound "tandem" form, of 100 nominal horse-power. The high pressure cylinder is 0·305 m. (12 in.) in diameter, and the low pressure 0·54 m. (21⅞ in.), with 0·86 m. (2 ft. 9⅝ in.) stroke. The valve gearing is a modification of the "Corliss" plan, which would be impossible to describe without drawings.

Messrs. Nicola Odero, of Sestri Ponente, contribute a horizontal condensing engine of 100 nominal horse-power. The cylinder, which is 0·53 m. (20⅞ in.) in diameter, and 1·10 m. (3 ft. 7⅝in.) stroke, is steam-jacketted. The valves are of the equilibrium form, and worked from excentrics on a shaft running at right angles to the engine.

The "Stabilimenti d'Industrie Meccaniche di Pietrasa e Granili, of Naples, show a compound condensing engine of 60 nominal horse-power. The cylinders are horizontal, placed side by side, and are respectively 0·34 m. (13⅜ in.) and 0·50 (19¾ in.) diameter, the stroke being 0·75 (2 ft. 5½ in.). Both cylinders are steam-jacketted, and the steam passes from the high to the low through a receiver containing 34 tubes heated by steam from the jacket of the high pressure cylinder. The valve gear is a modification of the Sulzer plan. The expansion in the high pressure cylinder is controlled by the governor, whilst that in the low pressure one is adjusted by hand.

The engine exhibited by M. Enrico, of Turin, is by far the most original in design of any shown; it is a horizontal high-pressure single cylinder condensing engine of 60 nominal horse-power. Its originality consists in the application of an incompressible fluid, viz., "oil," for working the valves, in the place of the usual rigid rods and levers as is the case with the gearing of ordinary steam-engines.

The two steam valves, which are placed upon the upper side of the cylinder, are controlled by means of a force-pump filled with oil, which is worked from an excentric fixed upon the crank shaft, the oil being forced by the pump through pipes communicating with small cylinders fitted with pistons which raise or lower the steam valves. The exhaust cocks, which are adapted to the lower side of the cylinder, are actuated by levers connected with a separate excentric in main shaft. The steam cylinder is not steam jacketted. The air-pump of condensor which is placed below the engine-room floor is rotary, and is driven by a belt from a pulley on crank shaft.

This enginc, which appears to work smoothly, has been purchased by the proprietors of a cotton spinning establishment at Pincrolo.

The total motive power of these eight engines is 500 nominal horse-power.

Two lines of shafting run nearly the whole length of the gallery, and are supported by a strong framing of cast-iron which carry the bearings. This shafting is put in motion by grooved pulleys, ropes being used instead of the usual leather belting, and this system appears to answer admirably, and must be advantageous, not only because of their cheapness as compared with leather, but also because they can be readily replaced, and it is almost impossible that all should break at once, and, lastly, because slipping on the driving pulleys is next to impossible on account of the great tension that they exert.

AMSTERDAM INTERNATIONAL EXHIBITION, 1885.

The enlarged buildings rendered requisite by the increased demands from foreign countries are being proceeded with. Many of the large Indian houses in London, such as Proctor and Co., Liberty and Co., Vincent Robinson and Co., and others, will exhibit, and the Calcutta papers are urging the

Indian Government to send a collection of raw materials. Nearly every foreign European state will take part. It is expected that the Dominion of Canada will be well represented, and that the British section of 3,000 square metres will be well filled. Mr. Simmonds, in a tour in the manufacturing districts, obtained many adhesions from the principal manufacturing and engineering firms. The extensive manufacturing industries of Belgium will also be well represented.

Mr. J. C. Humphreys has been ordered to prepare, for the reception of royal visitors, a pavilion similar to that of the Prince of Wales at the Health Exhibition. This will be furnished and decorated by the leading London firms. The Technical Committee, of which M. Delpaire is President, are about to form a Commission of practical men to test, examine, and report, at the request of the exhibitors, on all objects shown, whether metallic, chemical, or industrial, and to furnish a certified report, which the exhibitors can publish, or not, as they choose. The Government will place at the disposal of this Commission all the machines and appliances necessary for testing which are in the depôt of the State railway at Malines. These will enable a determination to be made, with mathematical precision, of the extension, compression, flexion, and tension of all materials. Trials can thus be made of steel, iron castings, bronze, chain cables, wire or hemp-rope, bricks, lime, wood, stone, and all constructive materials.

At the chemical laboratory can also be determined the lubricating properties of oils, the heating properties of coal, the illuminating power of gas, &c.

The King of Cambodia is desirous of showing some of the products and curiosities of his country, and the space of 40 metres by 25 metres which it will occupy, will be surmounted by a representation of the grand stand of the racecourse of Pnom-Peut.

In the maritime section will be shown a curious collection of all the boats and vessels of the far East, including the Annamite junks.

Austria is erecting a pavilion in the gardens for the use of the Arch-Duke Rodolph, the President of the Austrian Commission. From America, the United States, Brazilian and River Plate Governments have promised extensive contributions. As regards Africa, besides the French Algerian collections, the King of the Belgians is using his large staff on the Congo to make an exhaustive collection of African products and ethnological specimens, and to the attraction of the show, it is intended to set up a model African village in the Exhibition grounds, and people it with representative specimens of the principal races on the Congo.

TANEKAHA BARK OF NEW ZEALAND.

Consul Griffin, of Auckland, states that the tanekaha bark is a product peculiar to New Zealand, and is found in no other country in the world. During the last few years large quantities have been exported to Europe, where it is highly prized on account of its superior dyeing and tanning properties. Recent tests have established the fact that it is one of the best vegetable dyes in the world, and especially for yellow, pink, and fawn colours. The tree producing the bark belongs to the genus *Phyllocladus*, comprising the trees known as the "celery leaved pines." It belongs to the same section of the conifers, as the well-known yew of Europe and North America, although it differs widely from it in habit and appearance. Only five species of the genus *Phyllocladus* are known to exist. Three of these are peculiar to New Zealand, one is a native of Tasmania, and the other inhabits the mountains of the island of Borneo. The New Zealand species are as follows—the *Phyllocladus trichomanoides*, known as the tanekaha of the Maoris; the *Phyllocladus glauca*, or *toa toa*; and the *Phyllocladus alpina*, or mountain tanekaha. The two species found out of New Zealand are but little known, and are not applied to any economic purpose. The Tasmanian plant, the *Phyllocladus rhomboidalis*, is found in the hilly parts of the island, and grows to a height of forty or fifty feet. The Borneo species is called *Phyllocladus hypophylla*, and rarely attains a greater height than twenty feet. The New Zealand tanekaha at its full growth is from sixty to seventy feet high, and the trunk is about three feet in diameter. The timber from the tree is remarkable for its strength and durability; it is very close in the grain, and is of a reddish white colour. The tree has a peculiar appearance. It throws out its small thin branches with great regularity, almost at right angles with the trunk. The foliage consists of coriaceous, obovate, toothed phyllodia, so nearly resembling leaves that they are often mistaken for them; in fact, the so-called leaves of the tanekaha tree are composed of the flattened and expanded small branches of the tree growing together. The actual leaves are seen only on the seedling plant, and are linear and sharply pointed, but they soon drop off, and their places are taken by the small branches which are expanded horizontally and are variously lobed. An interesting fact connected with the tanekaha tree is that it makes a most beautiful walking-stick. The bushmen bruise the bark of the sapling at regular intervals, and after a few days cut the sapling down and peel off the bark. The stick then presents a mottled surface, and of a permanent bright red and white colour. In obtaining the bark of the tanekaha for exportation, the following is the method employed. The tree is stripped of its bark by making a transverse incision with a knife round the trunk at the bottom, and a similar cut just below the junction of the branches. Vertical incisions are then made with a very sharp knife, and the bark removed in long narrow strips, and all the branches large enough to contain bark of any value are stripped in the same manner. The tree, if not too large, is generally cut down, and the bark removed more easily, it being useless to endeavour to save the tree, as removing the bark invariably kills it. The tannin is deposited by the sap, principally in the inner portion of the outer bark, and the outer portion of the inner bark, or liber. In New Zealand, the bark is usually gathered in the winter, but Consul Griffin states that it is preferable to undertake this work in the spring, as the tannin is most abundant at the time of the greater flow of sap, which always occurs at this season. The bark, when peeled, is put up in bundles from 4 feet to 5 feet in length, and is then ready for shipment, usually to London, whence it finds its way to Grenoble, where it is largely used for the purpose of colouring kid gloves. It is only of late years that tanekaha bark has been exported from New Zealand, and owing to its valuable properties it is expected that the trade in this article will largely increase; in 1873, the amount exported was 24 tons, while during the first six months of 1883, the latest date for which returns are available, it exceeded 575 tons, with a value of £4,000.

TURQUOISE MINES AND PEARL FISHERIES OF PERSIA.

The United States Minister at Teheran says that turquoise mining has for ages been an important source of wealth to Persia. There appears to be no historical record of turquoise mining in Persia before the 10th century, but after that the industry seems to have rapidly developed. The mines which are now in operation are the same as those worked 800 years ago, and are situated in Kerman and Khorassan. The former are now almost abandoned, the light green colour of the stones found there fading easily, and being but little prized. The mines of Khorassan are near Nishapoor, and are of great depth. Access to them is very difficult. The number of small or seed turquoises of light tint found in these mines is enormous. Mr. Benjamin states that last January a pound and a-half of the better grade of second class stones were sold in Teheran for about £7 sterling. Stones of a dark sky-blue tint are comparatively scarce. The best turquoise mines in Persia, and indeed, in the world, are at Aboû Riâh. All the mines of Khorassan are farmed by the Mohpered Dowlet, the Nasirè Dowlet, and one or two other officials connected with the Government. For this privilege they pay 18,000 tomâns annually to the Shah, a sum equivalent to £6,000. The best stones are sent to Europe, and there is at present no evidence of exhaustion in the Persian mines. The pearl fisheries, on the contrary, appear to be in a languishing condition. Formerly a very large source of revenue, they are at the present day probably not worth to the Government more than 50,000 tomâns or £16,000 per annum. The pearl beds are farmed by the chief men of the adjacent towns, and, instead of being distributed in Persia, are for the most part sent to Europe by the steamers plying to the Persian Gulf. The reason for the present condition of the Persian pearl beds is that they have been allowed no rest, but have been constantly worked. In Ceylon, the pearl oysters are allowed a rest for intervals of two years, during which they are allowed to mature. Mr. Benjamin says there is reason to believe, however, that the beds at the island of Karâk, near Bushire, which have not been worked for some time, are now in a condition to repay capital expended there, especially if diving is extended to a depth of fifty to sixty fathoms. As the ordinary depth reached by pearl divers is rather less than this, the Persian Government have recently sent to England for diving dresses of the latest invention, and an experienced diver has been engaged at a high salary. With the assistance of these, it is expected that the pearl fisheries of Persia will regain their former importance.

SILK CONDITION HOUSES OF FRANCE.

Consul Peixotto, of Lyons, gives an account in his last report of silk conditioning in France, and says that Italy was the first country to discover and apply the method which now almost universally forms the basis for conditioning silk. It was at Turin, about the middle of the last century, that the first silk conditioning or assaying house was established. In 1779, this institution was transferred to Lyons, where it has been exceedingly prosperous. There are different processes of conditioning, all, however, having for their object to determine the weight of the silk after desiccation. Water, however, is not the only heterogeneous substance which increases the weight of textile fibres; other substances are also mixed more or less with wool, cotton, and silk, which disappear after washing or scouring the threads. This foreign matter is sometimes natural, and sometimes the result of fraudulent practices. Silk, for instance, while still enclosed in the worm, is a compound substance, a fibre wrapped up in an impervious envelope, the chemical composition of which, as shown by analysis is analogous to *osséine*. This envelope is technically termed *grés de la soie*. By the processes of boiling, the silk is divested of the *grés* which it contains. The operation, termed *décreusage*, or *cuite*, is applied for removing the *grés*; if prolonged, it gives a silk *cuite* or boiled, and it is this operation which is generally employed, as, if any other treatment were used, only a portion of the *grés* would be removed. The commercial value of textile fibres is only really ascertained and determined when the threads have been assayed or conditioned, that is, only after the operation of weighing and *décreusage* or boiling, which determines mathematically the thickness and the regularity of the thread. The test of the regularity of the silk thread is now perfectly determined by the "serigraph," an invention of an American engineer.* These tests may be made by every person interested in silk, private individuals as well as corporations. In Lyons, St. Etienne, Rheims, and Roubaix, where the manufacture of silk, wool, and cotton is extensively carried on, public condition houses have been for a long time established. The Lyons condition house became the property of the Chamber of Commerce, by a decree of Napoleon I., in 1805. Its transactions amount to above £24,000 per annum. In 1882, its business, after deducting expenses amounting to £8,000, showed a net profit of £16,000. The public condition houses of France are authorised by the Government, and are administered by the chambers of commerce, or municipal authorities. Their transactions are carried on by tariffs fixed by the Government which, however, are moderate, and have the advantage of possessing an official character as between seller and buyer. In France there are thirteen authorised silk condition houses. These consist, arranged according to the amount of business transacted, of houses at Lyons, St. Etienne, Avignon, Roubaix, Paris, Marseilles, Aubenas, Privas, Nîmes, Montélimar, Tourcoing, Amiens, and Valence. During the year 1883, these establishments received 104,049 bales, and conditioned 14,958,000 lbs. of silk. Lyons alone conditioned 70,528 bales, weighing rather over 10,500,000 lbs.

Obituary.

Sir Charles James Freake. — Sir Charles James Freake, of Fulwell-park, Middlesex, and of Bank-grove, Kingston-on-Thames, Surrey, who died at his residence, Cromwell-house, South Kensington, on Monday, 7th inst., had been a member of the Society of Arts for many years. He was a member of the Council in 1873, and a Vice-President of the Society from 1874 to 1877. When the National Training School of Music was formed, through the exertions of the Society, Mr. Freake, who was then a member of the Council, undertook at his own cost and risk to erect the necessary buildings for the school; and the first stone of these buildings was laid on the 18th December, 1873, by H.R.H. the Duke of Edinburgh, K.G., Chairman of the Committee of Management of the School. Sir Charles Freake was born on the 7th of April, 1814. The baronetcy was conferred upon him in 1882, and his son, Mr. Thomas George Freake, succeeds as second baronet.

* See *Journal of Society of Arts*, vol. xxx., p. 1022.

General Notes.

German Association.—The annual meeting of German naturalists was opened at Magdeburg, on September 18th. Among the addresses delivered may be mentioned:—On the relation of micro-organisms to the infectious diseases of man, by Prof. Rosenbach (Göttingen); on the importance of German colonisation in Africa, by Dr. Gerhard Rohlfs; various medical addresses by Drs. Schwarz (Cologne), Paetz (Alt-Scherbitz), Finkler (Bonn), and Prior. Strasburg was fixed upon as next year's meeting-place, with Profs. Kussmaul and De Bary as secretaries.

Separating Wool from Mixed Rags.—M. Heddebault finds that when rags, of cotton and woollen mixed, are subjected to the action of a jet of superheated steam, under a pressure of five atmospheres, the wool melts and sinks to the bottom of the receptacle, while cotton, linen, and other vegetable fibres stand, thus remaining suitable for the paper manufacture. The liquid mud which contains the wool thus precipitated is then desiccated. The residue, which has received the name of azotine, is completely soluble in water, and is valuable on account of its nitrogen; moreover, its preparation costs nothing, because the increased value of the pulp, free from wool, is sufficient to cover the cost of the process.

Plumbing.—The Plumbers' Company has arranged for holding a conference of metropolitan and provincial plumbers at the Health Exhibition, from the 15th to the 20th of October. The following syllabus of subjects was decided upon:—1. The technical instruction of plumbers. 2. Apprenticeship, the duration and condition of indentures suited to the present state of the plumbing trade and to the modern system of technical instruction. 3. The establishment of metropolitan and provincial boards of examiners of plumbing work. 4. The registration of journeymen plumbers. 5. The suitability of materials used in plumbing, and particularly of those materials recently introduced as substitutes for lead. 6. The desirability of fixing upon a system by which uniformity in the quality of material used in plumbing may be insured. 7. The formation of district associations of plumbers to investigate and secure, as far as practicable, correction of evils and abuses arising in connection with the trade. 8. A general and executive committee to be formed for the purpose of receiving reports from district associations of plumbers and others, with a view to the preparation of a general report of the Plumbers' Company, to form the basis for an appeal to Parliament for necessary amendments and extensions of the law relating to plumbers' work under the Building and Health Acts, and otherwise.

CANTOR LECTURES.

RECENT IMPROVEMENTS IN PHOTO-MECHANICAL PRINTING METHODS.

By Thomas Bolas, F.C.S.

Lecture II.—Delivered February 4th, 1884.

Type Blocks from Line Drawings or Half-tone Subjects.

Any impression in a fatty ink, of the nature of printers' ink, which may be transferred to stone or zinc for printing after the lithographic method, may be considered as the germ of a typographic printing block, as, if such an impression is transferred to a zinc plate, the uncovered parts may be etched away so as to leave the covered parts standing in high relief. The details of the method of this etching a zinc plate were given in one of the lectures of my previous series, and, therefore, it is needless to repeat them here. Let us take the reverse case. One has a typographic block, and it is more convenient to print impressions by the lithographic machine than from the block; it is only necessary to make a print from the block, and transfer it to the stone. Thus it will be seen that lithographic printing and typographic printing are very closely connected, so closely, that when a subject is prepared for one it may be printed by either, as convenience may indicate. The "Official Gazette" of the American Patent Office is set up in type, but the printing of all, excepting the index sheets and the covers, is done on a litho-machine.

These remarks bring us to the point where photo-lithography and photo-typography may be considered together, and that the making of a fatty transfer is equivalent to the production of a printing surface suitable for printing by either method. Still it seems to me that there is a large future before the litho-machine for commercial work, and that English printers are only beginning to see the real importance of Senefelder's discovery, for the production of commercial one-colour work.

Now, as to the making a photo-litho transfer from plain black and white work, some progress has been made of late by the introduction of the velvet roller as a means of inking the exposed gelatine paper; the application of the velvet roller to this purpose being due to Mr. F. Butter, of Woolwich Arsenal. The ordinary litho-roller sticks to the paper, and drags off the coating; so much is this the case, that, until the introduction of the velvet roller, but few persons attempted to ink up the image on the exposed gelatine paper with the roller; the usual practice being to follow the plan demonstrated in my last lecture—that is to say, to lay a ground of ink all over the paper, and, after softening the gelatinous film by soaking in water, to remove the excess of ink by dabbing, or some such process.

Mr. Newland will now assist in the demonstration of the mode at present adopted for making a transfer by the velvet roller method.

The sensitive paper was prepared by floating thin bank post paper on the following solution—the solution being, of course, warm:—

Gelatine	3 ounces.
Water	50 ,,
Bichromate of potash	2 ,,

An exposure of five or six minutes in the shade is sufficient, after which the paper is soaked for some minutes in cold water, and the excess of water is blotted off. All is now ready for the inking of the image, and Mr. Newland has clamped down one side of the paper to the front edge of a kind of table, formed out of a slab of thick plate-glass, after which he will apply the velvet roller; always rolling it away from himself, so as to keep the paper level and stretched. The exposed parts now take the ink, and a transfer of surprising fineness is obtained. The velvet roller is charged with an ink made by mixing commercial transfer ink with about one-eighth of its weight of olive oil, a little turpentine being added to thin the mixture, if required;* but it is well to avoid the free use of turpentine.

Mr. Frewing has been good enough to bring here some specimens of his line work, not only in the transfer but also put down upon zinc; moreover, he has brought some wood blocks upon which the fatty transfer has been impressed, as a guide to the engraver.

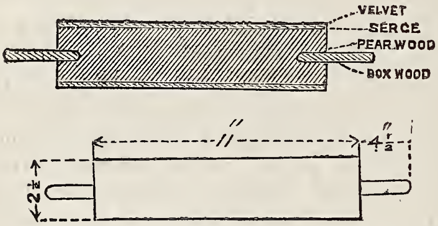
Wood-engraving has long held its own, but it is now very hardly pressed by the various processes, some of which are photographic and others not. Some years ago, the "graphotype" process made a little stir, but it did not compete with wood engraving to any extent worth mentioning, while, apart from the photographic methods, there are many others. Among the latest may be mentioned the glass etching process introduced by Mr. S. H. Crocker, of Sydney, and before you there are specimens of the *Australian Graphic* illustrated by this means. The resisting lines being obtained on the surface of the glass, hydrofluoric acid is used as an etching fluid, and, curiously enough, there seems to be scarcely any tendency to undercut under these circumstances.

So far we have only considered the use and production of transfers from such negatives as consist of only one gradation, clear white and intense black; and before passing on to the consideration of the means of obtaining transfers and blocks from ordinary negatives, in which every tint is reproduced more or less perfectly after the gradations met with in nature, let me point out to you some circumstances which will make it clear to you that we cannot, by simple photographic agency, produce representations from nature having quite the boldness of outline ordinarily met with in the most common kind of wood engravings; but there is now a movement among wood engravers to produce something better than was accepted twenty or thirty years ago—in fact, something more resembling a photograph.

Here is an engraving taken from the *Illustrated London News* of the year 1851—the year of the Great Exhibition—and here, on the other hand, is a quite corresponding subject from the number published last Saturday. In the older engraving the figures are outlined by bold black lines, and the attempts at reproducing the exact shades or gradations of lighting, which we may suppose were visible in the case of the originals, are crude in the extreme. To sum up, the outline is the essence of the engraving, and but little effort is made to reproduce the shades of the original. Now, look at the engraving taken from the last number of the *Illustrated London News.* We certainly have outlines of a similar character, but very much less clearly marked, and everywhere an attempt has been made to represent the lights and shades of the original by a corresponding closely packed collection of lines or dots. Now, look at a photograph of a strictly analogous subject. You see that the artificial outlines which the wood engraver uses to plot out his subject are altogether absent, and we only find that kind of shading which is altogether omitted in the less perfect example of wood engraving. To put the matter shortly, the second-rate wood engraver uses an outline as an index or pointer to his

---

* The following sketches and description, extracted from the *Photographic News*, will enable those who did not attend the lecture to sufficiently understand the construction of the velvet roller:—"Here is a sketch showing it complete and



in section. The measurements specified are those to be recommended, and in the section we show the materials of which the roller is made. After considerable experience, it is found that the best silk velvet is most suitable for the purpose. The body of the roller is of pear-wood, a light material most favourable to the purpose, while the handles are of box-wood. Over the pear-tree block are sewn two layers of thick serge, and over the latter one thickness of velvet, the price of which is about 12s. a yard. A nice brisk nap is required in the velvet, and this cannot be obtained unless a good price is given. The serge, before it is sewn on, should be scalded in hot water, so that it will not ruck afterwards, and the velvet must be fitted by a skilled seamstress. The so-called carpet stitch is best adapted to the purpose, the ends of the velvet not overlapping, but drawn together so as to meet. In this way the seam is not a ridge, but perfectly flat, and the roller does not set-off at this spot. It need scarcely be said that this can only be attained with very fine stitches. The velvet is cut out exactly to size, and sewn on the block. The velvet roller is ready for use as soon as it is made. Unlike the leather roller, there is no need to get it into condition. In the same way, it may be put away in its linen bag as soon as done with, though, perhaps, it is best to clean first; the bag keeps away dust, and the grease in the ink will keep the velvet from becoming hard. Of course you can't scrape a velvet roller, to get the ink off, as you do a leather one; you can only free the velvet of its ink by rolling. The roller is passed over a clean slab, and this is scraped from time to time. The slab gradually pulls the ink off, and this is then removed from the slab by scraping. If you are not able to get off all the ink in this way, pass the roller over a thin sheet of soft paper, and apply a little turpentine. After a little practice, you will soon know when the roller is free from ink."

subject, and he often contents himself with this index or pointer alone, making no effort whatever to represent the true shades of the subject; and the public often prefer this index to the representation of the actual object, because it is easier to follow and to understand. Hence one of the main reasons why a typographic block made from an ordinary negative does not give satisfaction to those who have become accustomed to the mode of treatment adopted by wood engravers. In the photographic block there is no artificial outline, but only the shading. In addition to this, when any part of a figure has the same tone value as an adjacent part of the background, the photographic block makes no distinction between them—they merge into one another; while, in such a case, the wood engraver can make a distinction between the two parts, by making the shading lines incline in a different direction. The effect of photography in bringing about a more perfect system of wood engraving is to be observed in studying the wonderful specimens issued with the Transatlantic monthlies, *Harper* and *Scribner*. Here we often find the artificial outline or index lines either reduced to a minimum or altogether absent, and a fine shading introduced which, when viewed from a little distance, almost strikes the eye like the gradated tints of a photograph. Side by side with the wood-engravings in *Harper*, one often sees phototypic blocks made by the method of Ives; and in noting the great similarity of the effect to the eye, one hardly knows whether to congratulate the phototypist for his near approach to the most perfect examples of wood engraving, or to give praise to the wood engraver for his skill in so closely realising the gradated lights and shades of the photograph.

In making a type block from a photograph, the first step is to translate the evenly gradated tints of the latter into a line system, or a stipple of corresponding intensities. When a photograph is transferred to a wood block, this is done by the personal skill of the individual who engraves the block; but this is by no means to be regarded as photo-engraving proper, so my remarks will be confined to processes in which the translation is effected automatically.

There are many methods of so translating the tints into points, lines, or dots, that even to mention all would be impracticable. In now talking to you, there is no alternative but for me to assume considerable knowledge of the subject on your part, this course of lectures being of the nature of a supplement or appendix to my previous course.

In my last lectures the method of Asser was illustrated, a photo-lithographic transfer being made on a sheet of starched or pasted paper, made sensitive by means of potassium bichromate; and by putting down such a transfer on zinc, and etching into relief, excellent results may be obtained. It may also be mentioned that, as long ago as 1866, Messrs. E. and J. Bullock, of Leamington, obtained a patent for a mode of photo-lithography in half tone, and a print issued during the year in question with the *Photographic News*, shows that their work was equal to anything that has been done since. The print is before you, and you can judge for yourselves. Why, then, you may ask, did not the process become a great thing commercially, and make its mark? The answer is simply this—the invention came before its time, neither good litho-machining nor zinc-etching being practised at the time. The expired patent of Bullock Brothers, No. 2,954, 1866, will be read with interest, and its value is well illustrated by the fact that the essential points of it have been claimed by very many subsequent patentees. Bullock claims the production of reticulated transparencies, by copying a negative over which a grained surface is laid; this transparency affords the means of making a grained negative; but the method by which their best work was made is a second process included in the same patent. Ordinary or photographic paper is coated with a glutinous substance, and printed with a reticulated pattern. Let me now quote from the specification:—"In this case the specks of ink themselves form a medium, and by their aid excessive contrasts are avoided, and half-tones secured. Such picture, when so obtained, is passed to a lithographic stone or zinc plate, and a printed proof produced therefrom; by the aid of chromo-lithography, coloured proofs may be produced." The coating of the paper with a glutinous substance may "be conducted in connection with bichromate of potash or bichromate of ammonia." The said transfer paper may be used, "whether the impression be a lithograph, a zincograph, an impression from an electrotype, or from an engraved or etched plate."

Mr. Dallas' work you have seen before, and there are some specimens before you. He tells me that he supplied tint blocks for journalistic work (*The Garden*) as long ago as 1872.

By transferring a coarsely grained collotype to stone or zinc, a very good grain image is obtained, and the coarse reticulation of the gelatine is very much facilitated by adding chloride of calcium to the sensitive mixture. The following answers very well:—

Gelatine	6 parts.
Water	60 „
Bichromate of ammonia	1 „
Chloride of calcium	2 „

Printing surfaces thus obtained, whether lithographic or typographic, resemble those of Pretsch or of Dallas on the one hand, and those of Sprague on the other hand.

In speaking of the work done by Messrs. Sprague and Co., in which the gradations of the original photograph are translated into a vermicular grain, suited for printing by means o the litho-machine, one must fully recognise the fact that this firm was the first to put photo-mechanical printing from the ordinary gradated negative on a large commercial basis in this country; while the great extent and variety of work executed by them during the last two years, abundantly proves that there is a large and rapidly extending field for work of this kind. Before you are numerous examples of their work, and in the extensive commercial application of this method, we have a very decided advance since the date of my previous lectures.

In order to obtain a transparency in which the tints are translated into points, lines, or dots, Algeyer and Bolhoevener have recently suggested a method in which a collotype plate is exposed under a negative; and after this plate has been soaked and inked up in the usual way, the fatty image is reinforced by dusting with an opaque powder. This method is of course dependent on the reticulation of the gelatine for the production of a grain. From such a transparency a negative may be made by contact printing, and from this a photo-litho transfer by any one of the well-known methods.

Meisenbach, of Munich, has recently obtained a patent, in which he claims some details as to well-known methods of breaking up the grain of a photograph by means of a network, and he more especially claims the shifting of the network during the time of exposure. As regards this point, something similar was described by Bertschold in the volume of the *Photographic News* for 1859. Notwithstanding the fact that one cannot find any very striking features in the patent of Mr. Meisenbach, this gentleman has produced some typographic blocks of surprising excellence, examples of which are now before you.

Having now touched on a few stray points, we come to an important feature in connection with the subject, that is to say, the direct translation, by mechanical means, of the gradations of depth existing in the Woodbury relief into corresponding shades of stipple or granulation; but before entering into these, let me call your attention to a method of granulating the relief itself, which Mr. Woodbury has made the basis of a method by which excellent printing blocks have been made.

