THE *Meteorologische Zeitschrift* (Vienna) for June contains the first part of an epitome of Dr. von Bezold's papers on the thermodynamics of the atmosphere, which have already been summarized in our notices of Societies.—Dr. J. Hann contributes a valuable article on the results of the meteorological observations of the late Prof. A. Ackermann at Port-au-Prince, Hayti, 1864–68, being a part of the world where they are of special value. The observations were rescued from entire loss by the exertions of Dr. Hann and Prof. J. Scherer, the originals having been wilfully destroyed. The distribution of rainfall is much affected by the mountain features of the island; in the north the rainy season is from December to April, while in the south it is from May to July. The average yearly rainfall at Port-au-Prince, from the above observations, was 61 inches, on 153 days. The greatest daily fall was 5·6 inches in May 1865, the rain lasting four hours. The climate is very equable; the mean of the absolute maximum temperatures was 98°·2, and of the minimum 56°·8.—Dr. von Lepel describes his experiments in passing electric sparks through glass tubes lined with a thin coating of paraffin, and containing a small amount of moisture, and points out that during thunderstorms many similar discharges may be observed, and may find their explanation in these experiments. The sparks differ in character and in colour, and the author argues that the humidity in the tube may be compared to the particles of vapour in the thunder-clouds, and that the coating of paraffin may have the same optical effect as the translucent clouds themselves. He gives the results of his thunderstorm observations on these lines during the summer of the year 1888.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, June 22.—Prof. Reinold, F.R.S., President, in the chair.—The following communications were made:—Note on some photographs of lightning, and of "black" electric sparks, by Mr. A. W. Clayden. The lightning photographs, three in number, were obtained during the storm on June 6. Two flashes, seen on one plate, show complicated and beautiful structure: one of them is a multiple flash, and flame-like appendages point upwards from every angle; the other is a broad ribbon, and, although the plate shows signs of movement, the displacement is not in a direction such as would produce a ribbon-like effect from a linear flash. The second plate shows four flashes, none of which are ribbon-like, though the camera had moved considerably. The third plate was exposed to six flashes, one of which was believed to pass down the middle of the plate; but, on development, only a triple flash in one corner of the plate was seen. Careful search, however, revealed the central flash as a dark one with a white core, and other dark flashes were subsequently found. The plate was very much over-exposed, and this suggested that black flashes might be due to a sort of cumulative action caused by the superposition of the glare from a white cloud upon the normal image of the flash. To test this, sparks from a Wimshurst machine were photographed, and, before development, the plates were exposed to diffused gas-light for a short time. The bright sparks yielded normal images with reversed margins, and the faint ones were completely reversed. Other experiments showed the reversal to spread inwards as the time of exposure to gas-light increased. Finally, reversal was effected by placing a white screen behind the spark, to represent a white cloud, the only illumination being that of the spark itself. In the discussion which followed, Mr. W. N. Shaw exhibited a photograph taken during the same storm, which is particularly rich in dark flashes branching outwards from an intensely bright one. In some places the bright line has dark edges, and in one part a thin bright line runs along the middle of an otherwise dark portion of the flash. In answer to Mr. Inwards, Mr. Shaw said the plate was exposed about half a minute, and the former thought that, under those conditions, the appearance of the plate did not contradict Mr. Clayden's hypothesis. Speaking of the same photograph, Prof. Perry considered that Mr. Clayden's observations would explain the result, for a bright flash required more exposure to diffused light to reverse it than a faint one did. Prof. Ramsay reminded the meeting that Prof. Stokes's "oxides of nitrogen" explanation was still a possible one; and Mr. C. V. Burton asked whether they may be due to faint sparks cutting off light from brightly illuminated clouds, just as a gas-flame absorbs light from a brighter source. In reply, Mr. Clayden thought the "oxides of nitrogen" hypothesis improbable, and said his experiments did not enable him to answer Mr. Burton's question. As regards Mr. Shaw's plate, he believed the diffused light from the clouds would be sufficient to reverse the fainter tributary flashes, although it was insufficient to reverse the primary one. From data obtained when the ribbon-flash was taken, he had made some calculations which gave the height of the clouds about 1000 yards, and the ribbon-flash 1300 yards long and 100 yards wide.—Researches on the electrical resistance of bismuth, by Dr. Ed. von Aubel. The paper, which is in French, was taken as read. A translation will appear in the Proceedings of the Society.—Expansion with rise of temperature of wires under pulling stress, by J. T. Bottomley, F.R.S. The investigation was to determine whether the coefficient of expansion of wires depends on the stress to which they are subjected, and was undertaken in connection with the secular experiments on the elasticity and ductility of wires, now being conducted at Glasgow University. Two wires, about 17 feet long, of the same material, were suspended side by side within a tube, through which steam could be passed to change the temperature. One wire was loaded to half, and the other to one-tenth its breaking weight, and, in the preliminary experiments the elongations were read by a Quincke's microscope cathetometer. About 150 heatings and coolings, extending over three months, were necessary to bring the heavily loaded wire to its permanent state, so that consecutive expansions and contractions were equal. When this stage was reached, hooks of peculiar shape were attached to the lower ends of the wire. These hooks form a relative geometrical guide, and their horizontal parts mutually support a small table which carries a plane mirror. If the wires expand or contract unequally, the mirror becomes tilted, and the relative displacement is observed by means of a telescope and scale fixed nearly vertically over the mirror. From experiments on copper wires, the coefficient of relative expansion was found to be 0.32×10^{-6} per degree Centigrade, or about 1/55 of the ordinary linear expansion of the material. The heavily loaded wire expanded most. The results for platinoid give 0.27×10^{-6} as the relative coefficient under the conditions named above; this is about 1/57 of the ordinary linear expansion, which, from separate experiments, was found to be 15.4×10^{-6}. Mr. H. Tomlinson thought the probationary period for copper might be considerably shortened by repeatedly putting on and taking off the load, and by subjecting the wire to torsional oscillation. With iron wires this would not be the case, for they behave in a most peculiar manner, and require long periods of rest after each oscillation. From experiments he had conducted during the last two years, he found that the permeability of iron could be enormously reduced by repeated heatings and coolings whilst undergoing magnetic cycles of small range. Mr. Gregory said the paper threw considerable light on some experiments on the sag of stretched wires upon which he was engaged. He also suggested heating the wires by electric currents. In reply, Mr. Bottomley said he had considered it important to leave the wires untouched after being suspended, and as regards heating by electricity he thought that convection-currents would make the temperature non-uniform.—Owing to the absence of Prof. S. P. Thompson, his "Notes on Geometrical Optics" were postponed.

Linnean Society, June 20.—Mr. Carruthers, F.R.S., President, in the chair.—Dr. H. Trimen exhibited specimens and drawings of the tuberculated lime of Ceylon, and made some interesting remarks thereon.—Governor Moloney, of the Colony of Lagos, West Africa, exhibited an extensive collection of butterflies and moths, the result of twelve months' collecting during the rainy season. The former, comprising representatives of 65 genera and 158 species; the latter, 78 genera and 112 species, had been named and arranged by Mr. Herbert Druce. A few Chelonians, belonging to the genera *Trinonyx*, *Sternothœrus*, and *Cinixys*, were also exhibited, and a remarkably large block of resinous gum, which, in the opinion of Prof. Oliver, was referable to some species of *Daniellia*, and which had been found in Ijo country. As an article of commerce, it possessed the advantage of requiring a heat of 600° F. to "run" it, so as to unite with linseed oil in the manufacture of varnish. In addition to these specimens, Governor Moloney exhibited some long bows and cross-bows obtained from chiefs of Ibadan from some battle-field in that neighbourhood, and used by natives 300 miles from the coast-line. A discussion followed, in which Dr. Anderson, Mr. D. Morris, and Mr. Harting took part.—Prof. Stewart next exhibited some skulls, adult and immature, of *Ornithorhynchus paradoxus*, and explained the very curious dentition of this animal; upon which Dr. Mivart and Prof. Howes made some critical remarks.—A paper was then read by Dr. John Anderson, F.R.S., on the mammals, reptiles, and Batrachians which he had collected in the Mergui Archipelago, and concerning which he had been enabled to make some interesting field-notes. Attention was particularly directed to a new bat (*Emballonura*), and to the occurrence, on some of the islands, of *Pteropus edulis*, besides a wild pig, musk deer, gray squirrel, and a crab-eating monkey (*Semnopithecus*), which hunts along the shore in search of Crustacea and Mollusca. Some remarks were made on rhinoceros going out to sea, and on a crocodile being found twenty miles off the coast.—A communication was read from Mr. Charles Packe, on a remarkable case of prolonged vitality in a fritillary bulb.—The meeting (the last of the session) was brought to a close by a most interesting demonstration on animal locomotion, by Mr. E. Muybridge, who illustrated his remarks with projections on the screen, by oxy-hydrogen light, of instantaneous photographs taken by him, to which motion was imparted by means of the zoopraxiscope.

SYDNEY.

Royal Society of New South Wales, May 1.—Annual Meeting.—Sir Alfred Roberts in the chair.—The report stated that twenty new members had been elected during the year, and the total number on the roll, April 30, was 474. During the year the Society held seven meetings, at which the following papers were read:—Presidential address, by C. S. Wilkinson.—Forest destruction in New South Wales, and its effects on the flow of water in water-courses and on the rainfall, by W. E. Abbott.—On the increasing magnitude of η Argûs; on an improvement in anemometers; on the storm of September 21, 1888; on a new self-recording thermometer; and on the thunderstorm of October 26, 1888, by H. C. Russell, F.R.S.—Notes on some minerals and mineral localities in the northern districts of New South Wales, by D. A. Porter.—On a simple plan of easing railway curves, by W. Shellshear.—On the anatomy and life-history of Mollusca peculiar to Australia; and on the desert sandstone, by the Rev. J. E. Tenison-Woods.—Description of an autographic stress-strain apparatus, by Prof. Warren.—Considerations of phytographic expressions and arrangements, by Baron Ferd. von Mueller, K.C.M.G., F.R.S.—Indigenous Australian forage plants (non-grasses), including plants injurious to stock; some New South Wales tan substances, Part 5, by J. N. Maiden.—Census of the fauna of the older Tertiary of Australia, by Prof. Ralph Tate.—Results of observations of comets I. and II., 1888, at Windsor, New South Wales, by John Tebbutt.—The Latin verb *jubere*, a linguistic study, by Dr. John Fraser.—Notes on some New South Wales minerals (Note No. 5), by Prof. Liversidge, F.R.S.—The Medical Section held seven meetings, at which the attendance was far above the average; the papers read and specimens exhibited were interesting and valuable. The Microscopical Section held seven meetings. The Clarke Medal for the year 1889 had been awarded to R. L. J. Ellery, F.R.S., Government Astronomer for Victoria. The Society's bronze medal and money prize of £25 had been awarded to the Rev. J. E. Tenison-Woods for his paper on the anatomy and life-history of Mollusca peculiar to Australia, and the Council has since issued the following list of subjects with the offer of the medal and a prize of £25 for each of the best researches if of sufficient merit:—(To be sent in not later than May 1, 1890): The influence of the Australian climate (general and local) in the development and modification of disease; On the silver ore deposits of New South Wales; On the occurrence of precious stones in New South Wales, with a description of the deposits in which they are found. (To be sent in not later than May 1, 1891): The meteorology of Australia, New Zealand, and Tasmania; Anatomy and life history of the Echidna and Platypus; The microscopic structure of Australian rocks.—The Chairman read the Presidential address, and the officers and Council were elected for the ensuing year. Prof. Liversidge, F.R.S., was elected President.

PARIS.

Academy of Sciences, July 1.—M. Des Cloizeaux, President, in the chair.—On a flow of molten glass occasioned by the accidental piercing of a glass furnace, by M. F. Fouqué. An account is given of the sudden escape of about 400,000 kilogrammes of molten glass from the Clichy-la-Garenne Works, and a comparison is drawn between the action of the discharge and that of volcanic lavas. The absence of bubbles near the surface of the former, and the other differences noticed between the two streams, are attributed mainly to the different chemical composition of the initial magma of each substance. The wollastonite peculiar to the vitreous flow solidifies under very different conditions from those of the feldspars and ferro-magnesian bisilicates occurring in the molten lavas.—The thermo-chemical compared with the surgical method in the study of the animal organism, by M. Sappey. In continuation of his recent communication on this subject, the author here contrasts the advantages and defects of the old and new processes, showing how they are complementary one of the other, and should consequently be associated in all important anatomical researches.—On the duration of lightning, by M. Daniel Colladon. In connection with M. Trouvelot's recent note, the author claims priority of discovery, having shown nine years ago that in thunderstorms the flash cannot always be instantaneous, and must last perceptibly longer than the thousandth part of a second assigned to it by Wheatstone.—Presentation of a volume of the "Annales de l'Observatoire de Paris: Observations de 1883," by M. Mouchez. The delay in issuing this volume is mainly due to the greatly increased number of meridian observations which were required to complete the revision of Lalande's Catalogue. The volume for 1884 is already half printed.—Note accompanying the presentation of M. Ch. Ed. Guillaume's work entitled "Traité Pratique de la Thermométrie de Précision," by M. Cornu. In this work is embodied a summary account of the researches that have been undertaken by the International Bureau of Weights and Measures for the purpose of removing the defects in the mercury thermometer, and giving the required degree of accuracy to that instrument.—On a new apparatus for zoological and biological research at determined marine depths, by Prince Albert of Monaco. With a view to remedying the defects of the instruments used in the expeditions of the *Challenger*, the *Blake*, and the *Vettor Pisani*, the author has prepared the instrument here described and illustrated. It is constructed on entirely new principles, and may be let down closed to any desired depth, then opened for purposes of observation, and re-closed before being brought to the surface. With this appliance Prince Albert has operated with satisfactory results to a depth of 500 metres in the Madeira waters.—Influence of temperature on the mechanical properties of metals, by M. André Le Chatelier. The mechanical properties of the metals at the different temperatures to which they are exposed in the various industrial processes have hitherto been little studied. The author here describes a series of researches that he has undertaken chiefly for iron and steel, but also for copper, zinc, aluminium, silver, nickel, and sundry alloys of copper, iron, and nickel. The results of these researches show generally that the mechanical properties of these metals are gradually modified with increased temperature. The detailed results obtained for iron and steel are reserved for a future communication.—On the malonates of barium, by M. Massol. The neutral malonates $CH_2(COO)_2Ba \cdot 2H_2O$ and H_2O, with their respective heats of solution and heats of formation, are described.—On the sardine fisheries on the coast of Brittany in 1888, by M. Georges Pouchet. The shoals were fully as abundant as in 1887; but for some unexplained reason there was a total suspension of the fisheries from about June 28 to July 20, during which period the sardines everywhere disappeared from the seaboard.—On the scales and calcareous epidermic glands of Globularia and Selago, by M. Edouard Heckel. During his general anatomical researches undertaken to establish a histotaxic classification of the Globularieæ, the author has detected in some species certain prominent anatomical characters, which appear to have escaped the notice of the numerous botanists who have occupied themselves with this family. They are described as calcareous epidermic glands of a scaly type, and are regarded by M. Heckel as condensed hairs clothing the outer surface with granular and crystalline calcareous concretions, instead of secreting an internal cystolith and localizing it in their unicellular chamber, as is the case with the Urticeæ, Verbenaceæ, and some other families.—On the occurrence of a granulite with riebeckite characters in Corsica, by M. Urbain Le Verrier. A microscopic study of this rock, which occurs in large masses about the middle of the west coast, shows that it is a hornblende of a special type, presenting the characters of the riebeckite recently described by M. Sauer.—On the leaves of Lepidodendron, by M. B. Renault. Since his last communication on this subject (*Comptes rendus*, November 28, 1887), the author has found a considerable number of leaves of Lepidodendron in the fossiliferous quartzes of Combres, de Lay, and Esnost near Autun. Some were still attached to the branches of *L. rhodumnense* and *L. esnostense*, and the present paper is restricted to a description of the former species.—The Quaternary stations in the neighbourhood of Lorrez-le-Bocage, Seine-et-Marne, by M. Armand Viré. In these stations, numbering about ten, and distant 25 leagues from Paris, M. Viré has collected several thousand flint instruments and weapons of different types, besides a few fragments of a blackish unornamented pottery.

Stockholm.

Royal Academy of Sciences, June 5.—On the heredity of exterior lesions and of acquired characters, by Prof. G. Retzius.—Prof. A. F. Smitt reported upon a paper, by Dr. Fr. Heincke, of Oldenburg, entitled "Researches on the Stickleback."—Baron Nordenskiöld exhibited some fine specimens of minerals from Norway, sent as a gift by Dr. Jellef Dahl.—Prof. Nilson reported upon an investigation by himself and Prof. O. Pettersson on the molecular weight of chlor-aluminium. They have found that it is expressed by the formula $AlCl_3$ and not by Al_2Cl_6, as given by Friedel and Craft.—On some definite integrals, by Dr. Lindman.—Observations on the tidal waters at Polhun in Spitzbergen, by Prof. Wijkander.—On the ammoniacal combinations of iridium, by Herr W. Palmar.—On amidoximes and azoximes within the triazol and tetrazol series, by Dr. Bladin.—On the action of cyanium on *a*- and *b*-naphthylamin, by Herr O. Nordenskiöld.—On *a*- and *b*-monofluornaphthalin, by Messrs. A. Ekbom and R. Manselius.—Observations on the radiation of the sun, by Dr. K. Ångström.—Ornithological observations made during the year 1887 at Sandhamn and its neighbourhood, by Herr O. Ekbohm.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Proceedings of the Society for Psychical Research, June (Trübner).—Proceedings of the Geologists' Association, November 1888 (Stanford).—Journal of the Royal Microscopical Society, June (Williams and Norgate).—Bulletin of the U.S. Geological Survey, No. 43 (Washington).—The Geological and Natural History Survey of Minnesota, Report for the Year 1887 (St. Paul).—Aus dem Archiv der Deutschen Seewarte, ix. Jahrg., 1886; x. Jahrg., 1887 (Hamburg).—Musical Instruments and their Homes; M. E. Brown and W. A. CONTENTS.

THURSDAY, JULY 18, 1889.

THE PROPOSALS OF THE COMMISSIONERS FOR THE EXHIBITION OF 1851.

THE Statement which the Commissioners for the Exhibition of 1851 have recently published, concerning their future policy in dealing with their Estate at Kensington Gore, is a reply to the memorial of the Metropolitan Gardens Association, a memorial in the same terms as that printed in NATURE of May 9 (p. 25). From the *Times* of July 9, it appears that various public bodies, Corporations, &c., who had memorialized the Commissioners, have been supplied with copies of this Statement. The result has been that further remonstrances have been addressed to the Commissioners. The Statement to which we refer is drawn up in ten paragraphs, the first of which quotes a sentence from the Commissioners' Charter of Incorporation, to the effect that they are to apply their resources "to increase the means of industrial education and extend the influence of science and art upon productive industry." By the side of this we may place a passage from the second Report of the Commissioners—the Report, in fact, which laid down in 1852 the broad lines upon which the Commissioners determined to act. The passage runs thus: "We are of opinion that if the surplus" (profits from the 1851 Exhibition) "were applied in furtherance of one large institution devoted to the purposes of instruction," &c., &c., "it would be productive of important results; whilst if subdivided amongst local institutions," &c., &c., "the effects produced would be comparatively insignificant."

The second paragraph of the Commissioners' Statement enumerates the number of museums and schools founded upon their estate, which form the "one large institution" originally contemplated. These, they state, prove "that their scheme has been in a great measure successful."

In the third paragraph the Commissioners argue in favour of now selling, leasing, or otherwise disposing of portions of their estate in order to do something more for promoting science and art than granting sites for public institutions. They then refer to the representations made to them, about 1878, by a deputation from certain large towns in England and Wales, with the object of obtaining funds which might be distributed as grants in aid to the formation of provincial Museums; and they explain why they rejected those representations at that time. The Commissioners' wisdom on that occasion has been justified by the number of important local municipal Museums of science and art which have been created by local effort, rates, and Government aid, as at Birmingham, Manchester, Nottingham, and elsewhere.

With respect to paragraph 5 of the Statement, which recognizes an expression of public antipathy "to the aggregation of public institutions in one locality" (South Kensington) of London, it may suffice to say here that the Commissioners did not feel the force of the arguments advanced against placing the Imperial Institute at South Kensington. But now, upon reconsideration, they admit the general justice of the representations from the country (eleven years ago) and from the metropolis (two years ago). They accordingly announce their intention "of disposing of portions of their estate for private building purposes" so as to raise "a considerable income" to be applied first to the reduction of the mortgage debt on their estate, and next to "the establishment of Scholarships" for science and art, and to the making of grants to "provincial local institutions."

This new departure was *in ovo* at least a year ago. Six months ago it was estimated that the portions of the "inner court" of the estate which the Commissioners were determined to sell "for private building purposes" would bring in an income of £10,000 a year. Recent circumstances have slightly modified the disposal of so large a portion of the "inner court" of their estate for private houses as was at first intended. There are difficulties in at once making a new public roadway from east to west across the northern gardens of the estate—it may be mentioned as a detail that this road is to be driven through the existing Science and India Museums—and housebuilders, not unreasonably, cannot come to terms with the Commissioners until these difficulties are got rid of. Instead, then, of aiming at £10,000 a year, the Commissioners contemplate getting an increase to their income of between £5000 and £6000 a year.

In thus diminishing their estimated new income by £4000 or £5000 a year, and so reducing it to £5000 or £6000 a year, we have it on good authority that the Commissioners do not intend to devote any of this money to the Imperial Institute. It is to be used, as shown in the Statement, (1) for the reduction of the mortgage debt, (2) for establishing Scholarships and Exhibitions, and (3) for making grants to "provincial local institutions." It is urged that no pressure in respect of clearing the mortgage debt on the estate exists. Last year it was £141,000. £5000 has just been paid off, so that it now amounts to some £136,000. In 1887, the announcement was made that in the three years from 1884 to 1887 the large sum of £40,000 had been paid off. The regular income of the Commissioners amounts to £12,000 from ground-rent and other sources, so that the repayment of the debt, under the mortgage upon the estate, is said to be in a healthy state, thanks to the shrewd economies and management of Sir Lyon Playfair. The founding of Scholarships and Exhibitions, as now proposed by the Commissioners, was certainly announced as one of the functions of the Imperial Institute. Accordingly the question has been asked, and not perhaps entirely without some sort of reason, why are the Commissioners to set about the same work as well, especially when in 1879 they decided against proceeding with a scheme of Scholarships which they had in contemplation at that time? An impression—as we now know, an erroneous one—is abroad that the revival of the Scholarship scheme and the sale of land for private houses are not due solely to an ingenuous wish on the part of the Commissioners to do the best for their public trust.

We are invited by those who disagree with the Commissioners to turn to the time when the Imperial Institute scheme was floated early in 1887, and when there was some discussion over the appropriation to the Institute of the land at South Kensington. Prof. Huxley warmly espoused the cause of an Imperial Institute, for reasons which he explained; but he regarded a congeries of Colonial and Indian commercial samples, reference libraries, conference and commercial intelligence rooms, deposited at South Kensington, as "fish out of water." Its proper habitat, according to the Professor, would be in the midst of men of business—in the City. To this a "Member of the Committee of Management of the Imperial Institute" responded by a letter in the *Times*, supporting the location of the Institute at Kensington, with arguments of economy, &c. He repeated, with a fervour which we are told might be ascribed to an original Commissioner for the Exhibition of 1851, and which should therefore have prevented the Commissioners from proposing to sell any part of their estate for building private houses, that the land at South Kensington had been "bought for the purpose of affording sites for public institutions by the far-seeing wisdom of the Prince Consort."

To elucidate the intentions of the Imperial Institute, Sir Frederick Abel gave a public address in the spring of 1887, in the course of which he said that "the organization of facilities, combined with material aid, to be provided to young artizans who shall afford some legitimate evidence of superior natural intelligence, and a striving after self-improvement, to enable them to abandon for a time the duty of bread-winning, and to work at one or other of the technical schools in London or the provincial centres, will be another object to which the resources of the Institute should be applied very beneficially." Not only was this to be in respect of "technical education," it was also to benefit "commercial education." Briefly put, one of the aspirations of the Imperial Institute was to establish Scholarships and Exhibitions for technical and commercial education. We can well understand the necessity at the time for publicly developing as fully as possible the intentions of the Institute. Half a million of money was openly quoted by its promoters as the amount necessary to the launching of the Institute. The recently published accounts show that the expectations of the promoters have not been completely realized, for not more than £300,000 has been collected for the Institute, and of that, some £140,000 has been set aside as an endowment fund to work and support the Institute. We may take it, then, that the Institute will start with an income of about £5000. Two years of "general administration," as it is termed, have cost £9134, of which £5236 went in salaries and wages. If these data of the expenditure, which has been incurred before the Institute is in working order, give any insight into what it will cost when at work, it is obvious that some portion of the Institute's proposed functions must be suspended.

But with this explanation of the situation, and notwithstanding the authoritative contradiction to the suggestion that the Commissioners are going to provide funds for the Imperial Institute, the Commissioners' opponents argue that, since many of the members of the Imperial Institute Committee are also Commissioners for the Exhibition of 1851, it is outside human nature to suppose that the ambitions of the one body exert no influence upon the actions of the other. And so, without actually putting money into the coffers of the Imperial Institute, the Commissioners may do as good, by undertaking the foundation of those Scholarships and Exhibitions which the Imperial Institute may not see its way to. It has been our wish, in thus frankly stating the objections and arguments which are raised to the Commissioners' proposals, to examine and discuss them in all fairness.

We may now at any rate dismiss the topics relating to the Imperial Institute, and offer a few remarks upon the Commissioners' proposals to establish Scholarships and make grants in aid of "provincial local institutions." The Commissioners are incorporated "to increase the means of industrial education, and extend the influence of science and art upon productive industry." One of their first steps, towards giving effect to the new proposals, must be to arrange for pulling down considerable portions of the buildings which house scientific and artistic collections. These operations will no doubt temporarily interfere with the study of those collections by the public from all parts of the country. This, however, is a minor point as compared with an apparent omission, on the part of the Commissioners, in framing their proposals, to take into account what the public have actually done towards establishing a system of science and art Scholarships, and towards securing grants in aid of provincial local institutions. A great organization, developed in the course of many years' experience, has arisen; it has, and must continue, to co-operate with local effort in extending the influence of science and art upon productive industry, so long as there is any local effort and any Parliament to appreciate that fact. This organization comes under the administration of the Vice-President of the Committee of Council on Education; its history and *modus operandi* are known to such Commissioners as Mr. Mundella, Sir Lyon Playfair, and Sir William Hart Dyke. The two former, it is almost needless to say, held the office of Vice-President before Sir William Hart Dyke, the present Vice-President. All these, however, have helped in continuing the policy of Mr. Lowe (now Lord Sherbrooke) and the late Mr. W. E. Forster—a policy, the central feature of which is to multiply the forms of Parliamentary aid to local bodies which take the initiative in themselves providing local means to extend the influence of science and art upon productive industry. Mr. Mundella, Sir Lyon Playfair, and Sir William Hart Dyke surely have brought their experiences before the Commissioners, in the discussions, upon the new proposals for Scholarships, and aid to provincial institutions. They must have told the Commissioners of the flourishing and growing co-operation between local effort and State aid; they must have explained the methods of its administration, and proved that experience and funds are necessary to pay for and organize an executive staff for the discharge of the same or similar functions towards science and art and local provincial institutions as are now discharged by Government. Roughly put, the Government aids to local effort are: (1) building grants for science and art schools; (2) grants towards the equipment of such schools; (3) grants towards the purchase of objects for local Museums; (4) grants towards founding local Scholarships and Exhibitions; (5) grants of national Scholarships and maintenance allowances whilst the holders of these Scholarships are undergoing instruction at one or other of the more prominent science and art institutions of the country; and (6) grants of Travelling Scholarships. The total cost of these varieties of grants, so far as Government is concerned, amounts, according to the Parliamentary Estimates, to not less than £20,000 a year. It is difficult to estimate how much local effort contributes, how much municipalities give out of local rates, how much private individuals give, &c. But putting aside great donations of tens, twenties, and thirties of thousands of pounds, towards building schools of science and art, technical schools, and provincial Museums, something like £40,000 a year are contributed by local effort, to meet which the yearly Government grant of probably £20,000 is made. It seems unlikely, but we shall gladly accept correction if we are wrong, that the Commissioners can allot more than £4000 a year for Scholarships and grants to provincial institutions. The beneficial and judicious administration of this £4000 would probably cost almost as much as if it were £20,000 a year. Have the Commissioners funds to pay for such administration? Apparently they have not. Will they therefore ask Government to administer their proposed grants? Government has certainly hitherto rather rebuffed advances of help made by the Commissioners, so that we confess to not at present perceiving how the Commissioners can successfully carry out proposals which seem to be beset with dilemmas.

On the other hand, if the Commissioners offer their aid to the country for its unconditional acceptance, it seems to us that they may be open to the charge of weakening local effort, and thus of decreasing the means of extending the influence of science and art upon productive industry. They realized, in 1852, that the subdivision of their means amongst local institutions would be productive of comparatively insignificant effects. A subdivision of smaller means, now that a new condition has arisen, does not under present circumstances appear to give better promise. The sacrifice of part of their estate, and the temporary disarrangement of a section of the national institutions upon it, are hardly warranted by what, at present, seems to be a scheme *in embryo*, the full development of which is not, in truth, forecast.

Without more precise information, therefore, we are rather driven to conclude that an effective and beneficial scheme of Scholarships and grants in aid of provincial institutions is beyond the reach of the Commissioners.

Under the presidency of the Prince Consort, the Commissioners took pains to collect a mass of information in regard to what had already "been done by the public in this country to promote the interests of science and the arts, and the diffusion of scientific principles amongst those engaged in their practical application." Thirty-six years ago they placed on record the evidence which led them to the opinion "that much zeal has been shown in this respect." If they would pause now, they might very well and usefully do again what they did thirty-six years ago—direct their inquiries particularly to the new developments and results of this zeal as demonstrated by its present co-operation with State aid. The result of such inquiries could but prove of high value to the Commissioners, and might, we venture to think, lead them to the conclusion that their present proposals are half a century too late, whilst the preservation of their estate, with its national institutions, including those already existing and those likely to exist, is really abreast of the serious wants of the time.

THE CYSTIDEA OF BOHEMIA.

Système Silurien du Centre de la Bohême. 1ère Partie, Recherches Paléontologiques. Continuation éditée par le Musée Bohême. Vol. VII. *Classe des Echinodermes. Ordre des Cystidées.* Ouvrage posthume de feu Joachim Barrande, publié par le Docteur W. Waagen. Pp. i.-xvii., 1-233; Plates I.-XXXIX. (Prague, 1887.)

To few is it given to accomplish the life-work that they have planned. Joachim Barrande, vast though his self-ordained task was, came nearer to his goal than do most men. Before the death of the venerable author in 1883, he had made some way with the last volume of the colossal "Système Silurien du Centre de la Bohême." The present work was destined to form the first section of Volume VII., "Echinodermes du Système Silurien." The plates were ready, the general portion of the work written and partly printed, and, on his death-bed, Barrande was still tracing out the descriptions of genera and species. The book has been completed by Dr. W. Waagen, who was appointed, in Barrande's will, editor of this volume. His admirable preface is rendered of practical value by the insertion of a complete list of Barrande's writings from 1846 to 1881.

The work itself is on the plan and in the style already familiar to us. It opens with an historical and critical account of the literature dealing with the Cystidea of the thirteen Silurian regions of the world. The term Silurian is, of course, used in the broadest possible sense. Even Sardinia, as one of these regions, has a section to itself, though the cystids of Sardinia have had less written about them than the snakes of Ireland. This retrospect brings us to 1883; the few observations published between that year and the end of 1887 do not affect the present work.

The second chapter is devoted to the morphology of the Cystidea, chiefly as exemplified in the Bohemian fossils. The arms especially are discussed at great length, and several tables show their presence or absence in the various species as yet known to science.

Then follow the detailed descriptions of the genera and species of Bohemian cystids. No classification is followed. On p. 49 a classification is indeed proposed, according to the number of major openings in the calyx. This arrangement, however, is impracticable, and apparently unnatural. Its chief merit is its simplicity; and yet, as the author naïvely complains, it is not so incomparably simple as the attempt of a certain English palæontologist to classify Silurian cephalopods according to their curvature. The order of description is therefore alphabetical, the only divisions being those of the three faunas. Such an arrangement, however, by no means does away with the necessity for an index, and the absence of that indispensable aid to the practical worker is the one great fault that we have to find with the work. At the present time some 240 species of Cystidea are known, and these belong to about 70 genera. The Bohemian species number 78, two varieties worthy of a name, and one or two indeterminable fragments. Of these species, 76 are here described for the first time, and the majority of them belong to new genera, of which 23 are here established. There are also represented the genera *Agele-*

crinus of Vanuxem, *Atelecystis* of Billings, *Echinosphaera* of Wahlenberg, *Lichenoides*, *Trochocystis*, and *Rhombifera* of Barrande, the latter formerly referred by him to the Pteropoda; and, lastly, the undefined *Cystidea*, which is reserved for the reception of eight or nine doubtful forms, some of which may, at a future date, form the types of yet more genera. It should also be noted that one species —*Echinosphaerites infaustus*, Barr.—has been taken by Prof. Neumayr as the type of his genus *Arachnocystis*. The same authority refers the somewhat doubtful *Rhombifera mira* to *Stephanocrinus*, and points out that *Staurosoma* is the same as *Tiaracrinus* of Schultze.

The genera of this group have been peculiarly unfortunate in the names attached to them. It is no longer necessary for palæontologists to cumber their generic names with the termination *ites*. This peculiar corruption of λίθος seems to set a stigma on fossils, as though they never had been living beings after all. The neontologist is ready enough to throw stones at the palæontologist; there is no need for the latter to supply him with ammunition. Prof. Lovén dropped this affix when editing the Cystidea in Angelin's "Iconographia Crinoideorum," and surely the names are long enough without it. Of far more importance is the correct use of the terminations *cystis*, *crinus*, *blastus*, and the like. We extend indulgence to certain old authors who gave such names as *Agelecrinus* and *Cryptocrinus* to cystids before the Cystidea were distinguished as a class; but when once the divisions were recognized, we must suppose that the eminent palæontologists who used these terminations attached to them some meaning. Even in 1843 we find Messrs. Austin suggesting that the names *Sycocrinites*, Austin, and *Echinocrinus*, Agassiz, "require amendment, as their terminations imply affinities which do not exist." *Apiocystis* means a pear-shaped *Cystid*, just as *Apiocrinus* means a pear-shaped *Crinoid*: the two terminations are *not* interchangeable. Posterity, for whom we labour, will lament that we had not the strength of mind to correct such names whenever we saw them to be misleading; but we ourselves should surely blame most severely those who still add to our perplexity. Why, for instance, should Prof. von Koenen give the names *Corylocrinus* and *Juglandocrinus* to two genera which he himself describes as Cystidea? In no other branch of science would such a use of language to conceal thought be tolerated. The present work we are glad to find free from such flagrant absurdities. The errors of nomenclature are slight: the name *Atelecystis*, Billings, the validity of which was upheld by Dr. H. Woodward, is, though not consistently, supplanted by its synonym *Anomalocystis*; there is also a want of consistency in writing *Pyrocystites pirum*. No attempt, however, has been made to revise the nomenclature of cystids foreign to Bohemia, in which direction much will some day have to be done.

Chapters iv. and v. are devoted to the geological and geographical distribution of Cystidea in general and of Bohemian cystids in particular. Chapter vi. describes the variations seen in the Bohemian species. The seventh and last chapter discusses the connection of these species with those of other countries. These questions are worked out, from a statistical if not from a philosophical point of view, in a large series of tables; a few graphic curve-diagrams would have been a more helpful guide through the wilderness of figures. The numbers of the species found in the various beds of Bohemia are:—

c.	*d1.*	*d2.*	*d3.*	*d4.*	*d5.*	*e1.*	*e2.*	*f1.*	*f2.*
7	12	12	4	46	2	2	3	0	2

This vertical distribution agrees in its main proportions with that observed in almost all other countries. The chief exceptions are the States of New York and Wisconsin, where a relatively large number of species are found in the Niagara limestone, and England, where seventeen species are recorded from Ordovician beds and nine from the Wenlock limestone: none of the Wenlock genera occur in the corresponding beds of Bohemia. The geographical diffusion of the Cystidea is very slight; the most widely distributed genera are *Agelecrinus*, *Atelecystis*, and *Echinosphaera*.

These elaborate comparisons and tabulations are, however, a little bit out of place in dealing with such a heterogeneous assemblage as the Cystidea. They are not a class, but a collection of puzzles to which we relegate all echinoderms that will go nowhere else. Barrande does indeed attempt a definition (pp. 23–24), but not one character mentioned is common to all Cystidea. What one really looks for in such a monograph as the present are new facts that may throw light either on the connection between individual genera and other classes of the Echinodermata, or on the origin and meaning of the various peculiar organs. Taking as guide the motto of Barrande, *C'est ce que j'ai vu*, we shall enter into no speculations, but shall mention such facts of morphological importance as appear to be new. The state of preservation of the Bohemian Cystidea is exceptionally bad; but it would be hard indeed if so rich an assemblage had not yielded to such an observer some interesting results.

Following the order adopted by Barrande in his second chapter, we begin with the stem. The stem of the Pelmatozoa typically consists of a single series of cylindrical joints with a central perforation. In the earlier crinoids the lumen is comparatively large; in most stalked cystids it is still larger. In *Atelecystis*, *Mitrocystis*, and *Trochocystis*, the proximal part of the stem consists of a double series of alternating plates which are thin and inclose a large hollow. In *Arachnocystis* the whole stem consists of four or five series of alternating plates. In *Dendrocystis* the plates forming the upper part of the stem can only be distinguished by their smaller size from those forming the calyx; below they merge into the normal series of single joints. *Cigara Dusli* is the fanciful name given to a stem entirely composed of small irregular plates, and probably belonging to *Lapillocystis fragilis*. These facts forcibly suggest that the Pelmatozoan stem originated as a mere evagination of the perisome. The curiously elongate *Pilocystis* (Pl. II. Fig. 26) may represent a still earlier stage in its evolution.

The test of Cystidea has usually been regarded as composed of one simple layer of plates. Eichwald, in *Lethæa Rossica*, mentioned an epidermis, but seems in many cases to mean by this nothing more than the outer surface of the plates. Lovén, in his monograph on *Pourtalesia*, seems to assume the existence of three elements or layers in the test. Barrande, however, has been the first to conclusively demonstrate that in a number of genera the main layer of the body-plates is closed, both inside and outside, by thin "*épidermes*," which appear to have been partially calcified. *Aristocystis* is the genus affording the most abundant material for the study of these coverings, but they have also been observed in *Arachnocystis*, *Craterina*, *Dendrocystis*, *Neocystis*, *Orocystis*, *Proteocystis*, and *Rhombifera* (*i.e. R. bohemica*): of *Deutocystis* and *Pirocystis*, the inner lining is the only part known. In *Mitrocystis* the great difference between the internal and external impressions (*vide* p. 65) *may* be due to the presence of an inner lining. The outer layer is continuous, and covers up all the pores of the body-plates; sometimes it is even thick enough to conceal their sculpture and the sutures. The inner lining appears to have passed up into the pore-canals, and to have been itself pierced at those points. There is, of course, no reason to suppose that this structure of the test was common to all the forms which we call Cystidea, but the observations of Barrande have undoubtedly opened a new field of investigation.

It has hitherto been usual to classify the Cystidea according to the disposition of their pores. Facts recorded in the present work are opposed to such an arrangement. In the simplest type, canals run right through the inner lining and the principal layer of the test, usually in a curved course: we may call these "haplopores"; they are best seen in *Aristocystis bohemica*. In other species of *Aristocystis*, *e.g. A. subcylindrica* and *A. grandiscutum*, the distal ends of two adjacent haplopores are often connected by a horseshoe-shaped groove on the surface of the middle layer. In the allied *Craterina* this groove appears to have expanded into an oval depression into which open the two canals. This, the familiar diplopore, is also seen in *Proteocystis*. In all these forms the pores do not open to the exterior, but are closed by the outer layer: the horseshoe groove and the oval depression are therefore nothing more than closed horizontal canals connecting the vertical canals; in these genera, at all events, the canals can have had nothing to do with tube feet. The structure of the hydrospire elements in such forms as *Echinosphaera*, *Arachnocystis*, *Caryocystis*, is essentially the same; that is to say, two vertical canals connected by a closed horizontal canal: the only difference is that the two vertical canals are separated by a suture line instead of being on the same plate. From a position originally just beneath the outer layer these horizontal canals seem to have sunk into the main layer of the test, and in *Caryocrinus* they are actually internal. *Rhombifera* (*sc. bohemica*) and *Homocystis* show the gradual specialization of certain portions of the test as canal-bearers: here it seems that the horizontal canals become more developed in proportion; in fact, they appear eventually to assume the whole function, whatever it may be. In such forms as *Lepadocrinus* they alone remain, and here they no longer connect the adjacent plates, but are transformed into two separate sets of folds. As to the function of these organs, Barrande regards it as respiratory, but drops the term *hydrospire*, for the quaint reason that they show no *spiral* structure. Instead, he calls them *hydrophores*. But he also applies this term to certain organs which can hardly be homologous with pore-rhombs. Around an opening, the interior of the calyx appears divided into five compartments; from the opening there passes into each compartment a branch, which subdivides into five or six smaller branches, and each of these ends in a double tubercle. It is impossible to see whether these branches were hollow tubes or no; they have no connection with the exterior, except at the central opening. These *hydrophores palmées* occur in *Aristocystis*, *Pirocystis*, and *Craterina*, forms already abundantly provided with canals: though simulating the hydrospires of Blastoidea as seen in section, they have an exactly contrary position. Neumayr thinks that the opening which they surround is the mouth, and that they are subtegminal ambulacral grooves. How this can be, when their distal ends are unconnected with the exterior, is not easy to understand. Barrande, moreover, cannot say whether they are at the oral or aboral pole. A comparison of Figs. 28 and 32 on Pl. XXIX. suggests that they are at the aboral end, and that the large opening represents the axial canal of the stem. May they not be connected with nerve-cords passing from a chambered organ?

As regards the major openings of the Cystidean calyx, the accepted views are confirmed by Barrande. Somewhat unaccountably, however, he speaks of the anus of *Agelecrinus* as the mouth (p. 84); perhaps he intended to quote Vanuxem, in which case the oversight is the editor's. In addition to the mouth, anus, and genital pore, Barrande describes for *Aristocystis* a slit-like aperture close to the mouth. This he regards as an organ hitherto unknown. At the same time he points out that its position is similar to that occupied by the peculiar folded structure described by Volborth in *Sphaeronis Leuchtenbergi*. More closely still does it resemble the "reniform groove," or "semilunar pore," figured by Forbes in the fossils which he called *Apiocystis* and *Echinoëncrinus*. We notice that *Atelecystis* is still quoted as having anal and genital openings, although neither in this genus nor in its near relation *Mitrocystis* do the Bohemian species show them. The fact is that even in *A. forbesianus* they have never really been found; the appearances described are only accidental. The true openings in all the Anomalocystidae must be looked for in the neighbourhood of the arms.

Although Barrande enters very largely into the question of the arms, he has brought out no results of importance. The arms of *Arachnocystis infausta* are perhaps more developed than those of any other cystid: it is curious how closely they resemble the stem in structure; one would almost imagine that they had originated in the same manner. A similar structure is observable in the process of *Dendrocystis* which Barrande regards as a ventral tube: there is, however, no reason to call it anything but an arm; and at the same time we may remember that the ventral tube of *Poteriocrinus*, to which Barrande and Trautschold have compared it, is not improbably itself derived from an arm.

Such are the points of greatest morphological interest in this fascinating work. Many peculiar and wonderful forms, such as *Acanthocystis*, *Trochocystis*, *Neocystis*, *Mespilocystis*, *Ascocystis*, and *Cystidea nugatula*, must be passed by with mere mention. The question of classification we have left where Barrande preferred to place it—on the shelf. Systematists may even wish that many a one of these new forms had been left in the earth—*irrepertum et sic melius situm*—and not dug up to disturb existing arrangements. We would not, however, seem ungrateful; rather let us hope that the future parts of this volume, though deprived of the care of the great palæontologist, may be equally fruitful of new and interesting facts, and that, in the hands of Dr. Waagen, they may, no less than this one, add still fresh lustre to the name of Barrande.

TEXT-BOOK OF PATHOLOGY.

Text-book of Pathology. By Prof. D. J. Hamilton. Pp. 719. (London: Macmillan and Co., 1889.)

ABROAD, it is usual for a pathologist to devote his whole life and energy to one subject, and to pay little or no attention to the clinical side of disease, concentrating all his attention on the anatomical and histological aspect. This system has both its advantages and its defects. As his future success in life depends solely upon his reputation as a pathologist, he is stimulated to write frequently and much; and one practical outcome is a large number of books, in both German and French, on pathology. These are of very varying excellence, some being mere compilations of the current standard works, while a few represent the results of a mature experience. For naked-eye pathology, English students have an unequalled work in Wilks and Moxon's "Pathology," of which a third edition has recently appeared. Morbid histology is a science of comparatively recent date, and English authors have hitherto confined themselves to writing short manuals for students, which have been supplemented by translations of the more elaborate foreign works.

This "Pathology" is the first English book which has attempted, in its completeness, to compete with the larger Continental works, and as it is the outcome of several years' experience, of one who is already well known for the original work he has published on many of the questions, it will meet with a hearty welcome. The author takes a very wide view of pathology, and includes under this term morbid anatomy, pathological histology, physics, chemistry, and comparative pathology. Theoretically, this is undoubtedly right; but it is extremely inconvenient, when a book is overweighted by collateral subjects; and we think the author would be well advised in a future edition, to omit the chapters on bacteriology and on the experiments which he conducted to illustrate the circulation of the blood. The greater portion of the information on bacteriology is of necessity a repetition of what is given in any text-book on the subject, and is therefore superfluous, except for the purpose of making the book theoretically complete. The experiments on the circulation should be relegated to a book on physiology.

The book commences with a very full account of the method of making a *sectio cadaveri*, with which we would in the main agree. Our experience, however, is entirely opposed to the separation of the heart from the lungs in the body, as he directs. We believe much more may, in a difficult case, be made out if the lungs and heart be removed, and examined together, the amount of blood in the various cavities of the heart having been previously noted.

One of the most valuable portions of the book is that which deals with the preparation of specimens for the museum and for microscopical examination. For the preservation of intestines and other delicate tissues as jar-specimens in a museum, the author recommends a saturated solution of boracic acid; and for eyes, brain, &c., glycerine jelly. Full details are given for the preparation of large sections of the brain by the gelatine-potash method devised by the author, by which he has been able to uniformly expand the sections, so as to more readily show the course of the various bundles of fibres.

The middle third of the book is occupied by a discussion of general pathological processes. The phenomena of inflammation are very fully discussed, and the author gives a good *résumé* of the views now held on the subject, and also of his own conclusions. He considers the blood-pressure to be the cause of the extrusion of the corpuscles which occurs in inflammation. In discussing the phenomena of inflammation of the cornea, he concludes that at first there is an influx into the cornea, which distends the canals and breaks up the endothelial plates; as a consequence, the so-called branching cells of the cornea, which were really the liquid in the plasma spaces, disappear; at the same time the nuclei of the endothelial plates proliferate. The fusiform nuclei which used to be looked upon as the nuclei of the branching cells, he considers to be the nuclei of the fibrous bundles, and as these run in laminæ of parallel bundles, which lie at right angles to those of the adjacent laminæ, the so-called spear-head bodies are formed by their proliferation. The pus comes both from the connective tissue corpuscles and from leucocytes. In granulation tissue, the author holds that the capillary vessels are mainly old capillary loops from the subjacent tissue, which have been pushed up by the pressure of the blood inside them, when the tense surface of epithelium has been destroyed; and he draws attention to the absence of granulations in a wound on the pleura or peritoneum where the surface pressure is still kept up, and considers that the vessels found, when the pores of a piece of sponge applied to a wound become vascularized, are at first not new vessels, but those of the tissue which have pushed up into the pores.

The third part deals with the diseases of the various organs and tissues. Some interesting facts are given as to the means by which tubercle may be spread:—

(*a*) By inoculation. When the poison is introduced subcutaneously, the disease is reproduced with great certainty. It is remarkable, however, how rarely the disease is contracted through superficial scratches by pathologists; for, although tubercle bacilli have been found in *post-mortem* sores, the author thinks no one has become tubercular in consequence; but this is too sweeping a statement.

(*b*) Through ingesta. Rabbits and guinea-pigs readily become tubercular when fed upon tubercular tissues or sputum, while dogs are less readily infected. Herterich has recorded the case of a healthy widow with two children, who married a second husband who had phthisis, by whom she had three children. She herself became phthisical, and her two youngest children developed deep yellow-coloured ulcers on the mouth and fauces, and ultimately general tuberculosis. The children had been fed on food which the mother had previously chewed. Reich records ten cases of tubercular meningitis in a country village, occurring within fifteen months in the practice of a phthisical midwife, who was in the habit of sucking the mucous from the mouths of the new-born infants, and of blowing air into their lungs. Pigs fed upon the milk of tuberculous cows became tubercular in five weeks.

(*c*) By inhalation. Animals after a few inhalations of tubercular sputum, disseminated in a spray, readily became infected. Koch holds that no other substances than tubercular products when introduced into an animal will produce tuberculosis.

The *résumé* of the changes which take place in the blood in various diseases is most complete and up to date. The latter part of the book deals with the diseases of the circulatory organs.

Among alterations which are desirable in a new edition we would suggest that the forms for the *post-mortem* reports which occupy four pages should be omitted; or, if not, they should be made much more complete. Many important headings, such as lymphatic glands, joints, prostate, &c., are wanting. Fig. 25 is an unfortunate illustration of lardaceous disease of the liver in which the liver cells are affected, and should be replaced by a more typical case with healthy cells. We would demur to the statements that lymphadenoma produces great anæmia and infiltrates tissues—that is, in the sense in which sarcoma is said to infiltrate. The growths extend only along lymph-channels, and do not infiltrate outside these. On p. 82, sulphide of potassium should be sulphite.

We congratulate the author on the general excellence and practical nature of his book, and shall await with interest the second volume. The arrangement of the type, the paper, and the illustrations are unexceptionable, and reflect the greatest credit upon all concerned.

OUR BOOK SHELF.

A Graduated Course of Natural Science. Part I. By Benjamin Loewy, F.R.A.S. (London: Macmillan and Co., 1889.)

THIS is an admirable little book which has been prepared for the use of teachers and students in schools where elementary ideas of physics and chemistry form part of the course of training. It is intended for elementary students only, and it is not too much to say that the various experiments and inferences are well within the scope of every boy and girl of ordinary ability. It is but to be expected that during his twenty years' experience the author has become thoroughly acquainted with the difficulties met with by young students, and with the best methods of overcoming them.

An experiment is first described, and the inferences to be drawn are then discussed, the simple conversational style being especially suitable for young pupils. The subjects are arranged in a very natural order, and it would be difficult to suggest improvements. Very practical suggestions are made as to the best way of arranging for each student to perform the experiments. A simple board, about 3 feet long by 18 inches wide, temporarily screwed to the top of the desk, has been found sufficient to accommodate two or three pupils, so that it is an easy matter to have thirty or forty working at the same time. To make the book more useful to teachers, a series of questions has been put at the end of each chapter.

We strongly recommend the book to the notice of teachers likely to be interested in the subjects of which it treats.

Flora of Switzerland for the use of Tourists and Field-Botanists. By A. Gremli. Translated from the Fifth Edition, by Leonard W. Paitson. (London: David Nutt, 1889.)

ENGLISH visitors to Switzerland who happen to be interested in botany must often have regretted that they did not possess a really good hand-book of the Swiss flora. The translator of Herr Gremli's well-known work has provided a volume which will exactly meet their wishes. The original book has been widely circulated in Germany, and its materials are so ample, and so carefully and intelligently arranged, that it well deserves its popularity. In the fifth edition many improvements were made, and these are, of course, embodied in the present rendering. Mr. Paitson has also been able to include the new matter presented in the French translation by M. J. J. Vetter (1885), and corrections and additions published (1887) in the latest—the fourth—of Herr Gremli's supplements. Although the work is intended in the first place for persons beginning the study of botany, it contains much information with regard to new species that will be of service to more advanced botanists. We may note that the English volume is clearly printed, and that it is of a size convenient for the use of tourists.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coral Reefs.

I AM obliged to Mr. Murray and Dr. Guppy for their courteous replies to my questions. Mr. Murray knows how pleasant a duty it is on the part of Admiralty surveyors to collect materials for the investigation of men of science like himself. Perhaps he will allow me to say that the theory of wave action spreading out the loose materials of a volcanic island is difficult to understand in view of the fact that islands in the same locality, such for instance as Mokongai and Wakaya in the Fiji Group, have their barriers far away from the land on exactly opposite sides. If he will excuse repetition, I desire again to point to the Exploring Isles, and to the great distance between the barrier and the island of Vanua Mbalavu; also to the fact that the waves, for all but a few days in the year, attack the island from a direction varying between south-south-east and east-north-east, principally east-south-east. Although there is much upraised coral at the north end of Vanua Mbalavu, the formation is chiefly volcanic.

The shallow nature of the Na Solo lagoon is, I presume, due to the detritus from the now sunken island, and the fragments from the reef washed over by the heavy seas at high tide. The bank west of Ono, in the Kandavu Group, is terminated by a sunken barrier, similar to that south of Viwa and north-west of Mbengha; and is not a continuous reef awash, because of the muddy streams from Ono sweeping to leeward, and also for the reason, admitted on all sides, that coral does not grow with so much vigour where there is no surf.

Dr. Guppy's simile, of an engineer having constructed and afterwards repaired a bridge, is not, in my opinion, a good one. A bridge is a structure accomplished on mathematical principles, good or bad. If good, it will stand; if bad, it will sooner or later fall. Mr. Darwin's theory, like other theories, is not capable of mathematical proof; and it is deduced from personal observation only in a very limited degree. The second edition of his work indicates, that after thirty-two years' further experience in weighing, deducing, and generalizing of a similar character in other branches of natural history, and receiving the views of those opposed to his theory on this special subject, he still adheres to his original opinion. The principle of his work was, in all cases, very much the same; and, considering the labour which he devoted to the first study of the question several years after he returned from his voyage, it is hardly conceivable that the origin and formation of coral reefs did not occupy a considerable share of his attention in the long interval between the publication of the first and second editions of his book. As to acquaintance with the objects of his writings, he had none, I presume, with that horrid creature with the swim-bladder from which he believed we are all descended; nor with most of the animals which have formed the connecting links between that distinguished progenitor and man; but, nevertheless, his great collection of facts and evidences have been of sufficient weight to revolutionize the history of creation, and to pervert hundreds of thousands from their faith in the poetical narrative of Moses.

However, Dr. Guppy is correct in saying that there are certain upraised ancient reefs in the Lau group of Fiji. Lieut. Malan was no doubt alluding to the islands of Tavuthá, Naiau, and Kambara, which have every appearance of atolls lifted out of the sea, for they are coral islands of considerable height, with an exterior rim and depression in the centre, between 150 and 200 feet deep. It does not follow that they may not form *now* part of a descending area; nor that the Bukatatanoa and Reid Reefs may not be participating in the movement. It is remarkable that only one reef has yet been discovered which connects the atoll awash with the island many hundreds of feet high which has been, to all appearance, an atoll in past ages. As far as I am aware, there is no island known, except Aldabra (which has a lagoon dry at low water, and is, therefore, an abnormal instance), of coral formation, with a lake in the centre and openings on the lee side; in such a stage as an atoll would be if it was elevated, say, 20 or 30 feet; nor do I believe that anyone has yet seen an upraised island *barrier* reef. The sight would be so phenomenal, that the news of its existence would speedily become public property. It must be remembered that, while proofs of upheaval are easily detected, direct *evidence* even, of subsidence, is most difficult to obtain. All searching under water is groping in the dark.

I may here remark, as it is our common object to arrive at the truth, and surveyors are not special pleaders, that there is an error in Mr. Dana's examples of subsidence (p. 310, "Coral Reefs," Darwin, third edition). Nanuku Islets are cays on a spur from a barrier reef, and Bacon Islets are formed of coral. It is unfortunate that these should have been inadvertently taken as types so late as 1885, three years after the charts were published, though it is easy to understand how Mr. Dana was mistaken in his first book when he had to rely simply on the excellent sketch made by the officers of Wilkes's expedition, to which he was attached; but these mistakes do not necessarily invalidate the conclusions of the experienced naturalist, who, had he thought of it, could have selected other and better examples from the same group.

It would be premature to discuss the cases of the Tizard and Macclesfield banks before Dr. Bassett-Smith records the results of his examination of the specimens collected, in pursuance of Captain Wharton's directions, chiefly by himself and Lieut. Parry, of the *Rambler*; but this much may be said—the existence of a submarine cliff is established in the former, and the sectional slopes have a great resemblance to those of mountains. The condition of the Itu Aba and its surrounding reef appears to favour Mr. Murray's views; but the general state of the reef does not, as far as I can see, disprove the theory of subsidence. The one Macclesfield bank section is not at all like that of a sinking mountain; and the condition of the coral on the top might indicate either a downward or upward movement, or neither. If we find, as in both these cases, a mixture of dead and live coral on the rim of an atoll, the inference seems more in favour of subsidence than elevation. It implies that a sudden descent to a depth beyond that in which the less hardy individuals of the species can flourish, has killed the growing insect; and that a new effort is being made to regain the surface. Specimens of reef-building corals were brought up from depths below even 30 fathoms; but, as far as the imperfect appliances which we have at present could help us, there was no evidence that *masses* of coral were at all common below 13 fathoms. The condition of the slopes could be safely compared to the banks of a river stream with the blades of grass growing thinner and thinner as the distance from the water was increased (Darwin, p. 111).

In the case of the Bukatatanoa, and other large reefs of a similar character, my difficulty with respect to Mr. Murray's theory is this: if corals commenced to grow on sediment which had lodged on a submarine inequality, why should nearly all parts have kept pace so evenly in their growth? The highest portion of the bank on which the Bukatatanoa Reef—according to the theory of Mr. Murray—rests, would surely not be around the sides, but somewhere in the centre. There would be a summit of some kind, to which the sediment would be first attracted. Is it not most improbable that first the pelagic organisms which are dead, and then the coral polyps which are alive, should maintain an even contour around three sides of a bank and many miles away from the highest part of it, and arrive at the surface of the ocean much about the same time? If it is said, How do you know it arrived at the surface at the same time? I point to the connected form of the barrier. According to Mr. Murray, had it not done so, it would have formed innumerable rings instead of being connected, without a break, for so many miles.

Reid Reef, to the north of Bukatatanoa, is a still more remarkable instance. Here, there is a feature, which Mr. Murray mentions, quite apparent, viz. the paucity of coral heads in a lagoon where the barrier is uninterrupted; but the difficulties which I have ventured to place before him are greater than ever: (1) Why should wave-action distribute a bank on the weather as well as the lee side of the land? (2) Why should the insect reach the surface simultaneously on all sides, as shown by the continuous reef and the uniformity of its breadth? To the best of my recollection, the islets within this barrier are of volcanic origin, but the point is not material.

With reference to Mr. Murray's explanation of the deficiency of reef under Mbuke Levu (Mount Washington), may I point out that it is of great assistance in showing why, when discussing subsidence, it is not necessary to hesitate for examples at those islands which have a barrier on one side and a fringe on the other. On a cliffy, steep side, the sinking fringe would, of course, remain very close to the new coast-line, and, if it assumed the barrier form at all, would rapidly become filled with pieces from the land.

The fragmentary character of the Great Barrier Reef of Australia does not seem to have excited the attention it deserves in this controversy. I believe that there are innumerable passages through it, and that, instead of being termed a "barrier," it might better be described as a collection of large patches.

The Hailstorm in Liverpool.

Sunday, June 2.—A very sultry afternoon, with heavy thunder-clouds in the south-west and west, and continual rumblings from the same direction, the storm evidently passing over the Dingle and Toxteth Park. Soon after 3.30 p.m. lightning became visible and the storm broke.

At first a few large drops of rain fell, making patches of $1\frac{1}{2}$ to 2 inches in diameter on the cement. In a minute or two, large lumps of ice came slowly down, rebounding to an astonishing height. As the stones became more numerous they decreased considerably in size and fell with greater force. This lasted for ten or twelve minutes. The rain had nearly ceased during the height of the storm, but began again towards the end for a short time. I immediately collected some stones off the grass, and placed them in a dish on some blotting-paper.

They were evidently of two classes; the one having clear ice kernels, the other white misty ice. If the stone was large the kernel was surrounded with another coating of the opposite kind of ice, a dark line intervening between the two, and here and there I noticed a third or fourth layer.

Many in themselves spherical had a pear-shaped appendage, which, however, soon melted away. One or two (Fig. 4) had the second layer thinner than the others, making a hollow between the centre and exterior layer, both above and below.

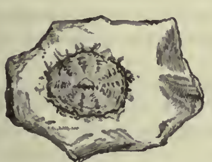
I found one of a most curious construction (Fig. 3). The stone was all composed of white ice except at one end. The white ice seemed to terminate like the petals of a flower, closing in round a centre of clear ice. This construction was entirely formed below the surface, the stone being otherwise smooth. I could not take accurate measurements owing to the absence of a correct scale, but approximately the stones I drew measured as follows:—

	Breadth.		Width.		Thickness.
(1)	$\frac{12}{16}''$	...	$1''$	...	$\frac{8}{16}''$
(2)	spherical, about		$\frac{10}{16}''$	...	
(3)	$\frac{15}{16}''$	...	$1\frac{3}{16}''$	...	$\frac{14}{16}''$
(4)	$\frac{14}{16}''$	...	$1\frac{4}{16}''$	...	
(5)	$\frac{14}{16}''$	...	$1\frac{5}{16}''$	...	$\frac{10}{16}''$

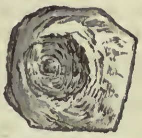
The stones had all a metallic taste and also a flavour of ozone.

I have examined some of the stones under the microscope. All have an air-bubble at the centre, and I thought in some I could distinguish a speck of sand or grit as well. The kernel appears to have infinitesimal cracks in the ice, going round the central bubbles in circles. Sometimes these are not spread out all round, but run up to the centre in spokes, widening out as they reach the edge. The dark line between the coatings appears to be composed of small pear-shaped air-bubbles lying with

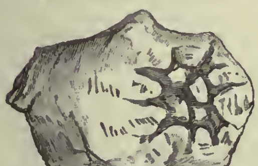
1.



2.



3.



4.

5.

their narrow end towards the centre, and here and there in the ring are specks of grit or dust.

In the pear-shaped prominences the minute ice cracks appear to be formed in waving lines.

In some (Fig. 4), the air-bubbles are formed near the surface round the second or third layer, and are much larger; in others (Fig. 5), they appear in the kernel instead of the spoke-like formation of cracks.

Sefton Park, Liverpool.

Use or Abuse of Empirical Formulæ, and of Differentiation, by Chemists.

PROF. THORPE'S review of the work of Mendeleeff suggests to me a question I have several times previously thought of putting, viz. whether chemists are not permitting themselves to be run away with by a smattering of quasi-mathematics and an over-pressing of empirical formulæ. I do not make the accusation; I merely put the question as one suggested by an incomplete and superficial perusal of one or two recent memoirs.

To make my meaning clear, I will state a few facts, and if they are unnecessarily obvious I shall be glad to find them so.

Take percentage composition (p), and specific gravity (s); s is a function of p, and the question is, whether it is a continuous or a discontinuous function. To obtain an answer to this question, the best determinations of s should be plotted on a large scale in terms of p, with the probable limits of inaccuracy laid down, and then the curve should be examined to see whether it possesses, at the points of definite constitution, any kind of discontinuity, whether of slope or curvature. The answer may come out, either that such discontinuity certainly exists, or that it possibly exists, or that, if it exists at all, it must be below a certain specifiable order of magnitude. One of these is the definite kind of statement that can be made, and nothing else.

In order to assist the eye in forming a judgment, some form of mechanical integrator or differentiator might legitimately be run over the curve, provided due care were taken to avoid the creeping in of errors; but I doubt whether anything could be certainly detected in the derived curves that ought not to be visible in the original curve itself.

The process adopted by chemists seems a less satisfactory plan. I speak under correction. They assume some elementary form of empirical expression for the function, say a quadratic expression with three arbitrary coefficients, and they determine these coefficients to suit three points on the curve, first for one portion and then for another, taking these portions in the stages between one definite constitution and another; they thus obtain a set of quadratic expressions for s in terms of p, each with a more or less different set of coefficients: in other words, they find bits of parabolæ which more or less fit successive portions of the actual curve. They then differentiate each of these, and plot $\frac{ds}{dp}$, and they appear to be struck with the fact that, for each portion, these plottings come out precisely rectilinear; while with the observation that discontinuities exist between successive portions they seem quite pleased.

They sometimes go on to plot $\frac{d^2s}{dp^2}$, and to deduce fresh support for their facts by means of it.[1]

Now, were it not that eminent persons appear to lend their names to this kind of process, one would be inclined to stigmatize this performance as juggling with experimental results in order to extract from them, under the garb of chemistry, some very rudimentary and commonplace mathematical truths.

I would not be understood as casting any doubt on the *results* which may, by ingenious and clear-sighted persons, have been arrived at, even by so questionable a process: I would not be so understood, partly because those results lie out of my province, partly because the hypothesis of definite constitution for solutions or for alloys seems a very probable one, partly because I have myself plotted the s p curve for dilute ethyl alcohol, and clearly perceive the varieties of slope and curvature detected by Mendeleeff, though the changes are scarcely so sharp and definite at definite points as one might wish them to be in order to support the *a priori* improbable hypothesis of actual discontinuity. But what I want to assert, perhaps unnecessarily, is, that no juggling with feeble empirical expressions, and no appeal to the mysteries of elementary mathematics, can legitimately make experimental results any more really discontinuous then they themselves are able to declare themselves to be when properly plotted.

Liverpool, June 29. OLIVER J. LODGE.

[1] Although Prof. Thorpe's review *suggested* the writing of this letter there is nothing contained in that review which prompts these remarks. Prof. Thorpe does not appear to have fallen into the errors which, in the writings of some chemists, I fancy I detect.

CHEMICAL AFFINITY.

IN the older days, chemists were willing to think that, when they had said of a chemical occurrence, "It is a manifestation of the affinities of the reacting bodies," they had given a fair explanation of the occurrence. Nowadays, we rather avoid the term affinity. The modern chemist is not comforted by the word as his fathers were. Phrases, he knows, have a way of decoying a man to destruction. But, although he does not use the word affinity so much, the chemist is more eager than ever to understand the modes of action of affinity.

Since the latter part of the last century, the prevalent views regarding affinity have fluctuated between the doctrines of Bergmann and Berthollet. Bergmann taught that the causes of chemical action and gravitative attraction are identical; this cause being manifested, in one case, in an attraction between minute particles, and, in the other case, between comparatively large masses, of bodies. Further, he said that the result of chemical attraction between different kinds of particles is a change of composition wholly in the direction of the stronger attraction. Hence, according to Bergmann, substances may be arranged in the order of their affinities towards some standard substance. If A, B, and C are each capable of reacting chemically with D, and if the affinities of the three substances are in the order A, B, C, this means that addition of A to the compound BD, or to the compound CD, will cause the production of the new compound AD, and the liberation of B, or C.

Berthollet, like Bergmann, regarded chemical affinity as an attraction between minute particles; but he asserted that affinity is conditioned by the physical properties of the attracting bodies, and also, and very specially, by the relative masses of these bodies. A relatively small attraction may overcome a greater, if the mass of one of the attracting bodies is largely increased relatively to that of the other. Berthollet's view is expressed by himself in the words, "Toute substance qui tend à entrer en combinaison, agit en raison de son affinité et de sa quantité."

These two conceptions still divide the allegiance of chemists. Berthelot's *law of maximum work* is the modern form of the Bergmannic doctrine. Guldberg and Waage's *law of mass-action* puts Berthollet's statement into exact form, and includes in its expression the conception of equivalency—a conception which has been developed since the days of Berthollet.

A great deal of work on chemical affinity has been carried on within the last few years. Ostwald has recently published a memoir of first-class importance. The present seems a good opportunity for endeavouring to give a sketch of the position of the subject.

The enunciation of Guldberg and Waage's law of mass-action, and of the *principle of the coexistence of reactions*, marks the beginning of the distinctly modern era of the study of affinity. The law of mass-action, first clearly put forth by the Norwegian naturalists in 1867, states that *chemical action is proportional to the product of the active masses of the substances which take part in the reaction.* The *active mass* of any member of a chemical system is defined to be the mass of that substance, stated in chemical equivalents, in unit volume of the system. Thus, if in a solution of hydrochloric acid, sulphuric acid, and caustic soda, the substances are present in the ratio

$$2HCl : H_2SO_4 : 2NaOH,$$

the active masses of the three substances are 1, 1, and 1 respectively, H_2SO_4 being taken as one equivalent of sulphuric acid. The investigations of Guldberg and Waage, and others, more especially of Ostwald, have shown that, if more than one member of a system is undergoing chemical change, each change proceeds as if it were independent of the other, and each substance obeys the law of mass-action. This statement is called by Ostwald the principle of the co-existence of reactions.

But the amount of chemical change which occurs when substances react is conditioned not only by the active masses of the substances, but also by their chemical nature, their states of aggregation, the temperature, and other variables. In their first memoir, Guldberg and Waage grouped these variables together under the name *coefficient of affinity*.

Let two substances, P and Q, react in solution to produce P′ and Q′, and let P′ and Q′ by their reaction re-form P and Q; let the active masses of P and Q be represented by p and q, and the active masses of P′ and Q′ by p' and q'; further, let the coefficient of affinity for the reaction between P and Q be represented by k, and the coefficient of affinity for the reaction between P′ and Q′ by k'; then the amount of decomposition of P and Q which occurs will be proportional to the product kpq; and the amount of decomposition of P′ and Q′ will be proportional to the product $k'p'q'$. When the equation $kpq = k'p'q'$ is fulfilled, the system will be in equilibrium.

The ratio k'/k is found by throwing the equation into the form—

$$(P - x)(Q - x) = k'/k\,(P' + x)(Q' + x);$$

where P, Q, P′, and Q′ represent the masses, stated in equivalents, of the four bodies initially present, and x represents the number of equivalents of P and Q which disappear, and also the number of equivalents of P′ and Q′ which are formed, when equilibrium results. Experimental measurements of P, Q, P′, and Q′, and x are required; from these the ratio k'/k is calculated, and, from this, values are found for x for different initial values of P, Q, P′, and Q′.

In their earlier treatment of the equation of equilibrium, given above, Guldberg and Waage spoke of the force which brings about the formation of P′ and Q′ being held in equilibrium by the force which brings about the re-formation of P and Q. The word *force* was used with a somewhat vague meaning, and certainly not with the meaning given to it in dynamics. Following the example of van 't Hoff, in their later memoirs the Norwegian naturalists regard chemical equilibrium as resulting when the velocity of the direct change—*i.e.* in the above case the change of P and Q to P′ and Q′—became equal to the velocity of the reverse change, *i.e.* in the above case the change of P′ and Q′ to P and Q. The equation of equilibrium arrived at by applying this conception is identical with that already given. By *velocity of the change* is to be understood the ratio of material chemically changed to time used in the change. Ostwald's analysis of the criterion of equilibrium, viz. that the velocities of the direct and reverse changes are equal when equilibrium results, is somewhat as follows. Let two bodies, A and B, be changed to A′ and B′; let the active masses of the four bodies, stated in equivalents, be p, q, p', q'; let x be the number of equivalents of A and B changed to A′ and B′, and the number of equivalents of A′ and B′ changed to A and B, at any moment; and let ξ be the value attained by x when equilibrium results; then

velocity of direct change $= (p - x)(q - x)c$; and velocity of reverse change $= (p' - x)(q' - x)c'$; and the velocity of the total change $= (p - x)(q - x)c - (p' + x)(q' + x)c'$.

Then $x = \xi$, and the velocity of the total change $= 0$, *i.e.* equilibrium results, when

$$(p - \xi)(q - \xi)c = (p' + \xi)(q' + \xi)c'.$$

This is the same equation as that given by Guldberg and Waage. But in this equation c/c' represents the ratio of the velocity-coefficients of the two parts of the change, whereas the ratio k/k' was called the ratio of the affinity-coefficients.

The simplest case in which to apply the above form of the equation of equilibrium is when A and B are caused to react in equivalent quantities without addition of A′ or B′; in this case $p = q = 1$, and $p' = q' = 0$, and the equation has the form

$$(1 - \xi)^2 c = \xi^2 c';$$

hence

$$\frac{c}{c'} = \left(\frac{\xi}{1 - \xi}\right)^2.$$

By determining ξ, *i.e.* the number of equivalents of A and B changed, and $1 - \xi$, *i.e.* the number of equivalents of A and B remaining unchanged, when equilibrium results, the ratio of the velocity-coefficients is found. This equation has been applied to varied classes of changes. Thomsen's measurements, by thermal methods, of the distribution of a base between two acids when one of the acids interacts with the salt of the base with the other acid, confirm the equation. Ostwald's measurements, by volumetric methods, of the same reaction which Thomsen examined by thermal methods, also confirm the equation. And the equation is confirmed by the determinations, made by Berthelot and P. de Saint Gilles by chemical methods, of the quantity of ethereal salt formed when an acetic acid reacts with an alcohol. The accuracy of the equation has also been confirmed by applying it to physically heterogeneous systems consisting of solids and liquids or gases; Ostwald (in his "Lehrbuch der Allgemeinen Chemie") gives the necessary forms of the equation for different cases.

The law of mass-action, and the principle of the co-existence of reactions, are thus amply confirmed. But the expressions, reaction-velocity, or velocity-coefficient, or coefficient of velocity, must be analysed.

The ratio $\left(\frac{\xi}{1-\xi}\right)^2$ is called by Ostwald the *partition-coefficient* of the reaction. The square root of this ratio, *i.e.* $\frac{\xi}{1-\xi}$, is the same as the square root of the ratio of the velocity-coefficients of the two parts of the change, *i.e.* it is the same as $\sqrt{\frac{c}{c'}}$; it is also identical with the ratio of the affinity-coefficients, k/k'.

When equivalent masses of one acid and the sodium salt of another acid interact in dilute solution, ξ represents the number of equivalents of the salt which are decomposed, and $1 - \xi$ represents the number of equivalents of the salt which remain unchanged, when equilibrium is established; or, to put the statement in another form, as each equivalent of salt decomposed produces one equivalent of acid and one of base, ξ represents the number of equivalents of base which have combined with the second acid, and $1 - \xi$ represents the number of equivalents of base which have remained in combination with the first acid. The ratio $\frac{\xi}{1-\xi}$ then expresses the distribution of the base between the two acids. In the case of sodium sulphate (Na_2SO_4) reacting with nitric acid ($H_2N_2O_6$), Thomsen found $\xi = \frac{2}{3}$; therefore, the ratio $\frac{\xi}{1-\xi} = \frac{2}{3}/\frac{1}{3} = 2$. In this case, the direct change consists in formation of sodium nitrate and sulphuric acid, and the reverse change consists in the re-formation of sodium sulphate and nitric acid; the square root of the ratio of the velocities of the direct and reverse changes in this reaction is $\frac{2}{3}/\frac{1}{3} = 2$. Or, one may say that the ratio of the affinity-coefficients of the acids nitric and sulphuric for the base soda is $\frac{2}{3}/\frac{1}{3} = 2$. These statements are identical. Two-thirds of the soda combines with the nitric acid, and one-third with the sulphuric acid, when equilibrium is established; or the velocity of the direct change is double that of the reverse change; or the affinity of nitric acid for soda is twice that of sulphuric acid for the same base. It must be remembered that the acids and the base interact in equivalent quantities and in dilute aqueous solution.

Proceeding in the way indicated by the foregoing example, Ostwald determined the ratio $\sqrt{c/c'}$, or k/k', for many acids reacting with a given base; he stated these ratios in terms of one acid taken as 100. For instance, taking the base soda (Na_2O) the ratio for $\frac{H_2Cl_2}{H_2SO_4}$ was found to be 1·94, for $\frac{H_2N_2O_6}{H_2SO_4}$ 2·0, and for $\frac{H_2Cl_2}{H_2N_2O_6}$ ·97. If the affinity of nitric acid for soda is taken as 100, that of hydrochloric acid for the same base, according to these results is 97, and that of sulphuric acid is 50. Ostwald examined many different experimental methods for measuring the distribution of a base between two acids in dilute solution. The experimental difficulties are great, and the results obtained by one method cannot be expected to agree very closely with those obtained by another. Secondary reactions very often complicate the change which it is sought to measure. The order of the affinities of many acids, for a specified base, was not altered by a change of method, except in a few cases: in these cases the affinities were very small, and therefore incapable of accurate measurement by any of the methods tried.

Ostwald next proceeded to examine the influence of the nature of the base on the affinities of acids. He showed that whether the base be potash, soda, ammonia, magnesia, zinc oxide, or copper oxide, the ratio of the affinities of hydrochloric and nitric acids is the same; but that the ratio varies in the case of sulphuric and hydrochloric, or sulphuric and nitric, acids. But it is known that sulphuric acid reacts with its normal sodium salt to form an acid salt ($NaHSO_4$); Ostwald was able to explain the results obtained with sulphuric acid on the supposition that the affinity of this acid for a base, as measured by any of the methods used by him, really represents only the affinity of that part of the acid which has not combined to form an acid salt. He concluded that the true relative affinity of sulphuric acid, like the affinities of hydrochloric and nitric acids, is independent of the nature of the base. Extending the investigation to other acids, Ostwald concluded that the relative affinities of the acids are independent of the nature of the bases with which they react, and can be expressed by constant numbers. If this conclusion is accepted, it follows, from the nature of the reaction examined, that the relative affinities of the bases are also independent of the acids with which they react, and can be expressed by constant numbers. From these conclusions, the further deduction is made that the affinity between an acid and a base is the product of two specific affinity-coefficients, one of which belongs to the acid and the other to the base.

This conclusion is of extreme importance and requires rigorous examination. In order to test the accuracy of the statement that each acid has a specific affinity-coefficient, Ostwald has determined the affinities of a series of acids by different methods, with the result that the affinity-coefficients determined by one method are as nearly the same as those determined by other methods as could be expected, considering the errors inherent in the methods themselves. If each acid possesses a specific affinity-coefficient, the value of this coefficient for any acid might be expected quantitatively to condition many, if not all, the reactions brought about by that acid. Several chemical changes brought about by acids, other than those in which an acid interacts with the salt of another acid, have been examined by Ostwald. Among these changes may be mentioned that of acetamide to ammonia and acetic acid, that of methylic acetate to acetic acid and methylic alcohol, and that of cane-sugar to inverted sugar. The rate of each of these changes varies according to the acid added to the system; the results obtained show that the square roots of the ratios of the velocity-coefficients are in the same order as, and are as nearly identical as could reasonably be expected with, the ratios of the affinity-coefficients of the acids employed, as determined by the division of a base between these acids. Hence the conclusion that each acid has a specific affinity-coefficient is verified, and at the same time new methods for determining these coefficients are put into the hands of chemists.

But none of the methods employed was found altogether satisfactory. In every case secondary reactions more or less interfered with and complicated the primary change.

There is, however, another and altogether different method whereby the affinities of acids may very accurately be determined. This method is based on the relations which certainly exist between the rate of a chemical change brought about by an acid and the electrical conductivity of an aqueous solution of that acid. If the electrical conductivities of dilute aqueous solutions of a number of acids are stated in terms of that acid which has the greatest conductivity taken as unity, and the numbers so obtained are compared with the relative affinities of the same acids determined by one of the methods already described, a very close parallelism is noticed between the two series of numbers. By carefully studying the effect of dilution on the conductivities of monobasic acids, Ostwald has arrived at the conclusion that the dilutions at which the molecular conductivities of monobasic acids exhibit equal values bear a constant relation to each other. For instance, the molecular conductivity of monochloracetic acid at any dilution is equal to that of butyric acid when the solution of the latter is 256 times more dilute than that of the former acid. By *molecular conductivity* of an acid is meant the conductivity of a solution of a quantity of the acid proportional to its molecular weight. If μ = molecular conductivity, and λ = electrical conductivity, as ordinarily defined, stated in mercury units, then $\mu = 10^7 n\lambda$, where n = number of litres to which the molecular weight of the acid taken in grammes is diluted.

The conductivities of the stronger monobasic acids, such as nitric, hydrochloric, chloric, vary but little with dilution; the maximum values are reached in moderately dilute solutions. The conductivities of the weaker acids, such as phosphoric, acetic, butyric, however, vary much with dilution, and increase very considerably as dilution increases. The rate of increase varies; as a rule, the weaker the acid the greater is the increase for a specified dilution. The maximum values are not the same for all acids. Ostwald's investigations show that the affinity of an acid is closely connected not so much with the maximum conductivity of a solution of that acid as with the rate of increase of conductivity relatively to the maximum conductivity. To determine the affinity of an acid, by the electrical method, it is, therefore, necessary to determine the molecular conductivity of an aqueous solution of that acid at varying dilutions until the maximum conductivity is reached.

But it is very difficult, if not impossible, to determine directly the maximum conductivity of a solution of a weak acid, because when very much water is present the unavoidable impurities in the water affect the conductivity more than the minute quantity of acid which is present. Ostwald has found that the maximum conductivity of a monobasic acid in solution can be calculated from determinations of that of the sodium salt of the acid, and moreover that the maximum conductivity of the sodium salt can be calculated from the observed conductivities at different dilutions. The method by which these results are arrived at cannot be gone into here; suffice it to say that it is based on an extension and modification of the generalisation made by Kohlrausch, to the effect that the conductivity of an aqueous solution of a normal salt of a strong monobasic acid is the sum of two constants, one of which depends only on the nature of the acid, and the other only on the nature of the base.