Mr. Woodbury exposes his ordinary relief tissue under a transparency with a piece of network interposed, the effect of this being to produce a decided grain all over the high portions of the resulting relief, and no grain over the deep parts, intermediate portions being grained to an intermediate extent. A reverse cast from the grained relief thus obtained is the printing block. This mode of procedure is subject to one disadvantage in actual practice, as the various printing parts of the resulting block do not lie accurately on one plane, as is the case with a block made by etching a plate of zinc into relief. Mr. Woodbury, however, informs me that he has recently overcome this objection, by a modification of the process in which a transfer is obtained directly from the relief. The specimen before you will show what good work this method is capable of yielding.*

* The following quotation from Woodbury's specification of 1873 will serve to fully elucidate the nature of the process referred to:—"I prepare sheets of bichromatized gelatine snch as is used in the process called 'Woodburytype,' and expose these under a photographic positive to the action of light, but interposing between the positive and the gelatine film a transparency on collodion or mica, of what is known as mosquito netting, Brussels net, tulle, and so forth, which has the effect of breaking up the resulting relief into a multitude of fine square hexagonal lines; or for some subjects I interpose a transparency on mica or collodion of any design of a similar nature that will have the same effect, such as an impression from a grained stone, or the same from a number of fine ruled lines. The sheet of gelatine, when washed, will give a relief having the positive photograph represented by a number of lines, instead of the simple half-tone it originally possessed; I then take an impression from this by means of hydraulic or other pressure in any soft metal, and use the block so obtained for printing at a type press where only a few copies are wanted; but where large numbers are required, I electrotype the same in the ordinary way. I prefer to use diffused daylight or sunshine through ground glass or tissue paper to produce the relief, as in that case the light in the parts that represent the white creeps round the lines, thus partially obliterating them in that part, and leaving them strongest only in the parts printing dark. I sometimes adopt another method. I take a negative of the network by transmitted light, and copy this together with the negative to be

Mr. Fred. E. Ives, of Philadelphia, published, in 1878, a method of translating the smooth photo-relief into stipple, and this method may be regarded as a new departure. According to the method of Ives, as described by him in 1878,* and patented in the United States, the essential features of his method consist in inking the Woodbury relief, and pressing against paper which has been grained or embossed, somewhat after the fashion of bookbinders' cloth. Under these circumstances the projections on the paper become completely crushed down by the inked relief where the gelatine is thickest, and a solid black results, while the more shallow parts of the relief only tip the projection on the paper with ink. Intermediate thicknesses of relief produced a medium effect. You will now please note the effect of pressing this sheet of grained paper against the inked Woodbury relief, a picture in black and white resulting, the shades of the original being represented by the varying extent of the closely packed dots which constitute the picture. The translation into stipple thus obtained may be used as a transfer for putting down on stone or zinc, but if preferred, it may be re-photographed. Ives also made printing blocks by casting from the grained surface which had been compressed by the gelatine relief, although these were not found to be quite equal in quality with those obtained by the first mentioned method. A subsequent modification of Mr. Ives's method gives results much more easily and economically, as he has succeeded in substituting a "swelled gelatine" relief for the more expensively produced Woodbury relief. In a letter to me, Mr. Ives says:—"The relief which I now employ is a plaster cast from swelled gelatine, which is secured so easily that an apprentice seventeen years of age makes them acceptably for Crosscup and West. On the relief the lines and stipple are impressed by means of a printing film of elastic V-shaped stippled lines, in a manner which gives the operator considerable control of the effect. The line and stipple picture on the plaster relief is then stripped off for lithographic transfer or etching, by a method so simple and perfect that it astonishes all who see it done. Formerly, I had to reproduce the impression by photography in the camera, and by this operation could not avoid losing much or the delicacy of the original, which is wonderfully delicate, sharp, and clear in line. I have to secure ruled plates for moulding closer lined printing films before I can apply the transfer method of reproduction for fine work; so it may be months before I shall show you what fine results I can secure in this way."

The broad principle of the Ives method, which consists in pressure of the relief against a grained or stippled surface, has been the subject of several subsequent patents and inventions. We find that, in 1879, Petit, of Paris, took out an English patent for a method nearly identical with that of Ives, and soon after another patent by Dredge followed; this latter, however, indicating novel methods of working. A process of quite a similar character is the "Crayontype" of Ad. T. Eggis, which was published in the *Photographic News* a short time ago. Mr. Eggis, instead of inking the relief, takes an inked film, such as manifold copying paper, and lays this on the relief. The grained paper is now placed over and pressure is applied. If the grained paper sold for producing crayon effects in lithography is used, very excellent transfers are obtained. Mr. Barker will illustrate the process to you.*

Other modes of effecting the translation of the

reproduced, thus producing a positive with the lines already thereon, from which I proceed to make a relief and blocks, as stated."

* The following reprint of Ives' original declaration will be of interest:—Ithaca, N. Y., Aug. 12, 1878. I, the undersigned, have, to-day, invented a method of obtaining relief plates for the typographic printing press, from ordinary photographic negatives, which may be described as follows:—1st. From an ordinary photographic negative, a relief in gelatine, similar to that used in the Woodburytype process, but perhaps in lower relief, is obtained. 2nd. This relief is carefully and uniformly inked with fine printers' ink, and pressed between two flat surfaces (or between rollers), against paper or other material, upon which is stamped, or otherwise produced, a fine grain, or other suitable surface. The inked relief being highest in the black parts, presses down the grain of the paper on the corresponding parts, and the removal of the ink by the paper from those parts of the relief produces a black impression, while upon those parts where the relief of the gelatine is lower, the grained surface is pressed less, and the ink taken up in spots, the size of which depends upon the grain of the paper and the amount of pressure, and producing an effect similar to that of crayon sketches made upon such a surface. 3rd. Relief plates may be made from this impression, either by the usual phototypographic processes, or, perhaps, by obtaining a cast or electrotype of the impressed surface of the paper or other material used to receive the impression from the gelatine relief.—Fred. E. Ives.

* Mr. Eggis, writing in the *Photographic News*, thus describes the method:—"This process gives results good enough to have allowed the taking of a patent, but I find it preferable to describe it for the public benefit. I call it crayontype, for the images it produces are much like those obtained by the artist with a lead pencil (crayon in French). This is how I proceed. I procure or produce, to begin with, a gelatine positive on best plate glass (*glacé*) obtained by the known ways, in relief. The highest point, when dry, should not have more than one millimetre. The other necessary implements are—1st, grained (or lined) paper, of same

relief by pressure on grained surfaces have been patented by Mr. Zuccato, and some of these will be demonstrated to you by Mr. Barker.

The first method consists in first planing a piece of type metal or similar surface in a series of ridges, or a series of pyramids, as the case may be. The plate is then inked, and instead of pressing the relief directly on the inked plate, a piece of very thin paper is interposed; the relief crushes down the pyramids in proportion to its depth. The pyramid of type metal is spread out, and forms a sharply cut outline on the paper, and in this way a transfer is obtained which has a remarkable clearness of outline, almost like the cleanest cuts of the graver.

It will illustrate the matter better if, instead of inking the plate first, the relief is pressed directly against it, and you will then be able to see the flattening of the lines or pyramids.

Two other modes of working have also been patented by Mr. Zuccato. In one he interposes between the relief and a sheet of transfer paper a piece of gauze, or a piece of silk which has been inked with transfer ink. Of course what then takes place is similar to what happens in the case of the plate; the threads of the gauze get crushed out to a greater or less extent, and form lines of greater or less width, but this method in which the gauze is crushed down is not nearly so perfect as the method with the plate of type metal.

A third mode of working, which Mr. Zuccato also claims in one of his specifications, is the pressing of the relief upon a lithographic or zincographic surface on which an ink stipple has been impressed. The stipple gets crushed out more or less, according to the extent of the pressure; this of course depends on the thickness of the relief.

Messrs. Brown, Barnes, and Bell, of Liverpool, have recently made some excellent blocks, and, judging from the appearance of the prints, they appear to me to be likely to have been produced by some method more or less resembling the Ives' process; still I have no knowledge on this point. These gentlemen have made certain patent claims, but as various methods are referred to, one cannot judge from the specifications as to what process is actually employed.

Before you go, perhaps you will look at some reproductions of phototype blocks, which Mr. P. Barry has made by casting in brass. The details are wonderfully preserved, but it does not appear to me that this process of reproduction is likely to supersede electrotyping.

kind as is used by the artists for their drawings destined to be etched; 2nd, a few sheets of blue or black transferring paper (*papier à calquer*, thin paper coated with a greasy substance and coloured); 3rd, a small press. Having these at hand, I take the gelatine positive, lay it on the stone or metal table of the press; on the relievo I place a sheet of transferring paper, the prepared face turned upwards. On this I lay the stippled or grained autographic paper, face downwards, touching the greased sheet. Over all this I place a fine polished steel sheet, well planed. I put the whole under the press, and slowly pull down the lever in such a manner as to give a smooth and graduated impression. Afterwards separating the whole, I find on the grained paper a good and often a perfect stippled reproduction of the gelatine relief. This reproduction being formed by a greasy substance, I am able to transfer it at once directly on stone, for lithographic purposes, or on metal, to be etched in the usual manner. The production of such an image will be easily understood; it is much the same as the direct drawing with a pencil on the paper. Instead of the artist pressing more or less his graphite on the paper, the gelatine relief (which corresponds more or less to the lights or shadows of the photo) presses more or less on the paper, and gives the true gradation of the original. The work of the hand is mechanically imitated very closely indeed. The crayontypes present a different grain, which may be chosen according to the work to be done. It is at least more artistic than the usual regular stippling."

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON PRESERVED MEAT. By J. J. MANLEY.

Though the exhibits of preserved food at the Health Exhibition are very numerous, and, it may be added, excellent after their kind, it can hardly be said that, generally speaking, they show much novelty, or suggest that any great advance has been made of late years in the art of food preservation. At the same time, however, the great variety of exhibits brought together at South Kensington may have the effect of drawing additional attention to preserved substances, and developing a greater appreciation than exists at present of this particular form of our food supply.

Confining my remarks for the present to preserved meat, it is evident that in this department of food preservation no very great improvement has been effected in the class of "tinned" or "canned" goods during the last ten years or so, except as regards the application of pressure, first practised in America, we believe, whereby the meat preserved is rendered more solid and capable of being cut into thin slices, and thus more presentable in appearance. But there is still the great drawback in the "overcookedness" of this class of preserved meats, which militates against their general acceptance amongst us, particularly in the southern districts of this country, the northern districts, and especially the mining populations, patronising them more freely. As a rule, the contents of the tins may be depended on, the great "packing" firms, especially those on the other side of the Atlantic, vieing with each other for popularity, not only by a competition in price, but also by a competition in the excellence of their products, well knowing that a good "brand" will establish itself in the market. The specialties produced mainly by firms at home, more as articles of luxury, and as food for invalids, leave little to be desired, though here, again, what at present seems to be the unavoidable "overcookedness" in order to ensure perfect preservation, detracts from their palatableness, if not from their nutritive value.

The preservation of meat has engaged the attention of mankind from very early times, ancient tribes having soon learned the process of drying animal food, and, later on, the Greeks and Romans having freely employed salt, after the modern fashion, and vinegar and honey, and other antiseptics, for the preservation of meat in enclosed vessels. But the ancients had little necessity for the preservation of fresh meat, as a more or less abundant supply of it in its natural state was always at hand. The case is different now, in the more thickly populated countries of the civilised world, and we have to reverse the well-known Mahomet experiment, and as we cannot go to the "mountain" of supply, the mountain is to some extent brought to us from countries where the meat supply is for the present practically inexhaustible. The methods of meat preservation may, in a general way of speaking, be said to be four, and these include all possible methods, viz., by dessication or drying; by the use of chemical antiseptics: the exclusion of atmospheric air, mainly by the application of heat or pressure, or a combination of both; and by refrigeration or the application of cold, though of course, strictly speaking, what we term "cold" is only a low degree of "heat." As long ago as 1689, in this country John White and William Porter obtained a grant from the Crown "to hold and enjoy for fourteen years" the sole right of preserving animal food, which they warranted would keep sweet for any number of years in any climate; but their process does not seem to have brought about any great result. Only three patents for food preservation were described in the 18th century, but over one hundred were described in the first half of the present. Since then this number has been greatly added to, though in very many instances the patents only vary from one another in detail, and not in principle. We shall only here briefly allude to the desiccation and antiseptic processes, because at the Health Exhibition they are hardly represented at all, except in the form of the familiar "provisions," such as hams, tongues, sausages, and so forth, which are more or less a combination of both, salt being the chief antiseptic used, and they hardly come within the scope of the present notice. The "charqui," or South American dried beef, however, was exhibited, as was also "powdered" meat. A specimen of the latter from Queensland was some years ago submitted to the Food Committee of the Society of Arts; but no form of simply dried meat is likely to secure a large demand, for animal matter is not well preserved by desiccation, as it loses its flavour, and becomes more or less indigestible; the fat has a tendency to become rancid; and the lean in damp weather, absorbing moisture, to become mouldy and sour.

It is with the preservation of meat by heat and cold (to use popular terms) we have here to do; and with examples of these processes the Exhibition abounds. Preservation by means of heat is effected by driving out the atmospheric air, and creating a vacuum round the substance preserved, in tin or other vessels. Hence the method is often called preservation *in vacuo*. The first simple process consisted in putting meat, with a charge of water, into a tin case with a small aperture or "pin-hole" at the top, and then placing it in boiling water nearly up to its top, and when the steam had displaced the air, stopping the hole with solder. This process dates back as far as 1829, but the first patent for it was granted to M. Pierre A. Augilbert, in 1823. An improvement was effected by Wertheimer, in 1840, and again by Gunter in the following year, when Goldner and Wertheimer obtained patents for using a bath of muriate of lime for heating the vessels. This is called the chloride of calcium process. But perhaps it is only fair to give M. Appert, of Paris, the credit for first preserving meat by the application of heat, though he did not use the "pin-hole;" and Messrs. Donkin and Gamble were, I believe, the first English firm which made a business of preserving meat on this principle. This is not the place to enter into a discussion whether the presence of oxygen is the sole cause of decomposition or putrefaction, or whether these are brought about by living "microscopic germs;" whether preservation by heat is effected solely through the expulsion of the atmospheric air, or by the actual destruction of the "microscopic germs;" but it may be taken for granted that, without a perfect expulsion of the air, and the creation of a perfect vacuum in the vessels, preservation is not effected. A moderate degree of heat, such as that of boiling water, is not sufficient to expel all the air from the vessel, and effect a perfect vacuum for preservation. Hence an extra temperature is required.

The four methods of applying heat to vessels containing meat (or fish) are known by the names of (1) the ordinary Aberdeen process; (2) the Steam-Retort process; (3) the Chloride of Calcium process; and (4) Jones's Patent Vacuum process. These, though varying in detail, are practically the same in principle; but Mr. Jones added the use of an external vacuum chamber, with which the tins are connected by pipes, to further assist in getting the air out of them. This was certainly the most successful method as regards its result, the meat preserved being much firmer, but the comparative complication of the process, and the fact that the contents of the tins lost more weight than when subjected to the other processes, prevented it being adopted by meat-preserving firms. It is by one or other of the first named three methods, with certain modifications in detail, but all on the vacuum principle, that almost all the solid meats, fish, poultry, vegetables, soups, stews, the variety of "odds and ends," such as kidneys, tripe, sausages, minced meats, and the several "made dishes," both in this country and abroad, are preserved.

The methods of drying, refrigeration, and use of antiseptics, and combinations and modifications of them, more or less important methods of preservation in themselves, are either too costly, or are not, strictly speaking, methods by which animal food can be preserved for any lengthened period, for the practical purpose of its being brought to this country as a substantial and cheap addition to our food supply. It is by heat alone, as applied in the above-mentioned processes, that it can fairly be said the food preservation question has hitherto been solved, and then only in a certain modified sense. By all the above methods, however, preservation—simply as preservation—is perfect. As long as the tins or other receptacles in which meat or any other substance, has been successfully preserved by the creation of a perfect vacuum through the application of heat, remain sound and air-tight, so long will their contents remain perfectly sound also. Tins with the meat perfectly sound in them, though preserved 50 years ago, are still in existence. At the London Exhibitions of 1851, 1862, and 1873, tins of meat which had been "put up" from 25 to 40 years ago, were exhibited, and when tested were found perfectly sound. Stores of preserved meats, &c., in tins, have been left in the Arctic regions for years, annually exposed to a temperature of 92° below, and 80° above zero. They have been brought back to this country, and the contents of the tins found to be as sound as the day they were "put up." As a matter then of mere preservation, the heat processes are an unquestionable success, and by their agency we have, in this country been able to obtain a large supply of sound, edible and cheap beef and mutton from the very ends of the earth.

It may here be well to repeat the instructions often given to purchasers of tinned meat, to the effect that the tins which are bulged out at the top or bottom, or in other words showing a convexity, give warning that the contents are bad, as the tins have become defective and let in atmospheric air, while what are called the "collapsed" tins, of which purchasers are often afraid on account of their irregularly indented sides, show that their contents are sound, the "collapsing" being caused by the very perfectness of the vacuum within them. A word here also may be useful in reference to the alleged poisoning, of a more or less serious character, which, it is said, has resulted from eating various kinds of preserved meats, fish, vegetables, and fruit from tins. But the instances are very rare, indeed hardly worth serious consideration, when compared with the millions of tins used annually all over the world. Some tins themselves are originally imperfect, or, for some reason or other, become so after keeping in stock; and consequently their contents become more or less unwholesome; but it need hardly be said that this is no more valid an objection to tinned goods than it would be to any other articles, liquid or solid, which require to be kept air tight. In some cases injurious effects may follow the consumption of tinned food, when the consumer has a predisposition to gastric, hepatic, or other internal derangement. But, perhaps, the most important consideration in the matter is the chemical action which may sometimes take place on bad metal after a tin of sound food has been opened, and the contents left in it exposed to atmospheric air. Any danger, however, from this is easily obviated by turning the contents of the tin into some glass or earthenware receptacle, if they are not all wanted for immediate use. But, after all, the danger of using tinned food is so infinitesimal, and the cases of injurious effects reported have been in most instances so grossly exaggerated, that it is hardly necessary to pursue this matter further. Practically, there is no more danger in eating tinned food than food in a great variety of other forms. In confirmation of this view there has just come to hand a report of Major-General Hawkins, of the United States Army, in which he says that the army outposts throughout the States have for nearly twenty years been largely supplied with "tinned" meats, vegetables, and preserves, and that he has never known a case, either among officers or men, or their families, of injurious effects from eating these goods. He further adds that the Medical Directory of the army corroborates this statement.

Among the exhibits of tinned meats those shown by Messrs. Chase and Co., of Adelaide-buildings, London-bridge, comprising a variety of American productions; by J. S. Laurie and Co., of 14, St. Mary-axe, E.C.; by Messrs. Dickson and Renwick, of 39, Lombard-street, E.C.; by Messrs. Libby and Co., of Chicago; and several other firms are well worthy of notice. The show of Australian, New Zealand, and other meats, by Messrs. Huckvale and Co., of Billiter-street, E.C., is an excellent one, the firm being one which deals in none but the best and most reliable "brands." The tongues they exhibited deserve special commendation, as also do the "potted" meats, mostly of English production, which would be welcomed at the breakfast and luncheon tables of the most fastidious.

CHINESE MUSIC, AND WEIGHTS AND MEASURES.

Chinese music can now be heard by all who desire to hear it at the Health Exhibition, and more may be learned on the subject from the pamphlet published by the Commissioners for the Chinese department. A curious account of the common origin of Chinese weights, measures, and musical notes is contained in a paper read some years ago before the German Asiatic Society of Japan by Dr. Wagener. The story is based on native legends, and is also to be found among the Jesuit "Mémoires concernant les Chinois." Dr. Wagener says there is not the slightest doubt that the Chinese system of weights and measures is more than 4,600 years old; and it is a highly remarkable circumstance that, quite irrespective of the fact that it is more scientific and exact, it possesses all the advantages for which the French metrical system is so much praised. In the first place, it starts from a basis supplied by Nature; secondly, the decimal arrangement is almost consistently employed throughout; thirdly, linear and dry measure proceed directly from the same unit as the measure of weight; and lastly, what the metrical system does not do, it regulates in the simplest manner the relations of musical notes, which latter form the starting-point for the whole system of weights and measures. The following account of the origin of this system (says Dr. Wagener) contains fact and fancy mingled, but it is easy to distinguish between them. In the reign of the Emperor Hoang-ti, who ruled over China in the twenty-seventh century before Christ, the scholar Lyng-lun was commissioned to complete the musical system which had been discovered 250 years earlier, and particularly to lay down fixed rules for making musical instruments. Naturally he had to commence with the bamboo, which had already been long used to give the note for other instruments. He, therefore, betook himself to the province of Siyung in North-Western China, where, on the northern slope of a range of high mountains, a species of bamboo grew, which, on account of its uniformity and its structure, being neither too hard nor too soft, was exceedingly suitable for a wind instrument. He cut one down and tried it. Tradition says that it gave the same note as his own voice when he was excited by no emotion; and the rippling of the sources of the great Hoang-ho, or Yellow River, which were in the vicinity, followed in the same tone. At the same time the fabulous bird Fung-Hiang, accompanied by his mate, flew to the place. Both perched themselves on a neighbouring branch, and commenced a song, in the course of which each of the birds gave six separate notes. These are the notes which are called the six male and six female tones in the scale discovered by Lyng-lun, and which correspond to the ancient doctrine of the male and female principles in Nature. As a matter of course, the deepest of the male notes was the one already discovered by the philosopher himself. He now endeavoured to reproduce the other notes with the help of bamboo pipes, and succeeded. His task was now to lay down fixed rules as to the length of the pipes, so that thenceforth they could be easily constructed everywhere. For this reason, and also because such a scale of notes depends upon slight differences of length, and there were scarcely at this time instruments to divide great lengths, he necessarily arrived at the notion of passing from the less to the greater, and of laying down an adequately small natural unit for his measurements. That could be nothing else but a grain of seed; and now the point was to get seeds of the greatest possible uniformity. He chose a sort of millet, the *Sorghum rubrum*, the seed of which is of a dark brown colour, and which is said to possess the advantages of greater hardness and uniformity than that of the grey and other kinds. The seed is pointed at the ends, and from one point to the other the length is somewhat greater than in the direction at right angles. Lyng-lun now fixed the length of the pipe, which gave the keynote at 81 grains of the seed placed lengthwise in a row. But when the grains were placed breadthwise it took 100 grains to give the same length. Thus the double division of 9×9 and 10×10 was naturally arrived at. According to the dimension in question, it was called a musical or an ordinary foot, the latter being introduced with the decimal subdivision as a measure of length. The breadth of a grain of seed was 1 *fen* (a line), 10 *fen* = 1 *tsun* (an inch), 10 *tsun* = 1 *che* (a foot), 10 *che* = 1 *chang*, 10 *chang* = 1 *ny*. In subsequent times the line was divided into tenths, hundredths, &c. Lyng-lun also laid down rules for the breadth as well as for the length of the pipe, because, although the note is essentially dependent on the length, it is nevertheless necessary for its purity that the pipe should be neither too broad nor too narrow. He therefore fixed the circumference on the inside at 9 grains laid lengthwise. With these dimensions, namely, a length of 81 grains, and an internal circumference of 9 grains, the pipe which gives the keynote contains just 1,200 grains, and this volume accordingly was made the unit of dry measure, and was called a *yo*; 2 *yo* = 1 *ko*, 10 *ko* = 1 *cheng*, 10 *cheng* = 1 *ten*, 10 *ten* = 1 *hu*. So far we see how the units of length and dry measure were connected with the musical keynote. The twelve notes of the scale are all derived from the keynote, and are to a certain extent comprehended in it. Hence, if the 1,200 grains contained in the pipe are divided among the twelve notes, it gives to each 100, and the weight of these 100 grains was made by Lyng-lun the unit of weight. This was divided and subdivided on the decimal system until a single grain became the lowest weight of all. At a later period even the coinage became connected with this system, for one of the weights, the *leang*, corresponding to our ounce, became the weight of metal put into a coin, so that the modern *tael*, in which mercantile quotations are found every day in the *Times*, is merely an ounce of silver, and is thus directly connected with the musical scale. Finally, says Dr. Wagener, it appears from this account that, in China, weights, measures, coinage, and the tuning of musical instruments have been derived quite consistently from a constant unit supplied by Nature herself, and that the essentials of this system are over 4,600 years old.—*Nature.*

PINE FORESTS OF NORTH CAROLINA.

Consul Walker says that little change has taken place during the last three quarters of a century in the preparation for market of the far-famed products of the pine trees of Carolina. The resinous product of the pine is of six sorts, turpentine, scrapings, spirits of turpentine, resin, tar and pitch. Turpentine is the sap of the tree obtained by making incisions in the trunk. It begins to distil about the middle of March, when the circulation commences and flows with increasing abundance as the weather becomes warmer, so that July and August are the most productive months. When the circulation is slackened by the chills of autumn, the operation is discontinued, and the remainder of the year is occupied in preparatory labours for the following season, which consist in first making the boxes, this being done in January and February. In the base of each tree, about three or four inches from the ground, and generally on the south side, a cavity is formed, large enough to hold about two pints, but proportioned to the size of the trunk, of which it should occupy a quarter of the diameter. Next comes the raking or the clearing of the ground at the foot of the trees from leaves and herbage, by which means they are secured against the fires that are often kindled in the woods, as if the flames gain the boxes, already impregnated with turpentine, they are rendered useless. At the sides of the box two oblique gutters are made about three inches long, to conduct into it the sap that exudes from the edges of the wound. At the expiration of a fortnight the first boxes are filled with sap, an iron implement called a "dipper" is used to transfer it to pails, which in turn are emptied into casks placed at convenient distances. To increase the product, the upper edge of the box is clipped once a week; the boxes fill every three weeks. The chippings extend the first year a foot above the box, and as the distance increases, the operation is more frequently repeated, to remove the sap coagulated on the surface of the wound. The closing of the pores, occasioned by continual rains, exacts the same remedy, and it is found that the produce is less abundant in moist and cool seasons. After five or six years, the tree is abandoned. It is estimated that 250 boxes yield a barrel containing 320 lbs.; and in general, 3,000 trees yield, in ordinary years, 75 barrels of turpentine, and 26 barrels of "scrapings," the scraping being a coating of sap which becomes solid befoie it reaches the boxes. The manufacture of spirits of turpentine is largely carried on in North Carolina. The turpentine is distilled in copper stills; formerly iron stills were used, and the method employed is as follows:—A 15 barrel still, the barrel weighing 280 lbs., is charged early in the morning, gentle heat being first applied, until the mass is liquified, and a coarse wire skimmer being used to remove the chips, bark, leaves, and other foreign substances that may rise to the surface, the temperature meanwhile rising until it reaches 316° Fahr. All the accidental water that is contained in the crude turpentine as it comes from the forest, having been distilled off, a small stream of cold water is then let in, so that the heat is kept at below 316° Fahr. the boiling point of oil of turpentine. The oil of turpentine and water now run over, and the mixture is caught in a wooden tub. The distiller tests the quality of the flow from time to time, in a proof glass, and the distillation is continued until the proportion of water coming over is nine of water to one of oil of turpentine. At this stage the heat is withdrawn, the cap is taken off, and the hot resin is drawn off by a valvular cock at the side of the still, near the bottom. This resin passes through a strainer before it reaches the vat, to rid it of foreign substances which may not have been previously removed by the skimmer. The yield of oil of turpentine from "virgin dip,"—that is, the first exudation from a newly boxed tree—is about five gallons to the barrel, about 20 per cent. being left in the resin, since the removal of a larger proportion would darken the colour, and consequently depreciate its value. The yield from "yellow dip" (the running from the second and subsequent years) is about four gallons to the barrel; that from "scrapings" is from two to three gallons and a-half. Tar is made from dead wood of the long-leaved pine. As soon as vegetation ceases in any part of the tree, its consistence changes; its sap decays, and the heart, impregnated with resinous juice, becomes surcharged to such a degree as to double its weight in a year: the accumulation is said to be much greater after four or five years. To procure the tar, a kiln is formed in a part of the forest abounding in dead wood. This is first collected, stripped of the sap, and cut into billets two or three feet long and about three inches thick, a task which is rendered long and difficult on account of the knots. The next step is to prepare a place for piling it, and for this purpose a circular mound is raised, slightly declining from the circumference to the centre, and surrounded by a shallow ditch. The diameter of the pile is proportioned to the quantity of wood which it is to receive; to obtain 100 barrels of tar it should be eighteen or twenty feet wide. In the middle is a hole, with a conduit leading to the ditch, in which is formed a receptacle for the tar as it flows out. Upon the surface of the mound, beaten hard and coated with clay, the wood is laid and arranged in a circle. The pile, when finished, may be compared to a cone truncated at two-thirds of its height and reversed, being twenty feet in diameter below, twenty-five or thirty feet above, and ten or twelve feet high. It is then strewed with pine leaves, covered with earth, and contained at the sides with a slight cincture of wood. This covering is necessary in order that the fire kindled at the top may penetrate to the bottom with a slow and gradual combustion, as, if the whole mass was rapidly inflamed, the operation would fail, and the labour in part is lost. As the tar flows off into the ditch it is emptied into casks containing about thirty gallons each. Consul Walker states that the quantity of spirits of turpentine exported from North Carolina now averages about 5,300,000 gallons, and of resin about 550,000 barrels annually.

MECHANICAL STENOGRAPHY AT THE TURIN EXHIBITION.

By P. Le Neve Foster.

Amongst the most important novelties at the Turin Exhibition, the stenographic machine of Signor A. Michela merits special notice.

Signor Michela has succeeded in grouping into various series, and in representing by means of certain combinations, all the phonetic sounds emitted in any language, and has formed a notation of language perfectly similar to that of musical sounds. As soon as they are pronounced, the different words, so to speak, are decomposed by the ear of the operator at the instrument, and a graphic representation of the syllables is printed upon a slip of paper which is drawn through the machine, and from this they can be read afterwards, and transcribed into ordinary writing, in order to reproduce the speech, such as it has been delivered, in whatsoever language it has been spoken.

The machine, which in form somewhat resembles a small harmonium, is about 18 inches in length, by 10 inches in width, and 8 inches in depth, and is mounted on a portable stand. It consists essentially of two parts. 1st. The printing mechanism. 2nd. That referring to the automatic drawing forward of the paper. The first consists of two keyboards, similar to that of a pianoforte or harmonium, arranged in a symmetrical manner, and having each 10 keys (6 white and 4 black). These keys, when depressed by the fingers of the operator, press on 20 studs, and through them a similar number of corresponding rods, and these lower the ends of 20 metallic levers, the arms of which have a constant ratio, and at the same time the opposite end, which carries a style, is lifted upwards, and a sign or character engraved upon it is reproduced upon the slip of paper. It is, therefore, only necessary to depress one of the keys in order to raise the style corresponding to it, and if several keys are depressed at one time, the corresponding combination of signs will be printed upon paper. The machine may be arranged as an "embosser," or as an "ink writer," which latter is the most preferable form, as the printing can be read off quicker, and with less fatigue to the eyesight than is the case when the signs are produced in relief.

The mechanism referring to the drawing forward of the paper is also exceedingly simple, and this motion can be produced in a variety of ways. In the machine exhibited, however, it consists of a small lid placed horizontally underneath the twenty keys, and which, when any one of them is pressed down, moves the end of a lever, which acting by means of a catch on a ratchet wheel causes it to revolve; a spring on the underside of the lever brings this latter back to its original position when the pressure is removed. The ratchet wheel, which is fixed on the same axis with a friction roller, gives motion to another roller placed above it, so that the paper band on another roller placed between the two keyboards, when caught between the two friction rollers which pull it forward, is moved automatically at each impulse of the ratchet wheel caused by depression of one or more of the keys. The pressure of these friction rollers on the paper is regulated by a screw, and guide bars are provided for the printing styles.

The essential feature in this invention is the manner in which the graphic representation of the various phonetic sounds is obtained, and the various combination of signs which correspond to the different syllables and words could not be explained clearly here without special diagrams. The manipulation of the keyboard of this instrument differs from that of an ordinary piano, inasmuch as the same finger always operates upon the same two keys, a circumstance tending to facilitate its use, especially amongst the blind. A skilled operator can take down 200 words per minute in any language he knows, which speed is more than sufficient to follow the fastest orator, as the delivery of speech varies from 80 to 180 words, or averaging 130 words per minute.

This machine has been lately adopted in the Italian Senate.

It will be readily seen that this apparatus can be applied with telegraphy to the rapid transmission of shorthand messages; and from experiments that have been made, there is every reason to believe that the paper bands can be printed with the same rapidity at distant stations, by the simple manipulation of the keyboard at the one end of the line, as they are now printed at the Exhibition.

THE SILK HARVEST OF 1884.

Consul Peixotto, of Lyons, states that the silk crop in France for the present year is now gathered, and, according to the most reliable accounts, will fall short short to the extent of about 25 per cent. compared with that of last year. As the harvest of last year gave but 611,000 kilogrammes of silk, the present will scarcely yield more than 460,000 kilogrammes of *grège* silk, which will thus prove inferior to any of its predecessors for the past six years, except that of 1879, when the total crop reached only 375,000 kilogrammes. The deficiency has been owing in great measure to the reduced quantity of eggs for incubation, and the unfavourable weather during the latter period of development. The Italian crop is found to be inferior by from 15 to 18 per cent., compared with that of 1883, as to quantity, while the quality is reported to be much inferior. The crop in 1883 reached 3,200,000 kilogrammes, but it is doubtful whether it will exceed 2,700,000 kilogrammes for this season. In Spain the crop is deficient to the extent of about 10 to 15 per cent. as compared with that of 1883, when it yielded 95,000 kilogrammes. The crops in the Levant, especially in the Broussa district and in Syria, have been in general excellent, and in production considerably superior to last year. Silk culture in these countries is greatly developing, each season witnessing an increased production. The crop of 1883 exceeded 600,000 kilogrammes, in 1879 it only amounted to 345,000 kilogrammes. This year it is estimated to be about 700,000 kilogrammes, and may even exceed that figure. The quality of the cocoons and the silk produced is remarkably good, and grows in favour. In China, it is estimated that the export crop will amount to 60,000 bales. In 1883, Shanghai exported 2,491,000 kilogrammes, and Canton 1,156,000 kilogrammes, and these figures, it is estimated, will be greatly exceeded this year. As regards Japan, a fine crop is reported, and it is estimated that the amount exported will surpass 30,000 bales. During the year 1883, the exports from Yokohama amounted to 1,612,000 kilogrammes. In India it is stated that the crop is considerably superior to that of last year, when 536,000 kilogrammes were exported from Calcutta. In Georgia and Persia the amount of silk consumed and exported in 1883 amounted to 250,000 kilogrammes, and though the news respecting this year's crop is contradictory, it is expected that the result will be quite equal to that of last season. Consul Peixotto estimates that the *grège* silk crop of the world for the year 1884 will amount to 10,000,000 kilogrammes, or but 7 per cent. less than that of the harvest of 1883.

General Notes.

ANTWERP INTERNATIONAL EXHIBITION, 1885.—Portugal has applied, through its Minister of Marine, for a space of 250 square metres in the grounds, for a pavilion to show the products of its colonies. The Presidency of Bombay will make a display of its artistic productions, and the Lieut.-Governor has ordered the Director-General of prisons to have carpets made specially for exhibition. He has also appealed to the native princes to participate. Calcutta is expected to forward a good collection of its raw products. In the last number of the *Journal* the notice of this Exhibition was by mistake headed Amsterdam Exhibition.

BRIGHTON ELECTRIC RAILWAY.—The extension of this line having now been in operation for six months, a few particulars may be interesting as showing the capabilities of a light line of this description. The car mileage amounts to 15,600 miles, or 100 miles per diem; and the number of passengers, in round numbers, to 200,000. These figures would have been increased, but for the fact that at certain hours the would-be passengers exceeded the capabilities of the car, which seat thirty persons only. No accident has occurred to either the general public or to passengers by the car. The consumption of gas in the gas-engine has been 300,000 cubic feet, or $1\frac{1}{2}$ cubic foot per passenger per mile. The total cost of traction, including the interest and depreciation on engine, dynamo, and motor, cost of gas, oil, and attendance, has amounted during that period to 15s. 6d. per day (100 miles run), say 2d. per mile. The car service has only been stopped for one day, through the tyres of the wheels giving out, owing to the heavy pressure of the holiday traffic, when there was no second car available.—*Electrician.*

CORAL INDUSTRY.—The best coral grounds, yielding the most and best coral, according to the *Times*, are still those on the Algerian coast, fished for that purpose from the middle of the 16th century, the others being the coasts of Sicily, Corsica, Sardinia, Spain, the Balearic Isles, Provence. Over 500 Italian boats, manned by 4,200 men, are employed in the coral fishery, 300 of these boats being from Torre del Greco, in the Bay of Naples. The quantity gathered by these 500 boats amounts in all to about 56,000 kilogrammes annually, valued at 4,200,000 lire; that by other boats, Spanish, French, &c., to 22,000 kilogrammes, at 1,500,000 lire—total for the year, 78,000 kilogrammes, at 5,750,000 lire. The taxes paid to the Government for the liberty of fishing on the African coast are very high, 1,166 lire per boat for the summer season, and half as much for the winter, so that in consideration of the toils and risks undergone, the profits are but very moderate. The gross gains, per boat, may be set down at 8,000 lire for the season, and the expenses at 6,033 lire, leaving only 1,967 lire net profit. In Italy are 60 coral workshops, of which 40 are in Torre del Greco alone, employing about 9,200 hands, mostly women and children. The principal markets are Germany, England, Russia, Austria, Hungary, and Poland, a large part going to Madras and Calcutta.

Journal of the Society of Arts.

CANTOR LECTURES.

RECENT IMPROVEMENTS IN PHOTO-MECHANICAL PRINTING METHODS.

By Thomas Bolas, F.C.S.

Delivered Monday, February 11th, 1884.

Intaglio Plates. Collotypes. Photo-Mechanical Methods, as applied to the Decoration of Pottery. Miscellaneous Processes.

Perhaps the most perfect mode of printing is from an incised or "cavity" plate, as by this method the most minute markings can be reproduced with a degree of perfection which is not attainable either in the case of lithography or typography; but what is, perhaps, of more importance, is the circumstance that by adjusting the depth of the cavities to the requirements of the subject, not only can the engraver of the plate determine which portions of the print shall be covered with ink, but he can also determine how much ink shall be devoted to each part of the subject. To put the case in another way, not only can the engraver plot out his subject in black and white, but, within certain limits, he can determine how black the lines shall be.

Intaglio plates made by the aid of photography have been produced in great perfection by several methods, but up to the present time there has not been a very large market for them; partly, perhaps, from the considerable expense attending the work of printing from them. Intaglio plates are, even in the present day, generally printed from by hand; and this notwithstanding the fact that very excellent machines have been constructed for the purpose of plate printing.

One may generally put it that any transfer method for the production of a lithographic or typographic surface may also be applied to the production of intaglio plates, it being merely necessary to make a transfer in which the whites and blacks are reversed, to put this down upon a copper or steel plate, and to etch away the uncovered parts by suitable means.

It will be thus seen that, by the Ives method and its modifications, intaglio plates may readily be made; but there is but little inducement to do so, as such plates will not give much better impressions than the typographic or lithographic surfaces produced by similar methods, so that the great expense of printing from the intaglio plate steps in as a determining circumstance. There is, however, an exception in the case of printing surfaces to be used for pottery decoration. For this purpose intaglio plates are generally used, the method of printing being so rough and simple that the impressions cost about the same as prints from a type block. Hence it happens that intaglio plates made by means of photography have a special value to the potter. On the bed of this little press is a Woodbury relief made from a positive, that is to say, just such a relief as is used for the stannotype method, those parts of the relief corresponding to the whites of the original being high, and those parts of the reliefs corresponding to the darks of the original being low. Mr. Barker has uniformly inked it by means of an ordinary printer's roller, and let me now take an impression from the inked relief on a sheet of paper which has been grained in relief by means of pressure against a ruled plate. You see that a negative transfer in stipple is thus obtained, and when this is transferred to a copper plate, it serves as a resist to the etching fluid, a solution of perchloride of iron in water being one of the best mordants.

An extremely simple and expeditious method of engraving line subjects upon copper plates is the bichromated albumen process, practised with much success by Gobert and others. A plate is covered with a film of bichromated albumen, and exposed under a transparency, until the whole of the ground—that is the part not covered by the lines of the transparency—is rendered insoluble. The plate is next washed with cold water, so as to remove the albumen from the lines, after which the etching is effected by an alcoholic solution of ferric chloride.

The following details will be sufficient to enable the method to be carried into practice. One hundred cubic centimetres of albumen are mixed with a solution of two and a half grammes of bichromate of ammonia in fifty cubic centimetres of water, and after having been well beaten, the mixture is filtered. A carefully cleaned plate of copper is now coated with the mixture, and after the excess has been well drained off, the plate is dried at a very gentle heat, it being retained in a horizontal position meanwhile. The exposure required is by no means a long one, half a minute in moderate sunshine being sufficient in ordinary cases; but this must, of course, be learned by experience. Instead of developing (washing away the unaltered albumen) in plain water, it is better to use a weak solution of aniline red or magenta dye, as under these circumstances the ground becomes tinted, and the progress of the development can be watched. When the plate has been dried, nothing now remains but to varnish the back and edges with an ordinary black varnish, such as the so-called Brunswick black, and to etch. The etching bath is made by dissolving one part of perchloride of iron in five of alcohol, and ten minutes is generally a sufficient time for etching to the required depth.

On the table are some early specimens illustrating the photo-engraving method of Mr. Woodbury—now so successfully carried into practice by Messrs. Goupil and Co., of Paris. A gritty powder—crushed glass answers well—is incorporated with the gelatine used for making the Woodbury relief, and a leaden reverse being taken by pressure from the rough relief, the leaden reverse is reproduced by a twofold electrotyping. This reproduction of the leaden reverse is the printing plate.

The method which Major de La Nöe calls typogravure is in reality an intaglio process, but the printing is conducted as in the case of ordinary zincography. The details are as follows:—A prepared zinc plate is coated with a film of sensitive bitumen by well known means, and exposure is made under a transparency or a tracing, so that when development is carried on with turpentine or benzole in the usual way, the lines alone are bare. The plate is now etched with dilute nitric-acid (1 and 40) until a depth of about a 250th of an-inch is reached, after which the plate is dried and once more coated with bitumen. The ground is now polished off with a stick of charcoal, leaving the bitumen in the lines; after which the plate is gummed and printed from by the usual zincographic method. This process is admirable for map work, although it is obviously inapplicable for the reproduction of subjects with widely extended blacks; and it has the advantage that the lines show no tendency to spread.

Before going any further, you may with advantage look back at some of the older examples of photo-engraving in half tone. Here are some specimens done by Talbot's etching process, over 25 years ago, and they are admirable; while yonder is an example done by Mr. Dallas, in 1864, and issued with the *Photographic News* of that year. These examples of work done by Pretsch about 20 years ago are quite sufficient to prove that good work is not altogether a thing of to-day. Among the newer methods, that of Klic deserves special mention; and this specimen, which was issued with the "Year Book of Photography for 1882," will serve to show you how perfectly this method can render the lighter or more delicate shades of a photograph. Messrs. Annan Brothers, of Glasgow, are working the process commercially in this country, and they have turned out some admirable plates. Klic has not published his method, but it is said to be an etching process, and the following details are given in a recent number of the *Photographic News*:—

"The process itself was a secret at first, but we are informed that the principle of working is as follows:—A copper plate is dusted with powdered asphalt, and the plate is heated, so that the asphalt becomes nearly melted. A negative carbon print is now transferred on to the copper plate, and the plate, now covered with the negative in carbon, is etched, at first by a strong solution of per-chloride of iron, which penetrates only the thinnest parts of the picture; then by a weaker solution of the same salt, the solution etching through the thicker parts. By employing more and more diluted solutions, it is possible to etch through thicker and thicker layers of gelatine, so that only the high-lights remain unetched."

On the table are some exquisitely fine plates made by Messrs. A. and W. Dawson, the managers of the Typographic Etching Company, these being reproductions of subjects after nature, and of difficult drawings in wash.

Major Waterhouse has been remarkably successful, during the past few years, in making intaglio plates, and he has published the details of his method. The process is a modification of one introduced some time previously by Geymet, and it is based on the mechanical reticulation or breaking up of the Woodbury relief.

A Woodbury relief is developed upon a plate of silvered copper (but the relief need not be nearly so high as that required for the Woodbury process; in fact, an ordinary carbon print will answer), and when the relief is taken out of the developing water, it is dipped into a solution of potassium bichromate, drained and dusted over with fine sand; this sand having been previously waxed by being heated in an iron pot, and stirred up with a small proportion of wax. The layer of waxed sand is allowed to remain on the film until it is quite dry, when it is brushed off, leaving the gelatine granulated or pitted all over; the pits being deepest in the thick parts. The plate is now blackleaded, and a cast is made in the electrotype bath; this cast being the printing plate.

The specimens on the table will show you what excellent work can be done with this method, and you must remember that Major Waterhouse has not only published full working details,* but he has demonstrated the process before several gentlemen interested in the matter; moreover, he has not patented the method.

Before you are some fine examples of the application of photo-engraving to pottery decoration, by Mr. F. S. Emery, of Burslem—and one photographic method which this gentleman adopts for the reproduction of pottery designs is of special interest. He coats a plate with sensitive bitumen, puts down upon this surface a transfer from the plate to be reproduced, and exposes to light until the ground is insoluble. Development is now effected with the usual solvents—say, a mixture of turpentine and benzole; only those parts of the ground which were protected by the transfer dissolving. The etching is affected by perchloride of iron.

As regards collotype printing, the progress to be reported is principally as regards extension of work and some minor details; while as far as this country is concerned, the Autotype Company practically hold the thing in their own hands. Excellent as the specimens of foreign work may be which are placed before you to-night, you will find nothing better than the specimens shown by the Autotype Company. In Germany, the steam press is largely applied to the rapid production of collotypes, and before you are drawings of the machine collotype press constructed by Messrs. Schmiers, Werner, and Stein; the most striking feature being the large number of rollers, used in order to ensure equal inking and damping. The transfer of collotypes to porcelain has been practised to a small extent, vitrifiable colours being dusted on afterwards, but the results obtained have not been very satisfactory.

* *Photographic News*, p. 1880, p. 568.

Collotyping in colours from several plates has been introduced to compete with chromolithography for fine work, but the only examples exhibited in this country are, I believe, some shown by Mr. Meyerstein, and a selection of which is now before you.

Before you go, do not fail to look at some intaglio plates intended for the decoration of porcelain as made by Mr. Dallas, and you will also find some prints from them. Mr. Dallas does not tell us how he makes them.

As you may well suppose, the things omitted from this short course of lectures are more numerous than the things discussed; far more progress having been made than can be described in three hours.

You will, before you go, allow me to express the obligation we are all under to Mr. Barker, who has so ably assisted me in showing you what you have seen.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

Report on Preserved Meat. By J. J. Manley, M.A.

Part II.

In adding a few words to the report on preserved meat in the last number of the *Journal*, mention may be made of the various essences and extracts of meat, semi-liquid and solid, which are shown at the Health Exhibition. They are very numerous. Baron Liebig, as is well known, was the original producer of extract of meat, and has had many followers, the popularity of his production increasing year by year. At South Kensington we see, among others, Kemmerick's extract of meat, and concentrated beef tea, both of excellent quality; Kopf's extract of meat; and the productions of Messrs. Brand and Company, of Mayfair, and of the firm of the same name in Vere-street, Oxford-street; as also those of Mr. George Mason, who, though comparatively a young beginner in this business, gives us an essence of beef which, after its kind, leaves nothing to be desired. He also shows some meat lozenges, which Messrs. Brand, of Vere-street, combine with milk. But while acknowledging the excellence of the exhibits in question, it must not be forgotten that the more solid extracts are obtained by the boiling down of lean meat, which involves the loss of fat, and as much of the gelatine and albumen as can be taken away, so as to render the preservation of the residuum possible. This residuum consists of fibrin, osmazone, and the extractives of flesh—or in other words, the flavouring matters and salts of meat—thus leaving out most of all that is popularly regarded as nutritious and strengthening in the shape of nitrogenous matter. Still, this substance has its value, as an addition to other foods, as a flavourer, and as a stimulant most acceptable to invalids. Liebig himself publicly declared that "it was not a nutriment in the ordinary sense."

Semi-fluid meat is also well represented by Cibil's (Buenos Ayres) fluid beef extract, and the liquid meat of the Kreochyle Company, of Leytonstone. Fluid meat differs from the various extracts of meat in retaining the fibrin, gelatine, and coagulable albumen—in fact, all the constituents of lean meat—and is therefore a convenient as well as valuable food. On an average, one pound of fluid meat is obtained from four pounds of lean meat. By the process pursued, all the constituents are brought into a condition in which they are soluble in water, and are not any longer coagulable on heating, in which state they have been designated "peptones." This change is effected, as in ordinary digestion, by means of pepsin and hydrochloric acid.

The exhibits of preserved meat in the foreign sections of the Exhibition are not numerous, and without wishing to pay a bad compliment to foreigners, not very important. Japan, China, and Siam send some curious preparations; and France, Belgium, Austro-Hungary, Italy, Sweden and Norway, and Venezuela are represented.

But even a brief report of preserved meat at the Exhibition cannot omit notice of the exhibits of frozen mutton from Australia and New Zealand, and of the "refrigerating chambers" which enable the carcases to be preserved, both on their voyage hither and after their arrival. "Refrigeration" is, of course, only a temporary method of preserving meat, and not, strictly speaking, a preservation process as is that in which extreme heat is used for the expulsion from vessels of atmospheric air; but we are indebted to it for a large and increasing portion of our meat supply. Not very many years ago, the entire body of a mammoth was found in the frozen soil of Arabic Siberia, where it had probably been for many thousands of years; and its flesh, when thawed, was found perfectly fresh. In like manner carcases of animals and men have been found embedded in ice, and without the slightest signs of decomposition during many years of their glacial interment. But meat can be preserved for a lengthened period in a temperature much above that of "freezing point," about 40° being sufficient to maintain preservation even in the hottest weather.

The first patent for the preservation of meat by refrigeration was taken out by John Lings, in 1845, and since then a variety of expedients have been employed by the use of ice, and by artificial processes of lowering the temperature of evaporation, in order to bring fresh meat from Australia and elsewhere to this country. It was at the Melbourne Exhibition of 1872-3 that Mr. James Harrison made most successful experiments in keeping fresh meat for forty days in a refrigerating chamber; and this led to his attempt to ship to England in the latter year several tons of meat in a similar chamber on board. The venture failed owing to the faulty construction of the chamber, and the want of sufficient ice; but very shortly afterwards successful shipments were made from Canada, Texas, and elsewhere. Several French inventors, among whom may be mentioned M. Tellier and M. Poggiale, had most ingenious refrigerating chambers, constructed both for shipping and other purposes; inventors and adaptors also came forward in this country, and a large number of ships are now fitted up with refrigerating chambers, and a regular trade in refrigerated meat has been established, good mutton from Australia and New Zealand being obtainable at from 7d. to 8d. per lb. When it is stated that during the months of January and February of this year 149,371 cwt. of beef, 87,929 cwt. of mutton, and 15,000 cwt. of pork were imported into this country by the aid of refrigeration, some idea may be formed of the business already being done; and it may be noted that the above figures show an increase of 72,864 on the quantity imported in the corresponding months of last year. The development of this trade depends mainly on the cost of refrigeration, and this will probably be lessened as different systems are improved upon, as we may reasonably expect they will be. There is no question as to the source of supply; Australia alone, it would seem, is able to send us nearly all the meat we want to supplement our home-grown supply. In a paper read before the Royal Colonial Institute in December, 1882, by Sir Francis Bell, the Agent-General for New Zealand, he stated that frozen meat in any quantity could be placed upon our markets at 6d. to 6½d. per lb., leaving a good profit to the grower. This, he added, ought ultimately to make meat cheaper here, or at least prevent the further rise threatened. Australia and New Zealand can in fact export 700,000 tons of meat a year, or 2,000 a day, which is not much more than we want in England even now, without reducing even the present capital number of their sheep and cattle; and they are able to send on sheep to Smithfield with greater ease to-day than the Tweed farmers could 100 years ago, when meat was selling at 1d. per lb. in Scotland, against 10d. in London. At the Victoria and other docks large cold-air storehouses are now constructed for the reception of the meat as it comes out of the ships, so that the market may be supplied according to the demand. I see it stated in a City paper that retail butchers of the metropolis last week actually paid at the Central Meat Market a higher sum for New Zealand than for English-grown mutton. I note also that from some statistics just come to hand, it appears that the import of refrigerated meat during last September was 66,519 cwt., as against 14,170 cwt. in September of 1883

There are at South Kensington several most interesting exhibits, illustrating the various principles of refrigeration and preservation of meat in large quantities, for instance that of J. and E. Hall. They show two of their cold-air producing machines, and a small chamber or store in which frozen mutton is constantly kept. One of these machines can deliver 2,000 cubic feet of air per hour, at 30° below zero (Fahr.), and the other 5,000, at 35° below zero. The general principle on which all cold-air machines act is this. The air is compressed in holders by means of pumps, driven by a steam-engine; the compression of the air generates a great deal of heat, which is abstracted by cold water circulating in tubes, similar to those of a surface condenser, and contained in the holder. When the air has cooled down, it is allowed to expand into the closed store-room, the work done in expanding absorbs all the heat left in the air, and consequently leaves it in an extremely cold condition. The Haslam Foundry and Engineering Company, Limited, also exhibit a dry-air refrigerator, to discharge 18,000 cubic feet of air per hour, at 60° (Fahr.) below zero, in connection with a freezing or chilling chamber in which meat is stored. Near this the committee of importers of Australian frozen mutton exhibit a freezing-chamber and meat store. It may be here mentioned that it is mainly to Mr. Kent (also an exhibitor at South Kensington), the well-known refrigerator maker, of 199, High Holborn, that we are indebted for the perfecting of refrigerating or cold storage-chambers on board ship and elsewhere. He has constructed such chambers on a large number of ocean going vessels, and by the application of the "downward draught" system of ventilation, of which he was the pioneer, has never failed to secure the object in view. It is this principle which he applies to all his "domestic" refrigerators. Visitors to the Exhibition not only see the carcases of refrigerated sheep hanging in the cold-air chambers, and even exposed as in Mr. Tallerman's exhibit, but a frozen Australian or New Zealand mutton chop, with bread or vegetables and attendance for 8d., can be obtained, and experiment made as to the excellence of the meat.

TURIN EXHIBITION.

The Executive Committee have decided to postpone the closing of the Turin Exhibition until the 10th of November.

Extensive purchases of machinery have been made, during the last few days, by the Ministers of Marine and Public Works, amongst which may be mentioned the engines in the electrical department of Messrs. Tosi and Co., of Leguano, of 200 horse-power, for the railway workshops of Verona; that of Messrs. Neville and Co., of Venice, 250 horse-power, for the Royal Arsenal at Spezia: the engine of 100 horse-power in the gallery of labour of the "Fonderia Fratte," Salerno, and that of the same power of Messrs. Luciano and Co., of Turin, for the new railway workshops now in course of construction at Turin; the engines of Messrs Calzoni, of Bologna, Cravero, of Genoa, and several others. The machine tools of Messrs. Güller, of Iritza; the Società Veneta, of Treviso; Fogliano and Co., of Turin; the water motors of Bossardt, of Turin; dynamos of Rivolta, of Milan, besides a variety of machines, &c., from other exhibitors.

A proposition has been made by various exhibitors to the Executive Committee to allow the Exhibition to remain open for a few days after the 10th of November, in order to hold a fair to enable them to sell off their goods.

TRADE SCHOOLS OF WURTEMBURG.

The following notes are taken from a report by Mr. Alfred Harris, printed in *The Textile Recorder:*—

Wurtemburg is one of the smallest of the South German kingdoms, containing about the same number of inhabitants as Yorkshire. The system of trade education in Wurtemburg is the work of the last thirty years, and it has been established and brought to its present state of success by the efforts principally of one man, Dr. von Steinbeis, of Stuttgart, who has had the liberal support of the State, and the active co-operation of an intelligent and well-educated people.

First, as regards national elementary instruction. In 1831, daily attendance at school had become universal; excellent State seminaries, as well as good private institutions for the training of teachers, had then existed for thirty years; and in 1836 the present complete system of national education was founded. In the year 1858, out of 41,000 recruits called to military service from all ranks of the people, there were only eight who could neither read nor write, and in all of these cases either mental deficiency or parental neglect were the proved causes of this slight residuum of ignorant persons. Attendance at elementary schools is compulsory to the fourteenth year, inclusive, except by special exemption of clever children who have attained the prescribed knowledge earlier. On leaving school, every child undergoes an examination, and if not found up to the mark, is sent back to school for another year. In these schools the subjects taught are of a generally useful character. There are very few schools in which drawing is not taught, although the subject is not compulsory. The masters are specially taught in drawing, however, and it is looked upon as a necessary part of elementary education, and is encouraged by a special grant of money to the teachers. All teachers have come to the conclusion that in elementary schools freehand and outline are indispensable. In 1860, the Central Office for Education started a National School Exhibition, in order to ascertain whether the teaching at the schools was such as to lay a good foundation for the various trades and occupations which the pupils would be likely to follow in after life. Besides the ordinary national schools, there are about fifty of a more advanced nature, in which art, science, and different branches of drawing, as applied to trades, are taught to the children who are capable of this higher knowledge. These schools receive extra grants from the State.

After leaving the national school, attendance at the Sunday school for secular and industrial training until the eighteenth year is compulsory, but this attendance is dispensed with on the part of youths who attend evening classes. The Sunday school was the real foundation of the industrial and trade schools of Wurtemburg.

The trade schools of Wurtemburg are in two leading divisions — (1) Agricultural Progressive Schools, and (2) Industrial Progressive Schools. I will speak first of the Agricultural Schools. The general management is controlled by the Central Department for Education, in Stuttgart, and the local superintendence by a committee chosen from the school authorities in the various places, and by the guilds of agriculture, of which there are sixty-five in the kingdom. The following are the institutions under this section:—

An agricultural academy for young farmers.

Agricultural schools for peasants.

Schools for vine-growers.

Schools for females, where house-keeping and domestic usefulness are taught.

Agricultural winter schools.

Voluntary agricultural progressive schools.

Evening meetings for adults.

Reading-rooms, libraries, distribution of pamphlets, &c.

Special classes for various branches of agriculture.

You will observe how wide a field is covered by these various institutions for the technical training and instruction of the agricultural population of this small kingdom.

To sum up this subject, there are in Wurtemburg:— 97 progressive schools for agriculture, with 2,094 scholars; 610 compulsory evening schools, with 12,283 scholars; 74 Sunday-schools, with 1,373 scholars; 27 evening schools for adults, with 960 scholars; 56 agricultural reading-rooms, with 2,400 members; 844 libraries, with 143,000 members.

We now come to the industrial progressive schools, the management of which is very similar in its functions and arrangements to that of the agricultural schools. The central authority first turned its attention to the question of teachers, who were trained in the Polytechnic Institute, at Stuttgart, and were generally practical men with a good knowledge of trade. They sent them to foreign countries to learn the best and newest methods, and then spread them over the country to give instruction at the various places in which their individual capacity enable them to teach special trades and industries peculiar to the localities. Classes were established everywhere, both for the young and for adults. Exhibitions of machinery, museums of tools and utensils, libraries of useful works on trade were established and thrown open free of charge to all who resorted to them. The various localities worked hand in hand with the practical efforts of the Central Department, and public funds were granted liberally, but with great judgment and care, in furthering local exertions. Emulation sprung up between different places, and in a few years the whole country was dotted over with centres of industrial teaching adapted to the special requirements of the places. Drawing schools were everywhere established, and whilst technical perfection was not aimed at in all the schools, yet technical practice was adopted wherever it was found necessary; and in many important centres of industry the progressive classes have gradually attained the importance and deserve the name of technical schools. In some of these, weaving is taught, and the pupils earn their own living by their work whilst at school. In other places wood-carving is taught, with successful results; also engraving, modelling in wax and clay, chasing metal, house decoration, &c. There are also special schools for commerce, and for female domestic management.