The further application of the electrical method to find the affinity-coefficients of acids rests to a large extent on the extension made by Arrhenius to electrolysis of van 't Hoff's *law of osmotic pressure*. The law asserts that equal volumes of solutions of definite substances, at the same temperature and osmotic pressure, contain equal numbers of molecules, which numbers are the same as would be contained in equal volumes of gases at the same temperature and pressure. The law has been verified in different directions; it cannot, however, be accepted as a final statement. One conclusion drawn from the law of van 't Hoff, by thermodynamical reasoning, is that solutions of definite substances in the same solvent which have the same freezing-point exert equal osmotic pressures at their freezing-points; and hence, solutions which contain equal numbers of molecules in equal volumes, and which therefore exert equal osmotic pressures, have the same freezing-point. This deduction is identical with the *law of molecular lowering of freezing-point*, empirically established by Raoult. This deduction, if granted, enables the osmotic pressures of solutions to be calculated from observations of the freezing-points of these solutions; the calculated pressures can then be compared with those determined by direct experiment. There are many apparent exceptions to the law of molecular lowering of freezing-point, and to the law of van 't Hoff. Arrhenius explains the exceptions by supposing that the substances in question are partially dissociated in aqueous solution, and that therefore a specified volume of one of such solutions contains a greater number of molecules than would be the case if dissociation had not occurred. This explanation rests on the analogy between the gaseous state and the state of substances in dilute solution. As the pressure of the vapour obtained by heating ammonium chloride is greater than that calculated by Avogadro's law on the assumption that the vapour consists of molecules of NH_4Cl, but as the observed pressure agrees with the calculated pressure when the vapour is assumed to consist of equal numbers of molecules of NH_3 and HCl, so the apparently abnormal osmotic pressures of many solutions may be reconciled with the law of Van 't Hoff by assuming that the compounds in these solutions are more or less dissociated into simpler molecules. Substances which are not (by hypothesis) dissociated in aqueous solution are generally, if not always, non-electrolytes. The exceptions to the law of van 't Hoff occur chiefly, if not wholly, among electrolytes. Ostwald, following Arrhenius, supposes such electrolytes to be more or less dissociated into their ions in aqueous solutions.

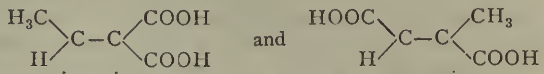
As this hypothesis of electrolytic dissociation rests on the identity of the laws expressing gaseous dissociation and dissociation in solution, it follows that generalisations made regarding gaseous dissociation may be applied to dissociations in solution. Suppose that a gaseous substance is dissociated into two gases; let the pressure of the undissociated portion be p, and the pressure of the dissociated portion be p_1; then, at constant temperature, the relation of p to p_1 is expressed by the equation $\frac{p}{p_1^2} = c$. Again, the pressure of a gas at any specified temperature is proportional to its mass, u, and inversely proportional to its volume, v: now, as the osmotic pressure of an undissociated compound in solution, according to the law of van 't Hoff, is equal to the pressure which the same mass of that compound would exert if it existed as a gas occupying the same volume as is occupied by the solution, the osmotic pressure in the solution, p, may be put as proportional to $\frac{u}{v}$; therefore, from the equation already given, $\frac{uv}{u_1^2} = \text{C}$.

Let μ_∞ = molecular conductivity of a binary electrolyte at infinite dilution, and let μ_v = conductivity of v litres containing one molecular weight in grammes of the electrolyte; then, the fraction μ_v/μ_∞ expresses the molecular conductivity at any stated dilution referred to the maximum conductivity, and on the hypothesis of electrolytic dissociation the same fraction expresses the portion of the electrolyte which is dissociated in terms of the whole quantity of the electrolyte taken as unity. If this fraction is expressed by u_1, and if u represents the undissociated portion of the electrolyte, we have $u = 1 - \mu_v/\mu_\infty$. If now we put $m = \frac{\mu_v}{\mu_\infty}$, and substitute in the equation $uv/u_1^2 = \text{C}$, we have $\frac{1 - m}{m^2}v = \text{C}$. This equation states that $\frac{1 - m}{m^2}v$ must have the same value for all dilutions of any one binary electrolyte; a statement which is amply confirmed by the researches of Ostwald. The constant C obtained by applying the above equation to a monobasic acid represents the affinity of that acid. The constant C measures the readiness of an aqueous solution of the acid to conduct electricity, as also its readiness to take part in chemical reactions; the value of C depends only on the nature of the acid, and is independent of dilution. As C has small values for strong acids and large values for weak acids, Ostwald prefers to put the equation in the form $\frac{m^2}{(1-m)v} = k$, where $k = \frac{1}{C}$. To avoid small fractions Ostwald multiplies m, and also k, by 100; he has determined $100k$ for more than 100 monobasic acids at dilutions varying from 8 to 1024 litres; finally, he expresses the most probable value of $100k$ as K. I cannot here give even a selection from the numerous measurements of K made by Ostwald, but must content myself with drawing attention to some of the conclusions he has come to regarding connexions between the affinities and the constitution of acids. The method has been worked out chiefly for monobasic acids.

In the acetic series of acids, affinity decreases from formic to propionic acid, and then remains nearly constant until caproic acid is reached. The substitution of chlorine or bromine for hydrogen in an acetic acid raises the affinity, bromine causing a smaller increase than chlorine. If S is substituted for O in the group COOH in acetic acid, the value of K is raised from ·0018 to ·0469; while the substitution of the group SH for H in the same acid is attended with an increase in the value of K from ·0018 to ·0225 only. The greater or less acidic character of such groups as OH, OCH_3, OC_6H_5, NO_2, &c., is quantitatively measured by the increase in the value of K attending the substitution of one of these groups for H in an acid. In the acetic acids, the change of H to OH is accompanied by an increase of affinity, OCH_3 is more acidic than OH, and OC_6H_5 is the most acidic of the three radicles considered. In studying the relations between the affinities of acids and their derivatives, attention must be paid not only to the composition and character of the replacing groups, and to the series of acids in which the replacement occurs, but also to the position of the replacing groups relatively to the other atoms of the molecules. The influence of position is very marked in the affinities of the isomeric oxy, chloro, nitro, methoxy, and acetoxy, benzoic acids. The following numbers exhibit the influence of the positions of the replacing groups:—

		K.
C_6H_3 . COOH . OH . OH	1 : 2 : 3	·114
,, ,,	1 : 2 : 6	5·0
C_6H_5 . COOH		·006
meta—C_6H_4Cl . COOH		·0155
ortho— ,, ,, ...		·132
meta—$C_6H_4NO_2$. COOH		·0345
ortho— ,, ,, ...		·616
ortho—C_6H_4 . OC_2H_3O . COOH ...		·0333
para— ,, ,, ,, ...		·00422
ortho—C_6H_4 . OCH_3 . COOH ...		·00815
para— ,, ,, ,, ...		·00302

It is seen that the group OCH_3, or OC_2H_3O, substituted for H in benzoic acid, raises the affinity, if the group is placed in the ortho-position, but decreases the affinity if the group is placed in the para-position. The influence of the position of the replacing groups on the change of affinity of many acids points to some connexion between the affinities of acids and the space-arrangement of the atoms which form the molecules of the acids; measurements of the affinities of such acids as maleic and fumaric, mesaconic, citraconic, and itaconic, confirm this conclusion. Maleic acid is about twelve times stronger than fumaric acid; these acids are probably geometrically isomeric, and the COOH groups are probably nearer one another in maleic than in fumaric acid. Again, if the formulæ of Wislicenus for citraconic and mesaconic acids are adopted we should expect the former to be the stronger of the two. These formulæ represent the acids as geometrically isomeric; they are—



citraconic mesaconic

The values obtained for K are, for citraconic ·34, for mesaconic ·079: the third isomeride, itaconic, is very weak; K = ·012.

Ostwald's researches open up a new path along which advance may be made: they show us how to connect the characteristic property of an acid, its affinity, with the constitution of the acid; they form a further and more important step towards solving *the* problem of chemistry, which is to find definite and measurable connexions between the properties and the composition of homogeneous kinds of matter.

But the coefficient of affinity of an acid has not yet been fully analysed. What is the meaning of the constant K? What is affinity? The value of K for a monobasic acid measures the readiness of that acid in solution to take part in chemical changes, and also the readiness of an aqueous solution of that acid to conduct electricity. Now, when a compound is electrolysed, the parts or ions into which it is separated are chemically equivalent and carry with them equal quantities of electricity, and the electricity travels only with the ions. The conductivity of the electrolyte will depend on the number of molecules electrolysed, and on the velocity of transference of the ions across the space separating the electrodes. The greater the number of molecules separated into ions, and the more rapid the migrations of these ions, the greater will be the conductivity of the substance. Hence the value of K for an acid will be conditioned by the amount of separation into ions, and the rate of migration of these ions; *i.e.* the affinity, as well as the conductivity, of the acid will depend on these quantities. The ions into which a monobasic acid is separated when electrolysis occurs are H and a negative radicle; the scheme of electrolysis may be represented as HR = H + R. As hydrogen moves much more rapidly than the most rapid negative acidic ion, the molecular conductivity of a monobasic acid in solution is chiefly conditioned by the degree in which the acid is separated into its ions. The affinity of the acid is sometimes dependent to a considerable extent on the velocity of the negative ion: in such cases acids which are separated into their ions to an equal extent will exhibit different affinities; in other cases the degree of electrolytic separation is the chief factor conditioning the affinity. Now the fact that, so far as accurate research has gone, electrolytes fully obey Ohm's law, or, in other words, the fact that the smallest electromotive force suffices to cause electrolysis, points to the action of the E.M.F. in electrolysis as being only a directive action on the ions already existing. This view of electrolysis has been developed by Clausius, and recently by Arrhenius, van 't Hoff, and Ostwald. The hypothesis, in its present form, bids us regard an aqueous solution of an electrolyte as already more or less completely dissociated; it bids us see the molecules of the electrolyte in the solution as dissociated into their ions; it says that the electrolytic and the chemical activity of the solution is dependent on the ratio between the number of dissociated, or "active," molecules, and the number of undissociated, or "inactive," molecules. This view of electrolysis, and of chemical change occurring between electrolytes, regards an aqueous solution of a strong acid as containing a great many free ions, which are, respectively, hydrogen and a negative radicle; it looks on an aqueous solution of a weak acid as containing only a few free ions.

There are difficulties in the way of accepting the hypothesis of electrolytic dissociation. At first sight one is shocked by being told that a very strong acid such as nitric acid, or a very strong base such as potash, is dissociated in aqueous solution, to perhaps 90 per cent., into its ions; in the case of potash, one remarks that the ions must be potassium and the group OH, and that each of these bodies reacts with water the moment they are brought into contact. To meet these objections, Ostwald reminds us that a chemically energetic compound is one which readily suffers chemical change, and the parts of which are therefore readily separated; and he remarks that the *ion* potassium is not the same thing as ordinary potassium; the ion holds a large electric charge; when it comes to the electrode it gives up this charge, and *then*, but not till then, it reacts with water. But difficulties still remain: one of the greatest is to explain the mode of action of the solvent. Does the solvent merely form a medium in which the separate ions move about? Why then does increase of solvent increase the amount of dissociation? May not the solvent react with the dissolved body to form complex molecular aggregates which then dissociate into simpler ions? Is the dissolved body the electrolyte, or is the electrolyte a compound, or aggregate, made up of the dissolved body and the solvent? Is the electrolyte actually separated into its ions in the solution, or does it only exhibit an "aptitude for directed dissociation"? These questions, and questions such as these, have yet to be answered.

The hypothesis of electrolytic dissociation has been worked out in detail in several directions, by Arrhenius and Ostwald, and has been found to give results in keeping with experiment. In considering its application to explain chemical change between electrolytes—for it really presents a theory of chemical changes between electrolytes—it is necessary to remember that, in its present form at any rate, it is applicable only to substances in aqueous solution. Because a solution of hydrochloric acid is very chemically active, it does not follow that liquid HCl should also be chemically energetic; nor, because gaseous HCl is not dissociated by heating to a fairly high temperature, does it follow that an aqueous solution of this compound should not be largely dissociated into the ions hydrogen and chlorine.

The hypothesis of chemical change between electrolytes in solution, which is based on van 't Hoff's extension of the law of Avogadro to substances in dilute solutions, and on the general close agreement between such dilute solutions and gases, cannot yet be finally accepted or rejected by chemists. It has already done much to draw closer the connexions between chemical and electrical phenomena, it has gone further than any other hypothesis of chemical change in helping forward the solution of the main problem of chemists, and it has opened up many new lines of advance.

There is one general conclusion to be come to from the study of all the recent work on chemical affinity: I think we may agree with Ostwald when he says that Bergmann was certainly right in assigning a definite affinity to each element and compound, and that Berthollet was right in asserting that affinity is modified by the relative masses of the reacting bodies, but that Bergmann erred in saying that chemical change always occurs in one direction only and that the direction of the strongest affinities, while Berthollet also erred in regarding the affinity between acids and bases as inversely proportional to the equivalent weights of the reacting compounds. Bergmann's error has been revived in modern times; it has now assumed a physico-chemical aspect; it finds its expression in Berthelot's so-called *law of maximum work*, which asserts that every chemical change accomplished without the addition of energy from without tends to the formation of that body or system of bodies the production of which is accompanied by the development of the maximum quantity of heat. In so far as this statement can be translated into precise terms it can be proved to be dynamically unsound. When applied to chemical reactions, it tells us that of several possible reactions that one which is accompanied by the production of the greatest quantity of heat occurs to the exclusion of others; but this has again and again been experimentally disproved.

M. M. PATTISON MUIR.

THE PASTEUR INSTITUTE.

LAST week the Lord Mayor received a letter from M. Pasteur, acknowledging receipt of the resolutions passed at the recent Mansion House meeting. In this letter M. Pasteur writes:—

"If the aphorism that science has no country has never received authoritative sanction, it did so at this meeting, in which the leading *savants* in biological and medical science of the United Kingdom took part. I wish I could thank them individually for having attended this gathering. I was filled with gratitude on learning that the Prince of Wales himself had accorded his high approbation of your initiative. Modesty compels me to pass over in silence the kind words of which my labours and those of the Pasteur Institute have been the subject, but I have a right to rejoice with all friends of the progress of humanity at the great moral effect of the meeting. The manifestation of July 1 had not only for its object the question of the treatment and possible extinction of hydrophobia in England, but in the nature of things it was also a protest against that false sentimentality which led certain persons, not—which was already a strong point with them—merely to put on the same footing the life of men and that of animals, but even to prefer the existence of animals to the salvation of human life. When this view is taken, what is the limit? We must become firm vegetarians. We must even extend our scruples so that no living being is sacrificed. We must endure the importunities of a mosquito, the daring of a mouse, the stings of a flea—false ideas or excuses for a tirade which one finds is most often at the bottom of all the attacks on experimental physiology. Certain credulous souls—by I know not what tales—imagine that our laboratories are chambers of torture. They ignore the fact that the rabbit or the guinea-pig is rendered insensible by chloroform before it is subjected to the most insignificant operation. As for me personally, the suffering of an animal affects me so much that I would never shoot a bird, and the cry of a wounded skylark pierces me to the heart; but if the investigation of the mysteries of Nature and the acquisition of new truths be at stake, the sovereignty of the object justifies all. Who, then, having the least regard for the pursuit of the knowledge of the mysteries of Nature, would put in the balance the sacrifice of a few fowls and rabbits with the discovery of the attenuation of virus and prophylactics which have resulted from such sacrifice? No one, my Lord Mayor, will have contributed more than you have done to rectify the errors which under a show of compassion can only hinder the progress of science and compromise even the most legitimate interests of humanity."

THE TERRESTRIAL GLOBE AT THE PARIS EXHIBITION.

SOME time before the opening of the Paris Exhibition it was announced that one of the attractions of the show would be a great terrestrial globe, one millionth of the actual size of the earth. This globe is now exhibited in a building specially erected, near the Eiffel Tower, for the purpose, and it excites the warmest interest among all visitors who have devoted the slightest attention to geographical science. It was designed by MM. Villard and Cotard, and these gentlemen, who have received many congratulations on their success, have lately issued an account of the manner in which their project has been realized.

Maps on a plane surface give, of cause, a very inadequate impression of the real appearance of our planet; and ordinary globes are too small to indicate, even vaguely, the extent of the spaces represented on them. The idea of making a globe one millionth of the size of the earth deserves, therefore, to be described as a "happy thought," for, although the meaning of a million may not be fully appreciated, it is not absolutely inaccessible to the human mind. When we see a place or a district marked on a globe, and learn that the reality is a million times larger, the proportions are impressively suggested, with at least some approach to accuracy.

The diameter of the globe constructed by MM. Villard and Cotard is 12·73 metres. It has a circumference of 40 metres, and a millimetre of its surface represents a kilometre. The globe consists of an iron framework made chiefly of meridians united to a central core. This structure is carried by a pivot resting on an iron support. To the meridians pieces of wood are attached, and on these are fixed the panels composing the surface of the globe. These panels are made of sheets of cardboard bent by hand to the required spherical shape, and covered with plaster specially hardened. Fig. 1[1] shows how they are applied to the underlying structure. The total surface

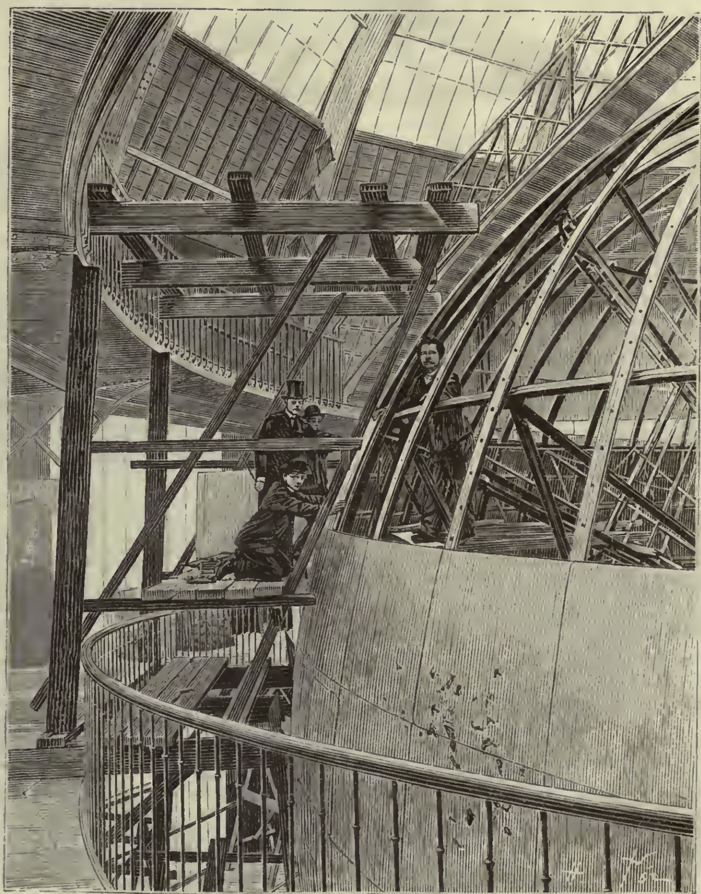


Fig. 1.

is divided into forty spindle-shaped spaces, the breadth of each of which at the equator is exactly one metre. Each "spindle" is itself subdivided, so that there are 600 panels of various dimensions. The designs are painted on the panels before they are put in their place, in order that the globe may ultimately be easily dismantled and removed.

The edifice in which the globe is shown has a metallic framework forming a cupola. It is lighted from above, and by the great glass frames of the sides. From a terrace or narrow foot-bridge at the upper part the visitor can see the polar and temperate regions of the northern hemisphere. As he descends, he is able to see in succession all the regions of the globe to the south pole. At the bottom he comes to the support of the globe with the apparatus for putting it in motion (Fig. 2).

Even the loftiest mountains, if shown in relief, could only have been represented by elevations a few millimetres in height. Consequently the various mountain ranges have been painted on the surface. The various depths of the ocean are indicated in a similar manner.

To facilitate the study of the globe, it has been mounted with its axis vertical, and it may be turned upon the pivot which carries it. If its rotation were made to equal that of the earth, at its equator, a point of its surface would move at the rate of half a millimetre in the second. This

[1] We are indebted to the editor of *La Nature* for the figures here reproduced.

movement would scarcely be visible, but it would, of course, represent an actual movement of the earth over half a kilometre in the same time.

A figure of the moon, corresponding to this one of the earth, would have a diameter of 3·50 metres, and would be 384 metres distant. A like figure of the sun would have a diameter of 1400 metres, and be distant about 150 kilometres. The diameter of a globe representing Jupiter on the same scale would be one-half, that of a globe representing Saturn on the same scale would be a little more than one-third, of the height of the Eiffel Tower.

Fig. 2.

This is not the first occasion on which an attempt has been made to suggest by means of a great globe the size of the earth, and the extent of its oceans and land-masses. The globe of the Château of Marly, which is still to be seen in the National Library of Paris, excited much admiration in the age of Louis XIV., but it has only a diameter of about 5 metres, and is much less effective for its purpose than its successor in the Paris Exhibition.

It is significant of the present stage of our knowledge of the interior of Africa that the makers of the globe, in preparing their maps, had twice to alter their representation of that continent in order to indicate the results of the most recent geographical discoveries.

MARINE BIOLOGY IN THE UNITED STATES.

THERE has recently been issued the first Annual Report of the Marine Biological Laboratory at Wood's Holl, Mass. The Laboratory is an outgrowth of a smaller predecessor maintained at Annisquam, Mass., for six years, by the Woman's Education Association of Boston, in co-operation with the Boston Society of Natural History; and the locality where it is pitched is one which has been in especial favour with marine zoologists of the New World, from Alex. Agassiz downwards. The edifice is a small one (63 × 28 feet), two stories high, of plain but very substantial build. It has been especially designed for the purpose to which it is put, and there are eight private rooms available for the use of investigators. Conspicuous among the names of those chiefly concerned in its maintenance are those of persons known to be familiar with the workings of the leading biological laboratories abroad; and Dr. C. O. Whitman, of Milwaukee, has accepted the office of Honorary Director. It is thus manifest that, in the selection of those who are to control the working of their enterprise, the promoters have secured the services of those of their countrymen whose influence would be most conducive to a successful issue.

The Laboratory is regarded by the Director as a "first step towards the establishment of an ideal biological station, organized on a basis broad enough to represent all important features of the several types of laboratories hitherto known in Europe and America." In a very interesting opening address, the same gentleman lays it down as a tenet that "a biological station should be a purely scientific affair from beginning to end," and the spirit of his words appears to have entered into the very organization of the institution over which he presides. Competent investigators not requiring instruction are invited to carry on their researches free of charge, and a small fee is asked only of those whose work requires supervision; while, with a view to developing the resources of the country, provision is made for the conducting of short seven weeks' courses of instruction in marine zoology and microscopical technique. Arrangements are also to be made for the delivery of "occasional lectures, or informal accounts of results obtained in special lines of research carried on at the Laboratory."

The above-named short courses of instruction are no mere vacation ones, whereby the Laboratory would be in danger of conversion into a summer *rendezvous*, but recognized portions of a working scheme; and, in providing for them, our American brethren have taken a new and most important departure in the advance of biological education, and one upon which we ourselves might well act. To many of us it has long been obvious that our own methods of teaching elementary biology are being overstrained. The type-system, in which we justly glory, is being pushed to an extreme not dreamt of by its founders; but while some such method must always be relied upon for a first beginning, we stand in need of a supplementary system, whereby there may be assured to the advanced student a field of labour less restricted than that now largely adopted. We would have him brought face to face with unfamiliar forms of life—forms of which he might probably never have heard—and left to himself (competent assistance being accessible in case of emergency) to identify and to determine them. The student is, at present, nurtured on too great a regard for authority; he is taught to rely too fully upon his teacher, and his powers of independent judgment become thereby stunted; and, unless some means be taken to dispel this delusion, the systematic work of even the near future must suffer. We are of opinion that the remedy is to be found in some such action as that instituted by the officers of the Wood's Holl Laboratory. We need more field-work, and the advanced student should be compelled to supplement the special training which he now receives with, say, a two to three months' course at the sea-side. Many of our existing schools are already located in situations favourable to the requirements of the case, but their movements are so hampered by the demands of the narrow "syllabus" that little opportunity is left them for the development of their special resources. Setting these institutions aside, however, we believe that access to a fully equipped laboratory is not a *sine quâ non* for the fulfilment of that which we desire. It is true that "any enthusiastic young person who may unfold his umbrella on the sea-shore" cannot be said to have "opened a zoological station"; but it is none the less certain that a born biologist will pursue his calling even under a sunshade, and it should be one of the highest aims of our educational system to single him out. To this end, let the student found his own laboratory in a convenient room in some good locality; set him to collect, to identify, and to preserve; let him rely upon his ingenuity for the construction and arrangement of his accessories; give him ample opportunity to make the most of the resources of the surface-net; and leave the rest to nature. The student who, granted a previous sound elementary training, free of bias, would most readily rise to the emergencies of the case we picture, would be he to whom we would most confidently intrust the future development of our science; and it cannot be denied that our existing methods of training fall short as a sure means of securing him.

Our American brethren are content with humble beginnings. Their Laboratory is small, but it is managed as such an institution should be. We believe our dream to be indicative of a general want; and, should its realization ever come about, to the women of the United States will be due the honour of having inaugurated a recognized system of training such as, to us, seems most desirable for its attainment. Better this than empty glory in a costly edifice.

Young as is the Wood's Holl Laboratory, a record is published, without ostentation, of work commenced in five definite subjects, and efforts are being made to establish a scholarship fund in connection with the institution. The citizens of the United States are now striving by private enterprise to do, for the pure science of aquatic biology, that which their legislators have so nobly done for the fish industries. We heartily wish them success.

G. B. H.

NOTES.

THE next International Archæological Congress is to be held in Christiania in 1891. It was originally intended that it should be held in London. Dr. Ingvald Undseth, of Christiania, is the General Secretary.

MORE than 500 members will take part in the forthcoming Oriental Congress in Stockholm, among them being official delegates from Egypt, Persia, India, Siam, China, and Japan. Two famous Arabic scholars of Medina—Mahomed Mahmud and Mahomed Chingîtbî—will also be present.

THE programme of the second summer meeting of University Extension students and others, to be held in Oxford next month, is now published. The programme, as compared with last year's, shows one remarkable difference. The summer meeting of this year is to be divided into two parts, the first of which, lasting from Tuesday, July 30, to Friday, August 9, reproduces the main features of the meeting of last year—meetings, *conversaziones*, excursions, lectures and visits to libraries, museums, and so forth. On the list of lecturers appear the names of Prof. Max Müller, Sir Robert Ball, Mr. Herkomer, Mr. Lewis Morris, Prof. Henry Morley, Mr. W. J. Courthope, Mrs. Fawcett, Prof. Thorold Rogers, Prof. Pritchard, Prof. A. H. Green, Prof. S. R. Gardiner, Mr. Arthur Sidgwick, Mr. R. G. Moulton, and many others. The second part of the meeting, which is the special feature and new departure of this year, is to begin on Saturday morning, August 10, and end on Friday evening, August 30. This is intended to be a period of more serious and sustained study and instruction for those whose leisure and industry have not been exhausted during the previous ten days, as well as for those who may prefer three weeks of more quiet and systematic reading and lecturing. The lectures in this second part are arranged in connection with lectures of a more general character delivered in the first part. It is estimated that the total expense of attending the first part of the meeting need not exceed £5 for each person (including railway fare and price of ticket), and may be considerably less if several persons live together; while £10, it is estimated, may cover the expense of attending both parts of the meeting. The Secretary is Mr. W. A. S. Hewins, 35 Cornmarket Street, Oxford. The number of tickets is limited to 1200, of which about five-sixths have been already applied for.

Sir Edward Watkin was the client for whom Mr. Perks bought the summit of Snowdon at Tokenhouse Yard last week. It is said that Sir Edward has intimated his intention of offering a site on the summit to the Royal Astronomical Society for purposes of an observatory similar to that on Ben Nevis.

On Monday a deep-sea exploration party started from Kiel, on board the steamer *National*, for the Greenland coast, where they propose to carry on a series of submarine soundings and investigations. The expedition is directed by Prof. Hensen.

According to the *Times of India*, Mr. Oldham, of the Geological Survey of India, who is at Simla at present, is to be deputed to Mergui, in Burmah, on geological work.

Mr. Elliot, head of the Meteorological Department, has, according to the *Times of India*, reached Simla after a long and useful tour. He has arranged for the publication of a map of Bombay, showing the daily state of the weather on the coast, similar to that issued in Calcutta.

The vexed and protracted question of a good zoological collection for Bombay is, after years of discussion, at last on the point of being settled. It came to the ears of the Governor, Lord Reay, that the terms on which the Victoria Gardens are held by the Municipality of Bombay were at the bottom of the whole difficulty. No charge for admission could be levied at any time without the express consent of the Government. But without the aid of fees it would be impossible to maintain, much less to establish, a really good collection. The Government thereupon intimated their willingness to see a moderate fee charged for admission on certain days in the week, and on June 17 the matter was brought before the Corporation, and the proposals of the Municipal Commissioner were accepted. Curiously enough, the *Times of India*, which brings this information, also contains a letter from Mr. H. B. Brady, F.R.S., from London, describing the present zoological collection of Bombay as "a few poor beasts wretchedly housed." But now that fees can be charged at the Victoria Gardens, the situation is entirely changed, and there is no reason why the Bombay zoological collection should not speedily equal the fine collection at Calcutta.

Dr. Francis Day died on July 10 at his residence, Kenilworth House, Cheltenham. He was appointed to the Madras Establishment in 1852, and after taking part in the military operations then in progress at Burmah, for which he received the medal, he devoted himself exclusively to the study of fishes, and became Inspector-General of Fisheries in India. The results of his labours he presented in reports to the Government of India of 1865 to 1877, in numerous papers to scientific journals, and in the following general publications:—"The Fishes of Malabar," 1865; "The Fishes of India," 1868; "The Fishes of the Andaman and Nicobar Islands," &c., 1870; "The Fresh-water Fish and Fisheries of India and Burmah," 1873; "The Fishes of India," second edition, 1875-79; and "The Fishes of the Nilghiri Hills and the Wynaad," 1876. The Imperial Museum at Calcutta possesses his type collection of Indian fishes; and collections formed by him are in the Natural History Museums at Leyden, Berlin, Florence, and Sydney, and in the British Museum, to which he also sent his collection of Indian crabs. Dr. Day retired from the Madras Medical Staff in 1877. He then began the study of the fishes and fisheries of the United Kingdom, and in 1880-83 published "The Fishes of Great Britain and Ireland." He was created a Companion of the Order of the Indian Empire in 1885, and about the same time received the cross of the Order of the Crown of Italy.

According to the *Colonies and India*, the Dunedin Acclimatization Society have solved one of the greatest problems in connection with the acclimatization of salmon. They have procured ova from fish reared from ova sent from this country. It is claimed that this has never before been done in any part of the world.

In connection with a note by M. Leroy, in the *Comptes rendus* of June 17, M. Landerer pointed out, in a note read at the meeting of the Paris Academy of Sciences on July 8, that he was the first to describe the phenomenon of the decomposition of the image of the horizontal lines seen with the eye which remains closed during microscopic observations. M. Landerer offered two remarks in addition to his former statements: (1) although the effort made by the eye in microscopic vision appears to be of the same nature as the effort demanded by telescopic vision, the trouble caused to the closed eye is much more sensible in the former case than in the latter, no matter what the telescopic object may be. (2) The disposition which must be given to the eyes during microscopic vision involves the crossing of their optical axes, producing an effect like that of "strabism." This is proved by the fact that, in giving them this disposition, and then applying the eye to the ocular, one perceives the image distinctly. It is this simultaneous work of the two eyes that explains the trouble experienced by the eye which does not take part directly in the act of vision.

The Reale Istituto Lombardo proposes as subject for the Cagnola Prize (2500 lire, and medal 500 lire) in 1889-90 ("ordinary" competition) the following:—Investigation of one of the (at present few) trisubstituted derivatives of benzol; their mutual relations, and relations to the bisubstituted derivatives to be studied, and facts ascertained which will throw light on the laws of their properties and constitution. Samples of new bodies to be furnished. The date is April 30, 1890. For the "extraordinary" competition (same value of prize), a physico-physiological monograph on one of the larger Lombardy lakes is invited. The research must be carried out according to the directions published by Prof. Forel, of Lausanne, in 1887. Date May 1, 1890. Thirdly, a similar prize is offered for discoveries on the cure of pellagra; or the nature of miasma and contagion; or the steering of balloons; or means of preventing the falsification of writing. Date December 31, 1889. Manuscripts (in French, Italian, or Latin) are to be sent, with sealed letter, to the Secretary of the Institute in Milan.

The Transvaal Volksraad is reported to have placed £20,000 on the estimates for the current year, for the purpose of endowing the first University of the Republic.

According to the Calcutta Correspondent of the *Times*, a herd of 100 wild elephants has been captured in Mysore by

Superintendent Sanderson. The same correspondent states that there were 6000 deaths by snake-bites in the North-West Provinces last year. In Madras, 10,096 cattle were killed by wild animals, and the loss of human life by snakes and wild animals was 1642.

In a telegram from Tashkend, dated July 12, it is stated that a shock of earthquake had occurred at Djarkend, in the Government of Semiretchinsk, by which half the town was destroyed.

Prof. W. Förster, Director of the Berlin Observatory, states in the *Reichsanzeiger* that shortly before midnight on the 11th inst., undulatory motions were observed in two water balances pointing north and south in the Berlin Observatory. These motions, he believes, were a distant effect of the earthquake near Tashkend. Similar motions were observed in Berlin, Breslau, and Königsberg on August 2, 1885, and it is concluded that they were caused by an earthquake which, as was afterwards found, had taken place at Tashkend half an hour earlier.

A slight shock of earthquake was felt at Charleston, U.S.A., at 9 47 on the evening of July 11. The disturbance lasted three seconds, and was accompanied by slight subterranean rumblings. The direction was from north to south.

At a recent meeting of the German Meteorological Society in Berlin, Dr. Lang, of Munich, read a paper on the velocity of propagation of thunderstorms in South Germany in the ten years 1879–88. This is, on an average, 38·4 kilometres per hour; but it has varied considerably from year to year, increasing in the years to 1884, and thereafter decreasing. To this corresponds a curious variation of van Bebber's fourth and fifth depression-paths: which lay in the north at the beginning of the period, then moved south to South Germany till 1884, after which they retired northwards. Hail frequency has varied in an opposite sense to the velocity; but the rapidly moving winter thunderstorms have most hail. The velocity is maximum in winter; it falls rapidly till May, slowly rising thereafter (with a second depression in September) till winter. The velocity is greatest in storms coming from the west. Dividing the region into four zones from north to south, there is a decrease in the velocity, at first slight, but getting very rapid on reaching the Alpine region. The velocity is greatest about midnight, least about midday. At the same meeting, thunderstorms and hail in Bavaria in 1880–88 were the subject of a paper by Dr. Horn. These phenomena in general correspond; both have a maximum early in July, but the hail has a second maximum, nearly as great, in May. Both phenomena show a pronounced day maximum about 3 to 4 (in winter about 2 to 3), and a minimum in the morning from 7 to 8. Dr. Horn said hail never fell in Bavaria without electric discharge, but Dr. Assmann maintained it did sometimes in Prussia.

We have received from Mr. A. L. Rotch the observations made at the Blue Hill Meteorological Observatory in the year 1887. This Observatory, which was established in 1885, is now one of the best-equipped stations in the United States; it is situated in Norfolk County, Massachusetts, about 635 feet above the level of the sea, being the highest point within ten miles of the Atlantic coast from Maine to Florida, and commands an unbroken view of the horizon in every direction. The value of the station has been recognized by the Harvard College, and the present volume appears as vol. xx. Part 1, of the Annals of the Astronomical Observatory of that institution, which is about twelve miles distant. Arrangements have been made for the continuation of this new form of publication, and the ultimate consolidation of the two institutions is contemplated—a step that will insure a more complete discussion of the observations than has been possible hitherto. In addition to monthly summaries, the present volume contains hourly values of all the principal elements. The hourly observations of rainfall, cloud, (7h. a.m. to 11h. p.m.), and sunshine are especially valuable. The sunshine observations are given in a novel and convenient form, showing the amount, in tenths, for each hour. The appendixes contain interesting discussions on thermometer screens, and on the differences of temperature between the base and the summit, as well as tracings from the self-recording instruments illustrating special meteorological phenomena. We congratulate Mr. Rotch and his staff on the completeness of their valuable work.

Amongst the many beneficial measures which have taken place in Mexico, during President Diaz's four years' administration, Sir Francis Denys, of the British Legation, Mexico, in his last report, mentions those for the study and preservation of ancient monuments and historical remains. An inspector has been appointed, the building for the National Museum improved, and various collections relating to natural history, as well as to archæology, have been added. An archæological map of the Republic has been made, and plans and photographs of the palaces of Mitla have been obtained. Explorations of the ruins of Xochicalco, and of the pyramids of Teotibuacan have been undertaken, many interesting discoveries rewarding the explorers of the latter. A wall, 360 metres long, 3 metres high, and 1 metre broad, has been constructed around the palaces of Mitla for the protection of these gigantic monuments. The Republic now possesses a fine public library, where ancient documents and a large collection of scientific and historical works are at the disposal of the student.

About fifty objects of various kinds from the early Iron Age—swords, axes, arrow-heads, &c.—have lately been excavated from a barrow at Hvideseid, in South-Eastern Norway.

An ancient canoe, hollowed by fire from the trunk of a tree, has been discovered in a moss at Thorsager ("Thor's Field") in Jutland, 4 feet below the surface.

In the Report, just issued, of the trustees of the South African Museum for the year 1888, reference is made to the unwelcome appearance in some number, in the entomological collections, of a pest very prevalent in Europe and elsewhere, but hitherto of comparatively rare occurrence in South Africa, viz. the minute neuropterous insects belonging to the genus *Psocus*, and commonly known to collectors as "mites." It is not improbable that the unusually wet weather of the latter half of the year favoured the multiplication of these destructive insects. Naphthaline has been found very serviceable as a check to their attacks.

We notice the appearance of the second volume of the "Ornitographia Rossica," by Th. Pleske, published by the Russian Academy of Sciences. It contains a description of the *Sylviæ* of the Russian Empire. A new edition of N. Kaufman's "Flora of the Government of Moscow," has also been issued. This remarkable work, which is regarded as classical by Russian botanists, was out of print. It has been thoroughly revised, and may be considered the most trustworthy source of information as to the flora of Moscow and the central plateau of Russia.

The third volume of the "Ethnography of the Caucasus," now being published at Tiflis, contains the researches of Baron Uslar relating to the Avarian language. This language is spread in Daghestan, over a territory which crosses the highlands from north to south, and separates the eastern group of the Daghestan languages from the western. It is used by most tribes of the highlands in their mutual relations. Although possessing in its alphabet a great number of consonants hardly distinguishable from one another by the untrained ear, it is said to be very agreeable on account of the excellent proportions between the consonants and the vowels in its words.

A FULL bibliography of Russian books and papers on mathematics and physical sciences since the earliest days of printing is being published at Moscow, by V. V. Bobynin. The first instalment of the second volume brings the work down to the year 1774.

IN the new number of *Harvard College Bulletin* Mr. W. H. Tillinghurst has the following note:—"It is believed that M. Chevreul reached a greater age than any other person who had received a degree from Harvard College, outliving by a year Judge Timothy Farrar (1767), born July 11, 1747, died February 21, 1849, at the age of 101 years, 7 months, 10 days, who received the degree of LL.D. in 1847 on the completion of his one hundredth year. Two graduates of American Colleges have outlived M. Chevreul. Rev. John Sawyer (Dartmouth, 1785), was born October 9, 1755, and died October 14, 1858, aged 103 years, 5 days. He received the degree of D.D. from Dartmouth in 1857, when 102 years of age. But the oldest College graduate in this country known to the writer was Nathan Birdseye (Yale, 1736), who was born August 19, 1714, and died January 28, 1818, aged 103 years, 5 months, 9 days."

SOME interesting facts concerning the "element" tellurium have been brought to light by Dr. Brauner, of Prague, during the course of a series of atomic weight determinations, an account of which is given in the July number of the Journal of the Chemical Society. A determination of the atomic weight of tellurium made by Berzelius in 1832 yielded the number 128·3, and a later one in 1857, by von Hauer, gave the value 127·9. Hence 128 has usually been accepted as the true atomic weight. The properties of tellurium, however, indicate that it belongs to the sulphur group of elements, and that its position in the periodic system lies between that of antimony, of atomic weight 120, and iodine, of atomic weight 127. But according to the above determinations the atomic weight of tellurium is higher than that of iodine. Hence we are obliged to admit one of two things: either that the atomic weight of pure elementary tellurium has been incorrectly determined, or that the periodic law of the elements, that grand natural generalization whose distinguished elaborator English chemists have recently been delighting to honour, breaks down in this particular case. In view of the overwhelming mass of experimental evidence which has now accumulated in support of this generalization, the latter assumption cannot for a moment be tolerated. The redetermination of Dr. Brauner becomes therefore of primary importance, and his results partake of the highest interest. The mode of procedure which afforded the most satisfactory results consisted in the analysis of tellurium tetrabromide, $TeBr_4$, purified in the most complete manner, by means of silver nitrate prepared from pure silver. The mean atomic weight from these experiments was found to be 127·61, the maximum being 127·63, and the minimum 127·59. Hence there can no longer be any doubt that the substance we term tellurium does possess a combining weight larger than that of iodine. Now comes the question: Is this substance pure elementary tellurium? If it is, then, as Dr. Brauner says, it is "the first element the properties of which are *not* a function of its atomic weight." Dr. Brauner, however, finds as the result of a process of fractionation that it is not pure tellurium, and that it consists of probably three elements, pure tellurium mixed with smaller quantities of two other elements of higher atomic weights; and he is at present engaged in studying the nature of these foreign substances, and in the endeavour to isolate pure tellurium itself. A few of the as yet unpublished results obtained in these latter researches were communicated personally by Dr. Brauner at the meeting of the Chemical Society on June 6, and among them the interesting fact was stated that one of the new elements is probably identical with Prof. Mendeleeff's recently predicted dwitellurium, of atomic weight 214, the other new constituent being an element closely allied to arsenic and antimony.

THE additions to the Zoological Society's Gardens during the past week include a Poë Honey-eater (*Prosthemadera novæ-zealandiæ*) from New Zealand, presented by Mr. Alfred M. Simon; two Razorbills (*Alca torda*), two Guillemots (*Lomvia troile*), British, presented by Mr. W. B. Roberts; a White-throated Monitor (*Varanus albogularis*) from South Africa, presented by Mr. H. L. Jones; a Macaque Monkey (*Macacus cynomolgus*) from India, two Argus Pheasants (*Argus giganteus* ♂ ♀) from Malacca, a Military Macaw (*Ara militaris*) from South America, deposited; an Indian Coucal (*Centropus rufipennis*) from India, two Diamond Snakes (*Morelia spilotes*) from New South Wales, received in exchange.

OUR ASTRONOMICAL COLUMN.

COMET 1889 *d* (BROOKS, JULY 6).—The comet reported in NATURE of July 11 (p. 255) as having been discovered by Swift on July 5 appears to have been an observation of Barnard's comet of 1888 September 2, there having been an error in the transmitted position. The position should have been:—

R.A. 21h. 24m. 20s. N.P.D. 89° 11′.

A faint comet was discovered by Brooks on July 6.

July 6·790 G.M.T.; R.A. 23h. 44m. 8s.; N.P.D. 99° 9′. A rough approximation by Brooks.

July 8·9561 G.M.T.; R.A. 23° 46′ 26″; N.P.D. 98° 55′ 57″. Observation by Barnard. Comet, slightly elongated, 1′ in diameter, 11 mag. or fainter.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JULY* 21–27.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 21

Sun rises, 4h. 10m.; souths, 12h. 6m. 8·4s.; daily increase of southing, 2·8s.; sets, 20h. 1m.: right asc. on meridian, 8h. 3·9m.; decl. 20° 24′ N. Sidereal Time at Sunset, 16h. 0m.

Moon (two days after Last Quarter) rises, 23h. 54m.*; souths, 7h. 0m.; sets, 14h. 19m.: right asc. on meridian, 2h. 56·6m.; decl. 12° 12′ N.

BABYLONIAN ASTRONOMY.[1]

III.

WHEN names had to be given to stars, the Babylonians naturally took them from the objects around themselves. The heavenly host was compared to an immense flock, and several stars were grouped together to form the imaginary figure of either a bull, or a ram, or a goat, &c. It is too often taken for granted that the constellations have received certain names, and that the march of the sun through these signs has given birth to various legends, but those who see everywhere solar myths do not say why the constellations were so named. The names given to them must have some connection with what took place at their appearance, mark the seasons, or indicate the work, agricultural or other, of the seasons. The stars of the ecliptic, placed on the path of the planets, were associated with the monthly motion of the moon, and divided accordingly into thirty groups. Each of these constellations was one of the houses of the moon, and marked in the sky the course followed by it in one day.

The constellations were but indirectly connected with the sun's journey through the ecliptic. The acronic, not the heliac, rising of the stars and signs was especially observed, for those which were shining all through the nights of a certain period were considered as the protecting gods of that period.

Many of the allegorical figures representing the constellations were engraved on the boundary stones as images of protecting divinities, and they show the process by which the Babylonian artists arrived at the creation of the composite animals that still adorn our celestial globes. For instance, the Goat coming after Aquarius was represented as coming out of the water, and the hind part of its body changed into that of a fish. Sometimes three or more constellations were combined to form one figure: the horse, the scorpion, and the bow gave birth to a Centaur, holding a bow, and having a scorpion's tail—our Sagittarius.

When the zodiac was borrowed from Babylonia by the Egyptians, they adopted these very un-Egyptian images. There is still some uncertainty as to the date at which the borrowing took place, for all the Egyptian zodiacal representations are posterior to Alexander, but the idea may have been imported about 1600 or 1500 B.C. The Egyptians did not borrow bodily, however, the Babylonian zodiac of thirty signs, but adapted it to their solar year, and according to their sun-worship ideas, so the thirty signs were reduced to twelve, and were connected with the sun's march through the ecliptic. The thirty-six decans were in the same way connected with the sun's march, and three given to every month or ecliptic constellation, one therefore marking the space covered by the sun in ten days.

All attempts made as yet to identify the Babylonian names of stars have failed, because there was no base or starting-point. But now, with the list of the thirty constellations answering to the thirty divisions of the sky, identification is practically easy. In this work we are also helped by the classifications made by the augurs of Babylon for omen-taking; for instance, the twelve stars of the south must be stars of the austral hemisphere. We must at the same time take into account any mention made of stars in the inscriptions, and not forget that the acronic rising was the one observed and noticed by the Babylonians. By this comparative method it can be determined, for instance, that the star *Sukudu* or *Kak-si-di* was Sirius, for we are told that it was one of the seven most brilliant stars, and a star of the south; as it does not appear in the list of the thirty groups of stars, marking the path of the moon, it must be at a certain distance from the ecliptic. In several inscriptions the appearance of this star is used to determine a date; it must therefore appear only for a very short period. This same star is also called "directing star," because connected with the beginning of the year.

By a similar process we can determine that the star *Su-gi* was Canopus; the star *Iku* (or *Dil-gan*), Fomalhaut; the star *Sib-zi-an-na*, α Centauri; the star *Id-khu*, Altair; &c.

The thirty constellations dividing the ecliptic are not, however, all exactly on this line; for instance, one of them is *Sar* or *Merodach* (Orion), another is "the Sceptre of Bel" (Procyon). Having once identified several of these thirty constellations or stars, it is easy to identify the others, as the list is given in the tablet according to their order. We are also helped in our work of identification by the Egyptian zodiac, and the names preserved by Ptolemy. In Egypt, Merodach has become Horus, and the "Sceptre of Bel" that of Osiris. In some cases we can even identify the name of a constellation, though we are not able to pronounce it on account of its being written with a group of ideograms.

The Babylonians often, in star nomenclature, confounded a star with the constellation it belonged to, and substituted for the name of a star that of the god associated with it. We must also take into account the two different points of view adopted by the Babylonian astronomers and their Egyptian imitators.

[1] Abstract of the third lecture delivered by Mr. G. Bertin, at the British Museum. Continued from p. 261.

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iv., troisième fasc. (Paris, 1889).—Examination of human bones found by M. Piette in the walled-in cave at Gourdon, by Dr. Hamy. The results of M. Piette's explorations, although of some interest, have not contributed very largely to our acquaintance with human fossil bones, owing to the fractured and mutilated condition of these finds, which, as is often the case in cave-deposits, were limited to cranial bones, the maxillaries, and one or two of the upper cervical vertebræ. The most perfect of these were found in the middle of the walled cave in *débris* of reindeer and other animal bones, together with carved reindeer horns, cut flints and stones, and numerous stone hatchets, chisels, scrapers, &c., these remains being similar to objects found in other prehistoric stations in the south of France belonging to the reindeer period in Central Europe. At a more remote part of the cave M. Piette discovered a deposit, containing implements of a more ancient type, intermingled with the bones of the mammoth and bear, as well as of the reindeer. The human lower-jaw, found here at a depth of 15 feet, has the special character of analogous cranial remains derived from the Naulette and Spy caves, and belonging to the most ancient type of primæval man, whom MM. De Quatrefages and Hamy include under the name of the Canstadt race.—On the gold of ancient Gaul, by M. Cartailhac. The writer gives a detailed account, with numerous illustrations, of the various gold ornaments found in France, and shows how numerous are the instances in which large and splendid treasures of older art have been irreparably lost in consequence of the finders having consigned them to the melting-pot of the local goldsmith, a practice which can only be stopped by an alteration in the state of the law regarding treasure-trove. The extreme beauty of some of the bracelets, necklets, &c., and the unique character of their ornamentation, are unsurpassed by other objects of the same kind found in different parts of Europe.—Notes on the colour of the eyes and hair in Norway, by Drs. Abbo and Faye, with tables and annotations, by M. Topinard. From these reports it appears that the population of Norway exhibits a higher percentage (97·25) of light eyes than any other country in Europe. Flaxen hair occurs in 57·5 per cent. of the people of the northern provinces, and while absolutely black hair is found only in the ratio of 2 per cent., red hair does not rise higher than 1·5 per cent. in the scale of hair-coloration.—Kashgaria, by Dr. Seeland. In this notice the writer records the incidents of his journey from Kashgar to Ak-Sou, over a distance of more than 350 miles along the sandy ill-kept track that constitutes the principal military Chinese post road. The narrative lacks the interest of the previous numbers already referred to in this journal.—On the cephalic index of the Provençal population, by M. Fallot, with tables referring to the several departments, which give the varying maxima and minima in accordance with special cranial types.—Hallstatt in Austria, its places of burial, and its civilization, by Dr. Hörnes. This is an extremely interesting summary of the important discoveries made within the last few years in the Hallstattian burying-grounds of Slavonian Austria, more especially at Watsch in Carniola, where the beauty and finish of the carved baldrics and belts have led contemporary palæontologists to regard them as an evidence of the existence in Central Europe of an early civilization which had already attained to considerable artistic culture before its extinction under the weight of advancing hordes of barbarian invaders. The necropolis of Hallstatt, for our acquaintance with which we are indebted to Baron Sacken, still remains unrivalled for the splendour and variety of its antiquities, notwithstanding the marvellous results of the recent Carniolian and Croatian finds. Between 1846 and 1863, Sacken and Ramsäuer published reports of their explorations of nearly 1000 tombs; while since that period the number of graves explored has risen to nearly 1900. Both at Hallstatt and Watsch the rites of interment and incineration had been followed with nearly equal frequency, but although in the case of the latter the graves appear to have been most richly supplied with gold ornaments and carved bronze arms, the abundance of yellow amber, and of decorative objects of the toilet which are found buried with the unburnt skeletons render it difficult to decide which of the two methods of disposing of the dead was regarded as the more distinguished. The cranial type is generally dolichocephalous, with a retreating forehead and long slightly prognathic face, resembling what is known in Germany as the "Reihengräbertypus." According to Sacken, the necropolis of Hallstatt dates from the third or fourth century B.C., revealing the presence in those regions of the Eastern Alps of the so-called Galli Faurisci, who prior to the Roman domination must have been familiar with an advanced stage of civilization and decorative art, in which the influence of Greek art is undeniable. This is indeed strongly manifested both in the workmanship and the forms of multitudinous objects revealed by the exploration not merely of the Hallstattian tombs, but of the prehistoric station of Salzberg, whose discovery last year has added new interest to the still contested problem of the origin of the early culture of the Alpine races of Central Europe.

Rivista Scientifico-Industriale, May 15.—On sand showers, by Prof. P. Francesco Denza. His protracted observation of this meteoric phenomenon leads the author to infer that it is not sporadic, as is commonly supposed, but periodical, though subject to occasional disturbances. Its recent reappearance in several parts of Italy, after a considerable interruption, confirms the opinion already advanced by him, that the sands have their origin in the North African deserts, whence they are borne by the high southern gales as far as, and occasionally even beyond, the Alps. About the beginning of May atmospheric waves of low pressure advanced from West Africa across the Mediterranean to South-West Europe, causing a heavy rainfall as far north as the British Isles. In Sicily and Piedmont the showers were mixed with sands, while elsewhere the foliage was covered with a perceptible layer of dust. On May 12 a violent sandstorm raged in the North Sahara, as announced by telegrams from Biskra (Algeria), and this was soon followed by fresh downpours and by another shower of sand in North Italy far more intense than the first. In many parts of the Ligurian Alps and of Lombardy not only the vegetation, but the roofs of houses, terraces, marble monuments (in Turin and Milan), were strewn with fine particles, specimens of which were collected in various districts. The coincidence of the African simoom and the Mediterranean scirocco charged with sand leaves no doubt as to the real origin of the phenomenon popularly attributed to the effects of the April *luna rossa* ("red moon"). Prof. Denza's interesting communication is dated from the Observatory of Moncalieri (Piedmont), May 18, 1889.

Bulletin de l'Académie Royale de Belgique, May.—On a new method of testing for bromine, by Fréderic Swarts. This method, which yields excellent results, is based on the well-known fact that resorcinic phtalin (fluorescin) is transformed to its tetra-bromuretted derivative (eosine) characterized by a beautiful pink colour. The reaction consists in liberating hydrobromic acid, which is immediately oxidized by the hypochlorous acid. The bromine thus obtained then acts on the fluorescin, converting it into eosine, which is transformed to a pink salt under the influence of a slight excess of alkali. This reaction is so sensitive that it succeeds with a tenth of a cubic centimetre of water containing a hundred-thousandth of potassium bromide, a quantity corresponding to a thousandth of a milligramme of this salt. In the case of iodine, it detects the presence of bromine in sea-water without submitting it to any preliminary treatment.—G. Van der Mensbrugghe describes a curious experiment in capillary attraction, the explanation of which is reserved for a future communication. The subject has engaged this physicist's attention since the year 1883, when he announced a simple method of demonstrating the contractile force of fluids which cannot easily be reduced to thin seams (*lames*).

Das Wetter (Brunswick) for June contains an article, by Dr. B. Andries, on the cold period of May, which generally obtains about the 10th of that month; the 11th to 13th being known as the three "ice-saints." There is no doubt that each year frosts occur in May, after several days of warm weather have led us to hope for continued increase of temperature. But the author shows, from long series of observations at Bremen and Paris, that the same thing occurs in April and June, and that the weather of May is more uniform than all the other months, except October, which exhibits the same regularity in decrease of temperature that May does in the increase of the same. The variability arises from the influence of cyclones advancing from the Atlantic. In the interior of the Continent, the temperature becomes more constant, as the influence of the ocean becomes less. Dr. R. Assmann (the editor of the journal) contributes an article on the microscopic observations on the structure of hoar-frost, &c., made on the Brocken and elsewhere. His observations seem to show that hoar-frost is not always crystalline, but that, if the temperature is only slightly below the freezing-point, the hoar-frost, or rime, is often composed of amorphous particles of ice. A third article, by an anonymous writer, deals with the winters of the south coast of the Crimea. The climate is far from unpleasant; in a normal year, a brilliant autumn follows a dry summer, and a soft air continues far into November. December is generally cold and wet, and January fine; hard frosts do not occur till February, and then the struggle between winter and spring lasts until April. An interesting phenological table is added, showing the different effects upon vegetation between a wet or dry November and December.

Bulletin de l'Académie des Sciences de St. Pétersbourg, nouvelle série, i. (xxxiii.), No. 1.—With this number the *Bulletin* begins a new series, printed in a handy octavo shape.—On the rattle-apparatus of *Crotalus durissus*, by A. Feoktistoff.—On a simplification of Wild's photometer, by H. Wild.—On the solution of mechanical problems resulting in hyperelliptic differential equations, by C. Charlier.—Entomological contributions, by A. Morawitz, being a description of two new Central Asian species of *Carabus* (*C. pupulus* and *C. eous*), and a detailed monograph of many species of the same genus.—On the embryology of *Pteromyzon fluviatilis*, by Ph. Owsjannikoff.—Researches relating to the basicity of antimonic acid, by F. Beilstein and O. Blaese.—On the preparation of rubidium, note by N. Beketoff.—On a new Central Asian Siluroid (*Exostoma oschanini*), by S. Herzenstein.—On the absence of the common squirrel in Caucasia, by E. Büchner. Although Pallas, Nordmann, and Ménétries mentioned the *Sciurus vulgaris* as occurring in the Caucasus, there is not the slightest mention of it in the descriptive parts of their works, nor any representative of it in Ménétries's otherwise remarkable collection, kept in full at the Academy. The common squirrel could not be discovered in the Caucasus by the late M. Bogdanoff, nor by MM. Rossikoff, Mlokossewicz and Ananoff, who searched for it for years. It may have been that Pallas, Nordmann, and Ménétries simply reported the words of the Caucasus Cossacks, who give the Russian name of *byelka*—usually applied to the squirrel—to *Myoxus glis*, which really appears in the Northern Caucasus. It is also worthy of note that the common squirrel does not appear in the Crimea.—Hydrological researches, by Carl Schmidt. Analyses of the thermal springs at Saniba, in the north of Mount Kazbek.—Analyses of the sulphate of aluminium, by Beilstein and Grosset.

SOCIETIES AND ACADEMIES.

London.

Entomological Society, July 3.—Lord Walsingham, F.R.S., President, in the chair.—A letter was read from Mr. E. J. Atkinson, Chairman of the Trustees of the Indian Museum, Calcutta, in which assistance was asked from British entomologists in working out various orders of Indian insects.—The following motion, which had previously been unanimously passed at the meeting of the Council, was read to the Society:—"That papers containing descriptions of isolated species widely remote in classification or distribution are, as a rule, undesirable for publication, as tending to create unnecessary difficulties for faunistic or monographic workers." Mr. McLachlan, Mr. Jacoby, Mr. Elwes, Dr. Sharp, and others took part in the discussion that followed.—Mr. McLachlan, on behalf of Prof. Klapálek, of Prague, who was present as a visitor, exhibited preparations representing the life-history of *Agriotypus armatus*, Walk., showing the curious appendages of the case. Prof. Klapálek, in answer to questions, described the transformations in detail. A discussion followed, in which Mr. McLachlan and Lord Walsingham took part.—Mr. H. J. Elwes exhibited a specimen of an undescribed *Chrysophanus*, taken in the Shan States, Upper Burmah, by Dr. Manders, which was very remarkable on account of the low elevation and latitude at which it was found; its only very near ally appeared to be *Polyommatus Li*, Oberthur, from Western Szechuen, but there was no species of the genus known in the Eastern Himalayas or anywhere in the Eastern tropics.—Mr. G. T. Porritt exhibited a remarkable series of *Arctia mendica*, L., bred from a small batch of eggs found on the same ground at Grimescar, Huddersfield, as the batch from which the series he had previously exhibited before the Society was bred. This year he had bred forty-five specimens, none of which were of the ordinary form of the species: as in the former case, the eggs were found perfectly wild, and the result this year was even more surprising than before.—Mr. R. W. Lloyd exhibited specimens of *Harpalus cupreus*, Steph., and *Cathormiocerus socius*, Boh., recently taken at Sandown, Isle of Wight.—Mr. O. E. Janson exhibited a fine male example of *Theodosia howitti*, Castelnau, a genus of *Cetoniidæ* resembling some of the *Dynastidæ* in the remarkable armature of the head and thorax. The specimen had recently been received from North-West Borneo.—Mr. W. White exhibited specimens of *Heterogynis paradoxa*, Ramb., and stated that this insect represented an extreme case of degeneration, the mature female being only slightly more developed than the larva, the prolegs being quite atrophied. Lord Walsingham made some remarks on the subject.—Mr. T. R. Billups exhibited a fine series of the very rare British beetle, *Medon (Lithocharis) piceus*, Kr., taken from a heap of weeds and vegetable refuse in the neighbourhood of Lewisham on May 19.—Mr. W. F. Kirby read a paper entitled "Descriptions of new species of Scoliides in the collection of the British Museum, with occasional reference to species already known."—Mr. J. B. Bridgman communicated a paper entitled "Further additions to the Rev. T. A. Marshall's Catalogue of British Ichneumonidæ."—Mr. J. S. Baly communicated a paper entitled "On new species of *Diabrotica* from South America."

Anthropological Institute, June 25.—Dr. John Beddoe, F.R.S., President, in the chair.—Prof. Victor Horsley exhibited some examples of pre-historic trephining and skull-boring from America.—His Excellency Governor Moloney, C.M.G., exhibited some cross-bows, long-bows, quivers, and other weapons of the Yorubas.—The Rev. Dr. Codrington read a paper on poisoned arrows, in which he stated that the natives relied upon the words of incantation used during the manufacture of the arrows much more than the toxical effect of any substance into which they might be dipped or which might be smeared upon them; indeed, that in many cases the so-called "poisoned arrows" were not poisoned at all.—A paper by Mr. Henry Balfour, on the structure and affinities of the composite bow, was read.

PARIS.

Academy of Sciences, July 8.—M. Des Cloizeaux, President, in the chair.—On two new mechanical appliances, by MM. G. Darboux and G. Kœnigs. The first of these apparatus has been devised for the purpose of describing a plane in space by means of jointed rods; the second supplies a representation of the movement of a solid body revolving freely round its centre of gravity. The principles are described on which both have been constructed.—On the relations between the fractures in the terrestrial crust of a given region, and the seismic movements of the same, by M. A. F. Noguès. The author's comparative study of earthquakes in various parts of the world has led him to detect certain relations between these disturbances and the breaks of continuity in the surface of the earth. In the present paper he shows that, in a given seismic region offering a complicated system of fractures and faults varying in direction, size, and depth, the underground convulsions are correlated with some one of these systems, and entirely independent of the others. His illustrations are drawn mainly from the seismic zone of Andalusia, extending from Séville to the frontier of Murcia.—Influence of temperature on the mechanical properties of iron and steel, by M. André Le Chatelier. In continuation of his previous paper on this subject, the author here gives the results in detail for iron and steel, which are shown to behave quite differently from other metals under like variations of temperature. Three chief phases are distinguished, ranging respectively from 15° to 80° C.; from 100° to about 240°; and from 240° upwards.—On the solubility of carbonic acid gas in chloroform, by M. Woukoloff. Continuing his researches on the law of solubility of the gases, the author here studies the conditions of the solution of carbonic acid in chloroform. With the data obtained he finds that at a temperature of 13° C. his solution does not conform strictly to Dalton's law, although the deviations are very slight, as was also shown to be the case for the bisulphide of carbon.—On the solidification of nitrous acid, by M. Fl. Birhans. In his attempts to solidify anhydrous nitric acid still containing small quantities of hyponitrous acid, the author found that it was necessary to operate at a temperature of from $-52°$ to $-54°$, obtained by the evaporation of the methyl chloride by means of a current of dry air.—On the cobaltites of baryta, and on the existence of a dioxide of cobalt with acid properties, by M. G. Rousseau. The experiments here described demonstrate the existence of a cobaltous acid analogous to manganous acid, but weaker. The maximum of stability of the manganite of baryta appears to be situated in the neighbourhood of 1100° C. At lower or higher temperatures this compound becomes dissociated like the hydrocarburets heated to the point of decomposition.—On an oxybromide of copper analogous to atacamite, by M. Et. Brun. M. Berthelot has noticed that when a clear solution of cuprous chloride in cupric chloride is exposed to the air, a greenish precipitate of oxychloride is formed, which is "probably identical with atacamite." The same reaction is produced by substituting for the cuprous chloride as a solvent the ammonium, sodium, and potassium chlorides. From the last two is obtained a crystalline powder, yielding on analysis the numbers corresponding to the formula of atacamite: $CuCl, 3CuO, 4HO$. M. Brun's present researches aim at the production of an oxybromide of copper from the corresponding bromides. The substance thus obtained possesses a constitution analogous to atacamite, which it closely resembles in its properties and mode of formation.—On the disturbances of the vision consequent on microscopic observation, by M. J. J. Landerer.—The large bones of the anthropoid apes, by M. Etienne Rollet. Since his communication of December 10, 1888, the author has made fresh measurements on the complete skeletons of forty-two adult apes, the results of which are here given in detail. From a comparative study of these figures it appears that the gorilla and chimpanzee approach nearest to man, but in different degrees, the orang holding the third place. But great differences exist between the proportions of the human frame and those of all the bimanous apes.

BERLIN.

Physical Society, June 21.—Prof. Kundt, President, in the chair.—Dr. Fröhlich demonstrated experimentally his new method of recording vibrations in the form of curves; the method has been recently described verbally to the Society. Light from an electric arc-lamp was made to fall upon a small mirror, attached either to the vibrating plate of a telephone, or to a piece of card covered with a thin film of iron, or to a thin india-rubber membrane. From this mirror it was reflected on to a polygonal rotating mirror, and by this on to a transparent screen, being thus made visible to the whole audience either as a spot of light when the rotating mirror was at rest, or as a line of light when it was set in motion. On sounding various organ-pipes in front of the receiver of the telephone, many very pretty curves were seen; on singing the vowels into the telephone, very characteristic curves were seen crossing the screen; so also with the consonant *r*, whereas on the other hand *s* produced no effect. The next experiment consisted in connecting the rotation of the mirror with the interrupted electric current, whose action was under investigation, in such a way that the vibrations of the membrane produced by the current gave rise to persistent curves upon the screen. The current from a battery produced an interrupted sinuous line of light, in which each rise of the curve was somewhat slower than the steeper fall of the same. On introducing a coil into the circuit the curve showed no change as long as the telephone was in front of the coil; when it came behind the coil, the curve described was almost a sine-curve. On putting an electro-magnet into the circuit the amplitude of the curves was less; so also when self-induction existed in the circuit, while at the same time the rise and fall of each part of the curve was less steep. A condenser gave rise to a curve with very sharp-pointed sinuosities. An apparatus for producing alternating currents gave rise to a regular sine-curve, which was affected by a co.l electro-magnet and condenser in the same way as was the curve due to a battery current. Lastly, experiments were made with an induction-coil. On placing the telephone in the primary circuit, the vibrations of its plate gave rise to uniform sine-waves, whose height was less when the telephone was introduced into the secondary circuit, while at the same time they showed a phasic difference of $\frac{1}{4}$ wave-length. This change of phase due to induction, as exhibited in most striking manner to the large assembled audience, can be recorded by photography of the curves and thus submitted to exact measurement.—Prof. Gad gave a short account of researches made, in conjunction with Dr. Heymans, on the effect of temperature upon muscular contraction. These are to be the subject of a more extended communication to the Physiological Society.

Physiological Society, June 28.—Prof. du Bois-Reymond, President, in the chair.—Prof. Gad gave an account of experiments which he had made, in conjunction with Dr. Heymans, on the influence of temperature upon the working-power of muscles. In accordance with Fick's procedure, the muscles were experimented upon not only in an isotonic condition, where there is no change of initial tension, and stimulation leads merely to a shortening of the muscle, but also in an isometric condition, where there can be no change of length in the muscle, and stimulation produces only a change of its tension. Various muscles from frogs were examined at temperatures of 36°, 30°, 13°, 5°, 0°, and − 5° C., being freely suspended in a metallic cylinder immersed in a water-bath. The muscles were stimulated electrically by maximal and super-maximal induction-shocks due to breaking the primary circuit, these being single or repeated or tetanizing. The curve of the isotonic muscle was symmetrical at 19° C.; at 5° C. it rose much more slowly, and was both higher and longer than at 19° C. At temperatures down to and below 0° C. the rise of the curve was still slower and its height less than at 5° C., but on the other hand its length was greater. At higher temperatures the height of contraction was greater than at 5° C., the duration less than at 19° C., and the curve of contraction was symmetrical. At still higher temperatures there was a very considerable fall in the height of contraction, and its duration was still shorter than before. Irritability disappears immediately before the occurrence of heat-rigor. The curves of a muscle in the isometric condition were an exact reversal of those for the isotonic: low and short at 40° C. to 36° C., they were longer and very high at 30° C. At 19° C. there was a very marked diminution in height, while the length was slightly greater; at 5° C. the curve was again higher than at 19° C. and much longer, and below 0° C. lower and longer. When stimulated by a tetanizing current the curve of the isotonic muscle was highest at 30° C., but fell very rapidly from this height, a sign of rapid exhaustion. At 19° C. the curve rose to a less height, and less precipitately, and fell quite suddenly on the cessation of the stimulus. At 5° C. the curve rose more gradually to a less height, and was prolonged considerably after the stimulus was removed, and this was also the case at temperatures below 5° C. The curve of tetanus for an isometric muscle was again, as in the case of single contractions, an exact reversal of that obtained from an isotonic muscle. When discussing the results of the above experiments, the author gave special prominence to the facts that the height of the curve of contraction is least at 19° C. (the temperature of the room) and is increased by either warming or cooling the muscle; further that the duration of the contraction, which is about 0·1–0·2 second at 19° C., increases rapidly as the temperature falls, and is as much as 2·6 seconds at − 5° C. In explanation of the first fact the author assumed that, in accordance with Fick's hypothesis, during the conbustion of carbohydrates and fats to carbon-dioxide and water some intermediate product (? lactic acid) is formed, and acts as a stimulus: the various temperatures under which the muscle works must then be supposed to have varying influences upon the formation and subsequent final oxidation of this intermediate product.—Dr. Obermüller described a new reaction for cholesterin which he had discovered. It consists in treating cholesterin with propionic-anhydride; this leads to the formation of a compound of propionic acid and cholesterin, which on being fused and allowed to cool shows, even in minute traces of the substance, a fine play of colours from violet through blue and green to red. In the green stage the compound consists of minute spheroidal crystals, which are larger in the red stage, and show a black cross when examined between crossed Nicols.

Vienna.

Imperial Academy of Sciences, April 11.—The following papers were read:—On the constitution of the quinine-alkaloids, by H. Skraup.—On some aldehyde-like products of the condensation of urea and their tests, by E. Luedy.—Remarks on the comet discovered by Barnard on March 31, by E. Weiss.—On the diffusion of bases and acids, by E. Stefan.—On desiccative oleic acids, by K. Hazura.—On oxidation of non-saturated fatty acids by potassium permanganate, by A. Gruessner and K. Hazura.—Contribution to the flora of the East (on the plants collected in 1885 in Pamphylia by Dr. Heider), by R. von Wettstein.

COMMERCIAL ORGANIC ANALYSIS.

Commercial Organic Analysis. A Treatise on the Properties, Proximate Analytical Examination, and Modes of Assaying, the Various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, &c.; with Concise Methods for the Detection and Determination of their Impurities, Adulterations, and Products of Decomposition. By Alfred H. Allen, F.I.C., F.C.S. Second Edition, revised and enlarged. Volume III., Part I. (London: J. and A. Churchill, 1889.)

IN this instalment of the amplified edition of Mr. Allen's well-known and valuable work of reference, the substances dealt with are the acid derivatives of phenols, also including aromatic acids and tannins, dyes, and colouring matters; the large additions made to the first edition necessitating the division of the concluding volume into two parts, of which this is the first, the discussion of organic bases, cyanogen compounds, and albuminoids, &c., is reserved for the second part. In consequence, the large majority of the present portion is entirely new, only comparatively short sections on picric acid and basic aniline derivatives having appeared in the first edition, in place of some 270 pages relating to dye-stuffs. Where references to English translations or abstracts of foreign papers are obtainable, the author has deliberately given them in preference to references to the original memoirs appearing in German and other foreign periodicals, on the ground that these publications "are practically, if not absolutely, inaccessible to the great majority of English readers." No doubt so doing saves a considerable amount of trouble to the reader in the first instance; but, on the other hand, concise abstracts such as are to be found in the Journals of the Chemical Society and the Society of Chemical Industry, NATURE, the *Chemical News*, the *Pharmaceutical Journal*, &c., are frequently of necessity shorn of many details of especial importance to the commercial analyst; whilst most chemists concerned in the analysis of dye-stuffs and analogous organic products probably possess in their own libraries the leading German and other periodicals, or at least have access to them in the various public libraries in the manufacturing towns and cities.

Amongst the phenol and aromatic derivatives Fahlberg's *saccharine* (benzoyl sulphonic imide) finds a place; this is stated by the author to be "quite uninjurious, even when taken in considerable quantities," passing unchanged through the system, so that it can be detected in the urine. It would seem, however, that the alleged freedom from noxious effect is a matter still somewhat in dispute, at any rate as regards habitual use; the difference of opinion on the subject being one reason why the Commissioners under the Customs and Inland Revenue Act of 1888 exercised their discretion in prohibiting the use of saccharine in beer (May 1888) until further notice. For similar reasons, the addition of salicylic acid to wine is forbidden in France and other countries, although only one part in 10,000 is essential even as a maximum for the preservation of the liquid; magenta being also prohibited as a tinting material for sweetmeats, wines, &c., on account of the frequent presence of arsenic therein. The use of picric acid as a bitter for beers or "hop substitute" is rightly condemned by the author, on account of the distinct poisonous properties of the substance, rabbits and dogs being killed by doses of from 0·06 to 0·60 gramme (nearly one to ten grains); similarly the employment of dinitro-cresol and naphthalene yellow as "saffron surrogates" for tinting butter, cheese, maccaroni, &c., is strongly objected to on the same ground. In all these and many other instances the various methods of detection of the objectionable substances are carefully detailed, the book being largely intended for the use of the public analyst in connection with articles of food and drugs, as well as for chemists and specialists working in other directions. One of the tests for salicylic acid in beer, recommended on the authority of Blas, is of a somewhat heroic character, and is hardly likely to be adopted by toxicologists as a process of general application: the analyst is required to *drink the beer*, and, after three hours, to examine his urine, the colour-reaction with ferric chloride being stated to be then seven times as delicate as with the original beer. Probably it is the adoption of analytical methods of this description that has led to the popular belief that an analytical certificate of having examined edibles "chemically, physiologically, and dietetically, without finding anything injurious to health in them," simply implies that the operator has lunched on the materials, and has not noticed any particular inconvenience resulting therefrom. In cases where injurious substances are believed to be present, it might be preferable to make the vendor of the suspected goods the medium for the application of the test, thus to some extent returning to the mediæval practice of punishing sellers of adulterated wine by compelling them to swallow a gallon or two of the liquor, and pouring the remainder of their stock over them as an external application of a sobering nature.

In the same section, the general chemistry of the tannins is discussed, so far as it is at present understood, and the various processes described for the valuation of the numerous tannin-yielding materials occurring in commerce. From the tanner's point of view, these are divisible into two great classes, viz. those which produce a "bloom," or fawn-coloured deposit on leather (such as gall-nuts, divi-divi, sumach, valonia, and oak-bark), and those which do not (such as catechu, hemlock, larch, and mimosa); broadly speaking, these two classes yield, with ferric acetate, somewhat different colorations, the first set producing a blue-black, and the second a green, the difference being mainly due to the presence of gallic acid and protocatechuic acid, or derivatives thereof, in the two classes respectively. Curiously, the author has omitted to give, in this connection, any directions for the testing of manufactured *leather*, the adulteration of which with sulphate of barium (mechanically forced in whilst moist and soft), glucose, and analogous weighting substances, has of late years come somewhat prominently into notice, and indeed occasioned special Government inquiry. In connection with tannin, some interesting facts are recorded concerning the examination of documents in cases of suspected forgery or alteration where ordinary ink has been used, more recent writing being frequently capable of detection by the use of chemicals carefully painted on (such as dilute hydrochloric or oxalic acid solution), on account of its fading out sooner under the treatment. Stephen's blue-black ink is described as composed of 15 parts galls, 5 ferrous sulphate, 4 iron filings, 200 water, and ½ indigo, in 3 of sulphuric acid, no gum, or other thickening being mentioned, whilst other inks usually contain a few per cents. of such substances, copying-inks chiefly differing in containing sugar or glycerine in addition. Sulphate of copper is stated to be added occasionally to inks "with questionable advantage"; the opinions of the vendors and users of steel pens on this point being doubtless dissimilar.

The major half of the book consists of a terse description of the general processes of manufacture, characteristics, and modes of examination of dye-stuffs, classified under the headings of nitro colouring matters, nitroso colouring matters, aurin and its allies, phthaleïns, azo colouring matters, rosaniline and its allies, safranines and indophenols, colouring matters from anthracene, sulphuretted and unclassified coal-tar dyes, and colouring matters of natural origin. On reading the systematic names of many of the artificial dye-stuffs, one can hardly wonder that practical dyers prefer to employ shorter and more colloquial terms, even though these lack somewhat in scientific precision: "xylidene-scarlet," for example, although not absolutely euphonious, is still a much more pronounceable word than sodium xylene-azo-beta-naphthol-alpha-disulphonate; whilst "night blue" is far less mouth-filling than hydrochloride of tetra-methyl-tolyl-tri-amido-alpha-naphthyl-diphenyl carbinol! It is, however, to be regretted when new dye-stuffs are designated by names already well known in connection with substances of wholly different chemical character: thus *narceine* is ordinarily understood to refer to one of the alkaloids of the opium family; but the term has also been applied to one of the modern hydroxy-azo-naphthol dye-stuffs. In describing the matter treated of in this section, the author is well up to date, such recent introductions to commerce as Green's "primuline," and the various derivatives thereof obtainable *in situ* on cotton goods by the "in-grain" process, being included. Suggestions also as to the direction which scientific investigation might take in improving certain technical processes are not wanting: for example, in the case of indigo dyeing, it is stated that a certain amount of indigotin is always lost in the process of reduction to white indigo, and its subsequent reoxidation; the cause of the loss being obscure, its investigation would probably lead to means of preventing it which would well repay the trouble.

In every book, with the greatest amount of care and vigilance, slips and misprints will inevitably occur: thus on p. 165 it is stated that alkaloids generally have no marked alkaline reaction on phenol phthaleïn, so that the amount of acid combined in salts of morphine, quinine, brucine, aniline, urea, &c., can be ascertained by titration with standard *acid*, just as if no organic base were present: obviously standard *alkali* is intended. Similarly, on p. 234, methyl violet is described as "produced by the direct oxidation of dimethyl aniline (from dimethyl toluidine)": the production of dimethyl aniline from dimethyl toluidine is scarcely a commercial process, although the converse formation of toluidine and its homologues from methylated aniline by "intra-molecular interchange" is so. It says much for the care and attention bestowed by the author in revising that such errata are but seldom noticeable.

C. R. ALDER WRIGHT.

THE FLOATING ISLAND IN DERWENTWATER.

The Floating Island in Derwentwater: its History and Mystery. With Notes of other Dissimilar Islands. By G. J. Symons, F.R.S., Secretary Royal Meteorological Society. (London: E. Stanford, and Simpkin Marshall, and Co., 1889.)

IN this little volume, Mr. Symons calls attention to some very interesting problems connected with a curious phenomenon that can frequently be studied in our own well-known Lake District. It may at first sight seem strange that the peculiarities of this remarkable freak of Nature—for such it really seems to be—are not more widely known, or that systematic and persevering investigations, carried on by competent observers, have not long since removed all the difficulties which still stand in the way of a complete explanation of the causes to which the peculiar appearances are due. But it may at all events be hoped that—now Mr. Symons has so patiently collected and sifted the results that have been already arrived at by various investigators, and added the by no means unimportant facts he has himself observed—the reproach to British science of an imperfectly investigated and unexplained "mystery" at our very doors may at no distant date be removed.

The "history" which Mr. Symons so clearly lays before us is, briefly, as follows. As far back as authentic records can be obtained, there has appeared from time to time, in the south-east corner of the Derwentwater Lake, a small island, or islands, which, after a certain interval of time, have sunk again and disappeared. The place at which this phenomenon is exhibited is approximately the same at each reappearance—namely, a point off the mouth of the Derwent, and about 200 yards to the west of the place where the Cat Gill Beck pours its waters into the lake.

The ordinary depth of the waters of the lake at this point is about 6 feet; but the island, when it rises, appears a few inches above the level of the lake, and its surface is perfectly green with vegetation. The island is sufficiently firm to allow people to stand on it; and on one occasion a band landed on the island and played a selection of airs. The area of this island has been found to vary, on different occasions, from a few square feet up to two acres. Sometimes, several small islets have risen instead of the single one, and not infrequently the island has been found to be divided by one or more deep clefts.

Careful examination shows that the island consists of a peaty mass several feet in thickness, having its surface covered by living specimens of *Littorella lacustris*, *Lobelia dortmanna*, *Isoëtes lacustris*, and other water-plants that abound in this lake. It is also manifest that the island is merely the highest part of a great blister-like upheaval of the peat which here forms the lake bottom; and that, when this blister-like elevation subsides, the island is submerged and disappears.

When sticks are forcibly pushed into the materials composing the floating island, abundant bubbles of gas are given off, the evolution of the gas being accompanied by the production of a very perceptible odour.

During the 150 years or more, over which the records so carefully collected by Mr. Symons extend, there are nearly forty during which appearances of the island have been noticed. Sometimes, however, intervals of as much as ten years have elapsed without any appearance of the island; at other times the island has been seen for a number of years in succession; and not unfrequently it has risen and sunk several times in the course of the same year.

The island only rises in hot weather. By far the most common period for the appearance of the island has been the months of July and August; never has it been known to appear before June 5, and only once has it remained up after October 8. An examination of the temperature-records of the lake-waters and of the atmosphere in the neighbourhood points to the conclusion that the years marked by the appearance of the island are those in which the summer has been exceptionally hot.

To come now to the serious attempts which have been made to investigate the nature and causes of this interesting phenomenon. We may pass over the hasty and crude guesses of Hutchinson, Clarke, Budworth, and others, and notice first the valuable investigation of Jonathan Otley, the author of the well-known Lake-Guide. Otley had the great advantage of the advice and co-operation of the celebrated Dr. John Dalton, himself a native of the district, who analyzed the gases collected from the "floating island." Otley and Dalton's observations were made between the years 1814 and 1830.