The details of this great network of schools, which is spread over this small but busy country, are far too numerous for me to attempt to enter upon, and I must sum up my subject by stating that they are carried on in 162 towns and villages, and they have 12,700 pupils. These include the female progressive schools with 3,243 pupils. There are 738 teachers, being one to every seventeen pupils. The work which is thus being done in Wurtemburg may be taken as an example—perhaps altogether the most complete example—of a similar work which is being carried out in the whole of Germany.

MANUFACTURE OF GAS FROM OIL.

Dr. Armstrong's paper on this subject has been published in the last number of the *Journal of the Society of Chemical Industry*. In his first part he deals with "Certain bye-products of the Manufacture of Gas from Oil by the Pintsch process," and concludes with these remarks:—

"The recent attempts to recover much that has hitherto been lost in coking coal are of the greatest importance, and have already led to results of high interest. In a recent paper in our Journal, Mr. Watson Smith has given an accouut of his preliminary examination of the tars from the Jameson and Simon-Carve's ovens, and has pointed out that the former contains but small quantities of the characteristic constituents of coal tar. I can endorse these statements, having had an opportunity, thanks to Mr. Jameson, of examining his oil. Evidently the Jameson oven gives a product which closely resembles shale oil in composition, and hence is at present of comparatively little value; in comparison with the Simon-Carve's oven, however, it has the great practical merit of cheapness. I have recently had the opportunity of seeing the two systems in operation, and am satisfied that the proposed adoption of the ordinary beehive oven has not yet received the attention it deserves, and that the arrangements which have been made for condensing and collecting the products are insufficient.

"The time must come when coal tar will not be regarded as a mere bye-product, and when attention will be paid, not only to the manufacture of gas, but also of coke, and of particular constituents of coal tar; when, in short, the material latent in coal will be progressively utilised. It may be that then the coal will first be coked, the oil which distils over being carefully condensed, and that the 'weak gas' thereby produced will be utilised as fuel; at the same time the ammonia and sulphur will be recovered. The paraffin, and whatever else of immediate value it may contain, having been separated from the oil, the residue will be utilised in the production of oil gas, and of benzene, anthracine, &c. Gas is daily becoming a more important article of consumption, and we may look forward to its use by the public in the near future, not only as an illuminant and in gas-engines, but also as a heating agent. The late Sir C. W. Siemens powerfully advocated a double supply, one of heating and one of illuminating gas, of which the former would necessarily be inferior, the latter superior in quality to the present supply, if the system he advocates were adopted of collecting in separate holders the gas given off at various periods during the distillation of coal. And this would also be the case if water gas came to be employed for heating. Such a system would involve a double set of mains, and that for the heating-gas would have to be of enormous size if gas were to be generally used as a heating agent. The proposal to introduce a gas rich in carbonic oxide for general household use, which the supply of water gas would involve, might also meet with considerable opposition, and it must be admitted that the mass of evidence on this subject recently collected in the inquiry at Massachusetts is not altogether reassuring. Lastly, I am of opinion that a gas of lower heating power than that at present supplied would be of little use to the general public, as distinct from manufacturers. It is impossible, with the stoves hitherto contrived, and with the present gas supply, to raise a surface to such a temperature that it will radiate sufficient heat to render it possible to use gas with economy in heating rooms in the manner which probably will always be preferred in this country, and, therefore, I venture to think that it will be better to have but a single set of mains, and to supply a gas of much higher illuminating power than that we now have. By combining the present system with the manufacture of oil gas, and systematically separating certain of the liquid bye-products, and re-incorporating them with the gas, this could readily be done, and the oil required might well be that obtained in coking coal."

VEGETABLE CULTURE IN BERMUDA.

Consul Allen says that onions, potatoes, and tomatoes comprise almost the entire production of Bermuda, and give employment to the greater portion of the inhabitants, and the prosperity of the colony depends largely upon the success of the crop and the demands of the markets. In onion growing the seed used is grown in the Canary Islands, and is imported in the months of August and September; it is sown in the months of September, October, and November, thickly in beds, the ground having been heavily manured with stable manure two or three months before sowing. The white seed is sown first and produces the earliest crop, the shipment of which commences in March. When the plants are sufficiently large—about 6 to 8 inches high—they are transplanted into beds about 4 feet wide, the plants being set about 7 inches apart each way. The plants from the white seed are transplanted as soon as they are large enough, but those from the red seed are not usually transplanted until the beginning of January, and the ground requires to be only moderately manured. If transplanted too early, and the soil is too rich, the bulb is likely to split into several pieces and is worthless. After transplanting, the soil requires to be lightened once or twice, and the weeds removed before they mature. As soon as the top begins to fall, the onions are pulled and allowed to lie on the ground two or three days, when they are cut and packed in boxes of fifty pounds each and sent to market. All the onions are delivered at the port of shipment in boxes, ready for the market, and for the past two years the producer has been compelled by law to place his name or initials conspicuously on each package. It is estimated that a large profit on the outlay is realised, when the crop is large and the market good, an acre of ground sometimes returning as much as £120 to £170. For the cultivation of potatoes the seed was formerly nearly all imported from the United States, but of late years has come largely from New Brunswick, Nova Scotia, and Prince Edward's Island. The ground for potatoes is usually ploughed or broken up with the spade and raked, the seed cut into pieces with one or two eyes, and planted by forcing into the ground with the fingers to the depth of about four inches, in rows about twenty inches apart, and about eight inches in the rows. From six to eight barrels of seed are used to the acre. When the plants are a little above the ground, the soil is lightened between the rows with a fork, and when about six inches high the earth from between the rows is hoed round the plants, only one hoeing being required. For growing tomatoes the seed is imported every year, and is sown about October, and transplanted in December, into rows about six feet apart, and the plants are put about four feet apart in the rows. As soon as transplanted, the ground round the plants is covered thickly with brush—chiefly the wild sage which grows over the hills—not only to protect from the wind, but to keep the fruit from the ground. The brush is usually raised once by running a stick under and lifting it enough to clear the soil of weeds, no other cultivation being required. Six or seven quarts of fruit from the hill is considered a fair crop. The fruit is rolled in paper and packed in boxes containing about seven quarts each. Consul Allen says that the price of land in Bermuda varies from £30 to £40 an acre, and in some cases not more than one-eighth is susceptible of cultivation. It is estimated that there is an annual export of 350,000 boxes of onions, the box containing about 50 lbs., and of potatoes 45,000 barrels.

FISHING IN JALISCO, MEXICO.

Consul Lambert, of San Blas, gives the following account of the methods employed in fishing in Jalisco. The fibrous roots of a small shrub called *varlasco*, which grows wild in the neighbourhood, are procured, and after being well broken up, they are placed in the bottom of the canoes. At high tide the fishermen proceed to the mouths of the *esteros* (small creeks), and erect a wooden fence. They then partly fill their canoes with water, which produces an intensely white liquid from contact with the root. Arriving at the source of the *estero*, or in some shallow places beyond which the fish are not likely to go, the preparation is thrown into the water, which also turns perfectly white. The effect of this is that the fish are blinded, and in a very short time they are found floating on the surface of the water at the fence erected at the mouth of the *estero*. The larger ones are then gathered into the boat, and taken to market. Another method, which is more fatal in its effects, though it is performed less frequently, is the employment of the milk of the *ava* tree. This tree yields, when tapped, a white liquid very much resembling the juice of the india-rubber tree. It is used in the same manner as the *varbasco*, and not only blinds, but kills the fish instantly. Fish killed in this manner have to be used immediately. In neither case is there any visible sign of the manner in which the fish have been killed. There is a law in existence against the use of poisons in procuring fish or market, but it is practically inoperative and void, for the reason that there is no defined method for determining the death of fish by these liquids, and the natives who take them in this manner are careful that each fish shows a spear hole in the back before landing it; and in the absence of any method of detection, the spear hole is *primâ facie* evidence that they not poisoned. Consul Lambert says that, as far as he has been able to ascertain, no bad effects from eating fish killed in this way appear to be known.

EULACHON OIL.

Dr. A. B. Lyons, of Detroit, has lately been investigating the properties of the oil obtained from the candle fish as a substitute for cod-liver oil, and in his paper on the subject he says:—

"The bays and estuaries of the Pacific coast of British America and Alaska are annually visited by immense shoals of a small fish popularly known as the candle fish, or, adopting the vernacular name, as eulachon or outachon. This fish belongs to the family of the salmonidæ, and bears the scientific name *Thaleicthys pacificus* (Richardson) Girard. It is nearly allied to the capelin, which it resembles also in its habits.

"The Indian name is variously spelled eulachon, eulachan, hoolacan, oolachon, ootachon, &c., and is corrupted by the English settlers at Victoria into hoolakins.

"The fish is also frequently confounded with other species, and in Oregon is generally known as smelt. Its habitat is the northern part of the Pacific Ocean. In spring it approaches the shores to deposit its spawn, entering the bays and estuaries in countless numbers. It never goes far from the ocean, however, although multitudes of the fish are taken near the mouths of the large rivers, particularly in Frazer's river and in the Naas.

"The candle fish is less than a foot in length. It is described as having a somewhat pointed and conical head, a large mouth, teeth on the pharyngeals, and the tongue rough; the lower jaw, palatines, and vomer destitute of teeth. Its colour is greenish yellow on the back, passing into silvery white on the sides and belly, sparsely spotted with dirty yellow. The spawning season is in April and the first half of May. During their run they furnish food not only to the Indians, but to thousands of sharks, halibut, porpoises, and other predatory fish. As a pan fish the eulachon is said to have no superior, but the fish is valued chiefly for its oil which is used as food by the Indians. So rich in oil is the entire fish, that when dried it serves the natives for torches, whence the name candle fish. The aborigines take the fish in immense numbers by the aid of a primitive contrivance, resembling a rake or comb, the moonlight nights being the most favourable time for carrying on the operation.

"The fish are submitted to a rude operation for 'rendering' the oil, or they are dried and smoked. In recent times the dried and salted fish have become an important article of export from Victoria, and there is now on the Naas river a manufactory for the oil, which has been employed to some extent as a substitute for cod-liver oil. It has been used medicinally to a considerable extent in British Columbia, but I do not find any record of clinical observations with regard to its therapeutic value.

"Chemical analysis, of course, cannot reveal the medicinal properties of any drug. Cod-liver oil itself is an example of this. While universally accepted as an agent of singular efficiency in promoting nutrition, particnlarly in strumous and tubercular patients, it has thus far guarded as a profound secret the cause of its efficiency, and the reason of its superiority in this respect over other oils, vegetable or animal. It has been frequently subjected to chemical analysis, and one wonderful discovery after another announced with flourish of trumpets, each supposed, for a while, to furnish the key to the mystery, but each in turn has been abandoned, and the medical profession generally regard the remedy as nothing more than a concentrated and easily assimilated food. Iodine, phosphorus, iron, biliary acids, cholesterin, and oxide of propyl are among the constituents of the oil, which have been supposed to give it its peculiar medicinal character, but none of these substances is present in a quantity sufficient to justify any such hypothesis, and, one after another, all have been abandoned as unsatisfactory.

"Some other animal oils, however, have been found to improve nutrition in much the same way as does the familiar cod-liver oil; only by clinical experiments can we determine the value of any new claimant for a share of the honours which cod-liver oil has monopolised."

After a comparison of the oils, Dr. Lyons says of eulachon oil:—"The oil was found to contain about 20 per cent. of palmitic and stearic acids, 60 per cent. of oleic acid, and 13 per cent. of an unsaponifiable substance, which is the most peculiar and interesting thing about it. This substance is of an oily consistency at ordinary temperature in summer, has much lower specific gravity than oleic acid, or any other constituent of ordinary fats, specific gravity ·865 to ·872, at 59° Fahr., and seems to resemble the unsaponifiable constituent of sperm oil.

"This interesting substance I hope hereafter to make the subject of further investigation to determine its chemical composition, and its behaviour towards reagents. At present it is enough to call attention to its existence as a considerable constituent in this oil, and to suggest the probability that it may give to the oil properties quite distinct from those of most animal oils. The low specific gravity of the substance, and its indifference to most reagents, remind one strongly of the paraffins, and now that petroleum and petroleum oil are recognised to have a positive influence in tuberculous complaints, we shall not be surprised if we find that eulachon oil owes any therapeutic power it may be found to possess to this peculiar body.

"Cod-liver oil, it is true, does not contain anything corresponding with this substance, or if it does the quantity must be very small. Cod-liver oil contains about 80 per cent. oleic acid, 8 or 9 per cent. of palmitic and stearic acids, and only 1·82 per cent. (Allen) of unsaponifiable matter, a considerable proportion of which is cholesterin."

Notes on Books.

DYNAMO-ELECTRIC MACHINERY: a Manual for Students of Electrotechnics. By Silvanus P. Thompson, B.A., D.Sc. London, 1884: E. and F. N. Spon.

This book is founded on the series of Cantor Lectures delivered by Professor Thompson before the Society in 1882. Considerable additions have been made to the original text of the lectures, and several entirely fresh chapters have been added. This new matter includes a consideration of "the Mathematical Theory of Dynamo-Electric Machines and of Electric Motors," and a description of "the Graphic Method of Calculation as applied to the Characteristic Curves of Dynamos." The various types of dynamos are fully described, and the theory of their action explained. The different motors proposed or brought into use are also described, and their relative efficiency compared. The book is fully illustrated.

OLD-WORLD QUESTIONS AND NEW-WORLD ANSWERS. By Daniel Pidgeon. London: Kegan Paul, Trench, and Co., 1884.

Mr. Pidgeon, whose book of travel, "An Engineer's Holiday," was favourably received a year or two back, gives, under the above title, the results of his observations during a short tour through the manufacturing districts of New England last year. He perceived, as all intelligent visitors to the United States must perceive, that many of the social and political problems which are now perplexing the Old World are being rapidly worked out in the new under the favourable conditions of a young and quickly changing civilisation. Possessed already of considerable experience in English manufacture, he devoted his holiday to an examination of the industrial condition of Massachusetts and Connecticut, and he presents his readers with a comparison of the state of the manufactures and the manufacturing classes on opposite sides of the Atlantic. So impressed was he with what he saw, that he has nothing but good words to say alike of employers and employed, and for almost every detail he has little but praise. Whether he was not in some cases unduly biassed, whether a longer experience would have modified the first favourable opinion, is a question which cannot well be answered without a knowledge of American institutions more complete than can be gained by a mere sojourn in the country. At all events it is pleasant to get, from so competent an observer, an account so satisfactory of the example we are ourselves to follow. A staunch free trader, Mr. Pidgeon sees in the reduction of the American tariff, and the consequent admission of the raw material of manufactures untaxed to her workshops, a great future for American industry—a future the approach which, it must be admitted, the American people seem in no mood to hasten; but with this sole exception, he sees little requiring improvement, little which he does not admire in the organisation of the New England factories or the condition of New England life.

ART YEAR BOOK, 1884. (AMERICAN ART.) Prepared and published by the New England Institute, Boston, Mass. 4to.

This volume is chiefly a record of the Art Exhibition of the New England Institute, and contains a catalogue and biographical notices of the exhibitors. It is fully illustrated with plates produced by a large number of the different processes now in use.

A TREATISE ON THE PURIFICATION OF COAL GAS, AND THE ADVANTAGES OF COOPER'S COAL LIMING PROCESS. By R. P. Spice, M.Inst.C.E. London: E. and F. Spon. 8vo.

Mr. Spice has given in his treatise the list of the various attempts to purify gas, and a special account of Cooper's process, which was described by Mr. J. A. Wanklyn in his paper on "The Manufacture of Gas from Limed Coal," read before the Applied Chemistry and Physics Section of the Society of Arts, on January 24th last. Mr. Spice has added a number of plates to illustrate the process.

ARCHITECTURE AND PUBLIC BUILDINGS, THEIR RELATION TO SCHOOL, ACADEMY, AND STATE, IN PARIS AND LONDON. By William H. White, architect. London: P. S. King and Son, 1884. 8vo.

The author of this book contrasts the treatment of architecture, and the education of the architect in France and in England. The first part is devoted to the history of the rise and foundation of the National Institute of France, the School of the Fine Arts at Paris, and the relation of the State and the Academy in France to the public of that country. The second part contains an account of the Royal Academy in London, and the Public Department of Works and Public Buildings. The last chapter treats of the profession of architecture, and the whole aim of the book appears to be to illustrate what is said in the first chapter:—"During my ten years' consecutive residence in Paris, the authorities seemed to know not only what the inhabitants wanted for the alteration and adornment of their city, but also to obtain for them what was wanted; during my ten years' consecutive residence in London, the authorities seemed not only to ignore the prevalent desire for improvements, but also quite unable to carry out the alterations they devised."

General Notes.

ST. LOUIS CATTLE CONVENTION.—The first National Convention of Cattlemen is to be held at Saint Louis, U.S.A., on the 17th, 18th, 19th, 20th, and 21st of November next, at which will be discussed the questions appertaining to the raising and improving the breeds of beef cattle in the states and territories, and other questions of kindred interest.

TRADE OF YUNNAN.—It appears from a report of Count de Kergaradec, French Consul, on the trade of Yunnan by the Red River (Songkoi), that the exports from Hanoi to Yunnan, during 1879, were as follows:—Salt, 120,000 fr.; tobacco, 680,000 fr.; raw cotton, 200,000 fr.; cotton goods (English manufacture), 50,000 fr.; cotton yarn (English manufacture), 24,000 fr.; light woollen cloths (German), 16,000 fr.; pedlers' ware (chiefly gilt buttons, &c., from England), 15,000 fr.; making total, with miscellaneous not mentioned, 1,700,000 fr. Exports from Yunnan to Hanoi:—Tin, 1,700,000 fr.; lead, 5,000 fr.; tea, 60,000 fr.; false gambier, 30,000 fr.; making a total of 2,055,000 fr. The excess of exports from Yunnan over its imports represents (the traffic being one exclusively of barter)—(1) cost of transport to and fro; (2) duties paid on the route to the Annamese interior customs; (3) duties levied by the Black Flags; (4) traders' profits.

FLAX CULTURE.—The culture has hitherto been much neglected, although it appears that flax and the various products of that plant can be cultivated in America quite as cheaply as in the various seed-producing countries of Europe. The imports of flax seed into the United States have reached as much as three million bushels in one year, the imports from India alone reaching 1,253,517 bushels in 1883-4, as compared with 558,249 bushels in 1882-3. The imports of raw flax into the United States during the nine years from 1871 to 1880 amounted to $10,987,549. The imports of flax manufactures during the ten years from 1871 to 1881 amounted to $177,747,371, or nearly $18,000,000 per annum. The average yield and prices of flax seed and wheat into the United States for the past ten years were as follows:—Wheat, 12¾ bushels per acre, cost 93½ cents.; flax, 9¼ bushels per acre, cost $1 44c. It has been ascertained that, with careful cultivation, an acre of flax can be produced for $24 98c., this sum covering use of land, seed, and all necessary expenses. The receipts from an acre of flax are estimated to be as follows—9¼ bushels of seed, at $1 44c. per bushel, $13 52c.; 350lb. long fibre, at 10 cents. per lb., $35; 350lb. flax tow, at 3 cents. per lb., $10 50c.—total, $58 82c. This shows a net profit per acre of $33 84c.

Journal of the Society of Arts.

No. 1,667. Vol. XXXII.

FRIDAY, OCTOBER 31, 1884.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

SOCIETY OF ARTS PRIZES.

The Council of the Society of Arts have awarded the following prizes in connection with the International Health Exhibition ;—

John Stock Prize, a Society's Gold Medal, or £20, for the best example of sanitary architectural construction, Classes 20, 28, 29, 30, 32, to Messrs. Doulton.

Shaw Trust, a Society's Gold Medal, or £20, for the most deserving exhibit in Classes 41, 42, 43, and 45, to the Compressed Lime Cartridge Company.

North London Exhibition Trust, a Society's Gold Medal, or £20, for the best set of specimens illustrating the handicraft teaching in any school, Classes 49 and 50, to M. Germain, on account of the Collective Exhibit from Belgian Norman Schools for Women Teachers.

Fothergill Trust, a Society's Gold Medal or £20, for the best exhibit in Class 26 (Lighting Apparatus), to Messrs. Noel Brothers (in Class 26).

Trevelyan Prize Fund, Five Gold Medals or five sums of £20), for the best exhibit in each of the following Classes—2, 3, 5, 7, and 11 (all comprised within Group 1. "Food"), to the San José Fruit Company (in Class 2); to Messrs. Moir and Company (in Class 3); to Mrs. Charles Clarke, of the School of Cookery (in Class 6); to M. Pasteur (in Class 7); to Messrs. J. and E. Hall (in Class 11).

The "Siemens" Prize, offered through the Council by Lady Siemens, a Society's Gold Medal, or £20, for the best application of gas to heating and cooking in dwellings, Class 25, to Thomas Fletcher.

The "Stacy" Prize, offered through the Council by Mr. J. Sargeant Stacy, a Society's Gold Medal, or £20, for the best exhibit in Class 30 (objects for Internal Decoration and Use in the Dwelling; Fittings and Furniture), to Messrs. Collinson and Lock.

Proceedings of the Society.

CANTOR LECTURES.

SOME NEW OPTICAL INSTRUMENTS.

By J. Norman Lockyer, F.R.S.

[The right of reproduction of these Lectures is reserved by the Author.]

Lecture I.—Delivered Monday, April 28th.

It is in accordance with the oldest traditions of the Society of Arts, that those interested in the use of any scientific instruments should come before the Society from time to time, to give an account of the progress which has been made in them. This does good to more than science, and it interests the Society from more than a scientific point of view. The history of many instruments is as follows.

The first is made roughly by the experimenter himself. Then some artist comes along almost as interested in its success as the inventor. At this stage, the instrument improves rapidly, and possibly some application turns up. Then comes the turn of the industrial arts. From this point of view, my subject is doubly interesting to this Society.

We begin with small spectacle glasses, charmed into a telescope by Galileo. We begin with a little prism, not much bigger than a finger nail, used by Newton, and the work of successive investigators and successive artists has shown the necessity and importance of lenses and prisms of colossal proportions, while the interest in the subjects which can be investigated by means of them is so continually on the increase, that the demand is in excess of the supply.

One would think that it was the time for the industrial arts to step in, but this is exactly what they have not done; and I for one believe that if the Society of Arts, or some such body, does not come to the rescue, the progress of astronomical science will be retarded in this country for many years, as it was before. If I am rightly informed, no optical glass of the size now required (for which almost fabulous prices are given) is being made in England. If I am again rightly informed, the only source of supply in the world now available for us will shortly run dry.

This, then, is my chief text in these lectures, and I shall try to prove my points by some references to history and detail, which I will endeavour to make as short and concise as I can. It is not, however, my only text, for I am aware that the members of the Society of Arts are not interested only in commercial processes.

That one of the improvements in optical arrangements, to which, perhaps, the greatest importance, having regard to the future of astronomy, attaches at the present time, is one the germ of which is to be found in the accounts of the earliest meetings of the Royal Society.

At the time the Royal Society was established, more than two centuries ago, in consequence of the then ignorance of any method for correcting the chromatic aberration of the lens, the aberration was kept down by an inordinate focal length; and lenses with focal length of 300 ft. were attempted to be used. Under such conditions, both observatories and even tubes were of course impossible, and the only movement was the movement of the observer with an eye-piece carried in the hand, and the only possible observation was that of a heavenly body rising or setting.

Hooke, the then Secretary of the Royal Society, pointed out how convenient it would be if, instead of thinking at all of having a tube and then moving it, a plane mirror might be made to move in front of the telescope, which might then be horizontal and fixed. This idea remained dormant until the year 1869, and the reason that it was resuscitated in 1869 was this. Two men, all unconsciously, had been working to the same end: Liebig,* the famous German chemist, had shown, in 1867, that it was possible to deposit a clear and bright film of silver on glass; and the illustrious Frenchman, Foucault, had shown that, by certain optical processes, a glass surface optically plane could be produced.

Here then at last we had the mirror of which Hooke had dreamed. This was not all. The ingenuity of Foucault found a way of mounting this mirror, so that, by means of clockwork, the light given out by any heavenly body could, from its rising till its setting, be poured into a horizontal telescope placed north and south, thus enabling an observer sitting at a fixed eye-piece to do his work quietly, free from any anxiety connected with the movement of either telescope, chair, or dome, so long as the heavenly body was above the horizon.

The extension of this capital invention of Foucault's, and what has come of it, forms one of the chief improvements upon which I have to address you.

The plane mirror in the "siderostat" (such was the name given by Foucault to the new instrument described by him to the Academy of Sciences in 1869) had a diameter of 12 inches. In consequence of the recent researches of M. Loewy and of the Brothers Henry, a mirror of 5 feet in diameter, optically plane, can now be constructed with the most absolute certainty and perfection.

Up to the present time, to satisfy preconceived ideas, it was believed that, to establish rapidly an equilibrium of temperature, it was necessary that the thickness of the mirror should be small. Then, under the influence of a tightening, however slight, or only a flexure, the mirrors were deformed unequally, and consequently produced an obvious diminution in the beauty of the images. In giving to the disc a sufficient thickness, the production of a

* Liebig, December, 1867, "Ann. de Chem. et Pharmacie" Sup., vols., 1865-68.

Note.—It may be convenient that I should give here a simple method of silvering glass :—

"Prepare two solutions.

"1. Argentic nitrate is dissolved in distilled water, and ammonia is added to the solution till the precipitate first thrown down is almost entiely redissolved. The solution is filtered and diluted, so that 100 c.c. contain one gramme of argentic nitrate.

"2. Two grammes of argentic nitrate are dissolved in a little distilled water and poured into a litre of boiling distilled water. 1·66 gramme of Rochelle salt is added, and the mixture boiled for a short time, till the precipitate contained in it becomes grey; it is then filtered hot.

"The glass having been thoroughly clean with (1) nitric acid, (2) water, (3) caustic potash, (4) water, (5) alcohol, and lastly distilled water, is to be placed in a clean glass or porcelain vessel, the side to be silvered being placed uppermost. Equal quantities of the two solutions are then to be mixed and poured in so as to cover the glass. This should be done while the glass is still wet with distilled water. In about an hour the silvering will be completed. Then pour off the exhausted liquid, carefully remove glass, wash it in clean water, rub off silver deposited where not required, allow to dry. The time required for the operation depends on temperature. If the solutions be warmed to about 30° C. the silver is deposited in a few minutes; but it is safer to use them cold."

plane surface is not more difficult than any optical surface whatever. The means of verification are so delicate that, in a mirror of 40 inches diameter, an error of $\frac{1}{50000}$th of a millimetre can easily be determined and eliminated. So if there be sphericity in the mirror, the radius of curvature will have at least 1,600 leagues, that is to say, about the radius of curvature of a bath of mercury; and in taking still greater pains, it will be possible to go further, and to reach an exactitude such that the radius of curvature might be twice as great. Under these conditions it is not possible, as one can readily see, that there can be any appreciable imperfection.

The attention of M. Loewy and the Brothers Henry, as will be seen, has been particularly directed to the thickness of mirrors. For a small mirror the thickness should be $\frac{1}{5}$ or $\frac{1}{6}$ of its diameter, but a larger mirror, say one of 40 inches, need only have a thickness of $\frac{1}{7}$.

With regard to the weight, a disc of 5 feet diameter of the proper thickness would weigh about a ton; a disc of 40 inches diameter, trimmed down to its proper thickness, weighs 380 kilogrammes.

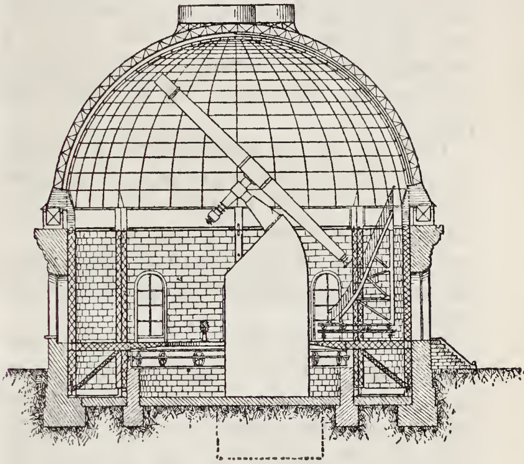
It is thus seen, then, that for our existing telescopes of 25, 26, and 27 inches aperture, we have already mirrors of which siderostats could be constructed to fill them with light at all usual inclinations; and that, if the definition is not effected detrimentally by the introduction of the mirror, Foucault's plan secures the almost complete realisation of Hooke's idea. There is this to be said, however, that with a siderostat the observation of the whole heavens is not secured. I have now, to direct attention to an instrument that does secure this.

The "equatorial *coudé*," an equatorial instrument in which two of these mirrors are used, to which I wish to draw attention, was designed by M. Loewy, and its construction was commenced in the year 1871, by Mr. Delaunay, who was then the Director of the Paris Observatory, who was much struck with the design. The construction was interrupted by the Franco-German war, and the premature death of the illustrious director of the observatory, and had it not been for the liberality of Mr. Bischoffsheim, it probably never would have been completed.

For modern instruments of existing dimensions—and it is certain that those dimensions will be increased—the construction of a dome is no easy matter. The conditions have to be sought for which will ensure a permanent and easy rotation of a circular roof of at least 60 feet in diameter. Two domes are now being constructed in Paris larger than this, that is, having a diameter of 20 metres. The old system of making the dome travel on wheels and circular rails, or cannon balls and gutters, and the like, has been abolished.