In 1874, Dr. Alexander Knight, of Keswick, laid before the Literary and Scientific Society of that town a series of careful observations and judicious inferences concerning the floating island; and in 1876, Sir G. B. Airy took a number of bearings on the floating island, so as to fix its exact position.

Such was the state of knowledge upon the subject when the author of the present memoir took up the investigation. In August 1884 he visited the island in company with Prof. Sylvester and some other friends, and made a set of careful investigations concerning the position and size of the island, the nature of the materials composing it, the gases given off from it, and the temperature of the water around. A second visit, in August 1886, enabled the author to see the island when at the bottom of the lake.

In September 1887, Captain Wharton, R.N., F.R.S., Hydrographer to the Admiralty, obtained a section of the island by pushing a tube through the peaty mass forming the island itself down into the lake bottom. The peat was found to rest on a layer, only a few inches thick, of a diatomaceous earth.

The gases collected by Mr. Symons, Captain Wharton, and several other observers, have been analyzed by Dr. W. J. Russell, F.R.S. The results obtained are in close agreement with those of Dalton. The gas evolved appears to be a mixture, in nearly equal volumes, of marsh gas and nitrogen, with only small quantities of carbonic acid and oxygen. Dr. Russell points out that the composition of this gas is nearly identical with that of a "fire-damp" from Killingworth Colliery analyzed by Graham.

That the "mystery" in connection with the floating island of Derwentwater still remains unsolved is freely admitted by the author of the work. It would seem that during warm weather a sufficient evolution of gases takes place to cause the peaty bottom of the lake at this point to rise in a great blister. But what are the causes that give rise to this evolution of gas at this particular spot—an operation that has been repeated many times during the last 150 years—it is not easy to suggest. Equally difficult is it to assign a cause for the appearance of this phenomenon at a definite point with such remarkable persistency, while nothing of the kind has been observed elsewhere. The peculiarities of the lake-bottom at this place which may exist and may conduce to such a result do not appear to have been as yet determined.

Mr. Symons calls attention to the numerous floating islands at many different localities, which consist of accumulated masses of vegetation that have accumulated near a shore, and have subsequently broken loose. From all such cases, as he points out, the Derwentwater Island differs in three important particulars: (1) in being usually at the bottom of the lake, and only floating for perhaps one month in four years; (2) in being a part of, and remaining continuously united with, the bottom of the lake; (3) in always occupying the same spot.

It is to be hoped that this able summary of the whole evidence bearing on the question, which has been prepared by Mr. Symons, may not only attract more general attention to a very interesting phenomenon, but induce some investigator with the necessary knowledge and leisure to make such observations as are still necessary before we can hope for a complete explanation of the exact causes to which it is to be assigned.

A JOURNEY TO THE PLANET MARS.

Mr. Stranger's Sealed Packet. By Hugh MacColl. (London: Chatto and Windus, 1889.)

A WORK of fiction, founded upon scientific facts, is interesting to us, inasmuch as it may extend, to no inconsiderable degree, the scientific knowledge of its readers. Such attempts, however, to assimilate science with fiction may have an injurious effect, unless treated by one having an intimate knowledge of the phenomena which he describes, and we have to congratulate the author of this work upon his acquaintance with the Cosmos, exhibited in this account of an imaginary journey through interplanetary space.

The many means devised by that clever author, Jules Verne, for such a journey, are too well known to need any comment here. Mr. MacColl lacks the minuteness of description peculiar to Jules Verne, but nevertheless fabricates a "flying machine" that may rank with the best products of that author's ingenuity.

The principle employed is stated as follows:—

The attracting force residing in every particle of matter, and drawing it towards other particles, is capable of conversion into a repelling force.

A body, half of whose mass has had its attracting tendency converted into a repelling tendency, will have a specific gravity of zero, and if placed in a vacuum will neither rise nor fall.

If more than half the mass of a body has had its attracting tendency converted into a repelling tendency, it will rise into the air, and, passing the limits of the atmosphere, will continue moving away from the earth with a velocity for a time accelerated by terrestrial repulsion, but tending more and more towards uniformity as it proceeds.

The "flying machine" was constructed of a substance that had undergone such a conversion. By means of a regulator the resultant of the attracting and repelling tendencies could be turned in any direction, and so the velocity of the machine could be increased or diminished *ad libitum*.

It was in this machine that Mr. Stranger made his journey to the planet Mars, and the work mainly deals with Martian history, the customs of the inhabitants, and adventures and incidents *en route*. The two satellites of Mars were met, and their diameters, distance from their primary, and period of revolution are supposed to have been approximately measured by the adventurer. Having reached the planet in safety, a long description is given of the startling difference one would observe on attempting to walk upon a globe where the surface gravity was only three-eighths that of the earth.

The Marsians, Martians, or Marticoli, as Prof. Young would call the inhabitants of our ruddy brother, were, according to the author, living very happily under a form of Socialism; and food was almost as free and plentiful among them as the air which they breathed, because they had learnt to manufacture it from its chemical elements—oxygen, hydrogen, carbon, and nitrogen—which existed in abundance on their planet as on the earth. In this Utopia, not only were electric lights in every house and street, and the phonograph an instrument in common use, but the sound-figures drawn upon the revolving cylinder were used as the representation of speech, such characters being truly phonetic. It appears strange, however, that although the Martians had attained such a high degree of civilization, yet they had no knowledge of gunpowder or any explosive whatever, or of any kind of telescope, a circumstance which seems contrary to our ideas on the evolution of inventions.

The inhabitants of Mars were supposed to have come from the earth, and their transference was effected in the following manner. A sun, accompanied by satellites, in revolving at an immense distance round a larger sun passed very near to Mars and the earth, and caused them to approach one another. In the words of the writer, "The common centre of gravity of the four bodies must have been so situated as to have almost neutralized the resultant of the attraction of the earth and Mars towards their respective centres, so that on one part of the earth's surface the attraction of Mars would overcome that of the earth, and gently and slowly draw a body from its surface to its own; while in other parts the attraction of the earth would be more powerful and prevent this. The two planets must also have been so near that their atmospheres were mingled, and hence the transference did not result in the death of those who had thus to emigrate against their will."

Such an explanation as this, of some perplexing phenomena, shows an intimate knowledge of the laws of gravitation. Again, whilst on a visit to one of the small Martian satellites, a fragment of rock was broken off, and instead of at once falling down on the ground, as it would have done on the earth or Mars, it sailed slowly and gracefully away, until it came in contact with another rock several yards off, when it descended softly and gently to the ground with the motion of a falling flake of snow in a perfect calm—an imaginary incident in perfect accordance with the laws of gravitation. Many similar incidents are just as ably treated, and the description of a meteor is worth repeating here:—"Its general shape was globular, and before we had got close to it, it seemed a perfect sphere, but at this near distance it looked like a round mass of incandescent liquid covered all over with bubbling and boiling protuberances, which every now and then emitted huge jets of flaming gas, or, detaching themselves from the general mass, shot forth as globules of white shining liquid. We were, in fact, the spectators of the early formation of a little world, a sun in miniature, but resembling the sun rather as it was many ages ago than as it is now."

We might quote many other descriptions of phenomena all agreeing with acknowledged facts and rigid scientific principles. We refer to observations of the extreme blackness of the shadows cast by the rocks of the Martian satellite which was supposed to have been visited, the noiseless explosions of the meteor above described, the apparent motionlessness in space of the flying machine, in spite of its enormous velocity, the inferior attraction of Mars and its satellites, and the explanation of how men got transferred from the earth to Mars. Indeed, the work is as interesting to us as to the general reader, and as a means of disseminating scientific knowledge may be eminently useful.

R. A. GREGORY.

OUR BOOK SHELF.

The Uses of Plants: a Manual of Economic Botany, with special reference to Vegetable Products introduced during the last Fifty Years. By G. S. Boulger, F.L.S., F.G.S. (London: Roper and Drowley, 1889.)

THAT a good manual of economic botany is really wanted no one who knows anything of the subject will deny, and pending the appearance of a satisfactory book any contributions towards such an end must be accepted with thanks, always supposing that those contributions are trustworthy and intelligible. Articles by competent writers on the various products of the vegetable kingdom are to be found in encyclopædias, and occasionally special subjects are taken up and worked out by individual writers; but the great want is a thoroughly good book treating of the whole range of economic plants.

The little book before us, which comprises 224 pages, is not one that will help to such a desirable end.

The plan adopted by the author, of classifying the products under distinct heads, is undoubtedly the best; but it is not equally carried out in all parts of the work. Although, under "Food, Food Stuffs, and Food Adjuncts," we find the products divided under different sections, as starches, sugars, roots, fruits, &c., no attempt has been made to classify the individual plants mentioned under each head, whether alphabetical or scientific, while those under materia medica, oils and oil-seeds, gums and resins, are placed in some sort of scientific classification of the natural orders. Nor is the produce of one plant, though of a similar character, always to be found in the same paragraph. Thus, on p. 40, under roots and tubers, the introduction and importance of the potato are referred to, then comes a paragraph on each of the following: sweet potato, yams, Jerusalem artichokes, turnip, carrot, parsnip, beetroot, onion, parsnip-chervil, salsafy, and radish; and then, on p. 43, we have another paragraph referring to the potato, especially to the disease and the recent introductions of *Solanum maglia* and *S. Commersoni*, which would have been better placed with the account of the potato on p. 41.

On p. 59 the Souari nut (*Caryocar nuciferum*) is printed *Somari* nut, and said to be Camelliaceous. Though it is closely allied to the Camellia, it would have been more correct to call it a Ternstrœmiaceous plant. It is, however, for the meagre character of the information generally that the book is unsatisfactory. The following examples, taken haphazard, will illustrate our meaning:—

"The Coriander, the whole fruit of *Coriandrum sativum*, L., is cultivated to a small extent in Essex, but is obtained mainly from the Mediterranean and from India."

"The fruits of Angelica (*Angelica Archangelica*, L.) are used in Chartreuse, and the leaf-stalks are candied as a sweetmeat" (pp. 66-67).

Also at pp. 160-61, under "Dyes and Tanning Materials," we find the following:—"Betel Nut (*Areca Catechu*, L.) is recommended by Mr. Christy." "Canaigre is the root of the Texan Dock (*Rumex hymenosepalus*, Torrey), recommended by Mr. Christy."

"Mimosa extract was sent from Australia as early as 1823, but dropped out of notice till recently. In 1880 we imported £682,296 worth of various bark extracts" (p. 161).

Though the book is stated to have "special reference to vegetable products introduced during the last fifty years," very few dates of introduction are given, and a large number of the plants referred to were known and valued before the present century.

Examination of Water for Sanitary and Technical Purposes. By Henry Leffmann, M.D., Ph.D., and William Beam, M.A. (Philadelphia: P. Blakiston, Son, and Co., 1889.)

THIS volume contains a great deal of clearly stated information in its 106 pages. The authors have succeeded in the endeavour expressed in their preface to select trustworthy and practical processes, and to exclude the description of methods not generally employed, with other matters only remotely connected with the subject. So far as organic matter in water is immediately concerned, the "albuminoid ammonia" and the "oxygen-consuming power" are relied upon by the authors. Special prominence is also given to the estimation of chlorine, nitrogen as nitrates and as nitrites (by colorimetric processes), phosphates, dissolved oxygen, and poisonous metals. A general method of quantitative analysis for technical purposes follows, including the estimation of hardness alkalimetrically, after Hehner—rejecting soap solution altogether—and the estimation of boric acid, after Gooch, as well as the constituents that invariably receive attention. A carefully compiled chapter on the interpretation of results, and a few other matters, complete the volume.

Celestial Motions: A Handy Book of Astronomy. By William Thynne Lynn, F.R.A.S. Sixth Edition. (London: Edward Stanford, 1889.)

THIS is the sixth edition of an interesting little book, which explains briefly the principal facts relating to the motions of celestial bodies, and to the dimensions of those belonging to our own system. The information has been brought up to date, and an addition of a chapter on "The Calendar" has been made. In the chapter on the sun we are told that "the solar spots are produced by tearings open of some of the luminous envelopes which surround the sun, so that we see in them to a depth below that of the solar surface." To an ordinary reader this statement would be rather misleading, since no mention is made of the absorption of the sun's light by the descent of the cooler particles on to the solar surface from the upper regions of its atmosphere, the spots thus being made to appear dark and not bright. In chapter x. a short reference is made to the refraction, propagation, and aberration of light, while in chapter xii. we have a brief sketch of the history of astronomical discovery. The book concludes with an explanation of astronomical and technical terms.

Science Examination Papers. Part I. Inorganic Chemistry. By R. Elliot Steel, M.A., F.C.S. (London: George Bell and Sons, 1889.)

THIS work, intended for teachers, consists of a series of examination papers arranged in a progressive and logical order. It is divided into two parts, theoretical and practical, and is written, as the author tells us, "not as a cram-book, but as a means of testing the student's knowledge and progress." The first part treats of questions on hydrogen, oxygen, ozone, &c., followed by a set of general questions on the above, concluding with a collection of papers taken from various examinations, such as the London Matriculation, Science and Art Department, Oxford and Cambridge Locals, &c. Part II. deals with questions on simple and mixed salts and elementary quantitative analysis. The work is one of the "School Examination Series" edited by A. M. M. Stedman, and should prove serviceable to those teaching natural science in many of our schools.

A Course of Easy Arithmetical Examples for Beginners. By J. G. Bradshaw, B.A. (London: Macmillan and Co., 1888.)

THIS is a very elementary book, suitable for the use of young boys. It consists of a collection of simple arithmetical examples. The first part deals with examples in simple and compound addition, subtraction, multiplication, division, and reduction. Part II., which has been in use for over a year in the Junior School at Clifton, treats entirely of vulgar fractions; Part III., of decimals, practice, and proportion. The various tables used throughout are given at the beginning, and the results of all the examples are collected together at the end.

The Prospector's Hand-book. By J. W. Anderson, M.A., F.R.G.S. Fourth edition. Pp. 145. (London: Crosby Lockwood and Co., 1889.)

THE general plan of this book was described on a preceding occasion, so that at present it is only necessary to notice the changes in the new issue. The work, we are told, has been thoroughly revised and enlarged. The enlargement consists of about eight pages of descriptive matter, mainly referring to South Africa; but the results of the thorough revision do not appear to be very considerable. Nearly all the mistakes and ambiguities in the original descriptions of metallic minerals are unchanged. The author calls attention to an addition descriptive of aluminium and its ores, from which we gather that bauxite is a ferruginous clay, a statement that is both original and incorrect. On pp. 94 and 96, one ton is said to contain 29,166 troy ounces, while in the table, on p. 121, 1 per cent., in an assay return, is given as equivalent to 326 ounces 13 dwts. 8 grains per ton. The latter statement is right, the former one is wrong, but the author does not attempt to explain the discrepancy. Perhaps he will do so in the next issue.

H. B.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coral Reefs.

WITH reference to Captain Moore's two difficulties, I have to say:—(1) The position of banks around islands depends, in my opinion, on the nature of the rocks; loose material, or easily disintegrated rock, may be found either on the lee or weather side of an island. There are many examples of these banks in all positions around islands where there are no coral reefs. (2) I do not think it is the case that corals reach the surface simultaneously on all sides. What Captain Moore refers to as sunken reefs is good evidence that they do not. The great uniformity in the breadth of the reefs in some regions is, according to my view, due to the play between the forces secreting and depositing carbonate of lime, and those engaged in its disintegration and solution whenever the organisms have died. Reefs are very often non-continuous, as Captain Moore himself points out in the case of the Barrier Reef of Australia. This, too, I have explained in the same way, but taking into account local conditions. I cannot admit Captain Moore's supposition about the filling up of the lagoon around Solo, nor his explanation of the bank to the west of Ono. I have no charts with me here, so cannot at present refer to the other illustrations he has given.

Grangemuir, Pittenweem. JOHN MURRAY.

An Earthquake?

ON Friday, July 5, the inhabitants of Lyme Regis were much astonished by some noises, which took place at intervals between 11 and 11.15 p.m., and which there seems good reason to believe were caused by an earthquake. In three houses the occupiers thought that heavy pieces of furniture were being moved about, which was of course found not to be the case; and in another the inmates thought at first that something was wrong with the kitchen boiler. The noises observed consisted of a distant rumble which grew nearer till at last the windows of the houses rattled, and in some cases distinct vibrations of the houses were felt. Some have supposed that these noises were caused by guns at sea, but this seems impossible, because (1) the rattling of the windows occurred after the distant rumble, and not simultaneously as would have been the case with guns; (2) a gentleman who has had much experience in guns and firing, has declared that the noise was not like guns; (3) after making enquiries we have been unable to discover that any firing at sea took place that night; (4) although the night was still, a heavy ground swell was observed. These phenomena have not received any notice as far as we know in the public press, and it seems a pity, if an earthquake, as we believe, really took place, that there should not be some record of it.

Lyme. A. R. SHARPE.

The Excursion to the Volcanoes of Italy.

THANKING you for noting the intended excursion of geologists to the active and extinct Italian volcanoes under the auspices of the Geologists' Association and Geological Society of London, I would like to draw the attention of your readers to the remarkable changes at Stromboli which have lately occurred. New eruptive mouths have opened, and there has been an outflow of lava, a phenomenon so far unknown (so far as recorded) from 2000 to 3000 years. There is an uncertain reference to such an occurrence, but the change at Stromboli from Strombolian to Vesuvian activity is remarkable. I am also informed that the eruption of Vulcano still continues with paroxysms of greater activity. Thus the excursionists will have the advantage of seeing changes that, even for a constant resident in such a region, are rare. H. J. JOHNSTON-LAVIS.

Naples, July 15.

Seismology in Italy.

I WAS glad to see that Prof. Grablovitz had laid claim to attention for some of his other memoirs which I had not at that time seen, and which are of much value. I would especially draw the attention of seismologists to his study of the relationship of temperature and outflow of a thermo-mineral spring at Porto d'Ischia to the tides and barometric pressure.

In my article I only reviewed those memoirs placed in my hands by the Editor of NATURE, or sent to me privately. I may, however, say that as near as possible a complete review of all the papers on seismology and vulcanology published during 1888 is being prepared by me for the *Annuaire Géologique Universel* of this year. I should therefore be glad to receive any other papers on those subjects, that have not been sent to me, as soon as possible. H. J. JOHNSTON-LAVIS.

Naples, July 15.

The Earthquake of Tokio, April 18, 1889.

READING the report on this earthquake in NATURE (June 13, p. 162), I was struck by its coincidence in time with a very singular perturbation registered by two delicate horizontal pendulums at the Observatories of Potsdam and Wilhelmshaven. These instruments, which represent, with some modification, Prof. Zöllner's horizontal pendulum, were established in March 1889, for studying the slight movements of the ground. The motion of the pendulum, which is left to oscillate freely whenever its equilibrium is disturbed, is registered by the same photographic method as that employed for magnetic observations. The pendulum is in the plane of the meridian, so that any shock, the direction of which is not in this plane, will produce oscillations of the pendulum, diminishing gradually, if it is left undisturbed after the shock. The pillars supporting the instruments are fixed in a depth of 1 metre below the ground of the cellar which was chosen as a suitable place for the erection of the instrument.

During the three months from April to June, the disturbance of April 17, 18h. G.M.T., was the most remarkable which occurred The following readings of Greenwich mean time, which are best explained by the accompanying figures, are taken from the original photographs; it must, however, be mentioned that the small scale of 11 millimetres per hour does not allow a very accurate determination of time, and that an error of one minute or two is quite probable.

(1) *Potsdam.*—1889, April 17. From 5h. until 17h. 21m., great steadiness of image.

h. m.	
17 21	First traces of disturbance.
17 39	Beginning of small oscillations.
17 54·3	Motion *suddenly* increases and reaches its maximum at
18 1	Amplitude of oscillation 154 millimetres. The amplitude then suddenly diminishes.
18 43 18 58 19 45	Maxima of oscillation.
20 0	Perfect steadiness of image.

(2) *Wilhelmshaven.*—Here, also, the image is perfectly steady until 17h. 30m.

h. m.	
17 30	Beginning of small oscillations.
17 48–17 51	A short interval of perfect steadiness.
17 51	The movement *suddenly* increased, and as the light is not strong enough to mark the single oscillations, the image disappears until
18 38	when the principal disturbance reaches its end.
18 51 19 6 19 22 20 2	Maxima of small oscillations.
20 7	Perfect steadiness.

If we compare these dates, it seems most probable that the moment which shows a sudden increase of motion, and is best marked on the curves, may be considered as the beginning of the principal disturbance. We thus have—

For Potsdam ... ... 17h. 54·3m. }
For Wilhelmshaven... 17h. 51m. } Mean, 17h. 52·7m.,

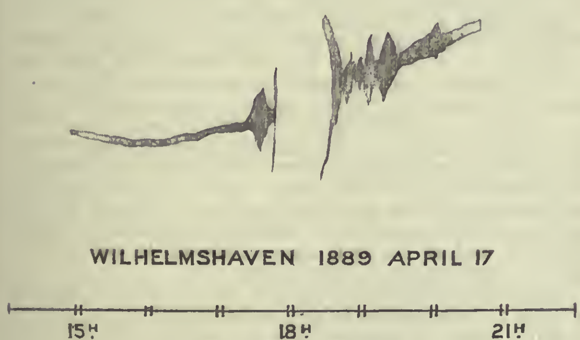
which, considering the error of the readings, may be taken as one and the same moment.

The beginning of the earthquake of Tokio was observed at 2h. 7·7m. Tokio M.T. The difference of longitude (taken from a map) being 9h. 19·3m. E., we find that the shock occurred at 16h. 48·4m. G.M.T. on April 17, and thus it took 1h. 4·3m. to travel across the body of the earth.

Taking the following longitudes and latitudes—

Tokio	139° 50′ E.,	35° 44′ N.
Potsdam	13 4 ,,	52 24 ,,
Wilhelmshaven	8 9 ,,	53 32 ,,

1889 APRIL 17. GR.M.T.
POTSDAM.



GR. MEAN TIME.

and neglecting the ellipticity of the earth, we find the following distances:—

Tokio to Potsdam	8221 kilometres.
Tokio to Wilhelmshaven... ...	8307 ,,

Dividing the mean 8264 by 3858s., we find a velocity of 2142 metres of propagation on the straight line connecting Tokio and a place between Potsdam and Wilhelmshaven, and consequently the shock ought to have been observed at Wilhelmshaven 40s. later than at Potsdam.

The above value of velocity is between the values found by Milne from seismic experiments, viz. 900-1400 metres for different kinds of rock, and by Abbot from the effect of dynamite explosions, viz. 2800 metres. We may therefore safely conclude that the disturbances noticed in Germany were really due to the volcanic action which caused the earthquake of Tokio.

Potsdam, July 5. E. VON REBEUR-PASCHWITZ.

P.S.—I add a list of the most remarkable disturbances noticed during the course of the observations. Unfortunately, the working of the instrument at Wilhelmshaven was often disturbed by the effects of an excessive dampness in the cellar. The time is G.M.T. as above.

1889, April 5.—A day of great steadiness. A small perturbation begins at 9h. (Potsdam) and 9h. 5·4m. (Wilhelmshaven). It is divided by a short time of steadiness, 9h. 11·4m. (Potsdam) and 9h. 16·8m. (Wilhelmshaven).

April 8.—A fine disturbance begins at 16h. 45·6m. (Potsdam) and 16h. 47·4m. (Wilhelmshaven).

April 15.—A day of remarkable unsteadiness; the principal perturbation at both places lasts three hours, and lies between 7h. and 10h. It is impossible to determine a certain phase.

April 25.—A perturbation from 16h. 48m. to 18h. 12m. at Potsdam. No photograph obtained at Wilhelmshaven.

April 28.—An earthquake, consisting of one principal shock, apparently took place at 21½h.; the times noted are 21h. 34·8m. (Potsdam) and 21h. 36·6m. (Wilhelmshaven).

May 21.—A pretty large disturbance at Potsdam, lasting from 10h. 33m. to 11h. 6m., interrupted by a moment of rest at 10h. 42m. No photograph at Wilhelmshaven.

May 25.—Two very remarkable disturbances at Potsdam—7h. 9m. and 10h. 42m.—each lasting 1h. No photograph at Wilhelmshaven.

May 26.—A disturbance noticed at Potsdam, at 9h. 24m. No photograph at Wilhelmshaven.

May 30.—At Wilhelmshaven, two shocks are noticed—8h. 18·6m. and 9h. 24m.—which are probably connected with the English earthquake of this day. Perfect steadiness at Potsdam.

May 31.—A disturbance of earthquake-like appearance. Time of beginning, at Potsdam, 8h. 48m.; at Wilhelmshaven, 8h. 44·4m.; the latter time being rather uncertain, on account of the faintness of the curve.

I hope that one or other of these facts may prove to be of interest to seismologists.

On the Phenomena of the Lightning Discharge, as Illustrated by the Striking of a House in Cossipore, Calcutta.

DURING a heavy thunderstorm which passed over Calcutta about 5.30 p.m. on Saturday, June 8 last, the house of Conductor W. Viney, at Cossipore (a suburb of the city), was struck by lightning, and I have thought that a description of the phenomena connected with it might perhaps be worth placing on record in the columns of NATURE.

I was myself watching the storm from the veranda of my residence about 300 yards distant, and observed that the discharge in question was one of extreme violence. I visited the scene of the accident within a few hours, with Mr. Viney's permission taking the notes from which this account is prepared; and, owing to the exceptional opportunities for observation which obtained in this case, have been able to secure trustworthy statements as to the appearance of the discharge, and further, by inquiry, to satisfy myself upon one or two points which I believe to possess considerable scientific interest.

The house which was struck is large, square, and flat-roofed, and is occupied by three foremen employed in the Government Shell Factory adjacent: it is provided with a lightning-conductor projecting 8 or 9 feet above the roof-level, and situated near to one end of the building, but apparently unconnected with any other portion of the roof. It is possible that a portion of the discharge passed harmlessly away by the conductor, but of this I have no evidence, positive or negative. The lightning entered Mr. Viney's portion of the house by a corrugated iron covered hatchway standing 6 feet high at the corner diagonally opposite to the conductor, and about 70 feet distant from it in a direct line: leaving the iron cover and its wood lining untouched, it broke through the masonry, hurling portions of the brickwork to a distance of 25 feet along the flat roof; then, bridging over 3 or 4 feet of air, it reached the iron hand-rail of a spiral wooden staircase leading into the house. Incidentally, it may here be noted that this house is the nearest to the factory, which bristles with lightning-conductors at every available point; and, further, that the charged cloud would in its course pass over the portion struck before it could reach either the factory conductors or that on the house itself. Passing down the hand-rail for 11 feet, it reached a point at which metallic continuity ceased, owing to the interruption of the hand-rail; here it appears to have divided, a portion leaping along 5 feet of the wall and stripping off the plaster in patches, until it reached the second section of the hand-rail; through this it passed harmlessly, and then flew through 2 feet of space to an iron rod resting in the corner of the wall, perforating a wooden "stair-rise" on its path. The other portion discharged through about 7 feet of space in the angle of the wall direct from an iron standard, supporting the first hand-rail, to the iron rod; here, reuniting with the other portion, the whole current broke through the wall into an adjoining bedroom, and thence through the wood flooring to a sitting-room beneath. It may be observed that the spiral staircase at one time communicated with the ground-floor, but has since been filled in and covered over; there is no evidence, however, to show that any portion of the charge made earth in this direction. Within a few feet of the point where the ceiling was penetrated (but round a corner) is a broad staircase with a wooden handrail, supported by uprights of iron rod placed about 4 or 5 inches apart from top to bottom; but this path was not taken. Having penetrated to the sitting-room, as above described, it appears to have passed in a direction precisely opposite to that ultimately taken, and to have circled in a spiral manner around one of two brick pillars at that end of this room, and having laid bare the bricks in several places, but chiefly at a height of 4 feet from the ground, it passed across the room in which Mr. Viney was sitting with seven members of his family and friends, and upwards to the ceiling at the opposite end. Breaking through the ceiling (which is, as usual in these houses of wood, not of plaster), it burst up the boarding and singed the matting above, and again descended, but now into the dining-room on the other side of a partition wall. Here, darting diagonally downwards to the opposite wall and stripping off a large area of plaster in one place, it made for an electric bell suspended in the centre of this wall, fused the contacts, and apparently passed along the connecting wire to the battery, of which two out of six cells were shattered, and finally escaped through a return wire to a cookhouse 30 yards distant in the compound. Strangely enough, these wires, although thin, are not fused, which serves to strengthen the opinion that only a portion of the charge penetrated at least into the lower rooms, even if the whole entered by the spiral staircase.

The path of the discharge from the first entrance into the sitting-room to the final exit by the bell-wire is somewhat inexplicable—especially the circuit of the brick pillar, which is said to be of solid masonry, with no iron core; it is true that a sewing-machine was standing on the further side of the pillar, but although within a few inches of the patch denuded of plaster, it appears to have been unaffected. Again, there were several metallic objects in the room—an iron chair close to the abovementioned pillars, and a square horizontal piano with the strings parallel to the line of discharge, yet both were untouched; the occupants of the room also were practically in the same line, but were perfectly uninjured. Then, too, there was apparently nothing to lead the lightning through the ceiling boards to gain access to the dining-room in preference to an open door a few feet distant. And, lastly, it did not pass across the latter room in a direct line to the electric bell, but struck the wall about 5 feet away, tearing away the plaster and leaving upon the bricks a netted marking recalling the branching discharges of a torrent of sparks from an induction-coil or Wimshurst machine; near this point, but a few inches to one side (the bell side) and in front, was a pendent iron chain, which may have determined the charge in that direction, but shows no sign of having been touched; and immediately beneath the spot through which the lightning entered the room was standing a member of the household, who also escaped with a severe shock to the nerves and a temporary tingling sensation. Attached to the affected pillar in the sitting-room was a cuckoo clock, and this alone in that room appeared to suffer; the weight chain was taken in transit, and the clock began vigorously to chime, which it has refused to do ever since.

Mr. Viney happened to be facing in such a direction that he could watch the progress of the discharge. He describes the effect as that of an intensely brilliant ball of yellow fire, about 6 or 7 inches in diameter, which passed from one end of the room to the other at a pace just sufficiently slow to allow it to be readily followed by the eye; about half-way across, it appeared to be momentarily checked, and then, seeming to burst with a deafening report which shook the whole house, it scattered and passed onward.

About certain points he is absolutely certain: there was no premonitory warning, no sound of a brush discharge or odour of ozone, the first intimation being the entrance of the fire-ball itself. Again, the direction taken was from the staircase to the bell (that is, from cloud to earth), and the direction was uniform, and no second ball was seen to enter from the opposite side to meet the first and so produce the apparent explosion, nor after the concussion was there any other phenomenon than the passing on of the ball.

Again, it has long been known that the passage of high tension discharges through mixtures of oxygen and nitrogen induced combination of these elements; I therefore asked Mr. Viney as to the after appearances, and as to the presence of unusual coloured gases, or of a suffocating sensation. He at once said that the whole house seemed to be filled with an orange-coloured gas (mixed, of course, with clouds of dust), the breathing of which was perfectly stifling, and was equivalent to inhaling the fumes from burning sulphur. I have since asked him to report upon a sample of nitrogen tetroxide highly diluted with air: he declared that the gas in his house was of a brighter orange shade, and of a somewhat similar yet not identical odour; on presenting him, however, with a stronger mixture, he was quite confident that both in colour and in smell the two gases were identical. I am here practically confined to my own library for books of reference, but am not aware that this observation has actually been made before, although, as above stated, theory has long since ruled that such a reaction must occur during the electrical discharges of a thunderstorm. But the proof is here not only that the reaction does occur, but that a very large proportion of the oxygen in the atmosphere immediately surrounding the path of the flash must be converted into oxides of nitrogen.

The appearance of the fire-ball was only within the house. The discharge as seen from my position appeared as an almost straight ribbon of light; owing unfortunately to intervening trees, the flash could not be traced quite to the house, or the question as to the branching of the lightning on entering the house might have been definitely answered.

Several points seem to be thus clearly brought out, *e.g.*, *inter alia*, (1) the futility of partial lightning-conductor protection; (2) the apparently erratic nature of the discharge; (3) the apparent conversion of the instantaneous discharge of ribbon-lightning into the slower travelling modification of globe-lightning; (4) the formation of large volumes of oxides of nitrogen by the lightning discharge.

The above recorded observations might appear to add colour to an authoritative statement on p. 629 of Nystrom's "Pocket-book of Mechanics" (Philadelphia and London; revised and enlarged edition of 1886), where, in speaking of certain explosions, the author (or at least the printer) lays down that "the explosion of nitro-glycerine is instantaneous like that of electricity passing between two points, decomposes a small portion of the air, and explodes the nitrogen by concussion, which makes the electric spark. Thunder and lightning are explosions of a kind of nitro-glycerine formed by electricity in the air." We might even be led to indorse this both novel and ingenious explanation could we but bring ourselves to reverse existing notions as to the properties of matter and the laws of thermochemistry, and, at the same time, reconstruct the principles of electrical science upon a suitable basis.

The accumulation of authenticated cases such as the above is of value in throwing more light upon the vagaries of the "electric fluid" at enormous potential, and in helping to elucidate the laws under which it acts, and hence the laws which should govern the protection of buildings; and it is in the hope that this account may form a small item in the mass of evidence, that I venture to forward it for publication.

The Circulation of the Atmosphere over the Equator.

ABSENCE from home has prevented my seeing Mr. Foulger's letter on this subject till to-day.

The observations on the upper winds over the doldrums, which I have described in NATURE, were taken in about 5° N. latitude and 28° W. longitude, and the whole section of the trades and doldrums lay in a line drawn from St. Vincent to Rio Janeiro.

When I stated that "low clouds from south-east flew over the north-east trade up to 15° N.," I meant to say that while the surface-wind from the doldrum to 15° N. was the north-east trade, the low or middle layers of cloud moved from south-east, all along the line of the section above noted.

Unfortunately I am unable at present to give a general scheme of the circulation of the atmosphere, though I have worked at the subject for years; and my recent observations in the Andes, from Peru to Cape Horn, throw much new light on the question.

What we do know is that the surface trades either die out at the doldrums, or unite into one moderate east current; that the low and middle currents over the doldrums are very variable, but that the wind at these low and middle levels—say 2000–20,000 feet—come usually from the south-east over the north-east trade, and from the north-east over the south-east trade; and that the highest currents—over 20,000 feet—move from east over the doldrums, from south-west over the north-east trade, and from north-west over the south-east trade. We also know that the high-level south-west and north-west winds near the equator gradually descend to the earth's surface about 30° N. and 30° S. respectively.

What we do not know is the relation of the south-east low and middle current over the north-east trade to the south-east trade on the other side of the equator, nor have we yet discovered what becomes of this middle current in the northern hemisphere. In like manner the origin and ultimate destination of the middle north-east current over the south-east trade is equally a matter for future research.

Of course, all meteorology turns round the general circulation of the air through the heating of the equatorial regions, but what I maintain is that the simple scheme which assumes nothing but an upward current over the doldrums and a return current towards each Pole is not confirmed by observation. The reality is more complex, for the centre of the high doldrum current is from the east, but diverges at the edges from south-west and north-west.

The discovery of the true nature of the general circulation of the atmosphere from the equator to the Pole—apart from any theoretical considerations—is a matter of so much importance for the future of meteorology, that I hope all future travellers across the equator will note carefully the direction of the clouds in low latitudes. I know this is somewhat difficult on board ship for want of a steady point of reference; but those whose zeal prompts them to look out between 5 and 6 in the morning, and from 6 to 7 in the evening, will usually find the moon, or some bright star, by means of which the direction of the cloud-motion can be accurately determined. Above all things, the relative, and if possible the actual, level must be carefully noted; and the observations should not be recorded as we so often see—wind north-east, clouds south-west—without any indication as to whether the south-west current is at a low, middle, or high level.

RALPH ABERCROMBY.

Changed Environment.

IT is generally known that the English sparrows were introduced into the United States on the supposition that they were insect feeders, and would protect our trees from the canker-worm. For the first time in my remembrance, I have seen one attack a caterpillar this summer. Their usual food appears to be the seeds found in horse-manure on the streets. They are now universally conceded to be an unmitigated nuisance, not doing their assigned work, and preventing others from doing it. They usurp the place of the more charming native birds, the blue-bird, the wren, and the Baltimore oriole, once common in our cities. Still, we have to confess that the sparrows are interesting little creatures, aggressive and pugnacious.

I was lately told of a circumstance, which I can myself now confirm. An "American robin" was seen watching a beetle, known here as the "June bug," that had just emerged from the ground. He tossed him about with his bill, and was closely watched by a sparrow who had alighted about a foot away. Seeing the latter, the robin at once attacked him, when the sparrow made a dive between his legs, seized the beetle and flew away. A robin rarely hunts for earth-worms, of which robins are especially fond, without being followed by one or more sparrows. These often get the worm for which the larger but less agile bird has laboured.

Another matter suggests itself to me. Mr. Wallace in his new and delightful book on "Darwinism," which reawakens one's old enthusiasm, says that many plants live "not where they must, but where they can." The natural habitat does not always appear to be the best. Thus, *Lobelia cardinalis*, so common in our Rhode Island woods, is always found on the brink of running streams, or where these *have* been, or near water. It is in such sense aquatic. But, removed to a garden, it will grow vigorously and multiply astonishingly exposed to full sunlight and in ordinary loam. Indeed, the plants prefer to escape from the beds into the gravelly paths. They will overrun a garden.

Aster Novæ-Angliæ is not one of our most abundant asters, but in a garden it will crowd out all else. The seedlings spring up even in the dry soil loved by *Plantago major*. *Viola pedata*, which grows naturally in sand, will flourish and increase in size by cultivation, becoming as handsome as a pansy. *Corydalis glauca* grows in nature on hot exposed rocks and cliffs; it will grow larger and better, and set seed abundantly, in rich loam.

I could multiply instances of such changed environment where the result was beneficial. W. WHITMAN BAILEY.

Brown University, Providence, Rhode Island, U.S.A., July 2.

Lamarck *versus* Weismann.

I SHOULD like to call the attention of those interested in organic evolution to a remarkable passage in Mr. Wallace's recent volume on "Darwinism." This work is throughout an argument in defence of Darwinian principles, in their original unmodified form as stated in the "Origin of Species," in opposition to all recent criticism or development of those principles. And yet on p. 129 the author publishes the following passage:—"Now the eyes of these fish (Pleuronectidæ) are curiously distorted in order that both eyes may be on the upper side, where alone they would be of any use. It was objected by Mr. Mivart that a sudden transformation of the eye from one side to the other was inconceivable, while if the transit were gradual, the first step could be of no use since this would not remove the eye from the lower side. But, as Mr. Darwin shows by reference to the researches of Malm and others, the young of these fish are quite symmetrical, and during their growth exhibit to us the whole process of change. This begins by the fish (owing to the increasing depth of the body) being unable to maintain the vertical position, so that it falls on one side. It then twists the lower eye as much as possible towards the upper side; and the whole bony structure of the head being at this time soft and flexible, *the constant repetition of this effort causes the eye gradually to move round the head till it comes to the upper side.* Now if we suppose this process, which in the young is completed in a few days or weeks, to have been spread over thousands of generations during the development of these fish, those usually surviving whose eyes retained more and more of the position into which the young fish *tried to twist them*, the change becomes intelligible."

A Lamarckian could accept the above passage almost without altering a word. The words I have italicized describe with absolute precision the muscular effort of the fish as the active cause, both of the individual and the ancestral metamorphosis. And yet, in chap. xiv., Mr. Wallace expresses his acceptance of Weismann's dogma of the non-inheritance of acquired characters with the words, "We cannot therefore accept any arguments against the agency of natural selection which are based upon the opposite and equally unproved theory that acquired characters are inherited; and as this applies to the whole school of what may be termed Neo-Lamarckians, their speculations cease to have any weight." J. T. CUNNINGHAM.

July 19.

Bored Stones in Boulder Clays.

STONES bored by *Pholas* and *Saxicava* are by no means rare in the shelly "Basement clay" of East Yorkshire, and I have occasionally found examples in which the shells remained in the borings surrounded by fossiliferous sand, just as described by Mr. T. Mellard Reade from the Lancashire area. These stones are generally limestones of various kinds—Carboniferous, Magnesian, Jurassic, or Cretaceous—and the diversity of their origin seems to show that they have first been scattered over a shallow sea-bottom by floating ice, and afterwards perforated, but I do not think that they can be taken as proof of the marine origin of the boulder clay in which they now lie.

The same boulder clay contains many detached valves of bivalve shells, and these very frequently still hold a pinch of sand under the umbo, though themselves firmly embedded in hard clay; and in one case I found, under such conditions, a perfect shell (*Tellina balthica*), with valves united, enclosing similar sandy material.

It seems to me very difficult to explain by any theory of floating ice how this sandy matrix could have been preserved in the holes of the stones and under the valves of the shells, while it is easy to understand how this might take place through the agency of land ice advancing over a sea-bottom.

Before the culmination of the glacial period, while yet the ice was encroaching upon the sea-bed, and long before it had reached its greatest extension, there must have been a vast quantity of floating ice in the waters, which would drop stones and other material over the sea-bottom; and there must also have been a great extrusion of matter from the various glaciers. And as the ice advanced this material would necessarily become part of the *moraine profonde* of the glacier, and would be more or less mixed up with the old sea-bottom, but the resulting boulder clay could scarcely be called marine. G. W. LAMPLUGH.

Bridlington Quay, July 15.

Mr. Lydekker on Phenacodus and the Athecæ.

IN his article on *Phenacodus primævus* in NATURE of May 16 (p. 57), Mr. Lydekker expresses his disbelief in my opinion that that animal is nearly related to the immediate ancestor of the line of the Quadrumana, and of man. I am somewhat surprised at the positiveness of Mr. Lydekker's expression, as he must be aware of the difficulties that still surround this part of the question. What may be known about it is as follows:—

First, I have always been careful to avoid the assertion that the genus *Phenacodus* was in the direct line of descent of man. When I first traced the ancestry of the Quadrumana, I indicated the sub-order Condylarthra as its source (*American Naturalist*, 1885, p. 347; "Origin of the Fittest," 1887, p. 343), not the genus *Phenacodus*. On a subsequent occasion I restricted the range of probable ancestry to the family *Phenacodontidæ* (*Naturalist*, 1888, p. 663). In the advertisement to which Mr. Lydekker refers, I say of the *Phenacodus primævus*, "Representative of type believed to be the ancestor of all hoofed Mammalia, monkeys, and man." Mr. Lydekker's reference to this advertisement is slightly different.

Second, Mr. Lydekker objects to regarding *Phenacodus* as within the ancestry of the lemurs and man, because it appears to have no clavicle. To this proposition two replies may be made. The first is, that it is by no means certain that it had no clavicle. The second is, that if it had none it is not certain that that fact would exclude it from the ancestry of the Quadrumana; certainly it would not exclude some near ally of the same family or sub-order which possessed a clavicle. On these points I remark further.

Third, nothing can be determined from the specimens as to whether the *Phenacodus primævus* or *P. wortmani* had clavicles or not. None were found, but this part of the skeleton was disturbed in both specimens. Thus the clavicles, if present, may have been like those of some Carnivora and Rodentia, connected with the manubrium sterni and scapula by soft tissue only, and so have been readily lost.

Fourth, the presence or absence of clavicles is not important in a systematic sense. It is not available as a definition in the orders Edentata, Rodentia, Insectivora, and Carnivora, where, as is well known, it may be present, rudimental, or absent. And in the phylogenetic history of a line, I see no reason why clavicles might not lose and later recover their osseous tissue under suitable stimulation.

Finally, I believe that the Condylarthra are in the direct line of ancestry of the higher apes, so long as no better objections can be found than those raised by Mr. Lydekker. Another objection exists which he has not pointed out; viz. the absence of anapophyses of the vertebræ. But this objection loses much point when we remember that anapophyses are also wanting from the vertebræ of the anthropoid apes and man. What their status was in the anthropoid lemurs (*Anaptomorphus*) we do not yet know. Moreover, a trace of the anapophysial structure does exist in both species of *Phenacodus*, as a fold continuous from the posterior border of the neural arch over the centrum. As regards the clavicle, it is highly probable that it is present in some of the genera of the Condylarthra, and even of the *Phenacodontidæ*, such, for instance, as *Protogonia*, but we know too little of the structure of the skeletons of several allied genera, to enable us to determine the points in question. On the presence or absence of anapophyses in such genus of Condylarthra will depend the solution of the question whether the descent of man passes through *Anaptomorphus* or *Adapis*, or some other undiscovered form of Quadrumana, to the anthropoid apes.

While on this subject I refer to Mr. Lydekker's reference to my term Athecæ (Testudinata), as "ungrammatical." He declares that the grammatical form should be Athecata. Now, while the latter expression is perhaps grammatical, it is not more so than the one which I elected to use. It is probably well known to Mr. Lydekker that scientific names are written in Latin, and not in Greek. The singular Atheca, although derived from the Greek, becomes Latin by scientific use and usage, and is declined, genitive *æ*, and nominative plural *æ* also. See Latin words derived from θήκη, as Bibliotheca, -æ. I used the substantive form, which is more usual than the adjective, in making scientific names. E. D. COPE.

Philadelphia, July 1.

Systematic Position of the Characeæ.

THE position in a natural system of classification of this small and strongly-differentiated group of aquatic plants has been so long a subject of controversy, that any additional light upon it will be welcome to vegetable physiologists. I therefore desire to call the attention of my fellow-botanists to the remarkable paper by M. Guignard, "On the Development and Constitution of the Antherozoids of Cryptogams," in the early numbers of the new botanical journal edited by M. Bonnier—the *Revue Générale de Botanique*. It is true that these observations only confirm the earlier ones of Thuret; but the care with which M. Guignard has worked out the subject, and his beautiful drawings, tend to emphasize the results previously obtained.

No one who compares the drawings of the antherozoid of *Chara fragilis* in Pl. 2 with those of *Fellia epiphylla* in Pl. 3 can fail to be struck with their remarkable resemblance. Each is a long, corkscrew-shaped body, with a pair of very long and slender vibratile cilia attached to its anterior extremity. The mode of development of the antherozoid is also the same in all essential particulars in both cases, and is thus described by M. Guignard. The body of the antherozoid proceeds from the nucleus of the mother-cell, and moreover gives all the micro-chemical reactions of nuclein. The vibratile cilia are derived from the cytoplasm. A thickening band first appears on the surface of the nucleus, and grows longer and longer, forming eventually a kind of beak, and the whole nucleus becomes twisted spirally as it increases in length. As soon as the outlines of the anterior extremity of the filament are discernible, the two cilia may be perceived in the thin layer of hyaline protoplasm which is nearest this extremity. Later on, the cilia, which at first lie close to the filament, become separated from it, and the rest of the protoplasm gradually disappears, being absorbed and used up for the nutrition of the antherozoid, so that only a few granulations are left on the posterior extremity of the filament. The only difference of any importance between the antherozoids of Characeæ and those of Muscineæ is the absence in the former of a vesicle formed from the cytoplasm of the mother-cell.

If now this is compared with the figures (Pl. 5) of the antherozoids of *Fucus serratus*, and the account of their mode of development, it will be seen how wide are the differences in many essential points between the corresponding processes in Characeæ and in the higher Algæ. These facts seem to me strongly to corroborate the view which I have on several occasions ventured to bring forward, and to support by other considerations, that the Characeæ are more nearly related to the Muscineæ than to the true Algæ.

I may mention in conclusion that M. Guignard adopts the revised terminology which I have advocated, of *antherozoid* instead of "spermatozoid" for the male fecundating organs of most Cryptogams, and of *pollinoids* (or rather *pollinides*) instead of "spermatia" for the corresponding organs in the Florideæ.

ALFRED W. BENNETT.

Make-believe.

I CAN well believe in Sally meaning a joke. Animals have a keen sense of "making believe" which is the essence of *play*. A child's first game is bo-peep—a make-believe. When a pair of friendly dogs have a jolly tussle, they make believe to engage in deadly combat.

A striking instance of this occurred to me some years back. I gave a dead mouse to a kitten. It was the first time she had seen one, and she sniffed at it inquisitively before deciding on tossing it about. A pair of slippers lay on the floor. She dropped it into one of them, and *immediately* proceeded to look for it most zealously in the other slipper, till I took up the first, which contained her booty; then she showed that it was no real lack of memory that had sent her on the bootless search.

The law allowed to game, when hunted for recreation, is perhaps the most marked evidence of the make-believe element which is to be found in the play of civilized adults.

Dublin, July 16. MARCUS M. HARTOG.

Dogs and Fire.

AN unrecorded type of the pluck of the fox-terrier was demonstrated to me recently. A young dog two or three years old, the property of Mr. Doyle, of Loretto Terrace, Bray, goes for fire with as much zeal as any of his race go for rats. When a newspaper thoroughly ablaze is thrown down, he stamps upon it with frequent short rushes till it is extinguished, and then worries the scorched remains before asking for a fresh opportunity. He gets excited and keen on being shown a crumpled newspaper or a match-box.

The possibility thus shown of educating dogs to tackle fire gives additional point to my friend Dr. Sigerson's published suggestion to use dogs as companions to night-watchmen, based on their keenness of scent. MARCUS M. HARTOG.

Dublin, July 16.

"The Theorem of the Bride."

REFERRING to the last paragraph of the review of my "Greek Geometry from Thales to Euclid" which appeared in NATURE of June 20 (p. 172) it may interest some of your readers to know that since the publication of my book I have found the expression—τὸ τῆς νύμφης θεώρημα—in the Scholia on the "Elements of Euclid." See "Euclidis Elementa," ed. Heiberg, vol. v. p. 217, Lipsiæ, 1888.

The expression seems to have been a common name of Euclid i. 47. GEORGE J. ALLMAN.

Belsito, Milford, Lymington, July 18.

RECENT RESEARCHES INTO THE ORIGIN AND AGE OF THE HIGHLANDS OF SCOTLAND AND THE WEST OF IRELAND.[1]

I.

THE records of geological history, like those of the human race, become more fragmentary and illegible, the farther back we trace them into the past. While the younger rocks of the earth's crust have been made to yield a more or less connected story of geographical and biological evolution, the oldest rocks have till comparatively lately been neglected, or have been tacitly left to mere speculation and conjecture. Only within the last few years have these ancient formations been seriously and sedulously attacked by scientific methods of inquiry. Though the progress of investigation has necessarily been slow, a steady advance in knowledge can be chronicled. There is a curious fascination in this department of geology. These venerable rocks reveal to us the oldest known part of the outer shell of our planet. The palimpsest of the earth's surface has been written over again and again during the long ages of geological history; but down among these bottom-rocks we reach the earliest recognizable inscriptions, and come as near towards the beginning of things as geological evidence by itself is ever likely to lead us. These records carry us back to a time anterior to that of the oldest fossiliferous formations, possibly to an epoch that preceded the appearance of vegetable or animal life on the globe. They reveal to us the very foundations of the earth's crust, on which all other known rocks rest, and out of the waste of which the greater part of these rocks has been formed.

Within the last ten years, after prolonged misconception and neglect, the most ancient rocks of the British Isles have come to occupy a foremost place among the researches of the geologists of this country. The tracts where they are now exposed to view, often among the wildest mountains, or "placed far amid the melancholy main," have become favourite geological hunting-grounds, and have furnished a notable amount of material for those disputes and combats which seem to form a necessary element in geological progress. Avoiding, as far as possible, matters of controversy, I propose this evening to offer a brief outline of the actual state of knowledge, up to the present time, of the history of those ancient crystalline masses of which our north-western mountains are composed.[1] The story is a somewhat involved and complicated one. But its main points may perhaps be conveniently grasped, if we bear in mind that they naturally group themselves into four sections: (1) the Archæan period; (2) the Cambrian period; (3) the Lower Silurian period; (4) the period of the younger Schists.

Let me at the outset remark that in the investigation of these early ages of geological history we enjoy in this country a special advantage. The British Isles stand on the oceanic border of a great continental region. They are therefore placed along that critical belt where not only have terrestrial disturbances been especially numerous and violent from the earliest geological times, but where an oscillation upward or downward of a few hundred feet has sufficed to make all the difference between land and sea. In the heart of a continent, as, for example, over the vast plains of Russia, long cycles of geological time have passed without serious disturbance of any kind. To this day some of the ancient Palæozoic sediments in that region, for hundreds of square miles in extent, lie as level as when they were deposited on the sea-floor. They have been uplifted bodily into land, but still remain little more than mere hardened mud and sand. In Western Europe, on the other hand, where from the remotest geological antiquity the oscillations and dislocations have been innumerable, every successive continental uplift has recorded itself in some crumbling or fracture of the rocks. Hence in the geological map of that region the various formations form a pattern of exceeding complexity, while in the maps of Eastern Europe each of them covers a broad unbroken expanse.

I.—*The Archæan Period.*

The oldest known rocks of Europe, now generally termed Archæan, are well exposed along the north-western borders of the continental area from the extreme north of Scandinavia, by the west coast of Scotland, to Galway Bay in the west of Ireland, a total distance of some 1600 miles. They give rise to topographical features which, where fully developed, strongly distinguish them from all younger formations. Nowhere else can such extraordinary unevenness of surface be found. Knobs, hummocks, and ridges of bare or almost bare rock, separated by narrow gullies or by wider winding valleys, roughen the ground in every direction. In the hollows lie innumerable tarns and lakes, or flat tracts of bog where lakes once were. In some districts, indeed, there is as much water as land in a given number of square miles. On a large scale, this type of scenery is perhaps

[1] The Friday evening lecture delivered at the Royal Institution on June 7, by Dr. Archibald Geikie, F.R.S.

[1] It would be obviously out of place to include here references to the voluminous literature of the subject. A condensed summary will be found in the Report by the officers of the Geological Survey, Quart. Journ. Geol. Soc., vol. xliv., 1888.

best displayed in Finland; on a small scale, it is repeated all through the chain of the outer Hebrides, as well as on the Archæan areas of the mainland. The most southerly points in Scotland where it can be recognized are the Island of Iona and the Ross of Mull. It reappears, however, far to the south in Ireland; standing out in the bold cliffs from Erris Head to Achill Island in the west of Mayo, and finally covering an area of more than 500 square miles in South-Western Galway. In this last-named district, as Prof. Hull has shown, so completely are the scenic features of the north-west of Scotland reproduced, down even to the minutest details, that the geologist, even before he stands on the rocks, has no difficulty in deciding that they can only be Archæan.

What, then, are these most ancient rocks of North-Western Europe, and what has been their history? Unfortunately, the answer to these questions cannot be succinctly and definitely given. Owing to the antiquity of the masses, and the prolonged series of geological revolutions which they have undergone, their original characters have been somewhat effaced. In those areas where they have been least altered, and where, therefore, they approach nearest to their primitive structure, they have been found by my colleagues of the Geological Survey to be crystalline rocks, such as gabbros, diorites, and other highly basic compounds. These occur in zones or bosses surrounded by and passing into rocks which have acquired the peculiarly banded structure characteristic of gneiss. That these various rocks were eruptive—that is, that they originally formed portions of igneous material that rose in a molten or plastic condition from below—can hardly be doubted. They remind us of the deep-seated portions of some of the eruptive bosses so abundantly intruded into the crust of the earth, and now so plentifully exposed at the surface after prolonged denudation. Like these, they show a rudely striped or banded arrangement suggestive of the planes of movement or flow-structure seen in consolidated igneous material. They have probably resulted from successive protrusions of eruptive rocks at some depth within the crust of the earth.

Nowhere, however, in the region to which I am referring, has any trace of superficial eruption yet been detected. There are no true volcanic ejections, nor any evidence that the rocks, though certainly of eruptive origin, were ever connected with the ordinary explosive operations of volcanic vents. Not only so, but after the most careful search from Sutherland to Galway not a vestige have we yet found of any unquestionable sedimentary material. There are no conglomerates, no sandstones, no shales; nor even any materials that might be supposed to represent these in a metamorphosed condition. Of the actual surface of the earth these Archæan rocks afford no recognizable trace. They obviously did not form the superficial layer themselves. They must have lain deep under a cover of other material, under which they acquired their crystalline structure, and by the subsequent removal of which they have been exposed to the light.

One of the most impressive features of our recent researches among these rocks is the evidence of the magnitude of the interval of time between their original protrusion and the formation of the next group of rocks overlying them. Of the many breaks in the geological record, none is more complete than this. We pass at one step from Archæan rocks, dating no doubt from an early stage in the consolidation of the crust of the planet, to the gravelly and sandy deposits of an inland sea, which already present all the familiar characters of the sedimentary accumulations of later geological time.

Some of the more prominent events in this protracted interval may be more or less clearly discerned; others can only be dimly conjectured. Arranging in chronological order the more important which have lately been recognized by the Geological Survey, I would direct your attention to four main episodes in the Archæan history of our North-Western Highlands.[1]

In the first place, the crust of the earth over that region was thrown into a series of low arches or folds, the axes of which ran in a general north-east and south-west direction. Its component rocks were crushed and sheared, so as to acquire the banded and crumpled structure of typical gneiss. Perhaps we may trace to these primæval terrestrial movements the first shaping of the European continent, which certainly has grown from north to south. At all events, it is interesting to note that the undulations into which the rocks were thrown took that north-easterly trend which is still so marked in the long belt of crystalline schists from the North Cape all the way to the west of Ireland.

In the second place, after these early disturbances, and probably long after them, a remarkable series of manifestations of plutonic energy occurred. The region extending from the north-west of Scotland to the west of Ireland was convulsed by the production of innumerable dislocations in the solid terrestrial crust, having a general west-north-west direction. Up these gaping rents, molten basic lava rose from some subterranean reservoir, and solidified in broad dykes of black basalt. Some of these dykes can be traced for ten or twelve miles, till they run out to sea at the one end and pass under younger overlying formations at the other. Yet again, at a somewhat later period, another series of fissures was opened slightly oblique to the direction of the first; and, in these, still more basic lava formed a second series of dykes trending nearly east and west. Nor was this all, for there followed a third period of convulsion, which gave birth to a series of huge dykes of granite.

Whether or not any of the eruptive material that filled these successive fissures ever rose to the surface and flowed out there, or gave rise to the explosive phenomena of true volcanic vents, cannot be certainly affirmed. But an interesting piece of evidence points to the probability that such a connection with the surface was really established. In some of the conglomerates of the next succeeding group (Cambrian or Torridon sandstones), there occur fragments of highly vesicular lavas, which show that at some time previous to the deposit of these coarse sediments, active volcanic vents existed somewhere in the region of the north-west of Scotland. As yet, however, no trace has been discovered of any of the lava streams which flowed out at the surface.

Although volcanic energy has long been quiescent over the British Isles, probably no area in Europe exhibits within so limited a space so long and varied a record of volcanic eruptions. There is, therefore, a peculiar interest about these traces of the ancient volcanoes which in Archæan time rose along the Atlantic border in the north-west of Scotland, for they stand at the very beginning of that long history. Moreover, so far as we can interpret their remains, they seem in a curious way to have anticipated the characteristics of the last great volcanic episode in Britain—that to which we owe the Tertiary basaltic plateaux of Antrim and the Inner Hebrides. In both cases the distinguishing feature was the fissuring of the terrestrial crust and the uprise of basic lava in the rents, with the consequent production of innumerable parallel dykes trending in a general north-westerly direction.

In the third place, after the production of the basic dykes, there came another prolonged interval, during which a series of remarkable terrestrial disturbances affected the north-west of Scotland. The crust of the earth in that part of Europe was once more dislocated by innumerable fissures, produced probably at successive epochs of paroxysm, for they can be grouped into three distinct series. Of these, one runs approximately parallel

[1] Those who wish fuller details on this subject will find them in the Survey Report already quoted.

with the north-west dykes, the second trends east and west, and the third runs north-east and south-west, or north and south. So far as yet discovered, no lava of any kind welled upwards into these fissures. They are ruptures, but not dykes. They were accompanied, however, by the manifestation of another form of terrestrial energy, the geological efficacy of which has only recently been recognized. The lines of vertical fracture became also lines of horizontal or oblique movement during the vast strain of terrestrial contraction. One side was driven past the other side, and with such irresistible force that the rocks for some distance on either side were dragged into the line of movement, crushed down, and forced to assume a new crystalline arrangement of their materials. The basalt dykes, reduced sometimes from a width of 50 or 60 yards to only 4 feet or less, were changed into diorites, and where the shearing was greatest, into hornblende-schists. The gneiss, in like manner, was thrown into sharp folds, and had a newer foliation developed in it parallel with the new planes of movement.

In the fourth place, during the prolonged succession of changes which I have thus briefly summarized, there must have been in progress a continuous denudation of the surface of the Archæan land in the north-west of Europe. Doubtless, each of the subterranean disturbances more or less affected the surface. The land was by degrees ridged up above the sea, and its height and breadth were probably from time to time increased by local uplifts accompanying the disturbances. But as soon as the land appeared, it began to be attacked by the waves, the air, rain, and running water. Terrestrial convulsions were intermittent, but superficial waste continued uninterrupted. Whatever may have been the character of its topography, the first formed land, as soon as it rose, became a prey to the denuding forces, and had its original surface gradually stripped off. We have no means of telling how great a thickness of material was in this manner removed from the land before the time of the next geological period, nor for how vast a time this slow process of denudation went on. All that we can now discover is a series of detached fragments of the surface of this primæval Europe, which have been preserved by being buried under the pile of material formed out of the waste of the Archæan rocks. From these fragments we learn that the rocks had been enormously denuded so as to lay bare to the surface some of their deep-seated parts, the land shaped out of them having been carved into dome-shaped hills and basin-like hollows, not very different from those which are so characteristic of the Archæan tracts to-day.

II.—*The Cambrian Period.*

We now reach the base of the stratified formations of the British Isles, and enter upon a series of records which deal not with subterranean but with superficial changes, and in which the earliest geographical conditions of our area are more or less fully chronicled. These records consist of a pile of dull-red sandstones, conglomerates, and breccias, with grey, green, and black mudstones, marls, and shales, attaining a maximum thickness of perhaps 10,000 feet. This great accumulation, chiefly of coarse sediment, was derived from the waste of the Archæan land. The pebbles in its conglomerates are fragments of that land, and enable us to form some conjecture as to the nature of the materials that composed its surface. An examination of these pebbles brings to light the important fact that besides the detritus of the gneiss and other Archæan rocks which can now be seen *in situ*, the conglomerates are made up of materials derived from some still older sedimentary formations which have entirely disappeared from our area. These included such rocks as quartzite, greywacke, shale, and limestone, besides abundant pieces from the lavas, which I have already referred to as having probably been erupted to the surface in pre-Cambrian time. The destruction of these intervening deposits, and the chance discovery that they once existed because fragments of them have been found in later conglomerates, serve to impress upon us the imperfection of the geological record, and the vastness of the intervals of time which may sometimes separate two successive groups of rock.

The thick mass of red sandstone and conglomerate which rests directly on the Archæan gneiss forms some of the most singular scenery in the north-west of Scotland. Owing to vast denudation, which began before the next group of strata was deposited, it has been worn down into isolated mountains, which rise like a chain of colossal pyramids along the western shores of Sutherland and Ross. The almost level lines of stratification give to these eminences a look of architectural symmetry, in striking contrast with the more tumultuous aspect of the other rocks of the region, while their red tone of colour marks them out boldly from the wastes of grey gneiss below and the crags of white quartzite beyond. From the far northern cliffs of Sutherland these massive red sandstones can be followed almost continuously to the southern headlands of Skye. They reappear in great force in the Island of Rum, beyond which they are not certainly traceable. A group of highly altered grits and schists, seen under the great basaltic plateau of Gribun, on the west side of the Island of Mull, may mark their extreme southerly limits.[1] The red sandstones certainly do not come so far south as Iona, and not a trace of them has been met with in Ireland. They extend westwards across the Minch, for a small portion of them skirts the eastern shore of the Long Island. How far they may have stretched eastward cannot now be determined, for their limits in that direction have been obscured or effaced by the extraordinary series of gigantic earth-movements to be afterwards referred to. There can be little doubt, however, that they did not reach the district east of the line of the Great Glen, though they not improbably lay in thick mass over much of the country to the west of that valley.

We cannot now trace the original limits of these red rocks, yet we can hardly doubt that they never covered an area at all comparable in extent to that of the rocks below and above them. They appear, indeed, to have been accumulated in one or more basins, shut off from free communication with the open sea, where the deposition of ferruginous precipitates among the ordinary mechanical sediment could go on during the deposition of many thousand feet of rock. Such conditions of sedimentation were not very favourable to the existence of life in the waters of these inclosed basins. Nevertheless, that the waters were not entirely lifeless is shown by the discovery of organic remains on two widely separated horizons among the sandstones. These remains occur in grey and dark shales, the colour and composition of which suggest a temporary influx of water from without, and the cessation for a time of the deposition of the iron-oxide. At the lower horizon the fossils consist of calcareous rods, the organic grade of which is still in dispute; at the higher they include some doubtful impressions and the casts of worms. The fossiliferous bands are to be more thoroughly searched this summer, and it is hoped that something more determinable may be obtained from them.

Nevertheless, indistinct though these relics undoubtedly are, they may claim the interest which arises from their being at present the very oldest traces of organized existence yet found within our islands. Murchison classed the red sandstones of Western Sutherland and Ross as "Cambrian," inasmuch as he found them to

[1] My attention was called to these rocks by the Duke of Argyll, who himself suggested their possible Cambrian age. I visited them this spring, and found them to be greatly metamorphosed. They do not appear in Iona, where the base of the sedimentary series is found resting on the Archæan gneiss.

underlie unconformably strata containing what he believed to be Lower Silurian fossils. It is not improbable, however, that they belong to an older time than any of the Cambrian rocks of Wales.

That the red sandstones of the north-west of Scotland were laid down in shallow water seems to be clearly indicated by their current-bedding and ripple-marks, as well as by the occurrence of bands of conglomerate among them on many successive horizons. Yet they retain these characters throughout a depth of some 10,000 feet. We can walk over their edges and count every successive stratum for a thickness of more than 3000 feet along the sides of a single mountain. How, then, could such a continuous mass of shallow-water deposits be accumulated? I am not sure that any wholly satisfactory answer can be given to this question, which is one that arises in the investigation of various epochs of geological history. That the basins must have been due to local subsidence can hardly be doubted. We may suppose that this downward movement continued at the same time that the ridges which bounded the hollows continued to be forced upward. New shore-lines would thus be brought to the level of the water, and coarse shingle might be swept down upon previously deposited fine sediment. If occasionally the barrier between the basins and the open sea were partially submerged, the muddy ferruginous water of the inclosed tracts might be cleared out, and the denizens of the sea might for a time enter them. Possibly the grey and dark shales may mark these irruptions of the ocean.

That similar conditions of geography prevailed at that period in the extreme north-west of Europe is indicated by the fact that in Norway a group of red sandstones and conglomerates, known as the "sparagmite rocks," is interposed between the Archæan gneiss and the oldest of the fossiliferous formations. In these Scandinavian rocks we probably see traces of the extension of similar inclosed water-basins along the eastern border of the primæval Atlantic Ocean northwards among the hollows of the Archæan land.

Before the next great geological period these basins had been entirely effaced, and the geography of the region had wholly changed. This transformation is probably traceable to two causes. First, the terrestrial movements which led to the formation and continuance of the basins may in the end have caused their extinction by raising them into land, and possibly at the same time by folding and fissuring their accumulated deposits. Secondly, as soon as these deposits, whether split open or not, were exposed to the atmosphere they would begin to be worn down. That erosion took place during a prolonged period, and to a vast extent, is shown by the fact that in some places the thick cake of sandstone was hollowed out down to the Archæan platform below it before the next succeeding formations were deposited. Here again we are presented with a striking example of the imperfection of the geological record.

(*To be continued.*)

THE PRIVATE LABORATORY OF MARINE ZOOLOGY AT RAPALLO.

THIS very modest zoological station does not in the least pretend to compete with the splendid ones of Naples, Plymouth, Roscoff, Banyuls, &c. Considerable sums are needed to build and keep up such establishments, so that their numbers will necessarily be always very limited.

We have thought that with relatively little expense it might be possible for zoologists to procure in great part the advantages that these larger stations offer, and to concur in their action, by establishing a certain number of small stations on favourable spots of the Italian coast. Our idea is to have dependencies of the zoological laboratories of the nearest Universities, almost as if parts of those laboratories were transported to the sea-shore. The cost of these stations would not be very great. All that is strictly necessary is a room with good light, and as near as possible to the sea, provided with small aquariums, with the usual pump, with fishing apparatus, and the ordinary furniture of every laboratory, except microscopes and other costly instruments, which every investigator would bring with him. The books also might be reduced to the treatises and the "Faunæ" ordinarily used. It is indispensable that the station should possess at least one boat for short excursions: for deep dredging, and for longer excursions that are less often made, the necessary vessels could be hired.

By these modest means notable results might be obtained. Almost all anatomical and histological researches would be possible, the inquirer either making them entirely on the spot, or limiting his work to the first observations that ought to be made on specimens freshly caught, and preparing the materials for later and more leisurely study.

Stations of this sort already exist abroad, such as the laboratory of marine zoology of Wimereux, the Netherlands movable station, the station of Misaki in Japan, &c.

In Italy, Prof. Kleinenberg proposed to found a station of this kind at Messina, but of greater proportions, hoping that it might serve principally as a school for beginners; but unfortunately his idea has not yet been realized. Neither has anything come of the project of Count Alessandro Ninni to establish a station at Venice that might serve at the same time for purely scientific researches, and for practical studies on the industrial cultivation of sea animals.

Convinced of the utility of small stations, we have made an experiment in forming one which we will now describe.

Unwilling to go too far from Turin, we have chosen the little town of Rapallo on the Eastern Riviera, near Genoa. It is situated at the end of the gulf of the same name, is one hour's distance by boat from Portofino, that marks the extremity of the gulf towards Genoa. The Gulf of Rapallo is pretty well sheltered from the winds; the shores are rather rocky, and vegetable and animal life is very various and abundant. It also presents notable variations of depth. From Rapallo to the extremity of the gulf, a distance of 4 kilometres, the depth gradually reaches 90 metres, and at a like distance in the open sea of Portofino, the depth is more than 400 metres. The movement in the haven is limited, and hence the waters even near the town are clear. As to the town, it is beautifully situated, and the neighbouring places are various and very pleasant. It is also a very quiet town, where the greatest liberty can be enjoyed.

Our station occupies a space of a hundred square metres, and it is placed a few metres from the sea, on the ground where the docks formerly stood. In this space, inclosed by a wooden palisade, is the little building which looks like a *chalet*, the lower part in brick-work, with wooden walls and a roof covered with zinc. The edifice consists of only one large room, 7 metres in length, and 4·50 in width (inside). The height up to the wooden ceiling, that is under the roof, is about 4 metres. One of the longer walls is turned to the north. A window, consisting of nine large divisions, runs the whole length of this wall; and against this wall is placed the working-table, which also occupies the whole length; at it six persons can work. The door is on the shorter side that looks on the sea; over the door is placed the reservoir of sea-water capable of containing more than 800 litres; it is filled by a small rotatory pump. By means of pipes the water is brought from this reservoir into the aquariums that are placed in the middle of the room on an iron support of two stories, provided with the necessary discharge-pipes to carry off the water that has circulated in the aquariums. Against the shortest wall, opposite that in which the door is placed, there is a table covered with porcelain for chemical manipulations. Above this table there is a reservoir of fresh water. In the middle of the room, behind the support of the aquariums, are two tables covered with marble. Against the wall opposite the window are the shelves for the instruments and for the collections. One corner is set apart for the principal fishing implements.

The station has a boat, the *Bonellia*, that serves for short excursions, and for researches in shallow water. The fishing implements consist principally of trawl-nets for the depth, nets for surface fishing, apparatus for extracting masses from the bottom, sieves, nets, harpoons, &c. These implements have been made expressly at Naples, under the supervision of Dr. Paolo Mayer, of the Zoological Station.

The station is also provided with numerous aquariums for study, and with the necessary chemical apparatus. The library is limited to the more common and useful treatises, and to a certain number of memoirs concerning the marine fauna.

We hope that even by these simple means it will be possible to obtain satisfactory results. Many important works on marine zoology have been produced far away from zoological stations under less favourable conditions than those of our little station.

WEISMANN ON THE INHERITANCE OF INJURIES.[1]

IN an address to the Naturforscher-Versammlung at Cologne, last autumn (now published in a compact pamphlet of fifty-two pages), Dr. Weismann examined the evidence for the inheritance of injuries. In earlier works he has shown that the facts of organic evolution can be explained without the hypothesis of the inheritance of acquired characters, and his theory of the germ-plasma as the basis of heredity is hardly compatible with the traditional and Lamarckian view. The supporters of the old view have laid great stress upon the transmission of the effects of injuries. A great many of the cases relied on rest on merely anecdotal evidence, and Weismann examines and dismisses many types of them. Such, for instance, is the case adduced by Dr. Zacharias, and quoted by Eimer, of a tailless cat which produced tailless kittens. Nothing whatever of how the mother lost her tail is known, and nothing is known of the father. Tailless kittens appearing suddenly in villages have been traced, more than once, to an imported male of one of the many tailless breeds. In any particular case, it is as logical to refer the appearance of tailless kittens to a hypothetical mutilation of the mother, as it would be to deduce from the many-toed Oxford cats that Mr. Poulton had fixed additional toes on the paws of their ancestor!

Weismann made an elaborate series of experiments on mutilation. On October 17, 1887, he had the tails removed from seven female and five male white mice. On November 16 the first brood appeared. These, and all subsequent broods, were removed from the cage. Up to December 17, 1888, 333 young were born, and in none of them was there any sign of the mutilation being inherited. In cage 2, fifteen young, of December 2, 1887, were placed, their tails having been removed. These, up to December 17, 1888, produced 233 young, all with normal tails. In cage 3, fourteen young of the second generation, with tails removed, were placed; and up to December 17, 1888, they produced 141 young, all quite normal. The experiment was carried, with a negative result, down through five generations of mutilated animals. The length of tail of new-born mice varies from 10·5 millimetres to 12 millimetres. In the series of experiments, 849 young were produced by mutilated progenitors, and in no case was a mouse produced with its tail less than 10·5 millimetres.

The author points out that, while it might be said that experiments through a far greater number of generations were needed, the so-called cases of inheritance of mutilation all imply that the mutilation is impressed on the immediately following generations. A mother breaks her finger, and her daughter has the joint of the corresponding finger imperfect. A cow has her horn torn off, and, in due course, gives birth to a one-horned calf.

Moreover, there are many cases of mutilations which have been made for hundreds of years without result. For instance, Settegast shows that all the crows but the rook have bristly feathers on their beaks. Rooks, too, have these feathers while nestlings; but, later on, they lose them by perpetually pushing the beak into the ground in search of food.

There are a great many cases which at first sight appear to prove the inheritance of injuries. As an example of how easy it is to be deceived, Weismann relates that a friend had a vertical scar (with comb-like striæ) on the left ear, the result of a sword-wound. On the left ear of this gentleman's daughter was a curiously similar marking. But it was ultimately noticed that on the right ear of the father was an appearance precisely similar to that on the left ear of the daughter. On closer examination of the father's left ear there was seen, under the scar, a linear streak, from which the striæ ran, forming a comb-like structure. It was this, doubtless a congenital variation, and not the accidental scar, that the daughter had inherited.

It is impossible to give, by extracts, an adequate conception of Dr. Weismann's ingenious analysis and masterly collation of evidence. There is enough in it to satisfy the most conservative of biologists (at least without a theory) that the transmission of injuries must be handed for ever to the "scientific novelist" and the jaded melodramatist. With them it may flourish, and rescue many a doubtful heir, and secure the happiness of many a heroine in the third volume, or before the curtain falls.

It is not so certain that all will admit Weismann's contention that the demolition of the inheritance of injuries furnishes strong presumptive evidence that acquired characters are not inherited. It might well be urged that there is a great distinction between characters which are obviously not useful (such as injuries) and useful characters. It is clear that if acquired characters are inherited it would be of the highest utility if the inheritance were selective. The tiny piece of ancestral germ-plasma increases exceedingly during the ontogeny. Has the distinction between germ-plasma and somatic plasma passed sufficiently out of the region of theory to let us infer, from the non-reflection of injuries during the process of growth, that all acquired characters are not reflected? Can we hold that, were acquired characters reflected, injuries too must be reflected? It is a question, on the one hand, of the nice adjustment of fine probabilities; on the other, of elaborate, long-continued, and specially directed observation. But, whatever is the final answer of science, this essay will be not the least of the author's many valuable contributions to it.

P. C. M.

[1] "Ueber die Hypothese einer Vererbung von Verletzungen." Von Dr. August Weismann, Professor in Freiburg i. Br. (Jena: Gustav Fischer, 1889.)

COAL AND TIN DISCOVERIES IN WESTERN AUSTRALIA.

MR. HARRY P. WOODWARD, Government Geologist for Western Australia, sends, under date May 28, 1889, some interesting particulars of both coal and tin discoveries in that colony. He writes:—

"From Vasse I made for the Lower Blackwood River Bridge, over the foot of the Darling Range, and so on to the Donelly River. On the south coast, where a small stream flows out, called the Fly Brook, coal has been found of a very good quality, but there is no port nearer than Albany or Vasse, and this latter is not a good one. There seems to be a line of coal-bearing country between the coast-range, which runs north and south from Cape Leeuwin to Cape Naturalist, and the main highlands, the southern continuation of the Darling Range; much of it covered with sand and swamps at the surface, but under which I believe we shall find coal-measures which may, in fact, extend west beneath Perth to the Irwin River, but this can only be tested by deep borings.

"There was nothing to be seen of the coal or rocks, as they are boring with a 'jumping-drill,' which reduces everything to mud, but there is one 5-foot seam and several smaller, averaging 17 feet of coal in 200 feet of rock. There are two or three outcrops in the bed of the Creek of a much weathered but good coal, some of which is highly bituminous. From Bridgetown I went to Albany, and thence east 200 miles to the Phillip River, and saw the Fitzgerald Coal-field. This is only brown coal or lignite of no value, but there is some good-looking gold-bearing country near it."

TIN-ORE.—In reference to the tin discoveries, Mr. H. P. Woodward writes:—

"From Bunbury I went towards the Upper Blackwood, to a place called Bridgetown, where tin has been found. Little work has been done yet, but, as far as I am able to judge, it seems to indicate the biggest thing of the kind that has ever been found. One shaft, 18 feet deep, will wash all the way down at about 4 or 5 pounds to the pan, and they have not got to the bottom of it yet. The richest works in other colonies are rarely more than 2 or 3 feet deep. Tin has been found at the surface, in the sand, over an area of about 100 square miles, but no sinking, except the one shaft, has yet been made; and as the surface is covered, either with sand or clay-ironstone, the formation cannot be seen at all. The late Mr. Edward T. Hardman suggested that tin would be found here. The shaft shows a few inches of soil or alluvium with gravel containing tin, where it was first found, resting on hard masses of clayey ferruginous sandstone, about 1 foot thick, then coarse quartz-grit with stream-tin and tourmalines and a few 'colours' of gold. 17 feet not gone through yet, as there was too much water, about $\frac{1}{6}$ in weight being tin-ore." H. W.

NOTES.

THE Committee appointed to consider the basis upon which the grant of £15,000 a year for University Colleges in Britain should be distributed have recommended that the grant should be divided as follows:—To Owens College, Manchester, £1800; to University College and King's College, London, £1700 each; to Liverpool University College, £1500; to Mason College, Birmingham, the Yorkshire College, Leeds, and Nottingham University College, £1400 each; to Bristol University College, the Durham College of Science, Newcastle-on-Tyne, and Firth College, Sheffield, £1200 each. The Committee are of opinion that University College, Dundee, should be dealt with in connection with the Scottish Universities, and especially with the University of St. Andrews; but they recommend that it should for the present year have a grant of £500.

A TESTIMONIAL is to be presented to Prof. Kennedy by his former students on the occasion of his resignation of the Chair of Mechanical Engineering at University College, London. A committee has been appointed to receive subscriptions, and no doubt many persons will be glad to have this opportunity of expressing gratitude for the profit they have derived from Prof. Kennedy's instructions. The Chair from which he is retiring he has held during the last fifteen years.

IN answer to a question put by Mr. Acland in the House of Commons on Monday, Mr. W. H. Smith said the Government were aware of the great interest taken by the country in technical education, and the pressing importance of dealing with it. They had been engaged during the previous few days in endeavouring to find some solution of the difficulty which surrounds the question in regard to elementary schools, but, he regretted to say, without success. The Government therefore proposed to introduce at once a measure dealing with the higher branch of the subject.

AT a general meeting of Welsh members, held at the House of Commons on Tuesday, for the purpose of conferring with Sir W. Hart-Dyke on the Intermediate Education (Wales) Bill, the Vice-President of the Council announced that, provided all the amendments on the paper were withdrawn, the Government were willing to accept an arrangement whereby the Education Council to be constituted under the Bill should consist of five members—three to be nominated by the County Councils, and two by the Education Department. Were the meeting to agree to this, then the Government would use their best efforts to pass the measure into law before the end of the session. The proposal thus made was debated at some length, and was finally adopted.

THE half-yearly general meeting of the Scottish Meteorological Society was held yesterday in Edinburgh. The Council of the Society presented its report, and the following papers were read:—"Proposed Investigation of the Numbers of Dust Particles in the Air at the Ben Nevis Observatory," by Prof. Tait; "The Distribution of Temperature over the Globe," by Dr. Buchan.

AT the last meeting, this session, of the Royal Society of Edinburgh, the Chairman, Prof. Chrystal, in closing the business, said that, during the period, 86 papers had been read, of which 21 had been in the department of natural philosophy, 16 in mathematics, 7 in chemistry, 2 in geology, 6 in zoology, 6 in botany, 23 in physiology, 2 in astronomy, and 3 in meteorology. A good number of these papers had come from the newly-instituted laboratory in the College of Physicians, and he congratulated that body on the public spirit manifested in the opening of the laboratory, and on the excellent results that followed. Eighteen new members had been added to the roll, the average in the three previous years having been 36; and 7 ordinary and 2 honorary members had been lost by death.