Let me give you an idea, by means of the accompanying drawing, of the two domes to which I have referred. The system is the one suggested by M. Eiffel. The dome is a steel one of twenty metres diameter,

Fig. 1.



and hemispherical. At the bottom of the dome is a circular caisson, also of steel, and connected rigidly with the dome. To the dome, by means of vertical pillars constructed of angle iron, is connected the floor of the observatory. The dome, the caisson, the pillars, and the floor form one whole, entirely metallic, all being firmly knitted together. At the top of the cylindrical wall which forms the body of the observatory is an annular trough holding liquid, in which floats the annular caisson. It is this liquid which supports the whole system of dome and floor, the friction produced by the rotation of these being only that of a ring immersed in liquid.

Experiments have shown that the tangential pull of a few pounds will suffice to rotate the dome, in fact 5 grammes applied to a model, and corresponding to a weight of 5 kilogrammes on the dome, gives a rapid rotation to it.

Below the floor, and running on a rail supported by an interior ring of masonry, there is a system of wheels. The dome and floor are floated, so that the floor is within a few millimetres above this ring, which is only to be used as a resource in case of accident.

The liquid proposed is a solution of chloride of magnesium, which is used by M. Pictet in his freezing machines. It is stated that this liquid does not attack galvanised iron, and is only slightly volatile; with a density of 1·25, it only freezes at a temperature of 35° to 40° Centigrade below zero. The section of the caisson is about 1 square metre, and is made of galvanised iron. The surface of the base is 75 square metres. In taking the height of the liquid line at 85 centimetres, there would be 64 cubic metres immersed. This will support 80 tons, which is the estimated weight of the dome and floor.

As the floor moves with the dome, and as the observing chair rests on the floor, the observer will be carried round by the movement of the dome, at the same rate as the telescope is carried round by the movement of the clock, and this obviously is a matter of extreme convenience to the observer.

It can easily be imagined that a case like this must cost something. In fact it will cost nearly three times more than the fiddle—I mean the telescope.

The telescope is to cost 183,000 francs; the observatory nearly half-a-million francs; and I am particularly anxious, for reasons which you will see by-and-by, to dwell on this great expense.

Observations made with reflecting telescopes without domes necessitate the astronomer doing his work in very inconvenient attitudes. Lord Rosse's 6-foot, Lassell's 4-foot, Lord Rosse's 3-foot, and the new Paris 4-foot, are cases in point. The position of the observer with Lord Rosse's 3-foot is here shown by means of a model. (Fig. 2).

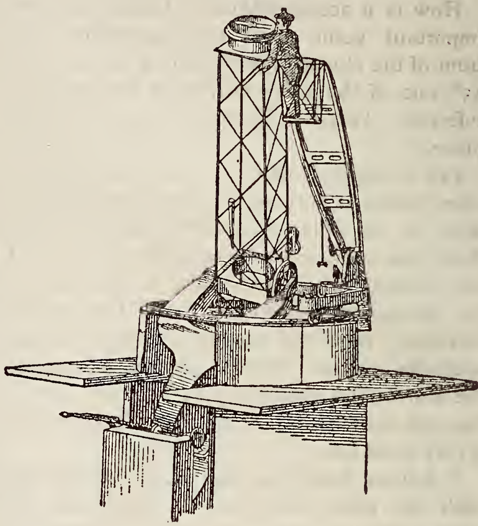
The great point of the equatorial coudé is, that the great expense of domes, and the risk and discomfort of the observer, are at once abolished. The observer can sit down in a comfortable arm-chair, in a warm room, in short, under all the best conditions for securing tranquillity of mind, which is so essential for all accurate observations.

The objects which M. Loewy proposed to himself, in his new instrument, are as follows:—

1. To produce a more stable instrument than the ordinary equatorial, and one enabling large angular measures to be made with certainty.

2. To perfect an arrangement which would enable the astronomer to observe any part of the sky, and to regulate all the movements of the instrument without quitting the observing chair.

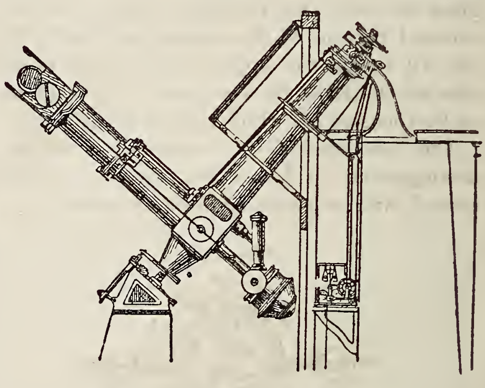
Fig. 2.



3. To avoid the necessity of rotating domes.

We next come to the manner in which M. Loewy has attempted to carry out these conditions (Fig. 3).

Fig. 3.



The polar axis is supported at its two extremities by two pillars. The upper part of this polar axis is hollow.

The principal part of the tube of the telescope is fixed at right angles to the polar axis. With an object-glass at the end of the tube, a right-angled mirror where the tube joins the polar axis, and an eye-piece (Fig. 4) at the upper end of the polar axis. While the instrument turns on its axis, the astronomer sees passing before his eyes the equatorial stars. With the instrument in perfect adjustment, the crosswire in a sweep marks the position of the celestial equator, and this is all that would be seen, but as I said before, the instrument is competent to observe the whole heavens.

How is it accomplished? This is the most important point about the instrument. In front of the object-glass is placed, at an angle 45°, one of the plane mirrors to which I have referred. This can be rotated from the eye-piece.

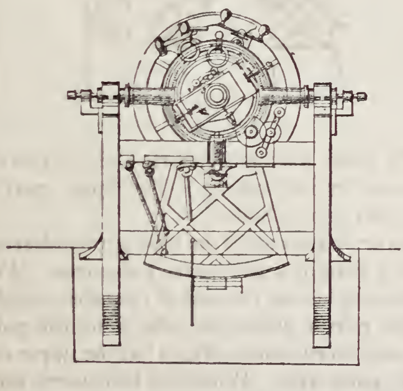
Let us suppose now that the tube with the object-glass is horizontal either to the east or west of the polar axis. The tube in both these positions extends beyond the sides of the building where the observer sits, and if the mirror be then rotated, the stars on the meridian, from the northern horizon to the southern one, are brought successively under the ken of the observer. In this position in fact, the instrument is a transit instrument, and a very good one.

It follows from what has been said that as both the polar axis and the mirror can be rotated through any angle, celestial bodies, in any right ascension and declination, can be observed.

There is this additional point about the instrument which M. Loewy very properly insists upon, that large angles are easily measured, and that the lenses of the object-glass are less liable to displacement. All the external portion of the apparatus, that is to say, all except the upper portion of the Polar axis which carries the eye-piece, is covered by an inexpensive hut which can be rolled away.

The best idea of the convenience of the arrangement, so far as the observer is concerned, will be gathered from the view of the

Fig. 4.



eye-piece. In the centre we see the micrometer with one of the eye-pieces. I shall have a word to say about this micrometer afterwards, as it is an improvement upon the ordinary form. The position circle and the vernier are seen above the eye-piece. Two other verniers on two other concentric circles are shown above, the outer one being the right ascension one. It will be seen, therefore, that the circles and verniers showing position angles and the right ascension and declination of any object visible in the field of view, are close to the observer's eye. Now, if we wish to sweep round the whole visible heavens in right ascension, all we have to do is to turn a handle. The observer, seated comfortably in his chair, not retarded by the necessity of any simultaneous movement of a dome, sees that part of the heavens which is above the horizon at the turn from east to west, having the same declination as the object at first visible in the field of view defiled before him. On the other hand, should he wish to observe bodies with varying declinations, he turns another handle; this causes the mirror in front of the object-glass to rotate, the telescope itself remaining at rest, except in so far as it is being driven by the clockwork at the time. One handle clamps in declination, and another below the eye-piece, is the clamp in right ascension. To the left of the clamp we have three handles: one handle for winding up the clock, another which gives a hand movement to the telescope when the clock is out of gear, while the third connects the tangent screw driven by the clock with the arc concentric with the circles. The eye-piece—indeed, the upper part of the telescope altogether—is fixed to the floor of the observing room by supports.

Two or three questions now present themselves:—What is the definition of this new telescope with the two additional mirrors? *A priori*, a long focus is an advantage, but the idea of two reflections from plane surfaces will frighten many. All I can say is that MM. Perrotin, Thollon, Trépied, Trouvelot, and Professor Newcomb, have all expressed their wonder at the definition, and that my wonder at it has not been less than theirs.

There has been severe, and in some respects unfair, criticism of the equatorial *coudé*. For instance, Mr. Grubb considers the great objection to lie in the necessity of an outside mirror, and states that no mirror of 40 inch, which would be necessary for a 27-inch object glass, has ever been attempted. This is an error, for such a mirror has been finished. And as he has also misread Loewy's statement of thickness, proposes finally a dialyte, an instrument in which the bi-concave is separated from the bi-convex, mounts this so that all the sky is not included, but retains the coudé arrangement, and uses a mirror with a differential movement to throw the light up the polar axis to an eye-piece in an observing room like M. Loewy's.

M. Loewy, with whom I have discussed this arrangement, objects that with the dialyte arrangement the useful field of view is always small, while it is obvious that astronomical precision is quite impossible with such an arrangement.

My own opinion with regard to the use of plane mirrors is that I should have no hesitation in using an equatorial *coudé* of 20 inches aperture, and mirror 30 inches, and I believe that this will be the form adopted for instruments of precision.

With an object-glass of 30 inches diameter for physical observations, I should certainly prefer the siderostat, thus reducing the cost of an instrument of this size to about one-third of the present price.

With regard to cost, the price of a plane mirror for an equatorial *coudé* is only about a quarter of the price of the object-glass, because although the diameter is much larger, the ratio being as 3 to 2 about, the glass of which the mirror is constructed is not optically pure, and there is only one surface to grind and polish instead of four.

Thus, the price an object-glass of 27 inches is 70,000 francs, while that of a plane mirror of 38 inches is 18,000 francs. For an object-glass of 40 inches, the price is 200,000 francs; the corresponding mirror of 58 inches only costs 40,000 francs.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON BEVERAGES. BY RICHARD BANNISTER, F.I.C, F.C.S.

Although foods, as a class, differ from beverages as commonly understood, yet the visitor to the Exhibition will soon make himself acquainted with certain commodities exhibited, which can with as great propriety be classed under one head as the other. Thus, for instance, chocolate, in its ordinary form of a confection, is consumed as a food, but when we approach liquid extracts of cocoa and coffee, they pass with propriety out of the category of foods, and ally themselves to beverages. It has been necessary to make these few introductory remarks, because, in the somewhat large exhibit of food and beverages, there has been considerable difficulty in dividing them into two distinct classes, on account of the many articles exhibited which stand on the border line of each class, and which may justly be placed in either class according to the definition of the terms "food" and "beverage." In the official catalogue the beverages are divided into three classes, viz., alcoholic, non-alcoholic, and infusions (such as tea, coffee, &c.). From a chemical or physiological point of view there would be little difficulty in making a report upon the lines thus laid down, for in two of the classes the presence or absence of alcohol would settle the matter, and little would have to be said, beyond recording the quantity of spirit or alcohol the articles exhibited contained. But in trade, alcoholic beverages such as wine, liqueurs, brandy, &c., do not depend upon the quantity of alcohol they contain as the criterion of value, but upon other qualities, such as fulness, flavour, aroma, &c., which, combined with the spirit in them, determine their value as articles of commerce. It will, therefore, be perhaps more convenient in this report to break down, to some extent, the distinction between alcoholic and non-alcoholic beverages, and bring the articles exhibited into their different commercial classes, without going into such details as are scarcely suited for general reading. It would, however, be scarcely just to the exhibitors to confine the remarks about to be made to the objects exhibited which strictly fall within the classes above enumerated; for there are exhibits of great interest which certainly demand a passing notice, and which cannot be classed. Thus in the South Gallery, amongst the tea exhibits, may be seen at one stall healthy coffee plants, and a series of illustrations showing the different stages of the process employed for curing Indian tea. At other stalls, in the tea and coffee section, can be seen specimens of tea and coffee of every description known in the European market; and although China tea, which forms the greater part of the tea sold in this country, is not fully represented, yet it is astonishing to see how many different sorts of tea and coffee are collected together in so small a space.

Passing down the gallery, there is reached the stall of the Austro-Bavarian Lager Beer Company, which attracts special attention on account of its being the first brewery in this country devoted to the sole manufacture of beer brewed on the German system. The German lager and other beers are now imported in large quantities to supply the growing demand for them, and as the price of the imported article is comparatively high, there is ample margin for the profitable brewing of similar home manufactured beer at a lower price. Healthy competition has already been of benefit to the consumer, and there is little doubt if the demand for this class of beer increases in future as it has in the last few years, we shall see this industry becoming established here on a somewhat large scale, to correspond with our national wants. Other English brewers have attractive exhibits which are deserving of praise, but the classes of pale, family, and strong ale are so well known and appreciated, that it is not necessary to dwell here on the merits of this national beverage.

In this gallery there are several excellent exhibits of Australian wines, the stalls on which they are placed being made to attract the attention of visitors, who will doubtless be struck with the quality and quantity of the wine which finds its way from this distant colony. Adjacent to these exhibits are several stands devoted to the display of Spanish wines, which have long been in favour in this country, and the method of arrangement of the specimens exhibited shows much taste and discrimination on the part of the exhibitors. Perhaps the stand which has attracted the most attention in this class is the "Weinlaube" or vineyard arbour, with its female attendant dressed in Dalmatian costume. Apart altogether from the display of Austrian and Dalmatian wines, there are exhibited here, among other curiosities to viticulturists, specimens of the *Phylloxera vastatrix*, the small insect which has caused such destruction in the vineyards of France and other countries. Vine roots are exhibited illustrating the method of attack of this pest; and it appears, from a close examination of the specimens, that the insects attack the young and tender shoots, and so puncture and wound them that they cannot supply nourishment to the vine. From want of sustenance the plants first cease to grow, and then sicken and die, without any apparent cause. A close examination of the root, however, soon reveals the presence of the phylloxera, which has not only appropriated the nourishment required by the vine, but also damaged the roots to such an extent that they cannot perform their natural functions. In France substantial rewards have been offered for the successful destruction of the phylloxera, but up to the present time no remedy has been perfectly successful. If the vineyards could be flooded at certain seasons of the year, the insects in question could be drowned without damage to the vines; but as the vineyards in France are generally on hilly ground, this remedy cannot be applied to them. In Austria and Dalmatia the vines are generally grown on level ground, and here the experiment of flooding has been tried with perfect success. Another suggestion has been made, that the vines should be trained high, on account of the difficulty the young insects would have in travelling from the upper branches, where they are hatched, to the roots of the plants where they obtain, their food. It has been said by the advocates of this plan that vines trained round dwelling-houses situated in districts infested with phylloxera are not injured, and the explanation of this immunity from disease is ascribed to the inability of the insects to travel from the high parts of the plant to the root. However exact this explanation may be, it is evident that in exposed districts the vines cannot be trained high, on account of wind and frosts, and that some other remedy must be found for the cure of the disease in plants growing in exposed situations. In France there seems to be a growing disposition to destroy the vineyards attacked, to cultivate the ground with care, and then to plant vines possessing very strong spreading roots, and afterwards graft on these stock vines the different varieties suitable for the district, and for the production of the special description of wine for which the district has been famous.

In this South Gallery are also numerous attractive stands for the display of aërated and other waters. Without giving undue preference to any of the exhibits, a careful inspection will convince even the most sceptical that in this large and increasing trade the efforts made for producing not only a pleasant, but also a pure article, are very great. At one stand the specialty is that the water employed is distilled with the greatest care; at another, that the filtration of the water before use is specially attended to; at a third, that the chemicals and essences employed are manufactured on the premises to secure purity; at a fourth, that the carbonic acid used for aeration is specially made so that it shall be quite free from the faintest taint of contamination, and all the exhibits show that the most scrupulous care has been taken that the liquids themselves shall be free from lead or other metallic contamination. Exhibitions, such as the present, where so many sections of the same commercial interests are brought together, must do incalculable good, for each manufacturer can see what his rival is doing, and by seeing improvements in some directions and blemishes in others, he is led to think out what improvements he can make in his own business, so as not to be left behind in the race.

The aeration of these beverages has led one exhibitor to show how bottled beer can be artificially charged with carbonic acid, and thus be ready for consumption as soon as bottled. This statement may appear very simple to those unacquainted with the bottled beer trade, but the initiated will understand the value of the problem to be solved by this process, which, if successful, will work a revolution in this particular branch of trade. Hitherto bottled beer has had to be kept until sufficient fermentation has been set up in the liquid to charge the beer with carbonic acid, and thus cause it to be somewhat effervescent and sparkling when poured out. During this fermentation certain matters are thrown out of solution and form a sediment. When the bottle is uncorked the pressure of the carbonic acid is removed, and almost instantly the sediment will be seen to become detached from the bottom of the bottle and diffuse itself through the liquid. The beer thus becomes muddy and unsightly, and displeasing to the eye and taste. The artificial introduction of the carbonic acid is set forth as a remedy for this defect, but whether in practice it will be found to possess all the advantages claimed for it, it is not for me to decide. At another stall milk has been submitted to the same treatment, and is sent out in syphons.

Another class of beverages is also very fairly represented in the South Gallery, viz., fruit cordials. Lime and lemon juice cordials have come prominently into use of late, as flavouring materials to be added to water for summer drinks. Preference is given to the class prepared from lime juice, on account of their greater stability; but, unfortunately, many of them possess such a distinct flavour of the chemical substances used to preserve them, that they are on this account rather objectionable, although not unwholesome.

As a step between the fruit cordials and effervescing wines of foreign produce, come two or three exhibits of wine of home manufacture, the basis of one being Devonshire cider, and of the other fruits and grapes of home growth. The names given to some of these productions are rather startling, they being so constructed as to lead the ignorant or thoughtless to believe that the liquids they represent partake of the character of certain well-known sparkling wines. One little exhibit in this section is apt to be overlooked, but as it is a novelty, it is here specially noticed. The samples in the exhibit are made of grapes which have been gathered from cottage vines, and as this is a somewhat new industry, it is deserving of attention, especially as the wine itself, considering its origin, is of very fair quality.

On passing from the south gallery to the foreign galleries, where the other portion of beverages is mainly exhibited, the stands of the Japanese section attract attention. Although late in their arrival, and collected and prepared with haste, the articles exhibited show the rapid strides made in the national life of the Japanese, and of the effect of the concord between the eastern and western nations, which now happily prevails. The statistics collected together, and printed either in the catalogue, or on sheets, are marvellous in detail, and the descriptions given of the different articles exhibited are unique. The national beverage is Saké, which is a kind of wine made from rice, and very similar to what is largely consumed in China. This saké is not of unpleasant flavour, and although very peculiar, would soon grow in public estimation. Probably the remark made by a friend who had lived long in China, respecting the Chinese national beverage, would apply to saké, viz., "That it is the most fitting drink to take with the kind of food we eat." A strong spirit made from rice, named Awamori, is also exhibited, as well as Shochiu, which is made by fermenting the saké residuum, and is said to be used as a medicine, and for dressing wounds. Homeishu, or life-keeping saké, is also exhibited. This spirit is a kind of liqueur flavoured with herbs, and is not at all unpleasant. In the exhibit are also found beer and wine made as in Europe. The wine has deteriorated by keeping, but the beer is of very fair quality, and compares favourably with the ordinary kind of ale brewed in this country. Specimens of tea are also exhibited, and they appear to be of very good quality. Taken altogether, this exhibition is an extraordinary one, and it is not too much to say that all who study it with care will be surprised to find that the Japanese are so far advanced in knowledge, or so well acquainted with what is necessary to produce a healthy, robust nation.

Near to the Japanese section are the stands representing the produce of Venezuela, and of the Cape of Good Hope. In the former exhibit there are scarcely any beverages, whilst the latter consists exclusively of wines. At one time the Cape wines were common in this country, and the Constantia deservedly commanded a very high price, but, from various causes the consumption has diminished, till at last the importation into this country is very small indeed. The wines are, however, well represented, and no doubt their quality will be properly appreciated. Near here are the Swedish, Danish, Swiss, and Russian exhibits. The Swedish beverages exhibited are of a highly alcoholic kind, as might be naturally expected; whilst Denmark shows beer and liqueurs, the latter being well known and esteemed in this country. Switzerland is represented by her champagne, and a medicine prepared from Alpine herbs; and in the Russian section is exhibited a very good selection of national beverages, some of which are very pleasant, and known on the English market. A medicine called wunderbalsam is also shown, which is said to possess extraordinary curative properties, and is in general use.

The Austria-Hungarian and the Italian Courts are made quite elegant by the rich display of wines natural to the countries, and some of the stands are costly, and prepared with very great taste. Altogether, the exhibits of beverages are very attractive indeed, and no doubt much pleasure has been given to the casual visitors by the taste shown in the arrangement of the goods exhibited; while the manufacturer and the student have been able to get much instruction from the different articles exhibited, and which otherwise could not have come under their observation, except at great cost of time and labour expended in visiting the countries from which the exhibits have been brought.

The survey of the products of different countries, brought together in the section of beverages, will not be satisfactory without trying to point out why it is that some of the countries which supply large quantities of such general beverages as wine, brandy, and rum, are scarcely represented. Thus, France, from whence we derive our large supplies of claret and champagne, Spain, which sends us in large quantities sherry and tarragona, Portugal, which provides us with port, and Germany, with hock, moselle, &c., are scarcely represented at all. All these wines are well known in the English market, and, therefore, are to a certain extent popular. Some of the vineyards of greatest repute either belong to Englishmen or are represented in this country by English houses who act as agents. In cases where the products are in good repute, there seems but little desire to exhibit. It is argued that as the goods are popular, that as they stand high in public favour, and command a high price, there is no necessity to bring them more prominently before the public. Again, it is said that it is useless to try to get medals or marks of honour for such products, because as public appreciation is the best of standards, so by submitting to competition there would be danger of loss rather than of gain. Which of these reasons may be right, or whether all are so, it is certain that in Exhibitions some of the oldest and best known houses do not exhibit, or if they do so, it is only to show what their products are, and not to enter into competition with others. This Exhibition is no exception to this rule, for in the case of France, there are but few entries of wines or other beverages either made by the makers themselves or their agents, and the same remark applies to Spain, Portugal, and Germany. There is no doubt that the difficulties to be overcome by shippers of wines from other countries to alter the taste of the British public for the wines now fashionable with them are well nigh insuperable. At the same time there is no doubt that wine consumers get their knowledge of wines of other growths than those in general use greatly increased by such Exhibitions as the Health Exhibition; and though the old wines may continue in favour, yet some of the new wines, possessing as they do a certain amount of excellence, may be used as adjuncts to the old standard sorts, and thus become better known and more appreciated.

It is only right to point out that some of the wines sold on the English market are not what they are said to be, but contain an abundance of other wines. Thus some of the sherry of the lowest class does not reach us from Spain, but from a free port in northern Europe, where it is made up of different kinds of wine, the greater proportion of which is not of Spanish manufacture. The same remark applies to the common descriptions of clarets, for during the last few years shippers of low class goods have been compelled to mix the very poor French wines with richer wines of the growths of other countries. It is fair to assume, therefore, that if some of the best wines which are used for mixing purposes get known here they will be properly appreciated and drunk, because they are sound and good. As has been before referred to, the Cape wines once in repute were brought into public notice through the energy of one or two individuals, and since that time Australian and Greek wines have also had a share of public favour. The present Exhibition has done much to make us familiar with the wines of Austria, Hungary, Italy, and Australia. All of them possess peculiarities of their own, but some of them improve greatly on acquaintance, and will no doubt come into general use. The great objection to many of them is that they are not so delicate as French wines of the same class, and that their palate flavour is faulty. But it must, at the same time, be considered that the growers of most of these wines are now seeking a new market, and that as soon as they are acquainted with the defects of the wine, they will try to remedy these defects, and strive to produce a typical wine which will be appreciated. To know what is wanted is half-way to success, and self-interest will, doubtless, spur on the wine growers to achieve the success they are now seeking for. Hungarian wines have been in favour here, and the description known as Carlowitz is the best known of them. Now, however, other wines are presented to us through the administration of the Weinlaube, who have done much for their country in showing the samples in such an attractive way, and Messrs. Palugyay and Sons have spared no pains in putting before the public the best wines of Austria-Hungary, among which tokay holds the premier place. From Graz, in Styria, are also exhibited champagnes, burgundies, hocks and clarets of Styrian growth, and from the varied assortment submitted there is little doubt but that some of them will come into favour.

The Italian wines are so numerous and varied that it is a matter of difficulty to know how to begin the description. The wines are contained in all sorts of bottles, some of which are quite unsuited for ordinary trade. The wine in flasks is, perhaps, known in England on account of its being exhibited in the windows of Italian cafés, &c., as an advertisement. A close inspection of such bottles shows the layer of oil on the top of the wine in the neck of the bottle, which is to keep the wine free from the air. When, however, the wine has to be used the oil must be got off, and the usual method of removing it must be seen to be appreciated. Though it may be carefully done, a small quantity of oil is left behind, which is sufficient to flavour the wine, and make it objectionable as a beverage to the large class who do not like oil as an ordinary drink. Fortunately, some of the exhibitors are fully alive to the fact that if the wine exhibited by them is to become popular, it must be contained in bottles of ordinary form and capacity, and that it must be bottled with care, and kept sound by ordinary means.

Several white wines of a low price are particularly pleasant and clean to the palate. They already command a fair sale, and are kept in stock by some of the largest wine dealers. Several red wines are also very good, but some are not as sound as they should be, and others have a flavour of sulphur, which is said to be obtained from the volcanic soil in which the vines are grown. Be this as it may, there is no doubt that the Italian exhibits show in special cases excellent value, and it is hoped that the Enological Society of Rome, Vitali, and other exhibitors, will do what they can to follow on with wines that shall exactly correspond in character and flavour with the wines now exhibited, to which distinctive names have been given. Wine is produced in almost every part of Italy, and as the country is now improving commercially, it is to be expected that wine will eventually be largely exported to other countries for direct consumption.

The Australian wines are so steadily making their way in the English market that they require but little comment. It will be a great gain to these wines if the alcoholic standard for the shilling duty on wines is raised, so as to include them in the lower rate. At present the wines are very full and heavy, but they have improved in this respect, and no doubt the improvement will continue.

With regard to whisky, gin, and other spirituous liquors exhibited, the two first classes are but poorly represented by manufacturers, but many different kinds are shown by dealers, and most of the exhibits are of very good quality. The whisky is chiefly blended whisky, each exhibitor having his own peculiar secret in making his blend. The large London rectifiers of gin do not exhibit, consequently this large and valuable industry is very sparsely represented. Spirituous liquors, such as cordials, liqueurs, &c., are exceedingly well represented. France, Germany, Belgium, Holland, Switzerland, Venezuela, Russia, Japan, Sweden, Denmark, Great Britain, and other countries, supply exhibitors, and some of the exhibits are of very great excellence. It must, however, be remembered that the aggregate quantity of liqueurs consumed is comparatively small, and therefore, though the exhibitors are numerous, the value of the exhibits does not fairly correspond with the large number of samples shown.

The number of exhibitors of malt liquors is not great, but the foreign exhibits are interesting as showing the different kinds of beer made in the countries they represent. The English exhibitors are, as before stated, very scanty, but the quality of the beer is good.

On the descriptions and qualities of the tea and coffee exhibited, a somewhat lengthy paper might be written. The specimens of coffee and tea shown are very numerous, but, unfortunately, there are very few specimens of China tea included in them, by far the greater part being India and Ceylon teas. The large increase in the mportation of India and Ceylon teas, and the falling off in China teas, point to the fact that the colonial teas are fast rising in public favour, and this appreciation of their good qualities is deserved on account of their strength and flavour, and their use in the blending of teas for home consumption. Some of them, such as the Darjeeling, can be used alone; but they generally pass into consumption as blended tea.

In the Chinese court only two specimens of tea are exhibited, but they are not for competition. They are sun dried, and contain flowers of the tea plant. The flavour of the tea in liquor is exquisite, but its character, appearance, and price preclude it from being a commercial tea, although it is greatly appreciated in China, and considered of the highest quality.

This report is necessarily very imperfect, on account of the difficulty experienced in bringing the different sections into one harmonious whole. Much might have been said on the properties of the different natural mineral and artificial waters exhibited, but the paper would then have been too long.

After a careful study of all the articles exhibited in the section of beverages, I am not surprised at the great success of the Exhibition. There is very much to be learned; and the regret of those who have devoted much time to study the lessons which can be taught by such an Exhibition is, that the time at their disposal is too limited to do justice to the privileges conferred on them by what can be with truth called a huge educational establishment.

Correspondence.

WATER STORAGE.

The late scarcity has brought before many the necessity for more water storage, and to which attention has been called in the *Journal*. My object now is to point to the storage of rainwater by house tanks. The late Sir Philip Rose was active as to this, and provided the cottages on his estate with the means for storage. Our kindred in Flanders have often been cited for their storage of manure, but their storage of water is also deserving of regard. Two months of the summer will sometimes pass with blue skies and no rain. The courses of the sluggish rivers and the canals they feed only give water for inferior uses. Large cities, such as in the Middle Ages held a hundred thousand people, are supplied with drinking water from the roofs. Each house has a tank under the house, and in some cases, a reserve tank. These tanks, dating from past times, in some cases three or four hundred years ago, are a valuable part of the national plant and resources. This position is also the reason for so many old houses of remote date being preserved from fire, for there is water on the spot. If those who are now concerned in building houses will, as Sir Philip Rose did, make provision, England would derive corresponding benefit.

HYDE CLARKE.

32, St. George's-square, S.W.
25th October, 1884.

It appears from recent statistics that 1883 was favourable for tea cultivation in Assam, the outturn being nearly 7,000,000 lbs. in excess of the yield of 1882. The total area of land held by tea planters in 1883 was 923,664 acres; the yield of tea was 52,171,207 lbs. There has been a steady increase in the production of tea in Assam during the past five years, from 31,386,636 lbs. in 1879 to 52,171,207 lbs. in 1883.

Journal of the Society of Arts.

No. 1,668. Vol. XXXII.

FRIDAY, NOVEMBER 7, 1884.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred and and Thirty-first Session of the Society will be held on Wednesday, the 19th November, when the Opening Address will be delivered by Sir Frederick Abel, C.B., D.C.L., LL.D., F.R.S., Chairman of the Council. Previous to Christmas there will be Four Ordinary Meetings, in addition to the Opening Meeting.

Ordinary Meetings.

The following papers (among others) will be read:—

"The International Health Exhibition." By George Buchanan, M.D., F.R.S.

"Electric Lighting in America." By W. H. Preece, F.R.S.

"Education at the International Health Exhibition." By J. G. Fitch, M.A.

"The Employment of Hydraulic Machinery in Engineering Workshops." By Ralph H. Tweddell.

"The History and Manufacture of Playing Cards." By George Clulow.

"The Musical Scales of Various Nations." By A. J. Ellis, B.A., F.R.S.

"The Painless Extinction of Life in the Lower Animals." By B. W. Richardson, M.A., M.D., F.R.S.

"Marine Biological Laboratories: their Organisation, Work, and National Importance." By Prof. E. Ray Lankester, M.A., F.R.S.

"The Preparation of Butterine." By Anton Jurgens.

"Recent Improvements in Coast Signals." By Sir J. N. Douglass.

"Present and Prospective Sources of the Timber Supplies of Great Britain." By P. L. Simmonds.

"The Influence of Civilisation upon Eyesight." By R. Brudenell Carter, F.R.C.S.

"The Evolution of Machines." By Prof. H. S. Hele Shaw.

"Tempered Glass." By Frederick Siemens.

Foreign and Colonial Section.

The Meetings of this Section will take place on the following Tuesday evenings, at Eight o'clock:—

January 27; February 24; March 17, 31; April 28; May 19.

Applied Chemistry and Physics Section.

The Meetings of this Section will take place on the following Thursday evenings, at Eight o'clock:—

February 12; March 12; April 23, 30; May 7, 28.

Indian Section.

The Meetings of this Section will take place on the following Friday evenings, at Eight o'clock:—

January 23; February 20; March 6, 20; April 17; May 15.

Cantor Lectures.

The First Course will be on "The Use of Coal Gas." By Harold B. Dixon, M.A.

December 1, 8, 15.

The Second Course will be on "Climate, and its relation to Health." By G. V. Poore, M.D.

January 12, 19, 26.

The Third Course will be on "The Distribution of Electricity." By Prof. George Forbes.

February 2, 9, 16.

The Fourth Course will be on "Artists' Colours." By J. M. Thomson, F.R.S.E., F.C.S., Lecturer on Chemistry at King' College, London.

February 23; March 2.

The Fifth Course will be on "Carving and Furniture." By J. Hungerford Pollen.

March 9, 16, 23, 30.

The Sixth Course will be on "Photography and the Spectroscope." By Capt. W. de W. Abney, R.E., F.R.S.

April 20, 27.

The Seventh and concluding Course will be on "The Manufacture of Toilet Soaps." By C. R. ALDER WRIGHT, D.Sc., F.R.S., F.C.S.

May 4, 11, 18.

HOWARD LECTURES.

A Special Course of Lectures will be delivered under the Howard Trust, on "The Conversion of Heat into Useful Work." By W. ANDERSON, M.Inst.C.E.

November 27; December 4, 11; January 22, 29; February 5.

JUVENILE LECTURES.

The two Juvenile Lectures will be given on Wednesday evenings, December 31, 1884, and January 7, 1885. Special tickets will be issued for these lectures, due announcement of which will be made.

PRIZES FOR ESSAYS.

The Council of the Society of Arts have had placed at their disposal by Mr. William Westgarth, a member of the Society, a sum of £1,200, to be awarded in prizes for essays on "Dwellings for the Poor," and on the "Reconstruction of Central London."

The first prize will be a sum of £250 for the best practical essay upon the re-housing of the poorer classes, and especially of the very poorest classes, of the metropolis.

The second prize will be a sum of £500 for the best practical essay upon the whole subject of the sanitation, street re-alignment, and reconstruction of the central part of London.

In addition to the above, there will be three further prizes of £150 each:—1. For the best treatment of the engineering considerations. 2. For the best treatment of the architectural considerations. 3. For the best treatment of the sanitary considerations. Any of all of these last-named prizes may be awarded to the same essay as that to which the £500 prize may be awarded, or they may be awarded separately.

The essays must be sent in to the Secretary of the Society of Arts, not later than December 31, 1884. No essays can be received in manuscript.

The Council reserve the right of withholding any of the prizes, or of awarding the amounts, or parts of the amounts, in any manner which may seem to them desirable. They also reserve the right of publishing any essay to which a prize may be awarded.

Further particulars can be obtained on application to the Secretary, John-street, Adelphi.

INTERNATIONAL INVENTIONS EXHIBITION, 1885.

At the request of the Executive Council of the Exhibition, the Council of the Society has readily consented to the Society of Arts *Journal* being made the official record of the Exhibition, in order that it may serve as the medium for the publication of official notices, and of information about the Exhibition.

Proceedings of the Society.

CANTOR LECTURES.

SOME NEW OPTICAL INSTRUMENTS.

By J. NORMAN LOCKYER, F.R.S.

[The right of reproduction of these Lectures is reserved by the Author.]

Lecture II.—Delivered Monday, May 5th.

In my last lecture I referred to the use of the plane mirror, in connection with the necessity of movement in those instruments which have for their object chiefly the investigation of the physical constitution of the heavenly bodies. We saw that the use of such mirrors was not confined entirely to this kind of observation, but it was pointed out that wherever there was any necessity for the continued following of a celestial body, then the plane mirror came in, and enabled us to construct a telescope of enormous proportions, which combined not only the maximum of cheapness, but the maximum of comfort to the observer.

I have now to discuss, as briefly as may be, another exceedingly important use of these plane mirrors, and in doing so we must never forget, however large the astronomical refractor may become in time, that the germ of those monsters which are now becoming familiar to us was the one constructed by the lamented Thomas Cooke, of York. It was he who first dared to advance from an aperture of 16 inches to an aperture of 25 inches. How did

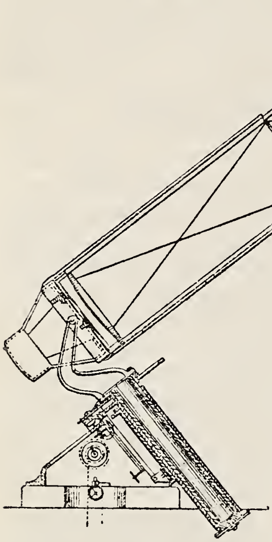
Cooke construct this object-glass? So soon as he had begun to work at it, he constructed a tower near the walls of the city, where his workshop was, and to this observatory, right away from his workshop, the lens or lenses, one or both of them, were taken when it was necessary to test them, because he imagined that it was absolutely necessary with such large surfaces to test them by observations on stars, and not by using artificial stars, which did very well with smaller lenses; so that, whenever it was a question of determining whether the surfaces were spherical, whether the curves of the crown agreed with the curves of the flat, whenever any aberration was in question, it was necessary to take down this object-glass from the chair on which it was being ground by the machinery, to put it in a cell, to mount it at the end of a tube, and then to go to work with this observing tower. Now it is true that other opticians, among them Clarke, of Cambridge, had shown beforehand that this was not absolutely necessary; that provided the optician had a sort of horizontal well, some 500 or 600 feet long, he could do without stars altogether; but horizontal wells 500 feet long are not common—it is not everyone who can command a dark chamber of that length.

Now, mark what happens the moment you introduce the use of the plane mirror. You mount this plane mirror vertically, put the object-glass vertically in front of it, and, at practically the focus of the lens you wish to test, make a little hole in a piece of wood or of metal, and let light through the hole from a lamp by means of a right-angled prism. Close to this hole mount another lens, by which you examine the image thrown by the lens after the light has travelled first through the little hole, then through the lens, then as a parallel beam from the lens to the plane mirror and back again, until at length it is received by the eye at the eye-piece. With an arrangement of this kind, which does not cost ten shillings, you can test every step of progress in any of your surfaces; and you may test it, whether it refers merely to the perfect sphericity of the surfaces, or to the under-correction or over-correction of the crown by the flint lens which you employ. So that the Brothers Henry, who are now using this system in Paris with object-glasses up to 20 inches in diameter, can deal with the four surfaces—the two surfaces of the flint and the two surfaces of the crown—at the rate of an inch a day. And if you say to them, "I want an object-glass of 16 inches in diameter," they will say, "You can have it in 16 days." Now that time for the construction of an object-glass of that size was not enough when it was a question of dismounting the lenses every time you wanted to test them, and putting them in a trial tube, and waiting for an image of a star during, probably, very cloudy weather. So that I think the future of this kind of optical work will show that the plane mirror is probably as useful in the construction of lenses as in the use of it to which I drew your attention in the last lecture. I told you, too, in that lecture, that I had just seen in Paris a plane mirror of 40 inches in diameter. This mirror really has been made with such an object in view. It was not made for use with the equatorial *coudé*, although of course it, or one like it, can be easily applied. The point that I had to bring to your attention in the last lecture was that it had been stated that such a mirror was impossible. This mirror is now made as a matter of business, not for any use directly of its own, but for its indirect use in enabling the very rapid testing of object-glasses to be accomplished. And I may say this particular plane mirror of 40 inches to which I have referred is wanted for those two object-glasses of 28 inches and 29 inches diameter to which I have also referred; and still having my text in mind, as the preacher should have, I have now to point out that that mirror is useless, and that those object-glasses are not being finished, because in the wide world the application of the arts has not succeeded in enabling opticians to procure crown glass of 30 inches in diameter.

Having the same ideas in our minds, let us change the *venue* of them slightly by passing on to reflectors. We discussed the mounting of reflectors in the last lecture somewhat, and it was pointed out that all the mountings which we have had, however good or bad they might be, have this terrible disadvantage connected with them, that the observer was hardly ever in the best possible conditions for making observations. I have now to bring to your notice another form of equatorial mounting of reflectors, which I think opens out a perfectly new use for that instrument. I do not mean to say that with this new mounting the observer will be absolutely comfortable, but I do say that it possesses an enormous number of advantages over the old forms, and it is one which, from our particular point of view, is well worth studying. By the kindness of Mr. Common, to whom this new form of mounting reflectors is due, I give two drawings, made to scale by him, which will give an idea of the difference between this form of mounting and the other ones to which I drew your attention.

Fig 1 is the mounting of a telescope of 3 ft. aperture, which is now at work in the neighbourhood of London, and the first point about it is that as Mr. Common had the very happy idea of floating its polar axis in mercury, the movement of its polar axis is perfectly easy, so that this telescope, although we have a distance of 3 ft. from

Fig. 1.

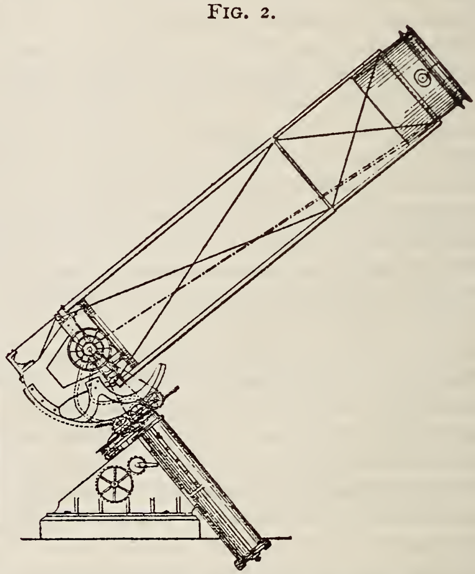


General View of Mr. Common's Method of Mounting, showing Floating Polar Axis.

side to side, and a distance of from 18 to 20 ft. from end to end, is moved with the most perfect ease. Another extremely important point about it is that the tube is reduced to a minimum. In the last lecture we saw a model of Lord Rosse's 3 ft. tube, in which the tube was certainly very simple indeed; it was almost a survival, as a naturalist would say, but it was not quite so much a survival as this one. Here we have simply four **T** pieces beginning with four angles, and the function of the whole thing is to carry the eye-piece, and the weight is reduced as much as possible, while strength and rigidity is retained by means of cross pieces. Why is it so important to reduce the tube in this way? For this reason, that practically the centre of support, and the centre of motion, lie in the mirror itself. That idea gives rise to another matter of very great importance, which is that, as the mirror can lie in the centre of motion, there is no necessity for any great mass of metal between the mirror and the eye-piece, either to abstract heat from the assembly of pieces or to give heat to it, so that one of the chief causes, I think, of the bad definition of reflectors generally has been abolished by this arrangement of Mr. Common's. With reference to that point, a comparison of the 4 ft. reflector at Melbourne will best point to the considerable difference in arrangements.

In that, although we have a lattice tube, the centre of motion does not lie anywhere

Fig. 2.



Showing Details of the Movement.

near the mirror, the result of which is that there is a considerable mass of metal between the mirror and the eye-piece, giving rise, in all probability, to convection currents—whether up currents or down currents does not matter at all for my purpose—and giving a very good reason why the disturbance of air between the eye-piece and the mirror should have a very considerable effect. I might have pointed that remark by showing you photographs of other reflectors, but I think I have said enough for the present purpose. Now, if you will think the thing out, you will agree to this statement, that with a mounting like Mr. Common's, or something like it, a mirror of 8 or 10 feet aperture is just as easy to mount as a mirror of

3 feet. We should get the maximum of rigidity, and with regard to counterpoising, and ease of motion, what is good so far as floating in mercury for 3 feet is good for the same reason for a mirror of 8 or 10 feet; and here, again, I come back to my text, and say that I believe the only reason in the world that we have not such a mirror at the present moment, is because the industrial arts have not yet succeeded in enabling opticians to obtain a disc of glass 8 feet or 10 feet in diameter to work upon. Now, before one makes a statement of that kind in the theatre of the Society of Arts, one ought to be sure of one's facts. Well, I have done my best to be sure of my facts in regard to that particular, and I will tell you what I have been told by those who are most likely to know. You remember we found, in the last lecture, that to get anything like good and permanent work without loss of definition with a plane mirror, the thickness of it for a diameter over 30 inches ought to be as one in six. Now, it is perfectly true that there is one place in the world—I am sorry to say, not in this country—where they can produce a disc of glass 8 feet in diameter, but that disc of glass can only weigh one ton, and if you come to work it out you will find that a disc of glass 8 feet in diameter, and weighing one ton, will only be 5 inches thick. Now we saw that was a fatal objection. It must be one-sixth; it must be more than one foot thick to be of any use to us as a mirror, whether plane or parabolised. It is thought by some who have studied the question that the matter may be got over for a reflector of the size I have indicated, namely, 8 feet in diameter, by getting two discs run each of one ton weight, grinding two of the surfaces so as to make them plane, then grinding the other surface so as to give it the required curvature, and then to make one mirror by fastening the two plane surfaces together. That is one way of getting over the difficulty, but then, practically, the mirror would be a little too thick, and it would weigh very nearly two tons, so that another method is now being considered, and it is this. Although with our present glass works it is not possible to run more than one ton of glass, it is possible to run very nearly two tons of porcelain, the density of which is very nearly the same as the density of glass; and one question being studied in France at the present moment is this, and it should be a very interesting one to many of you present—whether it is possible, having a disc of porcelain of the required diameter, and of the required thickness, for a large telescope, to put on this disc of porcelain a glass surface which may be subsequently parabolised to turn into a reflecting telescope. I need not tell you that that question is not yet solved, but it certainly is being considered. I should add that with the experience of the French astronomers, and I believe I may say also with that of Mr. Common, who is using mirrors of 3 feet in this country, one really need not consider the question of silvering the mirrors at all—the thing is perfectly simple. There are two or three ways of doing it. One obvious way which I believe, so far as the information which has reached me goes—I have no personal knowledge of the subject—is quite sufficient, is that the mirror, when you have once got it in a horizontal position, may be surrounded with cardboard, or anything which will hold a certain amount of solution; then the solution may be poured on to its first surface, as we saw it poured into the beaker in the last lecture, the old liquid being poured off, until at last one has a surface of sufficient tenacity and of sufficient brilliancy to be used for astronomical purposes. So that you see if we only have the glass, it looks very much as if at the present moment we might be utilising an instrument such as the world has never yet seen, that is to say, one of 8 feet aperture, with somewhere about 60 feet focal length.

Well, supposing this be so, should we be any better off than with the existing instruments? Should we be more likely to have these instruments multiplied? Yes, we should, for this reason. In these matters it is almost always a question of money. You have not got the thing because you want the money. The thing is multiplied when it is once shown to be possible, because it is cheap. Now this instrument to which I have referred, if we only had the glass, would, I am credibly informed, be produced in ten months for a sum of £10,000. Now that at first sight seems a great sum; but please remember the facts that I brought before you in the last lecture; and this is one of the reasons why I have brought them before you. The instruments of less than 30 inches aperture which are now being constructed in France—I am sorry to say none of those instruments are being worked here—are to have observatories put over them, which will themselves, without the instruments, cost between twice and three times as much as these instruments of 8 feet diameter would. The estimate for the observatory for this 30-inch telescope is about £35,000. We can get one of these 8 feet telescopes for less than £10,000. I make these statements with some certainty, because, in fact, during my official visit to France, a short time ago, I suggested the construction of such a telescope as this to the French astronomers, and the sums I have named, and the facts I have given you, are based upon actual estimates, and I have no doubt that before very long either in France, or let us say in America—the thing is quite hopeless here — such an instrument should be constructed.

Now, why this instrument is so valuable cannot, perhaps, be stated without reference to some more of these new optical methods to which I am bound by the title of my lecture to allude. The particular new optical methods and arrangements which make this telescope so desirable and feasible, are chiefly two, or rather two sets, the first has to do with the way in which we can now obtain permanent records of the spectra of the stars, and other heavenly bodies. The second has to do with the conditions under which we can obtain permanent records of the appearance of nebulæ, clusters, stars, and the like.

We will begin this, first, by referring to what may be included under the term "spectrum photography." In this we have to do naturally in the day with the sun, and at night with the stars and with the nebulæ. I have not much in this present lecture to bring before you with regard to the sun, because it is not necessary that such a large telescope as the one in question should be used for that body, for the reason that its light is so great that the small telescope will do just as well. Parenthetically, however, it is as well that I should refer to the sun somewhat, and draw your attention to some new optical methods and arrangements which are exquisitely beautiful in their way with reference to that body. The light of the sun is so very overpowering, and the light of the stars is so dim, that you may easily, without my telling you, come to the conclusion that the difficulties which have to be overcome in the two classes of research are of an entirely different character; and that is so. We have to succeed in solar photography by battling with the excess of light—we have to succeed in stellar photography by battling with its defect.

I have here, by the kindness of Dr. Janssen, what in France is called a trap, what we call a slide, and this instrument will give you an idea of the way in which the excess of light in the case of the sun has been dealt with, perhaps in the most satisfactory manner. It is a complicated instrument in appearance, but really it is simple when we look at it. It is intended to deal with the excess of light of the sun by only allowing that excess of light to fall upon the plate for an excessively minute portion of time. This apparatus, therefore, is placed in the telescope between the object-glass which collects the light and the photograph plate, and the only light which can fall on the photograph plate has to pass through an aperture. Now, in front of this aperture is arranged a sliding slit, the jaws of which can be regulated by means of a screw, so that I may bring the jaws together until they are almost in contact, in case the excess of light is very great, or I may separate them still more by moving the screw in the opposite direction. Then when I have got this slit as fine as I think it necessary to have it for that particular day, I can, by means of a trigger, allow this slit to snap very rapidly over this aperture through which alone the light of sun can fall on the photograph plate. There are several very beautiful contrivances in this instrument, one of them I will show you when I have again set the trigger. Here is the point at which is the opening which allows the light to fall upon the photographic plate, and this is the spring which produces the movement. Now you will see in a moment that if this spring were acting during the whole time that the light is passing over the aperture, the motion of the slit would be constantly accelerated, so that in passing through the solar image one part would be more exposed than the other, and in that way you would never get a proper photograph of the sun, because to get a perfect photograph you want the quantity of light passing through the slit to be always the same. Now that is managed by the length of this spring. The spring ceases to act the moment the slit is in front of the aperture, so that while the slit is passing over the aperture it only travels by means of its acquired velocity; its velocity is not being accelerated. I shall show you presently two or three photographs which Dr. Janssen has been good enough to give me, which show the magnificent results which have been obtained in this way. The most striking result is that he finds that an interval of two seconds is quite enough to change the physical distribution of the bright and dark portions of some parts of the solar surface near the spots. The instrument, in order to demonstrate that, must be so arranged that it will allow two exposures at an interval of two seconds. This is done very beautifully. I am now about to make one exposure; I have now made it, and want to make another; the slit brings with it a shield to prevent the light falling through the aperture until the trigger is again set; the instant that is done the shield flies back, and in that way it is possible to obtain photographic records over a part of the sun's surface, at an interval just long enough to enable you to do this. That then is the way by which the excess of light is got over.

The little patches of light and dark which on the photographs are something like half a second of arc apart, have a distinct existence on the sun, and have a spectrum of their own. That we learned from Sir William Herschel, although of course in his time he was not able to photograph them. But what we have learned from these beautiful photographs of Dr. Janssen, is that they are associated with cyclonic lines, and form part, in a great many cases, of thoroughly well marked and developed cyclonic curves. Dr. Janssen finds, and finds alone by this means—it is not a thing visible to the eye, the eye gets too tired and strained—that these markings, such as you see here, are distributed over the whole sun's surface, and that they vary frequently in exactly the same way as the sun's spots themselves vary. That is one of the results of that method of dealing with an excess of light.

You will understand, of course, that when we have to deal with the stars—and there Dr. Huggins has been as successful in one direction as Dr. Janssen has been in another—we have no longer to deal with an excess of light, but with its defect. And here comes in another beautiful optical method. For photographing spectra of stars, of course we want a spectroscope and a slit in the ordinary way, and what we have to do in order to get the best possible result, is to get it by reducing the part of the plate added on to the smallest possible extent. And while we reduce its exposure to the smallest possible extent, we use as large an instrument as we can, and then see that during the whole time the instrument is pointed to the star, that the light at the focus shall really be entering the slit. Now, it may be a familiar fact to most of you here, that if that exposure has to be, say for an hour, and some of Dr. Huggins's were for hours, no ordinary clock, controlled by electrical influences, will allow the image of any body to remain on slit or on a fine point for that time or anything like it. Dr. Huggins's method, therefore, was to use a Cassegrain reflector in an arrangement by means of which he could, with another telescope, observe the image of the star, and see whether it was on the slit or not; and if it varied however little from the slit, to bring it back at once to its proper line of duty. In that way you see the defect of light was battled with by the time of exposure. The more feeble your light, the longer the exposure; and that the longer exposure might be effective he wanted a process by which the light should be compelled during the whole time to pass through the slit, and through the system of prisms on to the photographic plate. Dr. Huggins has been good enough to allow me to show you to-night some of his beautiful photographs taken by this means, and I am sure you will be none the less glad to see them when I tell you that that part of the optical method which depended on keeping the image of the star on the slit for an hour together, was played not in all cases by Dr. Huggins, but very frequently by Mrs. Huggins.

This, in sum, is what we have learned of late years in spectrum photography in the case of a defect of light, and you see it is equivalent to what we have learned from Dr. Janssen, in the case of spectrum work, and ordinary work in fact when it is a question of excess of light.

But there are other things to do besides observing the spectra of these different heavenly bodies. We want to observe the heavenly bodies themselves. We want to see what they look like, and to know about them telescopically as well as spectroscopically. Now in this direction I have to refer to Mr. Common's photographs, which have recently been crowned, I am glad to say, by the Royal Astronomical Society by the award of their gold medal. The photographs of nebulæ and clusters which he has recently succeeded in bringing before us are just as valuable in their way, and are fully as important as a method of optical work, as those others to which I have just referred.

When we come to inquire into Mr. Common's work, we find that he is dealing, in some cases, with the very faint markings of nebulæ, and that some of his exposures have been upwards of an hour long; so that we may at once come to the conclusion that in his case also we are dealing with a defect of light. Now how does he get over it? You see there is a very great difference between using a spectroscope as Dr. Huggins did, and a slit; and using simply a photographic plate, as Mr. Common does, on which to receive an image. If we have our spectroscope, and the slit, if the image of the star does not fall fairly on the slit, it does not matter, except that you have to let the exposure go on for a longer time, because the image of the star must fall on the slit for a certain time to get a photograph. But Mr. Common's task was, so to speak, more heroic than that, because in his attempts to get images of nebulæ and clusters of stars, the nebulæ also of course including stars, it is a question absolutely of hit or miss. Dr. Huggins's star, if it were off the slit, did nobody any harm; but if Mr. Common wishes to take a photograph of a nebula with some stars in it, or of a cluster, if he cannot keep each star absolutely rigid on one point of the plate, it is perfectly certain we shall never get a photographic image, either of a nebula or of a star. Mr. Common therefore, having a clock perhaps no better and no worse than Dr. Huggins, was compelled to invent a new optical method or arrangement, and this is it. He has been so kind as to bring it here in order that you may see exactly what it is. In the photographs of spectra which you have seen on the screen, correction was made by altering the movement of the clock slightly, but Mr. Common, after a great deal of trial, found that that would not do; you must let the clock take its course, and you must get some other means of correction. What he did was this. On a plate which had two motions on the eye-piece of the telescope, you have separately first a photographic plate and then an eye-piece. Underneath the eye-piece is a piece of platinum supporting a system of cross wires, and then a system of rectangular screws by which, when you have once got the image of a star on the cross wires supported by the circle of platinum, you can keep that cross wire bisecting the image of a star for as long—in fact, as long as you can. Human effort probably would break down, generally in half an-hour; Mr. Common's human effort, I believe, has already extended to about an hour and a-half. You have then a fine delicate star, bisected by a still finer delicate web; your clock has to be going as well as it may, and your corrections are made by these two screws, with this important consequence, that if you can catch and keep your cross wire on your star in your eye-piece, you have kept the images of the stars absolutely rigid on the photograph plate which is beside the eye-piece.

In this way Mr. Common has obtained a photograph of the nebulæ in Orion. Of course we cannot determine the perfection of the method by the nebula, but we can determine it by the images of these smaller stars. This photograph was exposed for exactly one hour, that is to say, during sixty minutes, or sixty times sixty seconds, the eye-piece had to keep the image of some particular star (necessarily on one side of the photographic plate) by means of the two rectangular co-ordinates worked by the screws, exactly bisected by the fine cross wire, the cross wire being illuminated by a lamp.

This photograph I consider to be one of the greatest achievements of modern astronomy, and I have taken occasion elsewhere to say what I believe to be perfectly true, that if all the human efforts which have been directed, so to speak, to this group of nebulæ in Orion for two-and-a-half centuries were put in one scale, and this photograph were put in the other, it would weigh them down; in fact, that sixty minutes of nature are worth two-and-a half centuries of art. But that is not all. Not only has Mr. Common, by means of this photograph, shown us that his new method is good for taking a complete picture of that kind, but he has shown us that photography contains within itself, fortunately, the elements of its own correction. What do I mean? I mean that one of the points which now for 2½ centuries—for the work on the nebulæ of Orion began more than 2½ centuries ago—has occupied the minds of observers has been this. Does the nebula change, or does it not? And from their drawings astronomers have not been able really to determine whether there has been any change or not. Professor Holden, in one of the most voluminous and luminous and beautiful memoirs ever devoted to the consideration of one celestial object, a few months ago only, discussed every drawing which is extant, and his conclusion was that really you could not say from any one of those drawings whether the nebula was as it was first observed, or whether it had considerably changed. Now it will be obvious to everybody in a moment that by such photographs as these it will be quite easy to determine in one year, or one century, or a thousand years—art is long—if any change takes place. But we can do very much better than that. Mr. Common has shown that, by employing this method for different exposures, you have a perfect system of correcting the photographic record itself. If you change the salt of silver, which you use of course, you may change at any given time the picture you get. You may be using different kinds of light, and you may imagine a nebula of Orion painted by every wave length, you may get an entire belt of F light, G light, A light, *a* light, H^1 light, and so on; but without going into experiments on variation so far as wave lengths go, Mr. Common's method shows us that by a system which I have called a system of "contouring," to make things quite clear, you will be able in future times to get comparative results, quite independent or almost independent of the salt of silver which you employ. Let us see for instance, how Mr. Common has beautifully built up a nebula. We have here a photograph taken in one minute's exposure, one taken in 2½ minutes, one in 4 minutes, one in 10 minutes, one in 20, and then we have the one of 60 minutes exposure.

With an exposure of one minute we have nothing of the nebula, but we have simply a few of the brightest stars. That is the beautiful trapezium which has been a test object, time out of mind, for observers with small telescopes, and that beautiful line of three stars to the right. Now, passing to the one with 2½ mins. exposure we get them a little brightened: and just a little bit of the nebula round the brightest region. Now the 4 mins. photograph shows you some of the other stars coming out, which were not visible in the first photograph. The next brightens the nebula and also brightens the stars, and we have the nebula in full swing, so to speak. With the 20 mins. exposure it is again increased; and now with the 60 mins. we have the nebula in all its beauty. We have there established an absolute system of contouring, and that can go on quite independently of the telescope, independently of place; independently of everything except the salt of silver you employ.

There is one more photograph I wish to show you. You will see that this method is as good for clusters, as it is for nebulæ. This is not so good a photograph, the method has not worked quite so truly, but it will show us all how important it is for science that it should work well in subsequent cases. The stars should be quite round, and as a matter of fact they are a little elongated, but you see what an immense engine Mr. Common has placed us in possession of, if you take things as you find them; for an astronomer to measure a cluster of stars like that, and give the number of them, and the intensities is a matter which would take years; the photograph I suppose took, perhaps, thirty minutes.