THE floral *fête* of the Royal Botanic Society, held on the 15th inst., to celebrate the jubilee, is a fitting occasion to recall the memory of the founder, Mr. Philip Barnes, who originated the idea, and planned and carried into execution the installation of the Society. The faculty of creation is not given to everyone. Due honour should therefore be given to those who, endowed with it, use it for the interest of science and the public good.

AT the Congress of Physiological Psychology, to be held in Paris (August 5–10) the following subjects will be discussed: muscular sense; *rôle* of movements in formation of images; is the attention always determined by affecting states?; statistical study of hallucinations; the appetites in idiots and imbeciles; are there in insane persons motor impulsions independent o images and ideas?; psychical poisons; heredity; heredity of emotional phenomena and their expression; heredity of peculiarities in the perception of colours; heredity of special memories and of special aptitudes (technical, artistic, scientific); psychological analysis of some genealogical tables; hypnotism; causes of errors in observation of phenomena of hypnotic suggestion; normal and hypnotic sleep; motor power of images in hypnotized subjects, and unconscious movements (automatic writing, &c.); doubling of personality in hypnotism and mental alienation; phenomena of transfer; precise terminology in questions of hypnotism. (Communications to M. Richet, 15 Rue de l'Université, Paris.)

THE Leaf-insect of the Seychelles lately living in the Zoological Society's Insect House, which we figured in our issue of May 30 (p. 105), has unfortunately died, before attaining complete development. But specimens of two other scarce Orthopterous insects have lately been added to the collection. Many examples of one of the curious Stick-insect (*Diaphemora femorata*) of North America have lately been hatched from eggs received from Mr. Williams, of Toronto. The young insects are feeding well on the leaves of the common hazel and grass, and some of them have already attained a considerable size, while others are still emerging from the ova. Besides these, two examples of a very singularly shaped form of Mantidæ from South Africa (*Harpax ocellata*) have just been received from Colonel J. H. Bowker, of Durban, and appear likely to do well. A third object of considerable interest, lately lodged in the Insect House, is a fine example of the Cocoa-nut Crab of the East Indies (*Birgus latro*), presented by Commander Alfred Carpenter, R.N. This is a terrestrial Crustacean of peculiar structure, which subsists entirely upon vegetable food, and is said to be able to open cocoa-nuts. Darwin has given an interesting account of its habits in his "Naturalist's Voyage," and Prof. Moseley met with it in one of the Philippine Islands during the voyage of the *Challenger*. The Zoological Society's example appears to prefer bananas to other food, but has also eaten some lettuce.

M. DESCHAMPS, a French zoologist, has, says the *Ceylon Observer*, arrived at Colombo from Singapore. He has been sent out by the French Government to study the zoological features of the Laccadive Islands, but as it is almost impossible to reach them during the south-west monsoon, he will spend two or three months in Ceylon, during which time he hopes to pursue his researches in various parts of the island. About October he will make his way to the Malabar Coast, and from thence to the Laccadive Islands.

THE Government Geologist of New South Wales has prepared a map showing the areas within which artesian water-supplies may be bored for with good prospects of success. Water-bearing formations extend for 60,000 square miles in the arid parts of the colony, where permanent supplies are most needed; and the system of artesian wells is being widely adopted throughout Australia with the most satisfactory results. Large tracts of good pastoral country, which have hitherto been totally valueless through the want of a regular water-supply all the year round, are now capable of supporting flocks and herds.

THE Audubon Monument Committee of the New York Academy of Sciences complain that as yet comparatively few members of the Academy have given anything towards the erection of the proposed monument to Audubon. The considerable sum already received has come mainly from others. The plans accepted by the Committee will require from $6000 to $10,000 for their execution. Up to the present time, about $900 has been received. The Committee have issued a portrait of Audubon, suitable for framing, a copy of which will be sent to everyone who contributes to the fund to the amount of a dollar or more.

ACCORDING to an official notification of the trustees of the "Schwestern Fröhlich Stiftung" at Vienna, certain donations and pensions will be granted from the funds of this charity this year in accordance with the will of the testatrix, Miss Anna Fröhlich, to persons distinguished in any branch of science, art, or literature who may be in want of pecuniary support through accident, illness, or infirmity consequent upon old age. The grant of such temporary or permanent assistance in the form of donations or pensions is, according to the terms of the foundation deed, primarily intended for Austrian artists, literary men, and men of science, but foreigners of every nationality may benefit by the fund provided they are resident in Austria. Austrian subjects residing in England, who may desire to make application for a grant, can obtain all necessary information at the Austro-Hungarian Embassy in London.

ACCORDING to a telegram from New York, dated July 20, there had been slight shocks of earthquake at Memphis and in the vicinity.

THE Pilot Chart of the North Atlantic Ocean for July shows that two well-defined depressions moved up along the American coast during June. One originated over the Bahamas, on the 1st, whence it moved about north-north-east, accompanied by moderate gales, and disappeared in New England on the 5th. The other was a typical West India hurricane in every respect except violence; it first appeared south-west of Jamaica on the 14th. Heavy rainfall accompanied the passage of the storm, and caused great damage in Cuba, and on the 20th the depression seems to have united in Canada with another from the Lake region, and the combined storm moved east-north-east over Labrador, and out to sea. Much fog was encountered during the month, and many icebergs were reported between the 40th and 50th meridians, and as far south as 42° 54′ N., showing a marked southerly drift. The fact that the fog-belt is apt to overlap the iceberg region at this season makes navigation dangerous over the Transatlantic lines. One of the wrecks has an interesting history. The Italian barque *Vincenzo Perrotta*, abandoned on September 18, 1887, began her remarkable drift in about lat. 36° N., long. 54° W., and when last reported, on April 4, 1889, was about sixty miles north of Watling's Island, in the Bahamas, having made a distance of about 1400 miles in a south-west by west direction in little more than a year and a half.

AT the meeting of the Linnean Society of New South Wales, on May 29, Mr. C. T. Musson exhibited the leg of a pigeon to which a ball of earth, weighing, when dry, 9 grains, was found adhering. It would be hard to find a more striking illustration of the way in which birds may be the means of dispersing seeds. Mr. Musson also recorded a case in which a land snail (*Vitrina* sp.) was found adhering to the elytron of a beetle, whereby its migration beyond its normal habitat was to a limited extent rendered possible.

IN an article on "Blindness and the Blind," in the current number of the Journal of the Franklin Institute, Dr. Webster Fox refers, among other things, to the need for care being exercised with regard to the eyes of young children. The eyes are more sensitive to light in childhood than in adult life, yet a mother or nurse will often expose the eyes of an infant to the glare of the sun for hours at a time. Dr. Webster Fox holds that serious evils may spring from this, and he even contends that "the greater number of the blind lose their sight from carelessness during infancy." From the point of view of an oculist, he protests against the notion that children should begin to study at a very early age. He thinks that until they are between seven and nine years old the eye is not strong enough for school work. When they do begin to learn lessons, they "should have good light during their study hours, and should not be allowed to study much by artificial light before the age of ten. Books printed in small type should never be allowed in school-rooms, much less be read by insufficient light."

IN the new volume of the Transactions and Proceedings of the New Zealand Institute there is an instructive paper by Mr. A. Reischek on the wandering albatross (*Diomedea exulans*). Towards the end of January 1888, he had an opportunity of watching this bird closely among the hills of one of the Auckland Islands. Starting in search of some specimens, he was lucky enough, after a good deal of climbing, to come to a slope where a colony of albatrosses had established a breeding-place. The birds were scattered about among the tussock-grass, sitting on their nests, and from their white plumage could be easily distinguished from the vegetation at a great distance. Mr. Reischek found that their nests are always placed on sloping ground, and always on the most exposed side of the hill. The nests are composed of earth and grass cemented together, and are built in the form of a cone. They are usually about 2 feet in diameter and about 18 inches high. Outside they are surrounded by a shallow drain, intended to carry off the surface-water. Within is placed a single egg. This is white, with a few brown spots on the broad end, and measures about 5·5 inches in length by 3·1 inches broad. In most cases he found the female on the nest, the male bird standing close to her, and occasionally feeding her. Sometimes the male relieved the female, but they never both leave the nest until the young one is able to defend itself against the skua gull, a rapacious bird which devours every egg or nestling left unprotected. When Mr. Reischek approached an albatross's nest, the bird seldom left it, but set up a croaking noise, clapping its mandibles together and biting at the intruder. If it was turned off, and the egg taken, it returned and sat on the nest as before. The eggs were quite fresh on January 25, and good for eating when fried.

A VOCABULARY of physical terms, styled "Butsurigaku Jutsugo Jisho," has been issued in Japan. It gives the authoritative Japanese equivalents of an important group of Western scientific terms. In all, thirty-six Japanese gentlemen have been engaged in its preparation for the past six years. The Mathematical and Physical Society of Japan bears the expense of publication. The book consists of four parts arranged alphabetically under the four languages, Japanese, English, French, and German, each part extending over ninety octavo pages, and each page comprising from twenty to twenty-five distinct terms expressed in the four languages. This work, on which so much labour has been expended, can be purchased for the moderate sum of a dollar and a half.

MESSRS. MACMILLAN AND CO. have issued a "Syllabus of Modern Plane Geometry," by the A.I.G.T. The first few sections deal with harmonic ranges and pencils, the properties of the triangle, and properties of the complete quadrilateral and quadrangle; sections v., vi., and vii., with the properties of circles and geometrical maxima and minima; sections viii. and ix., with cross ratios, involution, and reciprocal polars and projection. The various subjects are treated concisely, and the work will be very useful to students.

"HAMPSTEAD HILL," a work on the natural history, &c., of Hampstead, will shortly be published by Messrs. Roper and Drowley. The contributors to the various sections include Prof. J. L. Lobley, H. T. Wharton, Rev. Dr. Walker, and J. E. Harting. The book will be illustrated by engravings of local scenery.

THE second part of Charles Fabre's treatise on photography has just been published (Gauthier-Villars, Paris). The subject of lenses is continued in great detail, and it is not too much to say that a more complete account has never been written. Diaphragms and instantaneous shutters are begun in this part. The illustrations are excellent.

THE Royal Physical Society of Edinburgh has issued its Proceedings during the session 1887-88. The volume includes, besides an opening address, by Prof. Duns, Vice-President, the following papers:—An ornithological visit to the Ascrib Islands, Loch Snizort, Skye, by John Swinburne; on the structure of the Graafian Follicle in *Didelphys*, by Frank E. Beddard; notes on Carboniferous *Selachii*, by Dr. R. H. Traquair, F.R.S.; further notes on Carboniferous *Selachii*, by Dr. R. H. Traquair, F.R.S.; notes on a visit to Fernando Noronha (with plate), by George Ramage; on a new Eurypterid from the Upper Coal-measures of Radstock, Somersetshire (with plate), by B. N. Peach; synthetic summary of the influence of the environment upon the organism, by J. Arthur Thomson; on the prevalence of Eurypterid remains in the Carboniferous shales of Scotland, by James Bennie; on the fructification of two Coal-measure ferns (with plate), by Robert Kidston; on the fructification and affinities of *Archæopteris hibernica*, Forbes, sp., by Robert Kidston; notes on the equipment of the Research Laboratory of the Royal College of Physicians, Edinburgh, by Dr. G. Sims Woodhead; the summer birds of Shetland, with notes on their distribution, nesting, and numbers, by Harold Raeburn.

THE July number of the *Board of Trade Journal* describes, from certain Austrian technical periodicals, the condition of pharmacy in Bulgaria. Most of the departmental capitals, towns of 9000 to 10,000 inhabitants, but including very often an administrative area of 60,000 to 70,000 inhabitants, have only one pharmacy each. These pharmacies might be supposed to do a splendid trade, and they would do so but for the fact that the illegal exercise of the craft, in spite of the stringency of the laws which are intended to protect the legitimate professors of the art, is almost openly practised throughout the country by itinerant hawkers, quacks, and priests. The establishment of pharmacies is only allowed by special concession, and they are subject to a Sanitary Council at Sophia composed of several members, including a chemist and a veterinary surgeon. Nominally there should be a pharmacy for every 8000 inhabitants. Every Bulgarian citizen who has passed the necessary examination is entitled to compete for a concession, but foreigners are only allowed to do so when they can show that they have been qualified in their own country, and after having passed a formal examination in Bulgaria. At least twice a year every pharmacy is officially inspected by the authorities, and subjected to a close examination, which also extends to the books, as there is an official scale of charges for prescriptions which may not be exceeded. The original of every prescription is kept by the pharmacist, who gives his customer a copy stamped with his name, and bearing the price charged, which price is also inscribed upon the original, and the same number given to both. At present the Russian Pharmacopœia is used in Bulgaria, but a native one is in contemplation. There is no Pharmaceutical Society or organization of any kind among pharmacists. A Society which was started about five years ago expired after an existence of three months. The formal examination which is obligatory for foreigners desirous of establishing business in Bulgaria embraces pharmacology, analysis, organic and inorganic chemistry. The fee is very high, £40, half of which is refunded in case of failure. Every foreigner establishing business in Bulgaria is required to sign a declaration placing him under the Bulgarian Pharmacy Law, and to keep at least two apprentices of Bulgarian nationality. The assistants are nearly all foreigners. They generally receive from £2 10s. to £3 per month indoors.

THE barium salt of a new acid-forming oxide of cobalt, CoO_2, corresponding to the black dioxide of manganese, MnO_2, has been obtained by M. Rousseau, and is described in the current number of the *Comptes rendus*. It forms large black prismatic crystals, and appears to be a very definite compound of the composition $BaO . CoO_2$, and possessing some stability. The most favourable method of preparing it is as follows. A mixture of 15 grams of crystals of barium chloride or bromide with 5 or 6 grams of finely-powdered anhydrous barium oxide is heated gradually to redness in a platinum crucible. The temperature is then raised in a good furnace to 1000°–1100° C., when 1 gram of sesquioxide of cobalt, Co_2O_3, is introduced by degrees into the fused mass, and the temperature maintained for about five hours. At the expiration of this time a ring of large black prisms, exhibiting beautiful iris-coloured reflections, is formed. The crystals are found to contain a little platinate of barium, owing to the platinum crucible being attacked at the high temperature, but after elimination of this impurity the analyses agree very closely with the formula $BaO . CoO_2$. The crystals of this monocobaltite of barium are soluble in cold concentrated hydrochloric acid with evolution of heat, and dissolve likewise in nitric acid with effervescence. At a higher temperature than 1100° they are decomposed with evolution of oxygen gas, the CoO_2 becoming reduced to a lower oxide, probably Co_3O_4, the usual product of the ignition of cobalt oxides. Hence the necessity for keeping the temperature below 1100° during the preparation. If the fusion be simply performed over the Bunsen lamp, another cobaltite is obtained containing two molecules of CoO_2. A crust of crystals of this second compound, $BaO . 2CoO_2$, is formed over the surface of the melt, consisting of brilliant black hexagonal lamellæ. These crystals are likewise soluble in hydrochloric acid with evolution of chlorine gas. In order to avoid the formation of this di-cobaltite it is necessary to maintain the temperature over 1000°, when the neutral monocobaltite is alone produced. Hence the limits of temperature during which the monocobaltite is produced are 1000°–1100°. Thus cobalt resembles manganese in forming a dioxide, capable of liberating chlorine from hydrochloric acid and combining with basic oxides to form cobaltites analogous to the manganites. But this dioxide of cobalt appears from its reactions to be somewhat weaker in its combinations than manganese dioxide, and to form them with greater difficulty, the barium cobaltites above described being as yet the only ones prepared.

THE additions to the Zoological Society's Gardens during the past week include two Crested Porcupines (*Hystrix cristata*), a Desert Buzzard (*Buteo desertorum*), two Natal Francolines (*Francolinus natalensis* ♂ ♀) from South Africa, presented by Captain Henry F. Hoste, R.M.S. *Trojan*; a Common Wolf (*Canis lupus*, juv.) from Provincia de Leon, Spain, presented by Mr. W. S. Lart; four Violaceous Night Herons (*Nycticorax violaceus*), a Green Bittern (*Butorides virescens*), a Dominican Kestrel (*Tinnunculus dominicensis*), a —— Pigeon (*Columba*, sp. inc.) from St. Kitt's, W.I., presented by Dr. A. P. Boon, C.M.Z.S.; two Ocellated Mantis (*Harpax ocellata*) from South Africa, presented by Colonel J. H. Bowker, F.Z.S.; a Wapiti Deer (*Cervus canadensis* ♀), a Peacock Pheasant (*Polyplectron chinquis*), eight Mandarin Ducks (*Æx galericulata*), five Summer Ducks (*Æx sponsa*), two Chiloe Wigeon (*Mareca chiloensis*), six Chilian Pintails (*Dafila spinicauda*), three Australian Wild Ducks (*Anas superciliosa*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE BINARY γ CORONÆ BOREALIS.—Prof. Celoria has recently determined (*Astr. Nach.*, 2904) a new orbit for this difficult binary (Σ 1967), which appears a decided advance upon that of Dr. Doberck's, published twelve years ago. A considerable uncertainty still attaches, however, to the elements, although the star has now been under observation for sixty-three years, and has been watched through nearly three-fourths of a revolution. This is due partly to the circumstance that the orbit is presented to us nearly in profile, and partly to the closeness of the two components. The measures in both elements, therefore, have been difficult to make, and have often been very discordant. Thus some recent position-angles by Engelmann show a systematic difference of 30° or more as compared with measures made at about the same epoch by Schiaparelli and Perrotin. The companion passed its primary on the north side about 1836, reappearing in 1840 on the preceding side. It re-passed the principal star on the south about 1878, and is now again on the following side. Celoria's new elements compare with Doberck's as follows:—

	Doberck.		Celoria.
T =	1843·70	...	1840·508
☊ =	110° 24′	...	113°·47
λ =	233° 30	...	250·68
γ =	85° 12′	...	81·66
e =	0·350	...	0·34827
a =	0″·70	...	0″·63103
P =	95·50 years.	...	85·276 years.

ECLIPSES AND TRANSITS IN FUTURE YEARS.—The Rev. S. J. Johnson, author of "Eclipses Past and Future," and well known as a calculator of eclipses, presented a large manuscript volume to the Royal Astronomical Society a few months ago containing projections and diagrams of eclipses from the year A.D. 538 to the year 2500. He has now published in a little pamphlet the dates of all the eclipses, both of sun and moon, visible in England from 1700 to 2000, with the solar eclipses for the two following centuries, and the larger solar eclipses up to 2500. The transits of Mercury and Venus are also included, of Venus up to 2500, and of Mercury to 2000.

The twentieth century is distinguished by three years in each of which seven eclipses take place. Of these, Mr. Johnson notices two, 1917 and 1935, the latter being particularly noteworthy as showing five solar eclipses, but does not mention the third case, 1985, though calling attention to the rare occurrence of three total eclipses of the moon which fall that year.

The little pamphlet, which is intended as a kind of supplement to the author's larger work, "Eclipses Past and Future," is illustrated by four pages of diagrams showing the greatest phases of the eclipses up to 1949, as seen from London. The diagrams are nowhere explained, and no indication is supplied as to which are solar and which lunar eclipses. It appears that circles on which the eclipsed portion is shown by deep shading, and which are surrounded by a ring of shade, stand for solar eclipses, the plain circles for lunar eclipses.

THE WHITE SPOT ON SATURN'S RING.—M. Terby, who still strongly contends for the reality of the bright white spot next the shadow of the planet on Saturn's ring, quotes, in the *Astronomische Nachrichten*, No. 2910, an observation of Ceraski's made in 1884, as showing that it is not a mere effect of contrast with the shadow. M. Ceraski, on November 1, 1884, noticed a bright white spot on the ring where it touched the planet in a similar position to M. Terby's spot, but the shadow of the planet fell at that time on the other portion of the ring, so that the spot could not be accounted for by contrast.

COMET 1889 *c* (BARNARD, JUNE 23).—The following ephemeris for this object is by Dr. R. Spitaler (*Astr. Nach.* No. 2909):—

For Berlin Midnight.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JULY* 28—*AUGUST* 3.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 28

Sun rises, 4h. 20m.; souths, 12h. 6m. 14·0s.; daily decrease of southing, 1·3s.; sets, 19h. 53m.: right asc. on meridian, 8h. 31·6m.; decl. 18° 54′ N. Sidereal Time at Sunset, 16h. 20m.

Moon (New on July 28, 0h.) rises, 4h. 27m.; souths, 12h. 33m.; sets, 20h. 28m.: right asc. on meridian, 8h. 58·4m.; decl. 19° 51′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′
Mercury..	3 13	11 19	19 25	7 44·6	22 4 N.
Venus ...	1 1	8 56	16 51	5 20·5	20 20 N.
Mars ...	3 10	11 18	19 26	7 43·1	22 20 N.
Jupiter ...	17 38	21 31	1 24*	17 58·1	23 22 S.
Saturn ...	5 46	13 11	20 36	9 36·7	15 27 N.
Uranus...	11 12	16 42	22 12	13 8·6	6 38 S.
Neptune..	23 56*	7 45	15 34	4 9·8	19 23 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

July.	h.	
28	5	Mercury in conjunction with and 0° 14′ south of Mars.
28	20	Mercury at least distance from the Sun.
29	7	Saturn in conjunction with and 2° 16′ south of the Moon.

GEOGRAPHICAL NOTES.

AN expedition is about to start for the exploration of Central Australia. Baron von Müller is interesting himself in the expedition, which will be under the command of the experienced explorer, Mr. Tietkens, who will also look specially after the botany and mineralogy. The point of departure will be Alice Springs, on the central telegraph line, and the country round Lake Amadeus will be carefully examined.

IT is reported from Brisbane, according to the *Colonies and India*, that the Queensland Government has concluded an agreement with Mr. A. Weston to lead an exploring party into the almost untrodden recesses of the northern portion of the colony, with a view to bringing to light scientific treasures supposed to be hidden there. Mr. Weston has accepted the undivided responsibility of leadership. Messrs. Broadbent and Bailey will be associated with him, and will respectively discharge the duties of collecting fauna and flora. The party will explore the region lying to the north-west of Cairns, including the Bellenden Ker Range and the shores of the volcanic lakes. It is also thought that something may be heard of Leichardt's expedition, traces of which are popularly supposed to be yet found in the back country. Mr. Weston has refused to accept any pecuniary assistance from the Government for his services.

M. A. DELCOMMUNE, who has been exploring several of the affluents of the Upper Congo, has arrived in Brussels. He has brought with him a valuable collection of African products, and some 200 views on the Upper Congo.

THE news that Dr. Macgregor, the Administrator of British New Guinea, has reached the summit of the Owen Stanley Range is of much interest. Since Captain Owen Stanley discovered the range, about forty-five years ago, various explorers have attempted to scale it, but all have failed. The summit reached by Dr. Macgregor is over 13,000 feet, and he reports several peaks almost equal in height. As Dr. Macgregor is a good botanist, his journey is likely to yield valuable scientific results.

DR. ALFRED HETTNER, in a communication to the *Verhandlungen* of the Berlin Geographical Society (No. 6, 1889), on his travels in Peru and Bolivia, gives the results of his observations on Lake Titicaca, which are of some interest. The surface of the lake, he states, has in the course of time been subject to great changes of level. The proof of these changes is to be found in the terraces around the lake. In a comparatively recent geological period, Dr. Hettner believes, the level of the lake must have been 20 metres higher than it is to-day, and the lake must have spread over the great part of the plain which now incloses it, perhaps as far as Lake Poopo. At a still earlier period the level of the lake must have been 200 metres above its present level, but between these stages, as many appearances indicate, the lake must have sunk below that level. The highest position of the lake-level is older than the glaciation of the district, and contemporaneous with a period of strong volcanic activity. The 20-metre high terraces may belong to the ice-period. For the idea of a former submersion below the sea Dr. Hettner can find no support; at the same time, he cannot altogether deny the possibility that at the time of the 200-metre terrace the lake may have had some connection with the ocean.

NITRATE OF SODA, AND THE NITRATE COUNTRY.[1]

II.

WE will now consider the structure of the actual nitrate beds. As before mentioned, there is no nitrate under the flat Pampa; but exactly where the first slopes of the coast range spring out of the plain, there nitrate is found at a small but variable distance below the surface. The width of the belt varies with the slope of the hill, being greatest where the slope is least, and the vertical height of the highest part of the bed appears to vary from 100 to 120 feet above the plain. It is, however, most important to notice that *the beds of nitrate follow the slope of the Pampa, and not a level line.* For instance, the northern extremity of the Pampa is some hundreds of feet higher than the southern portion, but the nitrate beds follow the spring of the hill from the plain, throughout their whole extent.

A very different sequence of beds lies under the slope of the hills from those alternating layers of mud, sand, and gravel which are found under the level Pampa. The surface covering of loose dust and small stones, extending to a depth of only a few inches, is locally known as *chuca* (see Fig. 3). This seems to be a native word, but I have been unable to ascertain its meaning. Below the *chuca* comes a very hard layer of earth and stones, almost compacted into rock, from 1 to 2 feet thick, which is called *costra* (Span. crust). Under this lies the *caliche,* or true nitrate deposit. This is a bed of from 1 to 3 feet thick, usually of a whitish crystalline structure, containing from 20 to 50 per cent. of nitrate of soda, with a residuum made up chiefly of common salt and earthy matter. *Caliche* is an Indian word, and may possibly come from the Aymara word *callachi,* a shell, or skull.

Passing through the *caliche,* a hard layer of stones and earth, compacted with salt crystals, is usually encountered. The Spanish workmen call this "*congelo,*" because it is congealed or concreted by the salt.

After a foot or so of this, there comes finally a bed of soft, loose, *sweet* earth, containing a few very small loose stones, known as *cova.* I could not discover the signification of this word; but the whole method of working a nitrate bed turns round the properties of the *cova.*

A workman, with three or four chisel-pointed bars of iron, hence called a *barretero,* stands on the surface of the ground, and chips out a round hole, about a foot in diameter, down to the level of the *cova.* This hole is called a *tiro,* or charge for

[1] Continued from p. 188.

gunpowder (see Fig. 3). A small boy then scrambles down the hole, and easily excavates the soft *cova* a little under the *congelo*, forming an opening called the *taza*, or cup. The *taza* only is then filled with a slow-burning gunpowder, made of nitrate of soda on the premises, a tamping put into the *tiro*, and the charge exploded. The valuable *caliche* bed is thus simply lifted and partially broken, without being blown into dust; and a party of men separate the nitrate from the worthless beds, and carry it to the factory, or *maquina*.

Caliche varies so much in composition that it is almost impossible to give a typical analysis. One very rich specimen gave:—

	Per cent.
Nitrate of soda...	50
Chloride of sodium	26
Sulphate of soda...	6
,, magnesia	3
Insolubles	15
	100

but a more average sample might be taken to contain one-third nitrate; one-third salt; and one-third earth.

The problem for the manufacturer is to get the nitrate without the salt and earth; and the simple basis of the whole process rests on the fact that, while salt is rather more soluble in cold

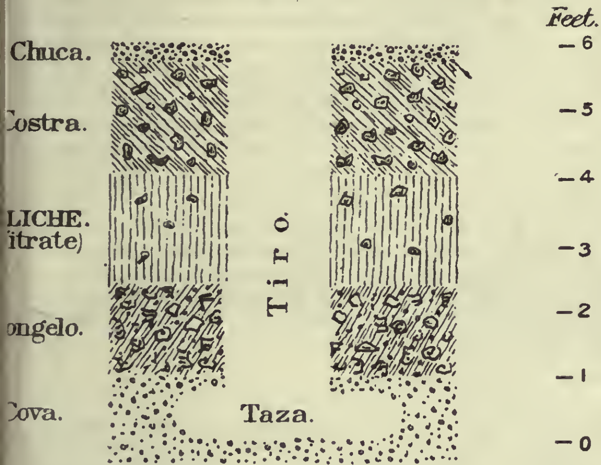

Fig. 3.

than in hot water, nitrate of soda is about four times more soluble in hot than cold water. It is also evident that, if a salty rock is washed with water already saturated with salt, no more of that material can be absorbed. The raw *caliche* is therefore first crushed into small pieces, washed with six changes of hot water, by what is known as the "passing system" similar to that used for lixiviating soda ash. After the last washing the waste *caliche* is known as *ripio* (refuse), and is thrown on to a rubbish heap; while the strongest hot water, which is drawn off the *caliche*, is known as *caldo*, or "broth."

The hot broth then runs for twenty minutes into a settling tank, where earth and salt are deposited, and after that into great square shallow *bateas*, or troughs. In about five days the greater part of the nitrate has been deposited nearly pure at the bottom of the *batea*, and a yellow orange liquid, known as *aqua vieja*, remains on the top. This liquid is drawn off, the nitrate crystals drained, thrown on to a flat floor or *cancha*, to dry for three weeks, and then when bagged are ready for the market.

In many factories the *aqua vieja* is then pumped into the iodine room.

One sample of this fluid gave the following analysis:—

	Per cent.
Nitrate of soda...	28
Sulphate ,, ...	3
Chloride of sodium	11
Iodate ,, ...	22
Sulphate of magnesia	3
Water	33
	100

besides a small quantity of iodide of sodium, which cannot be utilized.

To separate the iodine a mixture of nitrate of soda and coal dust is formed into a pyramid and set alight, by which means a crude carbonate of soda is formed. Fumes of burning sulphur are then drawn through a solution of this carbonate, and an acid solution of sulphite of soda is produced. A suitable quantity of this last liquid is added to the *aqua vieja*, when iodine is precipitated in an impure form, which after sublimation becomes the iodine of commerce.

Nitrate of soda thus manufactured contains from 95 to 96 per cent. of pure nitrate, with less than 1½ per cent. of salt, the remainder being chiefly water. The nitrate is sold in Liverpool for about 10*s*. a hundredweight, while the iodine is disposed of in London for about 3*d*. an ounce.

It is impossible to examine a bed of crude nitrate of soda, without thinking how it got there. We have described the facts as to the position of some beds relative to the lie of the country, and also explained the character of the layers which adjoin the *caliche*, but unfortunately we can do little more. Numerous theories have of course been started, but none have either accounted for all the facts, or obtained general acceptance. This may perhaps be the case because no competent geologist has as yet thoroughly examined the nitrate beds in different parts of the country, but still a few remarks on the subject may be desirable. There is no doubt that the coast range and the Pampa have been elevated out of the sea at a comparatively recent period, but it is also equally certain that since that elevation the climate was at one time far more rainy than at present. All over the plains there are dry river-beds, and the flanks of the hills are scored by water-cut channels which could not have been carved out under the existing conditions of rainfall. This would make it doubtful whether the nitrate could have been deposited immediately after upheaval.

It may be noted as a curious fact that the stones found both in the *costra*, *caliche*, and *congelo* are usually angular; but in one nitrate ground I have certainly seen rounded pebbles in all these formations.

Much difficulty is always found in accounting for the existence of nitric acid. The existence in some deposits of a layer of guano under the *caliche* is a very suggestive fact, but unfortunately our knowledge of the circumstances is far too limited to allow of any generalizations on the subject. The presence of iodine in *caliche* has often been appealed to as pointing to the decomposition of beds of seaweed; but it may be remarked that there is a good deal of iodine about in the neighbouring mountains in the form of iodide of silver. We can only repeat the statement that the origin of nitrate of soda is at present unknown.

Whatever may have been the origin of the beds, there is no doubt that their existence is due to the rainlessness of the west coast of South America, so that a few remarks on the climate and weather of the *caliche* districts may be of interest. All along the coast we find three belts of climate and weather: that of the coast, that of the Pampa, and that of the Sierra.

Iquique may be taken as a typical station on the coast, and here fortunately a considerable amount of material has been accumulated through the labours of the Meteorological Commission for Chili. Speaking broadly, temperature at any season will rarely exceed 80°–85°, or fall below 50° at any hour in the coldest season; and as the air is always tolerably dry the climate is very bearable and wholesome. The wind blows from south to south-west throughout the year during the day, but at night sometimes comes more off the land from some point of east. Though nothing approaching to a gale ever blows at Iquique, the effect of distant storms is often experienced in the form of a heavy surf, which entirely stops any shipment of nitrate. The surf days, or *Bravesas* as they are called, occur most irregularly, for while in some years only nine days are recorded, other seasons have been credited with no less than forty-three days of enforced idleness. Contrary to the usual opinion, three or four slight but real showers fall every year, mostly in the months of June, July, and August, though this precipitation does not extend inland to the Pampa. The sky is usually clear, but a low stratus or strato-cumulus cloud often covers the sea and coast range during the forenoon, but dissipates as the sun gains power.

On the Pampa, where all the nitrate *oficinas* are built, the temperature may rise to 85° or 90° on the hottest days; and at night may fall to the freezing-point during the winter months. The air is much drier than on the coast; and though rain has been known to fall, it is certainly of very rare occurrence. Cloud is more rare on the Pampa than on the coast; but nearly every night a very thick wet fog settles over the plain. This is locally known as *camanchaca*, probably an Aymara word, whose signification I have not been able to find out. The mist is popularly supposed to come from the sea, but this is only partly true. The fog doubtless rolls from the west or seaward side, but the origin is certainly due to local radiation, for the densest mist may lie over the Pampa, when there is no trace of fog on the sea-coast.

The nights and forenoons are usually calm on the Pampa, but about 1 p.m. a moderate wind springs up from the south-west, which falls away at sunset. During the night a light air sometimes blows from the Cordillera; and if the wind comes from the east, the *camanchaca* is immediately evaporated.

The Sierra or Cordillera is strangely enough governed by a totally different weather system from that of the coast; for it rains heavily in the mountains during the summer months of December, January, or February; and I have been assured that whenever it does rain on the Pampa, the precipitation has been blown over from the Sierra. *The extreme dryness of the Pampa is owing to its geographical position between the coast range, whose scanty rainfall occurs in winter, and the Sierra, where heavy rain falls in summer, but the precipitation of neither reaches the plain, which therefore remains a desert.* My own observations on the surface and upper winds along the whole length of the Andes, from Valparaiso to Lima, prove conclusively that the old theory that the dryness of the west coast of South America is due to the south-east trade rising over the Andes, and then descending as a warm dry current, is totally wrong, for I found all the winds over 10,000 feet, either from north-east or north-west.

The Pampa is very healthy, for fever is unknown, and though the heat and drought sometimes affect the liver, and a mild dysentery sometimes shows itself, still both are very amenable to proper treatment. There seems to be only one ailment special to the Pampa and the other nearly rainless districts of South America. This is the so-called "barley blindness" of mules and horses, which manifests itself by a white growth on the pupil of the eye. Absence of sufficient moist food is said to be the cause of this malady, and there is no doubt that if removed in time to a natural pasturage, the affected animal soon more or less recovers its sight.

RALPH ABERCROMBY.

FORTUITOUS VARIATION.

AT a meeting of the Biological Society of Washington (United States), held on December 15, 1888, Mr. Lester F. Ward read a paper on "Fortuitous Variation, as illustrated by the genus *Eupatorium*." He exhibited a series of specimens of that genus, mostly from the vicinity of Washington, and growing in great part in the same kind of soil and under the same general conditions. To simplify the question, the differences in the flowers, heads, and reproductive parts in general, which are less marked in this than in almost any other genus, were ignored, and attention was exclusively directed to the leaves. These, when closely compared, are seen to differ considerably in the different species, the forms ranging from the filiform dissected leaves of *E. fœniculaceum* to the broad ovate leaves of *E. ageratoides*. But between these extremes there are represented in the Washington flora numerous much more similar forms, which present to the observer a strongly marked family resemblance; from those with more elongate leaves, such as *E. altissimum*, *E. album*, and *E. teucrifolium*, through the increasingly broader more ovate forms, *E. perfoliatum*, *E. sessilifolium*, and *E. rotundifolium ovatum* (*E. pubescens*, Muhl.), with an intermediate undescribed form, which Dr. Gray regarded as a hybrid, connecting the last two to the typical *E. rotundifolium*, with its roundish, crenate, but still sessile leaves; and from this last form, with several similar Mexican species, on in the direction of acquiring a petiole, through several exotic forms, to *E. cælestinum*, *E. aromaticum*, and *E. ageratoides*, in an almost unbroken chain of modifications without any apparent advantage to the plants. Almost any other genus might have served the purpose of the paper, but this one seemed to possess the merit of simplicity.

The question naturally arises, in looking at such a group of clearly related forms, all of which, on the modern view, must surely have descended from some common ancestral stock, Why have they varied at all? Why need there be more than one species of Eupatorium in the same restricted flora? Or, if some can be shown to have probably varied in order to adapt themselves to different local conditions, why need there be more than one form occurring under precisely the same conditions? Variation caused by natural selection can only occur where some advantage is secured through it, whereby the new form becomes, by ever so little, better fitted to survive under the conditions of its existence. But here there seems to be no such advantage. It is easy to say that we are incapable of detecting the subtle influences that make one form surer of existence than another. The staunch believer in natural selection may be satisfied with such an explanation, but is it not too much to ask of the new convert or the sceptic? Is not the spread of the doctrine hindered rather than helped by such a demand? Moreover, it was shown that several different forms actually flourish together in the very same localities, and that this is not exceptional, but the common case, so that the idea of special fitness of form to station is precluded. And is it not antecedently improbable that there should be any advantage in a plant's having a sharp-pointed rather than a blunt-pointed leaf, a serrate rather than a crenate one, or a sessile rather than a short-petioled one? Science becomes metaphysics when such questions are discussed.

The speaker proposed to escape from the dilemma by denying that advantage, or fitness to survive, or natural selection, had anything to do with such variations; and he maintained that they were truly fortuitous in the only true sense of that term. By this he did not mean to say that they were due to mere chance in the sense of being without cause; and the remainder of his paper was devoted to an attempt to explain the cause of fortuitous variation. It may be briefly summed up as follows:—

Organized or living matter constantly tends to increase in quantity, which may be regarded as the true end of organic being, to which the perfection of structure, commonly mistaken for such end, is only one of the means. Every organic element may be contemplated as occupying the centre of a sphere, toward the periphery of which, in all directions alike, it seeks to expand, and would expand but for physical obstructions which present themselves. The forms which have succeeded in surviving are those, and only those, that were possible under existing conditions; that is, they have been developed along the lines of least resistance, pressure along all other lines having resulted in failure. Now, the various forms of vegetable and animal life represent the latest expression of this law, the many possible, and the only possible, results of this universal *nisus* of organic being. The different forms of *Eupatorium*, or of any other plant or animal, that are found co-existing under identical conditions merely show that there were many lines along which the resistance was not sufficient to prevent development. They are the successes of Nature.

Mr. Ward disclaimed any desire to discredit or impair in any way the great law of natural selection. The most important variations, those which lead up to higher types of structure, are the result of that law, which therefore really explains organic evolution; but the comprehension and acceptance of both natural selection and evolution are retarded instead of being advanced by claiming for the former more than it can explain, and it might as well be recognized first as last that a great part—numerically, by far the greater part—of the variety and multiplicity, as well as the interest and charm, of Nature is due to another and quite distinct law, which, with the above qualifications, may perhaps be appropriately called "the law of fortuitous variation."

SCIENTIFIC SERIALS.

American Journal of Science, July.—A new Erian (Devonian) plant allied to Cordaites, by Sir William Dawson. This unique specimen from the lower Catskill (Upper Devonian), Wyoming County, Pennsylvania, presents the peculiarity of combining the fructification of the Cordaiteæ with foliage akin to that of Næggerathia, thus connecting two Palæozoic groups which are now considered as allied to Cyadeæ and Taxineæ.—The law of thermal relation, by William Ferrel. The object of these researches is to compare Dulong and Petit's older formulæ and the more recent determination of Stefan with the principal available data derived from experiment and observation, with a view to ascertaining what modifications these formulæ may require in order accurately to represent the true law of relation between the intensity of the radiation and the temperature of a body. It appears generally that neither of the formulæ in question represents the true law of Nature through the whole range of experiments, but that different values are required for different ranges of temperature. To determine the true mean value with greater accuracy experiments upon radiation will have to be made at much lower temperatures than any yet made.—Stratigraphic position of the Olenellus fauna in North America and Europe (continued), by Charles D. Walcott. Since writing the first part of this article the author has completed the survey of all the species known to him from the Olenellus (Lower Cambrian) zone in North America. From a general comparison of this zone with the Ordovician the superiority of the latter in number of species, genera, and families becomes at once apparent. But when the comparison is extended to class characters, the disparity is much reduced, and it is made evident that the evolution of life between the two epochs has been in the direction of differentiating the class types that existed in the earlier fauna. It cannot be asserted that the Olenellus fauna of Europe and North America was contemporaneous, although its relations to the succeeding Middle and Upper Cambrian and Ordovician is everywhere essentially the same, the Olenellus being the basal fauna wherever it has been found.—On allotropic forms of silver (continued), by M. Carey Lea. The properties are given of the two already described insoluble forms of allotropic silver, which differ from normal silver especially in their sensitiveness to light, their brittleness and specific gravities (9·58 and 8·51, the normal being 10·5).—The peridotite of Pike County, Arkansas: Part I., description and general relations, by John C. Branner; Part II., microscopic study, by Richard N. Brackett. Though small in extent, the exposure of peridotite occurring near Murfreesboro, Pike County, is geologically important, as offering a clue to the time and character of the disturbing influences which about the close of the Cretaceous sank the greater part of Arkansas and other contiguous regions beneath the ocean. It is also interesting as being the third reported occurrence of picrite-porphyry in the United States. Its position and topographic features are shown in the accompanying map.—Papers are contributed by T. M. Chatard, on urao, shown to be the true natural form of sodium carbonate; by Edward F. Ayres, on the crystallization of trona (urao), from Borax Lake, California; by G. F. Kunz, on fluorite, amber, opal, and diamond; and by O. C. Marsh, on the discovery of Cretaceous Mammalia by J. B. Hatcher in the Laramie formation of Dakota and Wyoming. There is also a reprint of Mr. James Croll's paper in the Quarterly Journal of the London Geological Society for May 1889, on prevailing misconceptions regarding the evidence of former glacial periods.