These beautiful photographs have been taken by Mr. Common in a mirror with a 3 feet aperture. Now, if you were dealing with a mirror of 8 feet aperture, of course, we should be dealing with a quantity of light as 64 to 9, and as Mr. Common uses a flat, and as I have shown that a flat is not necessary, we may say practically that with an 8 feet telescope we get ten times more light, and, therefore, the exposure would be one-tenth, so that you see an exposure of sixty minutes would be reduced to six minutes, and, therefore, the labour of keeping the delicate star on the delicate cross wire would be reduced in the same proportion; further, with such a light grasping power as that to which I have referred, we may hope that some of the stars would give us absolutely instantaneous photographs, and if that were so, we might not only by this means get observations of spectra, but we might get observations of double stars. With regard to observations of double stars, there is just one point which may be argued, and it is this, Mr. Dawes, years ago, showed us that working gradually upwards from apertures of 1 inch to apertures of 30 inches, we enormously increased our separating power on double stars. For instance, he held that with an aperture of 1 in. we could only separate a double star with a distance of 4¼″; at 10 in. we could separate stars ½″ apart; and then he calculated that for 20 in. you could separate two stars ¼″ apart; 26 in., ·175″; 27 in., ·169′; and 30 in., ·152′; but what would that ·152′ become with an aperture of 96 in. We should get down to an exceedingly small fraction of a second indeed, and with a perfect mirror, and with Mr. Common's perfect system, I believe that the time will come when we shall get double star observations added, as a matter of course, to the observations which I have ventured to bring before you.

So that it comes to this, first with regard to the telescopic observations of the heavenly bodies, if we take the nebula of Orion as an example of them, we find that we have in this method certainly a better method than any eye method which the last two and a-half centuries has produced; that a system of contouring which we can apply in a few hours, will replace the work of months, and give us a record on which we can absolutely rely; while the work of months, and of years, and of centuries, has turned out to be absolutely unreliable, because it is human. In doing this, then, we establish nebula photometry, but we deal with stars in the field of the nebulæ. We must, therefore, deal with the photometry of stars in the field of the nebulæ, and if we can do that why should we be limited to that field;

why should we not take the average over the whole visible heavens, and bring star after star on the same plate, in the same way as has been suggested by Dr. Huggins and myself in other fields of work. It is absolutely unnecessary, so far as stellar photometry is concerned, that we should limit ourselves to any one nebula, or to any one hemisphere, and it is perfectly simple to get one photographic plate, and to put on it a dozen or twenty images of different stars which will give you, in terms of a certain salt of silver at one epoch, the different radiant energy of those stars for comparison in future time. Now, it is perfectly certain that if this is so, work like that is far superior to any work which any observer, however eminent, might accomplish, because the thing would be absolutely beyond all doubt, whereas one might doubt the observer. If we pass to spectroscopic work, the spectra might be chosen from every part of the sky, and you may have, as you have hypothetically for the intensities of the luminosities of the stars, the spectra of different stars culled, so to speak, from any part of the heavens you choose; and if you can get a dozen spectra of stars, culled from near or far regions of the heavens, on one photographic plate in a single night, is not that better than any work that one observer can do with that telescope? So that I would propose that, with this 8 ft. telescope, the observer should be absolutely abolished, that you should not allow the telescope's time to be wasted by being employed by an eye which can only see one thing at a time, and which after all may not be quite certain what it sees, or give rise to doubt when other eyes in future years come to examine what it has seen. This 8 ft. reflector I would make an instrument fitted only for such researches as those which Dr. Huggins and Mr. Common have shown us to be possible. I would then, by means of electro-magnets or what not—it is a perfectly simple thing to settle—get an arrangement by which a photographic plate could be sent up, capable of coming down again after a certain time, with ten, twenty, or thirty different images impressed upon it if you wished; if it came down with one photograph as good as those Mr. Common has enabled me to show you to-night, I, for one, should be perfectly content; but if you want quantity, it is quite easy to get it by lengthening your plate. Why do I insist upon this? For this reason, that the observatory is no longer necessary. This enormous instrument, with an 8 ft. aperture and 60 ft. focal length, can be sheltered by a hut costing £100, instead of being rendered useless by an observatory which would cost £40,000: and I, for one, believe that if we had such an instrument as that, made on such lines as I have indicated to-night—thanks to the specimens of work which Dr. Huggins and Mr. Common have allowed me to bring before you—one year's work with it would make the year's work with more expensive instruments absolutely ridiculous.

Then, to conclude, I refer to my text, and wish to bring pointedly before the Society of Arts the fact that this dream—this beautiful dream—lacks all chance of realisation at the present time for want of glass—for want of the applications of the arts to astronomical research.

A vote of thanks was passed unanimously to the lecturer.

Miscellaneous.

INTERNATIONAL HEALTH EXHIBITION.

REPORT ON PRESERVED VEGETABLES, FRUIT, AND MILK. By J. J. MANLEY, M.A.

The preservation of vegetables and fruit (using the ordinary nomenclature to distinguish between these commodities) was well represented at the Health Exhibition, and the different methods of preservation illustrated. The exclusion of atmospheric air from the vessels containing them is among these methods; and this was effected many years ago, by filling up the vessels containing the articles to be preserved with hot water or hot syrup. As long ago as 1807 Mr. Saddington obtained a premium from the Society of Arts for his method with hot water without sugar. He placed the fruit in a vessel of cold water, and heat was applied till it rose to the temperature of 160 to 170 degrees. After standing in this temperature for half an hour, the vessels were filled with boiling water to within an inch of the top, and then hermetically sealed. Fruit and vegetables are still so preserved, a little alum being generally added to the water in the vessel for the purpose of hardening the tender skin of the fruit. A process not very unlike the preceding is that which consists in the destruction of the oxygen air in the vessel by heating the substance in it. This was M. Appert's plan, who, in 1810, obtained the reward of 12,000 francs offered by the French Government for the best method of preserving food. In this process the vessels were wired and corked from the beginning, and kept so throughout. Another process was the artificial exhaustion of the air from the vessel. Various patents have been taken out to effect this, and in some cases arrangements were made for the admission of carbonic acid and other gases, or salt and water, or a warm solution of gelatine, into the vessel to supply the place of the exhausted air.

Vegetables are very successfully preserved by heat. Common kinds, such as carrots, turnips, onions, and parsneps, have been put up in large quantities for shipping purposes and exportation. It is to the French preservers, the disciples of M. Appert, that we look for the best productions in the higher classes. Beans, celery, spinach, artichokes, asparagus, and especially tomatoes, are so well preserved by the best French manufacturers, that though they lose somewhat of their flavour, they may be served by good cooks to the most critical company; while for soups, entrées, stews, and also for garnishing the tins of *macedoines* (mixed vegetables), are found most useful. But of all the vegetable preserves, the tinned peas hold the highest place. The best are preserved without any use of copper, their colour being retained, or rather restored, simply by a little spinach juice. At South Kensington, Messrs. D. A. McCorquodale and Co., of the Lochty Preserving Works, Carnoustie, N.B., exhibited carrots, onions, parsneps, and other vegetables preserved in tins. They were most excellent, and having been prepared in pure spring water, without the addition of anything whatever; many connoisseurs considered that their flavour was actually improved, the cause, probably, of this, being that the tins being pierced ("brogged") immediately after being taken out of the hot baths, as in the case of meat preservation, the air escapes, but the flavour and substance is retained by their being hermetically sealed up again. It is only within the last few days that newspaper correspondents in the Soudan have intimated that a large supply of such vegetables would be most acceptable "at the front."

The American preservers now send us, in tins, large quantities of preserved tomatoes, a vegetable (perhaps I should almost say "fruit") found, in some form or other, on the table at all meals across the Atlantic, but strangely neglected among ourselves. They are, perhaps, somewhat inferior in flavour to those produced in the South of France, but their cheapness should recommend them. From America we get, yearly, many thousands of tons of the various sweet products of Transatlantic gardens and orchards. In many parts of America, California, for instance, which seems likely to become "the garden of the world," fruit is a mere drug in the market, the supply of peaches, apricots, and pineapples, to say nothing of what we consider more common fruits, being unlimited.

The display of jams was, as might have been expected, very extensive; and one of the most attractive displays in the machinery in motion department was the admirable plant of Messrs. Pink and Sons, who showed the whole process of jam making with different fruits as they came into season. The products of this well-known firm are sufficient in themselves to recommend them to the public; but the method of production, as illustrated at South Kensington, will doubtless lead to a still further patronage of their most excellent preserves, to which have been awarded high honours. Among other jams most worthy of notice were those ("whole fruit") shown by Bloxall and Co., of 70, Lamb's Conduit-street, W.C.; and special attention should be called to their blackberry jam and jelly. Letters have recently appeared in more than one of our daily contemporaries reflecting on the general neglect of this "fruit" in many parts of the country. During a recent visit to Ireland I noticed that this neglect was very remarkable, no one apparently caring to take the trouble of gathering of the unusual abundance of these berries which hung exuberantly on every hedge, and on the brambles in the woods. In Yorkshire and Lancashire there is a great demand for them, and the poor gather them for the jam makers, who retail the preserve at about 6d. per lb., and seldom can obtain a sufficient supply of fruit to meet the demand for jam. It is more than probable that the bramble, if cultivated, would yield per acre a greater profit than any other fruit shrub or tree. The systematic cultivation of fruit for jam-making had attention directed to it by the display of the jams of Mr. T. W. Beach, who has in hand a fruit farm of some 500 acres, on the property of Lord Sudeley, at Toddington, in Gloucestershire. I regret that, not having had an opportunity of tasting the preserves, I am unable to speak personally as to their quality. The establishment, however, of such an enterprise may be taken as an augury of the future development of jam farms, in accordance with the advice given, not long ago, by Mr. Gladstone to the British farmer. Well made jam is a most wholesome and nutritive article of consumption.

The process of desiccation or drying is far better adapted to the preservation of vegetable than of animal substances. In this country, the first recorded patent for the preservation of vegetables by desiccation was granted in 1780 to John Graefer, who dipped his vegetables in boiling salt and water before drying them. In November, 1850, Masson obtained his patent for drying and compressing them, so that they were reduced to one-seventh of their original bulk, a cubic yard containing rations for 16,000 men. The French, with M. Cholet at their head, have been very successful in this line of preservation, which has been followed by several English firms. C. Prevet and Co., of 134, Fenchurch-street, E.C. (who have now succeeded to M. Cholet's business) had one of the most interesting shows in the Exhibition, comprising chiefly dried vegetables, either as "chips" or in a compressed form, the whole dried savoy cabbage being a marvellously good exhibit. These dried vegetables, and especially those compressed in tablets, have become indispensable to sportsmen in wild districts, and to all in camp or at sea, having been largely used in all campaigns all over the world, since the Crimean war down to the present Soudan expedition. Cholet's "Julienne," which is composed of no less than nine kinds of vegetables and seasoning herbs, according to the recipe of the late *chef*, A. Soyer, is a most useful and tasteful combination: and the condensed vegetable soups of the firm are in every respect most admirable productions. And it may not be out of place here to mention their compressed "Bologna meat," known by the name of "Mortadella," which is all that the most fastidious *gourmet* can desire. Another admirable vegetable preservation at South Kensington was Edward's desiccated potatoes, exhibited by F. King and Co., 6, Bishopsgate-avenue, E.C., which are easily converted into dishes of "mashed potato" without any loss of mineral salts and acid, as testified to in a Blue-book recently presented to Parliament, and containing a report of the committee on the outbreak of scurvy in the Arctic expedition, which shows the necessity of the potato element in diet. This preparation and the desiccated soups of the same firm were largely used in Mr. Stanley's African expeditions, and have been abundantly supplied to the troops on the Nile expedition. Considering the high price generally charged by greengrocers for vegetables, and the waste in utilising them in almost every household, all housekeepers, even the poor, would probably do well to turn their attention to dried vegetables, and experimentalise upon them. When soaked and carefully boiled, they will be found not only economical in their use, but excellent in soups and stews, and even for eating with roast or boiled meat in lieu of ordinary fresh vegetables.

A few words must be added in reference to preserved milk, as even brief reports on the preserved food exhibited at South Kensington would be incomplete without these, especially as preserved or condensed milk is now an established article of consumption in hundreds of thousands of households in this and other countries, notwithstanding the prejudice which existed against it on its first introdnction.

M. Appert—whose ingenuity and perseverance in the cause of food preservation has been already mentioned—recommended that milk should be boiled down to about half its bulk before putting it into bottles; and in 1847, Bekaert tried to improve the process by adding carbonate of soda to the milk. Later still, in the same year, Martin de Leignac, a Frenchman, obtained a patent for preserving milk by evaporating it to one-sixth of its bulk. This was probably the process which Mr. E. D. Moore, a medical man attached to our Court, adopted, and by which he produced concentrated milk, and also a combination of it with cocoa. In 1857, Mr. House, on the retirement of Mr. Moore, whose manager he had been, took up the business on an improved patent. He has continued to manufacture his article ever since with great success, though he has confined himself mainly to the shipping trade. It was from Mr. House, through a Captain Fletcher, that Mr. Gail Borden, of New York, got his idea, though he conducted his evaporation of the milk in closed vacuum pans, whereas Mr. House used open ones. It was with Mr. Borden's process, and perhaps with some improvements on it, that several American gentlemen established a milk preserving manufactory at Cham, in the canton of Zug, in 1866. The product of this manufactory has ever since been well known in the English market, and to the English public, as the "Anglo-Swiss milk," and has most deservedly established for itself a world-wide reputation, finding its way, as it does, to the very remotest countries, as well as being largely consumed among ourselves. In 1870, a company was established in this country under the name of the "English" or "Aylesbury Condensed Milk Company," and, being composed of some of the old members of the Anglo-Swiss Company, became, in a certain sense, rivals to it for public favour. Their first factory was established at Aylesbury, and they afterwards added another at Middlewich, in Cheshire, both of which I visited, in order to observe the process of milk condensing from beginning to end. Thus the English public had offered to them the two well-known brands, the "Milkmaid" of the Anglo-Swiss, and the "Lion" of the English company, to say nothing of one or two other brands, the products of other companies both abroad and in the United Kingdom. Eventually, however, the Anglo-Swiss Company acquired the business of the Aylesbury Company, with its factories at Aylesbury and Middlewich, in addition to which it has other manufactories both in this country and abroad.

The method of condensing and preserving the milk is substantially the same at all manufactories; and when all the conditions of successful manufacture are duly observed, the result is always satisfactory, and the products of the Anglo-Swiss Company and other recognised manufacturers can always be depended on. In the manufacture of condensed milk, the greater proportion of the original 80 to 85 per cent. of water is evaporated, but the casein, butter, or fat, and other solid and nutritive substances of the milk remain intact, in their original form. The colourless and almost tasteless stream which runs continuously from the condensing pans during the process of condensation is evidence that nothing but water is taken from the original milk. Thus we have an article which is in reality pure milk—not an article made *from* milk. It is hardly necessary to observe that it is next to impossible to adulterate condensed milk by adding any substance to it, except sugar, for the purpose of increasing bulk. The introduction of any foreign substance, for the purposes of adulteration, would at once defeat the one great object, namely, the preservation of the milk. The fact that a tin of the preserved milk may sometimes be found unsound is not to be attributed to any attempt to tamper with it in its manufacture, but to some undetected unsoundness in perhaps a very small portion of the milk delivered to the farmers; to a failure in some part of the condensing operation, which is a very delicate one; or to a flaw in the material of the tin itself. To object to the "tinned," or condensed, milk because it may be sometimes found bad, is not more reasonable than to object to ordinary milk because it is sometimes delivered sour. Baron Liebig, in his recorded analysis of the Swiss preserved milk, says:—"It consists of nothing but cow's milk and the best refined sugar, and possesses all the properties and qualities of a perfectly pure milk." Dr. Hassall, who made a very careful investigation into the matter, and watched the whole process of milk condensation at Aylesbury, from the receiving of the milk from the farmers till it was soldered up in small tins, said that "the milk used was the whole milk of the best and richest description;" and, referring to examinations made by him of condensed milk at different times, says:—"We have always found it to be both genuine and in a perfect state of preservation." It is in the power of anyone to test its genuineness without being a chemist. If sufficient water is added to the condensed milk to bring it back to its original state, *i.e.*, to re-establish the original proportion between the water and other constituents, cream will rise from it in the ordinary way; only it must be stood in open flat vessels, and not in high-class columns, called graduated test-tubes, because the sugar to some extent prevents the cream readily rising. Again, if the condensed milk, mixed with the proper proportion of water, be raised to a temperature of 70°, it will churn into butter like ordinary milk. These two simple tests will show that the condensed milk is real milk, and not an article made *from* milk.

The value of this milk for infants and children, especially during the prevalence of infantile diarrhœa, which in the opinion of the majority of medical men is to be attributed to the badness of the milk supplied to the poor in large centres of population, is greater than some suppose. Many medical men, and mothers who have had the courage to try the condensed milk for infants when the natural sources have failed, can bear testimony to the fact that infants will thrive well on the condensed milk for many months, without any other addition to their food; and I cannot help thinking that Mr. Edmund Owen, in his admirable lecture at the Health Exhibition, on the "Rearing of Hand-fed Infants," did injustice unconsciously to preserved milk as a food for them. In the first place I think it was unfair to class this milk as an "artificial milk," and incorrect to speak of it as "evaporated almost to dryness," which it is not; and in the second place to speak of it contemptuously as "soldered down in tin pots, sent on a long journey, and then stored for an indefinite time in the shop window of an oil and colourman," is not argument and teaching, coming though it does from so eminent an authority. If the article is sound when "put up" in the tin (in reality iron) pots, it does not matter a straw how long a journey it may take, even if it be to the North Pole, or the Antipodes, as long as the "tin pot" remains sound, nor whether it is "stored for an indefinite time in the shop-window of an oil and colourman," or in a private apotheca. "The proof of the pudding is in the eating," and in addition to the many instances which have come under my observation of the successful use of "tinned" milk as food for "hand-fed infants," I am in a position to state that one of my own children, now a healthy boy of fourteen, had nothing pass his lips from the age of five weeks to seven months but "tinned" milk and water. Dr. Cuibourt, of the French Academy of Medicine, says that cows' milk, with the addition of one-fifth of its weight of water, and a little sugar, is as nearly as possible the same as woman's milk, and has, moreover, the advantage of being a well-known substance, easy to be administered. It follows, therefore, that condensed milk, when diluted with seven to nine parts of water, scarcely differs from mothers' milk. It might be further added that condensed milk is even superior to cows' milk, from its uniformity. Being made from the combined milk of a large number of cows, practically it never varies in its quality and uniformity; hence it has an additional value as a food for infants, for, as is well known to physicians, the change from one cow's milk to another, even though both are excellent, disarranges the digestion of infants and young children.

The combinations of coffee and cocoa with the condensed milk, are very successful, and it is always handy for housekeepers to have tins of them in stock; while for sportsmen and travellers they are most useful companions.

But, of course, the above remarks apply only to the recognised "brands." Some recent cases of prosecution under the Food and Drugs Adulteration Act, in reference to the sale of condensed milk, show that some irregularities, to use a very mild term, exist in this business. Separated milk, *i.e.*, milk from which the cream has been taken by the now well-known "centrifugal-force" method, is certainly condensed and put up in tins, but when this is sold as condensed separated milk, and does not purport to be more than this, there is nothing to complain of. The brands of the recognised manufacturers of "pure condensed milk," *i.e.*, whole milk, can be depended on.

Ordinary preserved milk was shown at South Kensington by the Anglo-Scandinavian Condensed Milk Company, of Victoria Warehouses, Mansell-street, E.; the Swiss Alpine Milk Express Company, and by the Irish Company of Lansdowne, whose production I have always found most reliable. But the feature of the milk exhibits was the unsweetened preserved milk. This was shown by the Swiss Milk Company, represented by A Moos, of 84, Basinghall-street, E.C, its "Edelweiss" brand being put up in patent adjustable stoppered bottles; and by W. Müller, of 15, Abchurch-lane, who represented the Swiss Dairy Company, of Lucerne. The milk of the last-named company purports to be pure condensed milk, reduced to one-fourth its original volume, and preserved without the addition of sugar or any antiseptic chemical. Certainly no trace of salicylic acid, boracic acid, or any other chemicals used for the temporary preservation of ordinary milk can be found in it; nor can the addition of any foreign ingredient be detected on the most minute analysis. It is not improbable that the unsweetened form of condensed milk will supersede that to which we have been accustomed, especially for culinary purposes. For these it has been in constant use at the School of Cookery at the Exhibition.

In a brief survey like the present, of preserved food at South Kensington, it is impossible even to mention the majority of interesting exhibits; but in connection with preservation of food by "cold," I should wish to draw attention to the admirable dry air refrigerator and cold air chamber (Lightfoot), exhibited by Messrs. Siebe, Gorman & Co., of 187, Westminster-bridge-road, which is as practical as it is ingenious in its construction. Among the exhibits of tinned meat, I should certainly have mentioned that of McCall's Paysandu ox tongues, the annual sale of which reckons by hundreds of thousands. They are put up in South America, and are among the most successful of such productions. Another interesting exhibit was that of pemmican, by Messrs. Christy & Co., of 155, Fenchurch-street. This is dried meat in powder; and it is said that one pound of it, specially prepared by Dr. Bancroft, of Brisbane, is equal in nutritive power to four pounds of fresh beef.

Messrs. J. Moir and Son's exhibits embrace all these classes of preserved food, and consist of vegetables and fruits, cocoa and milk, and soups, and meats and game in tin and glass.

Several well-known firms of miscellaneous food preservers were conspicuous by their absence from South Kensington; and it is a matter for great regret that Messrs. Crosse and Blackwell, whose various productions cannot be excelled by those of any other house, were not represented.

Speaking of curries and chutnees, there was a large show of these in the Exhibition, especially in the Indian section; but Mr. Edmunds, of Stonefield-terrace, Liverpool-road, N., most deservedly obtained the Gold Medal in this section; in which another exhibitor, C. Wix and Sons, of Mitre-street, Aldgate, E.C., is entitled to the highest commendation, as all the productions of this firm are of the very best quality.

France, Japan, Venezuela, and some other foreign countries, notably Siam, contributed to the preserved food exhibits.

It is satisfactory to learn that, at a recent meeting of the Preserved Food Trades Section of the London Chamber of Commerce, it was resolved to appoint a vigilance committee, which should take cognisance of the selling of inferior tinned goods, and of the use of spurious and misleading labels on the tins and other vessels.

PLUMBERS' CONGRESS.

This Congress, in connection with the International Health Exhibition, was opened on Monday, 20th October, at the Technical School, South Kensington, under the presidency of Mr. George Shaw, Master of the Plumbers' Company.

Mr. Ernest Hart read a paper in support of the extension of the existing statute law as to house drainage in order to provide for the more efficient regulation and registration of plumbers.

The first subject for discussion was "The Technical Instruction of Plumbers," On this subject, Mr. W. Eassie, C.E., Mr. C. T. Mills, of the Technical College, Finsbury, Mr. J. W. Clarke, and Mr. E. G. Mawbey, read papers.

The following resolution was then passed:—"That, in the opinion of this Congress, it is desirable that in future architects should not include plumbers' work in builders' contracts."

The next subject discussed was "Apprenticeship, the duration and condition of indentures suited to the present state of the plumbing trade, and to the modern system of technical instruction." Mr. W. R. Maguire (Dublin), Mr. Frederick Fell (Worcester), and Mr. Smeaton, read papers.

Mr. Scott-Moncrieff thought that five years would be a good period, with perhaps another two years as a term of probation in other workshops. He moved: —"That, in the opinion of this Congress, it is desirable that the apprenticeship system should be continued, and modified, if necessary, to suit the improved course of technical education," This was seconded by Mr. Stolder, and agreed to.

The third question discussed was "The establishment of Metropolitan and Provincial Boards of Examiners of Plumbing Work." Mr. P. J. Davies and Mr. E. Knight read papers on this, after which the following resolution was carried:—"That this Congress is of opinion that in the event of the establishment of Provincial Boards of Examiners of plumbing work, such Boards (firstly) should be affiliated with a Metropolitan Board; (secondly), should consist chiefly of trained working plumbers; and (thirdly) should be in connexion with the provincial schools of plumbing."

The fourth subject was "The Registration of Journeymen Plumbers." Mr. R. Smith (Bermondsey), who read a paper, was opposed to the proposed registration, as it would open up a field for many abuses, and ultimately do great harm to the trade.

On the second day the following resolution was passed:—"That, in the opinion of this Congress, the registration of master plumbers and journeymen plumbers is expedient."

Mr. Webb read a paper on "The suitability of materials used in plumbing, and particularly of those materials recently introduced as substitutes for lead."

Mr. Buchan (Glasgow) read a paper on "The desirability of fixing upon a system by which uniformity in the quality of material used in plumbing may be insured."

After a paper on the same subject by Mr. Poole, of Norwood, the following resolution was passed:—"That the Congress is of opinion that it is expedient that the system of sealing or marking lead and solder of standard weight and quality be revived by the Plumbers' Company, and that the Plumbers' Company should be requested to consider whether the materials used in plumbers' work as substitutes for lead are suitable, and whether standards of quality for such materials could be advantageously fixed on and verified by a recognised mark."

Mr. F. Wells (Worcester) opened the question of "the formation of district associations of plumbers to investigate and secure, as far as possible, corrections of evils and abuses arising in connection with the trade."

After papers by Mr. Emptage and Mr. T. H. Court had been read, the following resolution was carried:—"That the resolutions and conclusions set forth in the preceding paper [by Mr. T. H. Court] be referred to the Plumbers' Guild, with a request that they will confer thereon, with a view to take such action as may seem best."

The Chairman, in summing up the work of the Congress, expressed the hope that it would result in the formation of a representative committee to carry out the recommendations and suggestions that had been made.

THE ANTWERP INTERNATIONAL EXHIBITION.

The public administrations of Belgium will, it is said, take an active part in this Exhibition; the necessary space has been reserved for the different Ministerial Departments, who will make their several arrangements as at the National Exhibition of Brussels in 1880. Owing to the great extension arrived at, the Belgian Commission has been increased from 400 to 1,100 members, to carry out the arrangements of the sub-committees. All the principal towns are making active preparations to have their separate industries properly represented. The outline of the Exhibition building begins to be perceptible at a distance with its entrance of 60 metres of height and its long avenues, the principal four central ones of 335 metres, and the others of 110 metres. The special pavilion of 1,000 square metres is being erected for the French Colonies. From the objects to be shown, and the style of its architecture and decoration, this will be a very attractive feature of the Exhibition.

Although Austria is much occupied with the approaching Exhibition at Buda-Pest, yet the various chambers of commerce are making strenuous exertions to have the empire well represented, and are voting large sums for the decoration of the Austrian section. A subscription has been set on foot to send workmen to visit the Exhibition, and the President of the Olmutz Chamber has headed the list with £100; the Prince Imperial Rodolph, and the Archduke Charles Louis are actively engaged in promoting the measures taken. The Marquis Maffie, Italian ambassador, and the Italian consul at Antwerp, have paid a visit of several hours to the building, to determine and arrange the site and decoration of the Italian section. A delegate of the Ministry of Commerce and Industry has been sent to the Turin Exhibition to select and arrange for objects to be sent to Antwerp.

The Minister of Marine at Lisbon has been instructed to subsidise for the transmission of objects from the Portuguese colonies, and 250 square metres has been taken for their display. A vessel of war has also been deputed to visit all their African settlements, to receive and bring over all objects, which will be sent free of charge to Antwerp.

The Brazilian Government has secured 300 metres, and the Committee of Agriculture and Commerce of Rio Janeiro is charged with the collection and transport of the objects.

The Antwerp Exhibition will differ somewhat from those of Paris, London, and Vienna, in having in view chiefly the promotion of the import and export trade, an important question at the present time, when so many industries are suffering.

MANUFACTURE OF PERSIAN CARPETS.

Consul General Benjamin, of Teheran, in his last report on the carpet manufacture of Persia, which he states is one of the most important features of the industries and commerce of the country, says that the carpets in question are rarely of large size, and they are woven chiefly by the women and children of the peasantry in the villages; thus a countryman will have a rug made in his own house, and when it is done, he takes it to the nearest town and sells it for what it will fetch. The rooms of the peasantry are small, and this may be given as the reason for the smallness of the rugs in the Persian market. Of late years, however, through European enterprise a very much larger carpet has been manufactured for the foreign market. The carpet industry is divided into three classes, the large-sized, and the small carpets or rugs, and the *ghilems*, to which may be added a fourth, consisting of the *umads*, or felt carpets. Most of the carpets intended for covering floors of whatever size, are produced in the central province of Irak, and chiefly at the city of Sultanabad, and in the districts of Sarravend, Garrouste, and Malahir. These carpets are known by the generic name of *pharaghan*. They are more solid and massive than other Persian carpets, and are adapted for rooms of large size. During the last ten years *pharaghan* fabrics have been exported in large and increasing quantities. Large Persian carpets, which deviate from the usual oblong shape, are made to order, and cost from three to four krans a square yard above the usual charge, the kran being equivalent to about elevenpence. This is partly owing to the increased difficulties of weaving such dimensions with the simple appliances in use, and the size of the rooms in the houses of the peasantry. Besides the *pharaghan* carpets, floors are also carpeted with fabrics from Kerwanshab, Hawadan, and the district of Lauristan, and for this purpose the carpets of Mech-Kabad, in Khorassan, are available, although they are of inferior texture to the *pharaghan*. The carpets of Kerwan have also the texture fitted to the rough usage required in floor coverings, but while of inferior quality to the *pharaghan*, they are always small and proportionately more expensive. There are numerous varieties of Persian rugs. In some classes, such as Turkowan, there is general similarity of design, although no two rugs are altogether identical. In other classes, such as the rugs of Kerwan, Dyochegan, or Kurdistan, there is endless variety in design and texture. The colours formerly used in the rugs of Persia were imperishable, and rugs one hundred years old show no deterioration in tint. The introduction of aniline dyes at one time threatened to ruin the manufacture of textile fabrics in Persia, but the law against the employment of these dyes enacted by the Persian Government is enforced with some vigour. The Turkoman rugs, which are in some respects unsurpassed for texture and beauty of design, are not within the Shah's dominions, although they are included among the classes of Persian rugs, as Turkomans until recently were under Persian rule. There is a description of rug called *ghileem*, which is largely made in the province of Kurdistan, and has the following peculiarity—the pattern is identical on both sides. The colours are at once firm and brilliant, and the designs often of extraordinary beauty. The lightness and flexibility of these carpets qualify them for *portières*, table and sofa covers, and at the same time render them easy for transportation; consequently a large sale is found for them in European countries. The *namâds*, or felt carpets of Persia, are made by forming a frame of the thickness required, or excavating a space in the ground-floor of the size and depth equivalent to the *namâd* intended. The hair is laid in this and beaten with mallets until the original disjointed mass is reduced to the dimensions of the frame, and a design of coloured threads is beaten into the upper surface. The best quality of *namâd* is made at Isfahân, but the most massive are produced at Yezd. Consul Benjamin says there is one species of rug peculiar to Persia, often spoken of, but rarely to be seen. This is the rug made of silk, though it is not uncommon to see rugs of the finer types with silken fringes, and sometimes with a woof of silk in the body of the rug. All silk rugs are, however, rare, and much more so than formerly. They are generally very small, and are not adapted for heavy use. The prices realised by this description of rug are sometimes very high, and Consul Benjamin speaks of one, which was used to hang over a tomb at Teheran, being valued at over £70, though the size did not exceed two square yards.

Correspondence.

SANITARY INSPECTION OF HOUSES.

Adverting to my letters in the *Journal* of the 26th of January and 16th February, 1883, on this subject, perhaps the relation of a little further experience, showing the inutility of irresponsible sanitary inspectors, may be useful. Finding that I could not live in the house I then occupied, I took another, in one of the most open and healthy districts in South-East London; this time subject to a sanitary inspection and certifieate. My new landlord not objecting, I went to an apparently high-class sanitary engineering company, paid the fee for inspection, and obtained a detailed report, showing what their engineer considered it was necessary should be done, when my landlord employed the same firm to carry it out, at a heavy cost, which he paid, and received a certificate that the house was then in a perfectly sanitary condition. On this I occupied it, but very soon found it was quite the reverse, upon which I telegraphed and wrote to the sanitary company, who, having received their money, took not the slightest notice; and so, as the matter was urgent, I was obliged to employ a series of plumbers and builders, from time to time, at my own expense, to effect partial remedies, until at last matters became so dangerously bad, that I was compelled to resort to another sanitary engineering company, whose superintendent discovered that the drains were improperly laid, not properly joined, and so otherwise defective, and leaking in many places; that the soil at the back and under the house was completely saturated with sewage, of which some cartloads were removed, and after a deal of misery and inconvenience, new drains were brought and properly laid, at a cost of nearly forty pounds, since which the house has been habitable. My object in relating all this is to point out as strongly as possible the absolute necessity for the appointment of properly qualified sanitary inspectors, duly examined and certified by the Local Government Board as responsible and competent men for the purpose, in accordance with the plan indicated by me in the letters referred to—only with this difference, that the officers in question should be appointed by and be responsible to that Board instead of any local authorities. Perhaps there could not be a more suitable class of men for such appointments than pensioned sergeants of the Royal Engineers, who already possess most of the necessary qualifications, and would require very little training. A word in regard to house drains. In my opinion, a plan of the basement and drainage arrangements of every house should be deeply engraved on a large smooth slate, which should be let into the wall (say in the scullery), so as to be seen by everyone. The cost would be a mere trifle, and the convenience great.

JOHN WM. WOOD, H.M.C S.

34, Great St. Helens, E.C.,
October 29th, 1884.

Notes on Books.

INTERNATIONAL HEALTH EXHIBITION — CONFERENCES. London: W. Clowes and Sons, 1884.

The publications of the Health Exhibition consist of handbooks, reports of conferences, and lectures. The various subjects connected with the objects of the Exhibition were discussed at conferences arranged by the different London scientific societies.

Dwellings of the Poor. Mansion-house Council on the Dwellings of the Poor. June 4, 5, 6.

The following questions are discussed in this volume :—The population of London and its migrations, the treatment of the London poor, overcrowding, suburban dwellings and cheap railway fares, the creation of a building fund, some difficulties and some defects of sanitary administration of the metropolis, and suggestions to the Royal Commissioners.

Domestic Sanitation. Society of Medical Officers of Health, Sanitary Institute, Parkes Museum of Hygiene. June 9 to 11.

Industrial diseases, the spread and notification of infectious diseases, disposal of the dead, and cremation, were dealt with at this conference.

Meat Supply. Central Chamber of Agriculture. June 18.

The sources of our meat supply, the causes which have checked the development of our home supply, the increased production of home-grown meat, and the means of securing the supply of meat to largely populated centres, were the titles of papers read and discussed.

Sanitary Legislation. Social Science Association. June 26, 27.

The papers in this volume refer to the progress of sanitary legislation, conditions essential for healthy dwellings, the employment of girls and women in workshops and factories, notification of infectious diseases, and legislation respecting the duties of medical officers of health.

Oral Instruction of the Deaf and Dumb. Association for the Oral Instruction of the Deaf and Dumb. June 30.

Electric Lighting in Relation to Health. Society of Telegraph Engineers and Electricians. July 4.

Sanitary Construction of Houses. Royal Institute of British Architects. July 10, 11, 12.

The opening paper deals with the subject as illustrated in London during the last 120 years, and among other subjects treated of is the hygienic value of colour in the dwelling.

Food Adulteration and Analysis. Institute of Chemistry. July 14, 15.

Meteorology in Relation to Health. Royal Meteorological Society. July 17, 18.

The subjects here discussed are English climatological stations, equinoctial gales, influence of occasional winds on health and cumulative temperature.

Epidemic Diseases. Epidemological Society of London. July 22.

Health in India, change of type of epidemic disease, leprosy in India, typhus fevers, and aspects of cholera are the subjects of this volume.

Water Supply and Distribution. Society of Arts. July 24, 25.

This is the same report of the Conference as was printed in the *Journal.*

Bee Keeping. British Bee Keepers' Association.

This volume consists of two papers and discussion upon them; the subjects being "Foul Brood, its Propagation and its Cure," and "Adulteration of Honey."

CHRISTMAS AND NEW YEAR CARDS. London: Hildesheimer & Faulkner, 41 Jewin-street, E.C.

It is to the late Sir Henry Cole that we owe the Christmas card. In the second volume of "Fifty Years of Public Work of Sir Henry Cole, K.C.B.," just published, the first Christmas card, which was designed by John C. Horsley, R.A., in 1845, and published at Felix Summerly's Home, Treasury Office, in 1846, is reproduced. It shows a jovial family party in the centre, and examples of the relief of the poor and sick at the two sides. The inscription is, "A Merry Christmas and a Happy New Year to you." In a note in the first volume of his autobiography, Sir Henry Cole says that he was informed by Mr. Blackwood, Secretary of the Post-office, that in the year 1881 "the estimated number of extra letters dealt with was 12,500,000. The number of extra sacks of letters received was 3,704. The extra number despatched was 4,700."

Messrs. Hildesheimer & Faulkner have produced a large number of cards of different designs for the coming Christmas, and their catalogue of these occupies some five and twenty pages. There are many varieties of screens, designed by Messrs. Albert Bowers, C. G. Noakes, A. & F. C. Price, B. D. Sigmund, and E. Wilson; studies of trees, by Mr. A. Glendinning, jun.; the Dream of Patience, by Miss Alice Havers. Floral designs are numerous, as also are specimens of landscapes, rustic cottages, and river scenery, and studies of children and animals are not overlooked. The artists who have produced the designs, in addition to those mentioned above, are Miss Eleanor Manley, Miss Helena Maguire, and Messsrs. E. Carrington, H. H. Couldery, E. B. Driver, W. Duffield, Fred. Hines, W. J. Hodgson, Reginald Jones, W. J. Muckley, E. G. Noakes, M. Page, F. Noel Paton, A. Ramsthorn, and C. A. Wilkinson.

General Notes.

The International Inventions Exhibition, London, 1885.—In consequence of a request from several foreign countries, the time for receiving foreign applications for space has been extended up to the 1st December. In the case of the United States, applications may be received up to the 31st December. It will, of course, be convenient that intending exhibitors should apply at an earlier date when possible. Between 4,000 and 5,000 applications have come in from British exhibitors.

School of Art Wood-carving.—The School of Art Wood-carving, at the Royal Albert Hall, in connection with the City and Guilds of London Institute for the Advancement of Technical Education, has re-opened for the winter session, with improved accommodation for pupils. Full particulars of the classes and the lessons by correspondence, also as to work executed in the school, can be had from the manager. The school has been awarded a silver medal in the Educational Section of the International Health Exhibition, and the following students also gained honours:—Miss M. E. Reeks, silver medal; Miss H. E. Wahab, bronze medal; Mr. D. Chisholm, bronze medal. The sehool also gained the highest award for wood-carving—a silver medal—at the Art Exhibition held in September last at Eastbourne.

Turin Exhibition.—A large number of persons still continue to visit the Exhibition, and especially those of the working class. It is estimated that on Sunday, 19th October, the number of arrivals by rail at the Turin station was upwards of 18,000, comprising the representatives of forty-three workmen's societies, the greater number of whom were brought by the lines of Genoa, Cuneo, Milan and Chieri. It was also a great field day for the steam tramways, which brought to Turin a large contingent from the neighbouring towns and villages. The official returns of the 19th inst. give the number of visitors on that day at 42,722. A gold medal has been awarded by the jury to Signor Michela, for his stenographic machine described in *Journal*, p. 1097. In consequence of the general desire of the public, the Executive Committee, at a meeting held on the 25th inst., have decided to extend the date for the closing of the Exhibition until the 15th November. The date for the ceremony to be held for the distribution of the medals awarded to the various exhibitors has not yet been definitely fixed.

Leaves of Trees.—In some recent investigations on the growth of leaves, Messrs. Zöller and Rissmüller have shown that while in early summer the leaves of plants contain very considerable amounts of nitrogen, phosphoric acid, and potash, these substances are withdrawn into the wood of the tree with the advancing season; so that before the leaves fade they have lost the larger part of what was most valuable in them, which the tree retains for its future use. In some of these investigations on the leaves of the beech tree it was shown that in their water-free substance the highest "per-centage amount" of nitrogen, phosphoric acid, and potash is found when they open or expand in the month of May, and this per-centage quite regularly decreases till they ripen and fall, but the "absolute" amount of nitrogen, phosphoric acid, and potash, is greatest in July, and from that time on decreases.

Copper in New South Wales.—The Great Cobar Company raised, during 1883, 19,000 tons of ore, and smelted 18,096 tons, producing 2,401 tons fine copper, value £158,464. The total quantity of ore raised by this Company, since it started in July, 1876, is 98,916 tons, which produced 13,388 tons of fine copper, valued at £858,464, and it is estimated that there is sufficient ore in sight to keep the mine in full work for the next 25 years. The deepest shaft in the mine is 552 ft., and the deepest level is 324 ft., and the width of the lode is 60 ft. From the Great Central Company's mine, 1,139 tons of ore, raised in 1883, made 187 tons of copper, value £8,700. Total ore raised since starting in April, 1882, was 1,551 tons; ore smelted, 1,148 tons. There are in this mine nine shafts, the deepest 120 ft. The deepest level is 120 ft., and the width of the lode is from 3 ins. to 11 ft. At the Nymagee Company's mine, 10,236 tons of ore was smelted in 1883, producing 1,714 tons of fine copper, value £96,000. The depth of deepest shaft is 390 ft.; deepest level, 310 ft.; width of lode, 3 ft. to 18 ft. The total quantity of ore smelted since the mine was started in 1880, is 23,007 tons, making 3,717 tons fine copper, value £236,100

Journal of the Society of Arts.

No. 1,669. Vol. XXXII.

FRIDAY, NOVEMBER 14, 1884.

All communications for the Society should be addressed to Secretary, John-street, Adelphi, London, W.C.

NOTICES.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred and and Thirty-first Session of the Society will be held on Wednesday, the 19th November, when the Opening Address will be delivered by Sir Frederick Abel, C.B., D.C.L., LL.D., F.R.S., Chairman of the Council. Previous to Christmas there will be Four Ordinary Meetings, in addition to the Opening Meeting.

Candidates proposed for election as members are privileged to attend the opening meeting.

The following arrangements for the Wednesday evenings before Christmas have been made :—

November 19.—Opening Meeting of the Session. Address by Sir Frederick Abel, C.B., D.C.L., LL.D., F.R.S.

November 26.—"The International Health Exhibition." By Ernest Hart.

December 3.—"Electric Lighting in America." By W. H. Preece, F.R.S.

December 10. "Education at the International Health Exhibition." By J. G. Fitch, M.A.

December 17.—"Present and Prospective Sources of the Timber Supplies of Great Britain." By P. L. Simmonds.

At the meetings after Christmas, the following Papers (among others) will be read.

"The Employment of Hydraulic Machinery in Engineering Workshops." By Ralph H. Tweddell.

"The History and Manufacture of Playing Cards." By George Clulow.

"The Musical Scales of Various Nations." By A. J. Ellis, B.A., F.R.S.

Sea Fisheries." By Prof. E. Ray Lankester, M.A., F.R.S.

"The Preparation of Butterine." By Anton Jurgens.

"Labour and Wages in the United States." By D. Pidgeon.

"Recent Improvements in Coast Signals." By Sir J. N. Douglass.

"The Influence of Civilisation upon Eyesight." By R. Brudenell Carter, F.R.C.S.

"The Evolution of Machines." By Prof. H. S. Hele Shaw.

"Tempered Glass." By Frederick Siemens.

Foreign and Colonial Section.

The Meetings of this Section will take place on the following Tuesday evenings, at Eight o'clock :—

January 27; February 24; March 17, 31; April 28; May 19.

Applied Chemistry and Physics Section.

The Meetings of this Section will take place on the following Thursday evenings, at Eight o'clock :—

February 12; March 12; April 23, 30; May 7, 28.

Indian Section.

The Meetings of this Section will take place on the following Friday evenings, at Eight o'clock :—

January 23; February 20; March 6, 20; April 17; May 15.

Cantor Lectures.

The First Course will be on "The Use of Coal Gas." By Harold B. Dixon, M.A.

December 1, 8, 15.

The Second Course will be on "Climate, and its relation to Health." By G. V. Poore, M.D.

January 12, 19, 26.

The Third Course will be on "The Distribution of Electricity." By Prof. George Forbes.

February 2, 9, 16.

The Fourth Course will be on "Artists' Colours." By J. M. Thomson, F.R.S.E., F.C.S., Lecturer on Chemistry at King's College, London.

February 23; March 2.

The Fifth Course will be on "Carving and Furniture." By J. Hungerford Pollen.

March 9, 16, 23, 30.

The Sixth Course will be on "Photography
"A Marine Laboratory, as a means of improving

and the Spectroscope." By Capt. W. DE W. ABNEY, R.E., F.R.S.

April 20, 27.

The Seventh and concluding Course will be on "The Manufacture of Toilet Soaps." By C. R. ALDER WRIGHT, D.Sc., F.R.S., F.C.S.

May 4, 11, 18.

HOWARD LECTURES.

A Special Course of Lectures will be delivered under the Howard Trust, on "The Conversion of Heat into Useful Work." By W. ANDERSON, M.Inst.C.E.

November 27; December 4, 11; January 22, 29; February 5.

ADDITIONAL LECTURE.

On Tuesday, December 16th, at 4 p.m., B. W. RICHARDSON, M.A., M.D., F.R.S., will deliver a lecture on "The Painless Extinction of Life in the Lower Animals."

JUVENILE LECTURES.

The two Juvenile Lectures will be given on Wednesday evenings, December 31, 1884, and January 7, 1885. Special tickets will be issued for these lectures, due announcement of which will be made.

ADMISSION TO MEETINGS.

Members have the right of attending all the Society's meetings and lectures. They require no tickets (except for the Juvenile Lectures), but are admitted on signing their names. Every Member can admit *two* friends to the Ordinary and Sectional Meetings, and *one* friend to the Cantor Lectures. Books of tickets for the purpose have been issued to the Members, but admission can also be obtained on the personal introduction of a Member.

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held on Wednesday, June 24th, at Four o'clock.

Miscellaneous.

THE FORESTS OF RUSSIA.

In a report which has recently been made by Mr. Herbert, Secretary of Embassy at St. Petersburg, on Russian forests, it is stated to be a matter of extreme difficulty to determine even approximately the area covered by forests in Russia, but the area for European Russia, including Poland, has been set down by competent authorities at 177,286,000 dessiatines, the dessiatine being equivalent to a little over two acres. The latest returns, however, have shown that this is an under-estimate, and for the 435,788,457 dessiatines in European Russia, exclusive of Poland or Finland, about 183,700,000 dessiatines, or 42 per cent., is represented as being covered with trees and shrubs, but of this only 79 per cent., or 146,460,000 dessiatines, are capable of bearing forest trees, so that not 42 per cent., but nearly 33 per cent., of the total area of the country may be reckoned as forest land. As compared with this extent, Austria has 29 per cent. of her area, forest; Germany 26 per cent.; France 19 per cent.; Italy 18 per cent; and Turkey 14 per cent. This great store of wealth in Russia is very unevenly distributed over the whole country, some governments having forests to the extent of 50 per cent. of their total area, and others not so much as 3 per cent., and it may be said that in four governments three-fifths of the whole forest land of the country is concentrated, which leaves but two-fifths to the other forty-five governments. Dividing the Empire into seven zones, it would be found that the northern and eastern governments have 54 per cent. of their area forest; those governments adjacent to the Volga 23 per cent.; the governments in the centre of the Empire, 15 per cent.; the Baltic provinces, 16·8 per cent.; the North-Western provinces, 23 per cent.; the Ukraine, 14 per cent.; and the Steppe Governments, 1·3 per cent. Of the total area under forests, viz., 183,700,000 dessiatines, 122,944,000 belong to the Crown, but of this 99,000,000 dessiatines can be taken as productive forest land. In Poland, 787,514 dessiatines belong to the Crown. Up to the 1st January, 1882, 10,872,000 dessiatines of the Crown forests, or only 8 per cent., were under properly regulated forest control. In the North and North-Eastern provinces the Crown possesses 79 per cent. of the forests; in the Volga, 33 per cent.; in the Baltic provinces, 27 per cent.; in the North-West and Ukraine, 22 per cent.; and in the Steppe country, 15 per cent. According to the population, Russia has 2 dessiatines of forests per head of population; Austria has 0·47; Germany, 0·33; and France, 0·2. Owing to the climatic conditions of the Empire, a great variety of trees thrive in the forests of Russia. If a line be drawn from Orenburg towards the west, through the governments of Samara, Pensa, and Tamboff, as far as Tula, then to Charkoff, Kieff, to Volhynia, it may roughly be said that south of this line deciduous trees will be found to predominate, and coniferous trees to the north of it. The *Pinus Sylvestris* is the predominating forest tree, as far as 67° north latitude. It is to be found over two-thirds of the extent of Russia in Europe, predominating in the north, and found in the south only in isolated cases. It is found, however, as far as 70° north latitude, and towards the east as far as the Petchora, 66½° north latitude. The southern boundary where this species is found is at 44½°, but passing over the Steppes it is found again in the Caucasus, at from 41½° to 43° north latitude. *Abies excelsa* takes the second place, and in Finland is found as far north as 68¾°, and extends to the south as far as the north boundary of the black earth country; in the east the variety *Abies obovata* predominates. The larch (*Larix Europœa*) is only found in Poland. The Siberian larch is found throughout the governments of Olonetz, Nijni Novgorod, and the Ural as far as the River Sakmara (51¾° north latitude), and yields excellent wood for ship-building. The cedar reaches in the north-east to 64½°, and in the northern part of Orenburg to 51° north latitude, and in the governments of Perm and Volgoda are large forests of this tree whose cones are exported very largely. Of the deciduous trees the following are found:—The birch and its varieties; the oak, which is not found further north than St. Petersburg and South Finland; the aspen, which, like the birch, flourishes almost throughout the country; the lime tree, which is chiefly to be found in the governments of Volgoda, Perm, Kostroma, Kazan, and Simbirsk, and is employed in the bast manufactories, and in the making of matting which is largely exported; the red beech, which grows largely in Volhynia, Podolia, Bessarabia, and in the Crimea, and flourishes at heights varying from 1,500 to 4,000 feet above the level of the sea; the white beech, which is chiefly found in the south-west of the Empire, and also in the Caucasus and the Crimea, and in the neighbourhood of Kieff and Poltava it constitutes whole forests; the elm, ash, maple tree, alder, and willow are also found in their different varieties throughout the Empire, as also the wild apple, pear, and plum tree. In the northern provinces the cutting down of trees and sawing them into planks forms a very large and exceptionally profitable trade, and a very large population is employed in floating timber or barges laden with firewood, down the rivers to the ports of export or to places unable to supply themselves with wood. Thus Kostroma, Yaroslav, Nijni-Novgorod, Kazan, and Viatka supply building timber for the Volga, and its lower tributaries down even as far as the Steppes of the Don. The principal use that the logs floated down the rivers as rafts or sawn into planks are put to in Russia, is that of house building, for which purpose it is reckoned that 30,000,000 cubic feet are annually used. According to Professor Stieda, out of 1,820,000 inhabited houses in the central agriculturial districts, that is in the governments of Riazan, Tula, Kaluga, Orel, Kursk, Voronetz Tamboff, and Pensa, only 74,000 are built with stone and mortar, and in the manufacturing districts, in the governments of Moscow, Tver, Yaroslav, Kostroma, Nijni-Novgorod, and Vladimir, out of 1,400,000 inhabited houses only 6,800 are built of stone. The amount of wood delivered from the forests of the Crown amounted in 1880 to 727,000,000 cubic feet, and the income accruing to the Crown from these forests for the same period exceed 13,600,000 roubles, or £2,100,000. Although the income from the forests has increased considerably, about 50 per cent. of the gross income is required to cover the expenses of administration, &c. In 1866, they were set down at 1,575,000 roubles, but in 1878 they had increased to 5,054,368 roubles. The organisation of the forest administration is as follows:—The Forestry Department, under the Ministry of Domains, has the management of all Crown forests, excepting those in the Caucasus, which are placed under the control of the Governor-General; those in the country of the Cossacks, under the War Ministry; those belonging to the Government works and mines, under the Finance Ministry; those situated in Finland, under the control of the Finnish Government; and those forming part of the Imperial appanage which are placed under the control of the Ministry of the Imperial Court. At the central administration there is a director, vice-director, eight heads of department, and 192 vice-inspectors, controllers, and valuers.

Correspondence.

PRESERVED MILK.

The lecturer on the rearing of hand-fed infants at the International Health Exhibition writes with respect to the remarks on his lecture in the report on preserved milk at the Exhibition (see *ante*, p. 1131):—"At the hospital for sick children, Great Ormond-street, amongst the little out-patients, I found that the most miserable, the most rickety, and the children with the most irritable stomachs, were those reared on lacteal jam—condensed milk. The fact of your reviewer having reared a healthy boy on condensed milk, though very much to his credit, does not affect my opinion, which is strongly this—the best substitute for mother's milk is cows' milk, freely diluted with hot water, with sugar and salt added, as the lecture suggests. It is very essential for infants that their food be fresh. With all respect to your reviewer, his statement that 'condensed milk, when diluted with seven to nine parts of water, scarcely differs from mother's milk,' though satisfactory to the analytical chemist, should not be so to the hygienist. The analytical chemist would be able to discover no difference between Gladstone claret and Chateau Lafitte (1868); to his tests, one 'scarcely differs' from the other; but I apprehend that your reviewer's son, though only fourteen, would say that they were not quite the same thing."

General Notes.

Antwerp International Exhibition, 1885.—The Lords of the Committee of Council on Education have received information through the Secretary of State for Foreign Affairs, that the Executive Committee of the Antwerp Exhibition have decided to extend the time for receiving applications for space to Saturday, the 15th November.

Alexandra Palace.—An International Exhibition is to be held at the Alexandra Palace next year, commencing about the 31st of March next, and remaining open for six months. It is proposed that ten per cent. of the gross receipts from admission money shall be set apart for distribution amongst the principal London hospitals. For this purpose a committee has been appointed, with Colonel Sir Herbert Sandford, R.A., as chairman, and Admiral Sir Edward Inglefield, C.B., as vice-chairman.

Paris Exhibition, 1885.—The International Exhibition of Manufactures and Processes (*Exposition du Travail*) will be opened on the 23rd July, closing on the 23rd November, next year. The Exhibition is under the patronage of the Minister of Commerce, the Minister of Public Instruction and Fine Arts, and the Minister of Public Works. It will be held at the Palais de l'Industrie, Champs Elysées, and is to include a Science Annexe and a Fine Art Annexe. The London Offices are at 1, Castle-street, Holborn where applications for the remaining available space, and all communications from British exhibitors, should be addressed to Mr. Edmund Johnson, *Commissaire Delégué.*

New Orleans International Exhibition.—Mr. de Fonblanque, Her Majesty's Consul at New Orleans and British Commissioner for the Exhibition, in a despatch to Lord Granville, has drawn special attention to the advantages likely to accrue to British manufacturers exhibiting. He writes:—"I do not think that any important efforts have been made of late years to encourage British trade in this city and the district of which it is the distributing centre. Owing to its French origin, and the number of its inhabitants of continental birth, it became committed to other markets than our own, and thus it remains. Most of the British firms here are exporters only, so that there is no natural inlet for British goods to compete (as I flatter myself they could do successfully) with French and German articles liable to similar duties. There is a superstition abroad, even amongst otherwise well-informed persons, that we cannot produce fine or fashionable goods, or objects of art." M. de Fonblanque further states that although the Exposition may open in the first week of December, it cannot possibly be in order till February, 1885, when the larger number of visitors will begin to arrive.

MEETINGS FOR THE ENSUING WEEK.

Monday, Nov. 17...London Institution, Finsbury-circus, E.C., 5 p.m. Rev. W. Benham, "The French Revolution." (Lecture I.)

Tuesday, Nov. 18...Civil Engineers, Great George-street, S.W., 8 p.m. Discussion on A. Jamieson's paper, "Electric Lighting for Ships."

Statistical, Royal School of Mines, Jermyn-street, S.W., 7¾ p.m. Sir Rawson W. Rawson, President's Inaugural Address.

Wednesday, Nov. 19...SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Sir Frederick Abel, Chairman's Opening Address.

Meteorological, 25, Great George-street, S.W., 7 p.m. 1. Hugo Leupold, "A New Method of Reading the Direction of the Wind on Exposed Heights and from a Distance." 2. A. N. Pearson, "Description of a Component Anemograph." 3. C. C. Walker, "The Injury by Lightning (April 28th, 1884) to the Monument to the first Duke of Sutherland at Lilleshall, Shropshire." 4. Col. the Hon. A. Parnell, "The Mechanical Characteristics of Lightning Strokes."

Geological, Burlington-house, S.W., 8 p.m. 1. Sir R. Owen, "Note on the Resemblance of the Upper Molar Teeth of an Eocene Mammal (*Neoplagiaulax*, Lemoine) to those of the *Tritylodon*." 2. A. T. Metcalfe, "The Discovery in one of the Bone-caves of Creswell Crags of a portion of the Upper Jaw of *Elephas primigenius*, containing, *in situ*, the First and Second Milk-molars (right side)." 3. Sir R. Owen, "Notes on the Remains of *Elephas primigenius* from the Creswell Bone-cave." 4. E. A. Walford, "The Stratigraphical Positions of the Trigoniæ of the Lower Jurassic Beds of North Oxfordshire and adjacent districts."

Archæological Association, 32, Sackville-street, W., 8 p.m. 1. C. H. Compton, "The Roman Bridge recently Discovered in the River Trent." 2. C. Lynam, "The Excavation of Hulton Abbey."

Thursday, Nov. 20...Royal, Burlington-house, W., 4½ p.m.

Linnean, Burlington-house, W., 8 p.m. 1. E. H. Holmes, "Remarks on Cinchona Ledgeriana as a Species." 2. H. L. Rott, "Notes on the Habits of Australian Hymenoptera." 3. C. B. Clarke, "Botanical Notes from Darjeeling to Tonglo and Sundukphoo."

Chemical, Burlington-house, W., 8 p.m. Ballot for the election of Fellows. 1. Dr. Bomanji Sorabji, "Some New Paraffins." 2. Drs. F. R. Japp and N. H. Miller, "Additive and Condensation Compounds of Di-ketones with Ketones." 3. Dr. W. Ramsay and Sydney Young, "A New Method of determining the Vapour Pressure of Solids and Liquids." 4. Dr. L. Dobbin and Orme Masson, "The Action of the Halogeus on the Salts of Trimethysulphine." 5. S. U. Pickering, "Notes on the Sulphates of Potassium and Lithium." 6. Dr. A. B. Griffiths, "Researches on the application of Iron Sulphate in Agriculture."

London Institution, Finsbury-circus, E.C., 5 p.m. Rev. W. Benham, "The French Revolution." (Lecture I.)

Friday, Nov. 21...Philological, University College, W.C., 8 p.m. Whitley Stokes, "The Neo-Keltic Verb Substantive."

Saturday, Nov. 22...Physical, Science Schools, South Kensington, S.W., 3 p.m. A. M. Worthington, "Note on a Point in the Theory of Pendent Drops, and on a Capillary Multiplier."

CONTRIBUTIONS TO THE READING-ROOM.

The Council beg leave to acknowledge, with thanks to the Proprietors, the regular receipt of the following Transactions of Societies and Periodicals during the year.

TRANSACTIONS, &c.