In the *American Meteorological Journal* for June, Mr. A. L. Rotch contributes an interesting article on the organization of the meteorological service in Belgium. The Royal Observatory was established in 1826, and deals with astronomy, meteorology, and magnetism. The present net-work of stations consists of three Observatories (including Liége, which is independent of the Royal Observatory), fifty stations of the second order, and about 120 rain-stations. Instruments are generally lent, but the observers are volunteers. The most notable instrument in use is the electrical meteorograph, invented by F. van Rysselberghe, which engraves its indications on metal plates, from which copies can be printed. The recording apparatus can work at any distance from the meteorological instruments.—Lieutenant J. P. Finley gives a chronological table of tornadoes in the State of Michigan for sixty-six years ending 1888, with a chart. The total number of storms observed was seventy-six; the year of greatest frequency, 1886—eighteen storms. The greatest monthly frequency was in May and September, and the prevailing direction of movement, north-east. The publication of these statistics is the more valuable, as we learn from another part of the *Journal* that recent restrictions on the publications of the Chief Signal Office prevent it from issuing Lieutenant Finley's tornado charts.—Prof. F. Waldo has a review on some important tornado literature. The author points out where the most important discussions of the subject can be found, and calls attention to some particular points therein. Most of the authentic accounts between 1835-50 are contained in *Silliman's Journal*, since which time most prominent meteorologists have investigated the subject, especially Loomis and Reye.—Mr. W. W. Harrington contributes an article on the whirlpool theory of storms. The object of the paper is to lay before the readers of the *Journal* the views of M. Faye, as formulated in his work, "Les Tempêtes" (1887), which work was reviewed in our columns. Mr. Harrington offers no opinion upon the theory itself, or upon the criticisms of the same.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 15.—M. Hermite in the chair.—Observations of the small planets and of Barnard's comet made at the great meridian instrument of the Paris Observatory during the second half of the year 1888, by M. Mouchez.—Thermic researches on the isomeric nitric camphors and on cyanic camphor, by MM. Berthelot and P. Petit. From these researches it appears that, between Cazeneuve's two isomerous nitric camphors, answering to the formula $C_{20}H_{15}NO_6$, there exists the same difference as between a nitrified body and a nitric ether, or any substance of analogous function; further, that nitro-phenol camphor must be less explosive than the corresponding isomerous body. For cyanic camphor the mean heat of combustion has been determined at 8445·3 calories.—On the decomposition of the sulpho-conjugated acids by means of phosphoric acid, by MM. C. Friedel and J. M. Crafts. On recently resuming their study of this question the authors have found that owing to the secondary reactions the decomposition of the acids in question in presence of sulphuric acid does not usually yield all the hydrocarburets contained in them. But the complete decomposition may be effected by mixing the sodium or potassium salt of a sulphonic acid with a considerable excess of concentrated phosphoric acid at a temperature of 60° Baumé.—On the studies in atmospheric micrography undertaken at the Imperial Observatory of Rio de Janeiro, by M. L. Cruls. Considerable interest attaches to these researches, made in a tropical region and in the immediate vicinity of a large city frequently visited by epidemics. Some of the atmospheric particles, obtained in the usual way, have been photographed M. Morize, of the Rio Observatory, and enlarged by 150, 500, and 1000 diameters. In order to collect sufficient data for comparative purposes, M. Cruls has been authorized by the Brazilian Government to organize a special laboratory to carry out a systematic series of microscopic studies on the site that has been chosen for the construction of a branch of the Rio Observatory.—Observations of Barnard's comet (June 23, 1889) made at the Observatory of Algiers with the 0·50 metre telescope, by MM. Trépied and Sy, on July 1 and 5.—On the Brownian movement, by M. Gouy. The author has studied this phenomenon under a great variety of conditions and with diverse kinds of liquids and particles. It results from his observations that this movement is produced with particles of every description, its intensity diminishing in direct ratio to the viscosity of the fluid and the size of the particles; also that it is a perfectly regular phenomenon, produced at a constant temperature and independently of all external influences. Thousands of particles have been examined, and in no single case has any particle in suspension failed to present the usual movement, with its normal intensity regularly decreasing with the increased size, but not with different kinds of particles, the solid, liquid, and gaseous all behaving much alike under like conditions. This fact clearly shows that the cause of the phenomenon is to be sought, not in the bodies themselves, but in the fluid element, whose internal movement they serve to render visible. Hence the Brownian movement alone of all physical phenomena reveals to the eye a constant state of internal agitation in bodies independently of all outward influences. The fact here established will naturally be associated with current kinetic hypotheses, and may perhaps be regarded as a faint and remote result of calorific molecular movements. In this phenomenon the velocities may be estimated at some microns per second, or about 1/100,000,000 of those attributed to molecular movement.—On the electrolysis of distilled water, by M. E. Duter. These experiments, and especially that conducted with aluminium, point to the inference that there are formed at the negative pole metallic hydrides, which are destroyed by the water with formation of an oxide and liberation of hydrogen.—On the ammonio-cobaltic molybdates, tungstates, and vanadates; separation of cobalt and nickel, and of the cobaltous and cobaltic salts, by Adolphe Carnot. The ammonio-cobaltic salts differ in many respects from the corresponding salts of the cobalt and nickel protoxides. But their respective characters are not, as a rule, sufficiently marked to serve to discriminate and separate these salts. M. Carnot, however, now finds that this advantage is presented by the molybdates, tungstates, and vanadates. In the present paper he deals with the molybdates alone.—On the reactions of oils with nitrate of silver, by M. Raoul Brullé. During his researches on the character of different oils, the author has been led to employ the nitrate of silver as a reagent. The results present remarkable differences in the case of olive, cotton, linseed, colza, and other vegetable oils.—On the egg of the sardine, by M. Georges Pouchet. The author's observations show that the sardine *de rogue* (the small sardine of commerce) is a young fish not yet arrived at maturity, and presenting the greatest irregularity in the development both of the ovaries and the ovules; nor, as a rule, is the size any clue to its state of development.

VIENNA.

Imperial Academy of Sciences, May 9.—The following papers were read:—On the preparation of indol from phenyl-glycocoll, by J. Mauthner and W. Suida.—On amides of carbonic acid (second communication), by F. Emich.—On the knowledge of some non-drying oils, by K. Hazura and A. Gruessner.—On the transplantation of bone, by A. Adamkiewicz.—On nerve-corpuscles in their physiological and pathological state, by the same.—Experiments on the decomposition of albumen by anaërobous micro-organisms, and on the aromatic products of decomposition, by the same.—Contribution to the knowledge of gases developed by the fermentation of albumen, by M. Nencki and N. Sieber.—On the formation of para-lactic acid by the fermentation of sugar, by the same.—On benzoyl-compounds of alcohols, phenols, and sugars, by Zd. H. Skraup.—On the constitution of grape-sugar, by the same.—Experimental researches on the periodic law, Part I, by B. Brauner.—Researches on musical psychology and acoustics, by K. Stecker.—Preparatory studies for a monograph on *Muscaria schizometopa*; Part I, synopsis of genera, by F. Brauer and J. von Bergenstamm.—On the crystals of grape-sugar and optically-active substances in general, by F. Becke.—On new improvements of the usual process of combustion, by F. Blau.—Note on the preparation of mono- and dibromo-pyridin, by the same.—On dry distillation of picolinate of copper, by the same.—On a new test for albuminous bodies, by C. Reichel.—Monograph on the fossorial wasps allied with Nysson and Bembex, by A. Handlirsch.—Embryological researches on Ascomycetes, by H. Zukal.

AMSTERDAM.

Royal Academy of Sciences, June 29.—Prof. v. d. Waals, Vice-President, in the chair.—M. Franchimont stated that, as early as the beginning of this year, he prepared the pentamethylene glycol, its oxide, and an unsaturated alcohol of five C-atoms, by boiling pentamethylene dinitramine with diluted sulphuric acid, as also the bromide agreeing with the glycol; and that M. Dekkers had treated the tetramethylene-dinitramine in the same manner. The properties of the pentamethylene glycol agree with those published a few days ago by M. Gustavson, who obtained this compound by another method. He spoke further of the action of nitric acid on carbonic and nitrogenic compounds, and of the influence exercised upon them by certain atomic groups. As instances of carbonic compounds he cited malonic acid esters and their derivatives; of nitrogenic compounds, all kinds of amides, urethanes, &c., so that the extraordinary strong influence of the group $COOCH_3$ appears most clearly, even in the derivatives of piperidine.—M. Pekelharing treated of the destruction of the virus of anthrax in the subcutaneous tissues of rabbits. Small pieces of gelose with a culture of anthrax bacilli, whether containing spores or not, packed in parchment-paper, introduced under the skin in rabbits, not only do not superinduce anthrax in the inoculated animals, but are themselves deprived of virulence. This is the case even when the wound remains perfectly aseptic, of course without application of any antiseptic matter. Leucocytes penetrate into the packets, but the bacilli or spores are not materially affected thereby. Therefore, next to the phagocytose, whose existence is nowise denied, the action of a dissolved substance for the destruction of bacilli must be taken into account.—M. de Vries read a paper on the spiral torsion in wild teasel (*Dipsacus sylvestris*). In opposition to the prevalent opinion, which regards the cases of spiral torsion (called by Alex. Braun *Zwangsdrehung*) as accidents, the speaker deemed himself justified in regarding this phenomenon as an hereditary variation; and this in consequence of an experiment begun by him in 1885 with two twisted individuals. From the seed of the same about 1650 plants were reared in 1887, among which were again two twisted specimens. The seed of these gave in 1889 above 1500 plants, among which were found a little more than 4 per cent. of twisted individuals. The torsion is, therefore, not only hereditary, but will gradually become fixed by the customary method of artificial selection. From the 4 per cent. twisted specimens the best have been selected for seed-bearers further to improve the race.—M. van Bemmelen mentioned the results obtained by M. Bakhuÿs Roozeboom in the pursuit of his researches concerning the behaviour of salts with regard to water. The normal course of the solubility may be disturbed by the appearance of a second layer of fluid when the salt and water are not mixed in all proportions. Mr. Bakhuÿs Roozeboom succeeded in illustrating the peculiarities of the behaviour in such cases in two examples: $AsBr_3$, and a salt recently detected by M. van Romburgh—

MICROSCOPICAL MINERALOGY.

Petrographical Tables: an Aid to the Microscopical Determination of Rock-forming Minerals. By Prof. H. Rosenbusch. Translated and Edited (with the Author's permission) by Dr. F. H. Hatch, of H.M. Geological Survey. (London: Swan Sonnenschein and Co., 1889.)

DR. HATCH has rendered a great service to English-speaking students by the preparation of this careful translation of Prof. Rosenbusch's very admirable "Hülfstabellen zur mikroskopischen Mineralbestimmung in Gesteinen," which appeared a few months ago. These tables may indeed be regarded as an index or summary to the same author's invaluable "Mikroskopische Physiographie der petrographisch wichtigen Mineralien," the English translation of the second edition of which, by Mr. J. P. Iddings, was reviewed not long ago in the pages of NATURE. The two works together supply a want that has long been felt by English students—namely, a complete summary of all that has been done in the way of making the optical and other characters of minerals available as means of recognizing them when seen in thin sections of rocks under the microscope.

Of the admirably lucid and exhaustive manner in which Prof. Rosenbusch, in these works, has compared, arranged, and not unfrequently verified the results accumulated by Zirkel, Tschermak, Von Lausaulx, Fouqué, Michel Lévy, and a host of other observers, who, during the last thirty years, have followed up the suggestive work of Mr. Sorby, the original founder of the science of microscopic petrology, it is not necessary to speak in this place. Geologists and mineralogists are alike placed under a great debt of gratitude to one who—besides making many original observations of great value himself—has so admirably systematized and correlated the results obtained by a great number of other independent workers; nor can they forget that Prof. Rosenbusch is the founder of the now famous Petrographical School of Heidelberg, in which many of the foremost investigators of this branch of science, now engaged in the study of rocks on both sides of the Atlantic, have been so well trained.

The first attempt at the construction of a series of tables, on something like the same lines as those in the work before us, was made as long ago as the year 1876, by Dr. C. Doelter, of Vienna, a pupil of Prof. Tschermak. It was only three years before this that the earliest endeavours to systematize the results arrived at by the study of rocks, with the aid of transparent sections under the microscope, had been given to the world in Zirkel's "Die mikroskopische Beschaffenheit der Mineralien und Gesteine," and in Rosenbusch's "Mikroskopische Physiographie der petrographisch wichtigen Mineralien": the former dealing more particularly with various characteristic peculiarities of the different rock-forming minerals, as a means by which they may be identified in thin sections; the latter aiming at the utilization of the important results arrived at by Des Cloizeaux and his pupils, in their important determinations of the "optical constants" of minerals, as a basis for the exact diagnosis of the constitution of rocks, under the difficult conditions presented by very thin sections which intersect the crystals in varying and unknown directions. Doelter's tables, appearing after these systematic works, constituted a very valuable addition to the scanty petrographical literature of that day. In this work of Doelter, "Die Bestimmung der petrographisch wichtigeren Mineralien durch das Mikroskop; eine Anleitung zur mikroskopischen Gesteins-Analyse," an attempt is made to construct a mineralogical key, similar to the "keys" published with certain floras, and so familiar to all students of systematic botany. Every mineral observed under the microscope was to be submitted to certain optical tests, and then relegated to a particular class; and by the further applications of the similar tests new points of distinction were to be detected, till at last the species or variety had been correctly identified. The process recommended to be pursued was, in fact, exactly similar to that which is usually followed by chemical students in the work of qualitative analysis.

In 1885, Dr. Eugen Hussak, of Gratz, a pupil of Dr. Doelter, published his "Anleitung zum Bestimmen der Gesteinbildenden Mineralien," in which the same method of procedure is illustrated in greater detail, and with the assistance of many new facts and methods that had been discovered since the publication of Dr. Doelter's tables.

In 1888, MM. A. Michel Lévy and A. Lacroix issued their very valuable work "Les Minéraux des Roches," in which the characters of the rock-forming minerals are also exhibited in a series of tables. In this treatise, the authors—we think wisely—abandoned the idea of making anything like analytical keys for the determination of the rock-forming minerals, and arranged the various species and varieties simply in alphabetical order. Just as few practical botanists or chemists find it necessary to go through the whole of the elaborate schemes of research contained in the text-books, though these may be of much educational value to a beginner, so no student of the microscopic character of rocks is called upon to pursue the exhaustive method of analysis illustrated in the tables of Doelter and Hussak. As a rule, the result of a preliminary examination of a mineral seen in a thin section is to make it obvious that we are dealing with some one out of two or three possible forms; and what the observer most needs for deciding between these, is a statement of the characteristic and distinctive peculiarities of every species, arranged in such a manner as to facilitate reference to them.

Prof. Rosenbusch, in his tables, combines to some extent the methods of his predecessors. The main grouping of the rock-forming minerals is into (1) singly-refracting minerals; (2) doubly-refracting uniaxial minerals (there is an unfortunate misprint in Dr. Hatch's translation of "biaxial" for "uniaxial" in table ii.*b*); and (3) doubly-refracting biaxial minerals. In each of these classes, the several species or varieties are arranged in groups according to their general affinities, and irrespectively of their system of crystallization. Dr. Hatch has very wisely supplemented this arrangement by an alphabetical index, and has thus secured almost the same facility of reference which is so conspicuous and valuable a feature in the tables of Michel Lévy and Lacroix.

If we compare the several series of tables to which we have referred, it is impossible to help being struck by the numerous and important additions which have been made to our knowledge of this branch of science during the last decade. Doelter, in 1876, recognized only 64 species or well-marked varieties of minerals as occurring as rock-constituents; Hussak, in 1885, raised this number to 107; Michel Lévy and Lacroix, in 1888, give 160; and Rosenbusch, in 1889, no less than 162 rock-forming types, although none of the opaque minerals are included in these later works.

Still more striking is the contrast between the earlier and later works of this class, when we come to examine the methods employed for the discrimination of the several species of minerals. In the two later works, the results obtained by the important methods of mineral isolation, first discovered and pursued in the famous petrographical laboratory of the Collège de France, under MM. Fouqué and Michel Lévy, and the methods of micro-chemical analysis so well elaborated by Bořický, Behrens, Streng, and other observers are all made use of. Perhaps the most important and characteristic new feature in the two latest published works will be found in the attempt to substitute exact measurements of the double refraction of minerals, for vague statements as to the intensity of the colours which they give with polarized light. It is perhaps too early to pronounce upon the applicability and practical value of the ingenious contrivances of M. E. Bertrand, and of M. Michel Lévy for determining respectively the index of refraction and the double refraction in the thin microscopic sections with which petrographers have to deal. If, however, the micro-refractometer and the *comparateur* fulfil their promise, it is not too much to hope that the methods of discriminating minerals in cleavage-flakes and thin sections will be as greatly facilitated by the exact determination of their refraction and double refraction as by the study of their positions of extinction or of the optical pictures which they give with convergent polarized light.

We have spoken of these tables as being of very great service as an index or summary of the excellent "Physiographie" of Prof. Rosenbusch, and, indeed, we think their chief value will be realized when they are thus employed in conjunction with that important systematic work. In the treatise itself, it has been possible to point out many important limitations and qualifications of general statements, though these have of course to be frequently omitted in the terse indications necessary for the tabular mode of presentation.

An illustration of the caution which ought to be exercised in applying determinations of the so-called optical "constants" of species as *absolute standards* for the identification of unknown forms is afforded to us in the work before us. In many basalts, like those of Bohemia, there occur large porphyritic crystals of an undoubted amphibole. It has long been known that this "basaltic hornblende" presents some very anomalous characters, especially in respect to its pleochroism and absorption, as well as to the curious chemical changes which it is found in whole or in part to have undergone. The important series of determinations of Michel Lévy and Lacroix, which have been incorporated in these tables by Rosenbusch, show that this form of amphibole is not less anomalous in its double refraction, than in some of its other properties. While the difference between the maximum and minimum indices of refraction in all other forms of hornblende ranges between 0·021 and 0·028, that of the basaltic hornblende is found to be as high as 0·072! Whether this remarkable and anomalous departure from the typical characters of an amphibole can be accounted for by the peculiar and somewhat exceptional conditions under which this particular variety is found to occur, it is not necessary here to discuss. But petrographical students cannot be too frequently reminded that—as the isolation and chemical analyses of rock constituents have so often proved—the minerals in rocks may present important differences from those which crystallize out in veins and cavities, and constitute the "types" of our mineralogical collections. Moreover, even small differences in the proportion of certain chemical ingredients have been shown again and again to exercise a very important influence in modifying the values of the so-called optical "constants."

The great interest of the determinations of Michel Lévy and Lacroix, which are adopted in these tables—and indeed constitute their most novel and striking feature—is derived from the fact that the observations on which they are based were made upon actual rock-constituents, and not upon the large crystals, often of exceptional character, which have hitherto been chiefly employed in investigations of this kind. A reference to the numbers representing the refraction and double-refraction of ægyrine among the pyroxenes, and of the several varieties of the epidotes and scapolites, will show that this remarkable case of basaltic hornblende does not by any means stand alone. We trust that the valuable contributions to our knowledge of the characteristics of the actual rock-forming species and varieties of minerals which have been made in M. Fouqué's laboratory, will be greatly added to in the future:—for by such researches only can we hope that many of the difficulties and anomalies which still surround the pursuit of petrological science will in the end be removed.

With the kind co-operation of Prof. Rosenbusch, Dr. Hatch has been enabled to bring these tables quite up to date; and he has fairly earned the thanks of all students of petrography by the careful and thorough manner in which he has performed his task. JOHN W. JUDD.

THE INFLUENCE OF SNOW ON THE SOIL AND ATMOSPHERE.

Der Einfluss einer Schneedecke auf Boden, Klima und Wetter. Von A. Woeikof. Pp. 1–115. *Geographische Abhandlungen*, herausgegeben von Prof. Dr. Albrecht Penck in Wien, Band III. Heft 3, pp. 321–435. (Wien und Olmütz: Eduard Hölzel, 1889.)

IN a country such as ours, which lies on the borders of a great ocean and a great continent, the protean phases of the weather are so greatly determined for us by causes which operate at a distance from our shores, that the influence of any temporary variation in the condition of the local surface is comparatively unimportant, and, excep locally, perhaps altogether inappreciable. But the furthe we recede from this border-land and penetrate to the interior of the continent, the more influential do such temporary and local variations become; and since also, as a rule, they are there more lasting than in our changeable climate, and take effect simultaneously over vast areas of country, it becomes an important object of inquiry how and to what extent they react on the atmosphere, and indirectly affect not only the local weather, but even that of surrounding regions. In the case of a sheet of snow, attention was first drawn to this question by Prof. Woeikof in 1871, in a paper published in the Transactions of the Russian Geographical Society, in which he endeavoured to show that as regards certain portions of Russia, the spring temperature depends very much on the quantity of snow that has fallen in the previous winter, a snowy winter being followed by a cold spring, and *vice versâ*. In 1878 he adduced further evidence of the effects of snow on the temperature, in a notice of the weather of December 1877, in the *Zeitschrift für Meteorologie*; and in 1880 Prof. Hann and Dr. Assmann, in the same periodical, traced the remarkably low temperature of Central Europe and the persistent anticyclone which lay over that region in December 1879 to the effect of the heavy snow that had fallen in the beginning of the month. In Northern Europe, where snow had not fallen, the temperature was not merely relatively, but absolutely higher, and it lay beyond the limits of the anticyclone.

Meanwhile, in 1877–79, the Indian meteorologists, being unacquainted with Prof. Woeikof's earlier work, had independently arrived at the conclusion that variations in the quantity of the winter and spring snowfall of the Himalaya exercise an important influence on the monsoon rains of the Upper Provinces of India; the consequences of an unusually heavy and especially late snowfall on the mountains being the persistence of dry westerly winds on the plains to the partial exclusion or enfeeblement of the rain-bearing summer monsoon; and it was shown that this sequence of land-winds on the plains after snow on the mountains is a common recurrent feature of the winter and spring months. In consequence, for some years past, monthly reports on the state of the Himalayan snows in the first six months of the year have formed a part of the regular routine of the Indian Meteorological Service, and they have afforded important data for forecasting the character of the monsoon rains.

In 1886 a system of snow reporting was adopted in Bavaria by Dr. Lang, and as the result of Prof. Woeikof's labours, a similar system was established in Russia two years later. In India, the system was established under a general order of the Government in April 1883, and that country, therefore, and not Bavaria, as stated by Prof. Woeikof, has considerable priority in this matter.

In his recent work, referred to at the head of this article, Prof. Woeikof sums up the present state of our knowledge of the influence of a snow-sheet on the soil, climate, and weather. The protection of the ground against frost, which is afforded by a covering of thick and loose snow has long been familiar, and was, indeed, the subject of detailed observation by E. and H. Becquerell in 1879–80; but additional observations of much value are given in evidence on this head, especially an elaborate series carried on during two years at the Russian Polar station Segastyr, in the Lena delta, in N. lat. 73° 23′. At this place, when the ground is covered with snow during more than six months of the year, the temperature of the coldest month at 1·6 metre beneath the ground surface was found to be less than 1° C. below the annual mea temperature of the surface (alternatively snow or soil) exposed to the air, while that of the warmest month was 15°·4 C. above it. The greater part of this difference of the excess and deficiency must be attributed to the non-conducting layer of snow and the protection thereby afforded against radiation and contact with the cold winds.

Of the differential cooling effect of a snow-sheet on the atmosphere, as compared with that of a bare land surface, the systematic evidence hitherto available for a rigorous comparison is less extensive than could be desired, owing to the fact that, until recently, but very few meteorological observatories have recorded the presence or absence of snow on the ground. But it fortunately happens that one first-class Observatory, that of Upsala, has done so for a period of fourteen years, and the discussion of these observations forms one of the most interesting and important chapters in the book. Comparing month by month the mean temperatures of all periods during which the ground was under snow with those with an unsnowed surface, Prof. Woeikof finds that the former are lower in November by 4°·7, in December by 5°·1, in January by 6°, in February by 5°·1, and in March by 5°·2 C., respectively equal to 8°·5, 9°·4, 10°·8, 9°·2, and 9°·4 F. The effect of a snow-sheet in lowering the temperature of the air, and in helping to establish anticyclonic conditions, such as prevailed over Central Europe in December 1879, appears, therefore, to be very considerable.

In another chapter of the work, Prof. Woeikof applies the conclusion thus established to the explanation of certain anomalies in the winter temperatures of parts of Asia and North America, and shows that the lower temperatures coincide with the prevalence of snow, and *vice versâ*. The most striking instance given is that of the Armenian plateau, the mean winter temperature of which, after reduction to sea-level value, would appear to be from 4° to 7° C. lower than that of the lower parts of the Transcaucasian province to the north and east. On the former, the snow lies for four or five months of the year; on the latter there is but little snow, and the mean temperature, even of January, is from 2° to 4° C. above the freezing-point. This exceptional area is well shown on Hann's isothermal chart for the month of January, in the new edition of Berghaus's "Physical Atlas."

In discussing the effect of a thick winter snow-sheet on springs and rivers, a variation is pointed out, which is not without importance in its bearings on some points of physical geography. In latitudes where the winter cold is sufficient to freeze the ground to a considerable depth, if heavy snow falls early in the winter before the cold has penetrated deeply below the surface, the protection thereby afforded allows the ground to thaw by conduction from the lower strata, and the water from the slow melting of the basal snow-layer, and much of that which is produced in the spring thaw, soaks into the soil and affords a supply which maintains the rivers more or less full through the succeeding summer. But if, before snow falls, the soil has been frozen to a great depth, a rapid thaw setting in in the spring floods the rivers and the surrounding tracts, while little or none enters the ground, and but little supply is stored up for maintaining the summer flow.

In this short notice we have been able to indicate only a few of the more interesting topics dealt with in Prof. Woeikof's treatise. The effects of the agent to which he has directed attention are undeniable and far-reaching, and the publication of his investigations should have the result of making the registration of the depth and duration of snow a part of the regular work of meteorological observatories. Other observations of a more detailed character, which he specifies in the course of his work, are also much needed. H. F. B.

THE "CIRCOLO MATEMATICO" OF PALERMO.

Rendiconti del Circolo Matematico di Palermo. (Palermo: Sede del Societa, 1887-89.)

THE "Circolo Matematico" is one of the junior members of the now large family of Mathematical Societies. We have before us Tomo I., which gives an account of the proceedings from March 1884 to July 1887. Tomo II. contains like matter for 1888, and of the current volume we have three parts, each of which contains an account of the proceedings for a period of two months, terminating with June last. The first general meeting of which there is any record was held on March 20, 1884, and in that year eleven meetings are recorded, and the proceedings published within the narrow limits of thirteen pages: it was then the day of small things, and we presume the gatherings were confined almost to conversational expositions of mathematical problems. With increase of days came increase of strength, and the first volume contains seventy communications from twenty-one authors; of these the only foreign contributors are Messrs. E. Catalan, F. Cavallaro, Hirst, and Schoute. Dr. Hirst's short note is "Sur la congruence Roccella, du troisième ordre et de la troisième classe," and in it he points out that Dr. Roccella's congruence is a particular case of the Cremonian congruences discussed by him in his memoir "On Congruences of the third order and class" (L. Math. Soc. Proc., vol. xvi., 1885). These congruences are also the subjects of papers read by Signor Guccia. Amongst the longer papers in this volume are: "Intorno ad alcune formole nella teorica delle funzione Ellittiche," by Signor Albeggiani; "Sulle superficie dell' n^{mo} ordine immerse nello spazio di n dimensioni," by P. del Pezzo; "Sopra un metodo per formare le equazioni a derivate parziali, delle superficie che ammettono una generatrice di forma costante," by M. Gebbia; "Sopra alcuni sistemi lineari di curve piane algebriche di genere *due*," by V. Martinetti.

In the second volume there are thirty-nine papers by twenty-six authors. The only long papers are: "Intorno alle curve razionali d'ordine n dello spazio a $n-1$ dimensioni," by G. Loria; "Sul carattere aritmetico dei coefficienti delle serie che soddisfano ad equazioni lineari differenziali o alle differenze," by S. Pincherle; "Sur la marche du cavalier," by C. Jordan. These papers are of no great length; the remaining communications rarely exceed four or five pages.

The May–June number of this year contains a "Solution du problème de Malfatti," by M. Lebon, and an "Étude d'un déplacement particulier d'une figure de forme invariable par des procédés élémentaires et purement géométriques," by M. Mannheim. In selecting papers we have had regard mainly to those which may be called memoirs; the smaller notes treat of similar matters, so that it is readily seen that the field at present occupied by the "Circle" is that of pure mathematics.

The names of the majority of the contributors are well known by their writings in other journals, and their work here is in all cases interesting, and of a high class. A peculiar feature of these volumes which strikes us is the amount of space devoted to the "Biblioteca matematica." In Vol. II., 236 pages are given up to the usual matter of a Society's Proceedings, and 83 pages to the titles of papers, &c., presented to the Society by individuals, or contained in the journals for which the *Circolo* exchanges its Proceedings. This is a useful piece of work, as the circle of exchanges is a large one. We wish the junior member every success.

OUR BOOK SHELF.

Names and Synonyms of British Plants. By G. Egerton-Warburton, B.A. Pp. 160. (London: G. Bell and Son, 1889.)

THIS little book is a synonymic catalogue of the British flowering plants and vascular Cryptogamia, in which are given the names under which the species stand in the last edition of the four standard hand-books, Sowerby's "English Botany," Hooker's "Student's Flora," Bentham's "Flora," Babington's "Manual," and in the London Catalogue. In a considerable number of cases the five differ more or less in the names which they adopt. This arises partly from the five authors taking a different view of specific limits. About two hundred of what Sir J. D. Hooker and Dr. Boswell call sub-species are usually regarded as species by Babington and as varieties by Bentham. The whole series of genera has lately been revised and redescribed by Mr. Bentham and Sir J. D. Hooker, and many which have been proposed by other authors are now placed as sub-genera or sunk altogether. In the preparation of the great Darwin catalogue of plants, under the editorship of Mr. B. Daydon Jackson, the priority of names has been more systematically investigated than has ever been previously attempted, and this has led to a great many changes. These are embodied in the last edition of the widely-used London Catalogue; but as the new or revised names stand there without any explanation, those who wish to use the list are often greatly puzzled, and it was a good idea of Mr. Warburton to prepare the present synonymic catalogue. It appears to have been drawn up very carefully, and gives a reference to the page or number indicating where in each of the five books every species will be found, and in an appendix there is a list of synonyms used by older British or Continental authorities. There is also a full list of the original authorities for the specific names, with the titles and dates of the books and papers in which the plants were originally described. The author omits to enumerate in his list two very useful books, the "Conspectus" of Nyman, and "Salictum Woburnense" of Forbes. He has failed, and no wonder, to run down some of the London Catalogue names of Rubi (*e.g.* *echinatus* and *longithyrsiger*), that refer to long-known plants, fully described in Babington's "Manual and Synopsis." J. G. B.

Geology in Systematic Notes and Tables for the Use of Teachers and of Taught. By W. F. Gwinnell, F.G.S., F.R.Met.Soc., &c. (London: Allman and Son, 1889.)

WHILE we cannot but regard the chief educational value of summary statements of the bare facts of a science, like those contained in the work before us, as consisting in the influence they exercise on the thought and memory of him who compiles them, yet it is impossible to ignore the fact that, in these days of many examinations, there is a persistent demand for works of the class. It is well, therefore, that books of the kind should be prepared with reasonable intelligence, and with such care against the propagation of glaring and misleading errors as the author of this work has certainly shown. It would undoubtedly be better that the *teachers* should prepare their own lecture-notes, with illustrations derived from personal reading and study; and no less desirable is it that the *taught* should make such notes of the facts referred to in illustration of the lessons given them, as to be able to recall to their minds the arguments of the teacher, and the principles which he has aimed at enforcing. For teachers and students who are incapable of following this very obvious and desirable method, however, notes and tables of the kind before us certainly have their use. Mr. Gwinnell's book is happily free from the gross absurdities and mistakes so common in many of the books prepared with the avowed aim of meeting the wants of those preparing for examination; and, for those who must have a crutch, we may admit that this is a very excellent one of its kind. We have noticed a few unfortunate errors, such as the statement that granitite contains pink orthoclase, and that graphic granite consists of "quartz and felspar arranged in lines like writing." The pretty geological map of Great Britain forming the frontispiece, too, which has been adopted from a work that appeared a good many years ago, exhibits nearly the whole of the Scottish Highlands as consisting of Lower Silurian rocks. On the whole, however, the book has the merit of being accurate and up to date, and the author is entitled to the praise of having very carefully selected, arranged, and verified the mass of miscellaneous information which he has brought together.

La Période Glaciare: Étudiée principalement en France et en Suisse. Par A. Falsan. (Paris: Felix Alcan, 1889.)

THIS volume, which is the most recent addition to the collection of the "International Scientific Series," published in the French language, contains a most admirable *résumé* of facts and opinions bearing upon the Glacial period, as illustrated in France and Switzerland. The author shows a very extensive acquaintance with the immense body of literature dealing with glacial questions, by English, American, German, and Scandinavian geologists; and very fairly and temperately discusses the bearings of the numerous theories that have been put forward upon the facts observed in France. As the references to original memoirs are very full and complete, the work cannot fail to be of much value to glacialists and geologists in general, while it admirably fulfils its main object, that of giving an accurate and popular account of the current knowledge and opinion of geologists upon glacial questions, especially adapted to the want of French readers.

Even when compelled to express his dissent from extreme views upon such questions as the recurrence of glacial periods in past geological times, the influence of glaciers in excavating lake basins, and the existence of man in Tertiary times, M. Falsan clearly states the grounds on which conclusions different from his own have been arrived at by other authors. In his presentation of the arguments for and against the various glacial theories, his moderation and his fairness are alike conspicuous.

The author of this book has taken an active part in the important work of preserving the most conspicuous of the fine boulders scattered over France; and numerous sketches of these boulders, with many interesting details concerning them, find a place in these pages. Two plates, a map showing the former extension of the French glaciers, and a series of sections illustrating the former dimensions of the Rhone Glacier, accompany the work; but the other engravings are wanting in the beauty and finish so often found in books published in France. The very full table of contents does not compensate for the total absence of an index to the book.

Physiological Diagrams. With an Index. By G. Davies. (Edinburgh and London: W. and A. K. Johnston, 1889.)

THESE diagrams are designed for use in schools, and to "supply the teacher with a means (by teaching the pupils to draw from them) of impressing the form and organs of the different parts of the body on the pupils' minds." There are nine in all (each 22×30) printed in black upon cardboard, with eyelet holes for hanging purposes. The parts are represented in hard outline, each being numbered, in accordance with a series of explanatory reproductions in miniature, which accompany the "text." The whole production is most feeble. It is only when the author relies upon standard works that his diagrams are tolerable, and his only really useful sheet (No. 1) is a copy. Seeing that much better wall diagrams have long been before the public, we are at a loss to see any *raison d'être* for these poor apologies. We are told that "the principal object of these drawings is to facilitate the teaching of physiology in schools." So much the worse for the schools! We cannot congratulate either author or publishers upon their venture. The day is past in which anything in outline will pass current for an atlas; and pictorial aids to the teaching of elementary physiology, to be of any service, must be produced by competent authorities.

Woolwich Mathematical Papers, 1880–88. Edited by E. J. Brooksmith, B.A., LL.M. (London: Macmillan and Co., 1889.)

IN this book we have a collection of the various papers in mathematics prepared during the last eight years to test the knowledge of candidates for admission into the Royal Military Academy. The subjects are: geometry, arithmetic, algebra, plane trigonometry, statics, and dynamics. The volume will prove most useful to those who intend entering for these examinations, and will also be of service to many teachers in our public and private schools. The answers to the examples in the various papers are collected together at the end.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Head Growth in Students at the University of Cambridge.

UNDER the above heading there appeared in NATURE, vol. xxxviii. p. 14, an article in which certain very weighty conclusions are drawn from grounds which I hope to show are quite inadequate. These conclusions are as follow:—

(1) Although it is pretty well ascertained that in the masses of the population the brain ceases to grow after the age of 19, or even earlier, it is by no means so with University students.

(2) That men who obtain high honours have had considerably larger brains than others at the age of 19.

(3) That they have larger brains than others, but not to the same extent, at the age of 25; in fact, their predominance is by that time diminished to one-half of what it was.

(4) Consequently "high honour" men are presumably, as a class, both more precocious and more gifted throughout than others.

These conclusions were deduced from measurements taken in the following way. The maximum length, width, and height (above a specified plane) of the head are taken in inches and decimals of an inch. Since the quantities lie between 5 and 8 inches, each measurement is open to an error of from 1·3 to 2·0 per cent.

The product of these three is found, and is supposed proportional to the cranial capacity. That this is most imperfectly so in individuals is manifest; but the author hopes that in the average of a large number of cases the effect of the extreme variability of shape of the head may be obliterated. He therefore tabulates the products, using the first decimal place, *i.e.* up to four significant figures. Since the original measurements only included two figures, the last two of the four must be inaccurate. The product is open to an error of 3 or 4 or even up to 6 per cent. Since the probable error is from 3 to 6 per cent., which is nearly the same size as the difference between the "honour" man's and "poll" man's heads, and also the difference supposed to be due to growth, I therefore hold that there is no evidence for any of the author's conclusions.

I have recently had a better opportunity of judging the value of the statistics, for two of my friends, who have been several times measured, have kindly shown me the results.

	Width.	Length.	Height.	Product.
X., June 1888	5·8	7·7	5·6	250·1
,, Nov. ,,	5·9	7·8	5·2	239·3
,, Dec. ,,	5·9	7·7	5·5	249·9
,, Jan. 1889	5·8	7·6	5·4	238·0
,, March ,,	5·8	7·6	5·4	238·0
,, May ,,	5·8	7·7	5·3	236·7
,, June ,,	5·8	7·8	5·5	248·8
Y., Jan. 1888	5·9	7·5	5·6	247·8
,, March ,,	6·0	7·4	5·4	239·8
,, Aug. ,,	6·0	7·6	5·5	250·8

From the above table it will be seen that (1) in the measurements of the same individual taken at different times the width may vary 0·1 inch; (2) the length may vary 0·2 inch; (3) the height may vary 0·4 inch; (4) the above variations are not due to head growth, for they are as often negative as positive.

As anyone would expect who had seen the instrument used, the height measurement is most unsatisfactory. The error of 0·4 inch is not an isolated case. Yesterday another friend of mine, who was measured for the second time, found that his height of head had apparently decreased 0·5 inch.

The products are seen to vary in the first case from 236·7 to 250·1, nearly 6 per cent. So far are the figures capable of affording good evidence of head growth of either individual, they are so inaccurate as not to make certain whether X. or Y. had the bigger head. It is quite evident that numbers, each open to an error of 5 or 6 per cent., cannot, when combined into averages, teach us anything about differences as minute as 3 per cent.

Trinity College, Cambridge, July 16. F. M. T.

THE errors made in measuring the height of the head are certainly much larger in the instance given by "F. M. T." than they should be; still they do not seem to me large enough to throw doubt on the truth of the general conclusions to which he refers. (1) As regards the difference between the means of the "products" in the high honour and the poll men. Those means are 224 and 237, and they depend on 258 and 361 observations respectively, which numbers are much the same as 16^2 and 19^2. Therefore the probable error in the determination of each of these means will be equal to the probable error of a single "product" divided by 16 in the one case and by 19 in the other. I have as yet no data to determine the probable error of a single "product," due to faults of measurement alone, other than those given by "F. M. T.," which suggest, though in the rudest way, that it is about 4 units. Accepting this for the moment as a basis, the probable error of the means of the two sets of "products" would be 4 divided by 16 and by 19, equal, say, to $\frac{1}{4}$ and $\frac{1}{5}$ respectively. Now, the chance of an error exceeding 4 or 5 times the probable error is not worth regarding; therefore safety, so far as regards the effects of inaccuracy of measurement, is practically to be found in each mean value beyond a range of about 1 unit. In the differences between the mean measures, safety will be found beyond the range $\sqrt{2}$, say $1\frac{1}{2}$ units. But the two means 224 and 237 differ by as much as 7 units. It should, however, be remarked that the seven observations fall into two well-marked groups, each of which is very consistent within itself, but which differ from one another by 10 units. This raises strong suspicion of some peculiarity in the shape of the head, which caused doubt as to the exact line of maximum height, and that one line was followed in three of the measurements and another line in the remaining four. (2) As regards the differences between the high honour and the poll men at different ages, the observations at each stage are, of course, much less numerous than in the sum of all of them, still they range in all cases but two between 25 (or 5^2) and 102 (or say 10^2). Each person must judge for himself, from the diagram that accompanied my little paper, how far the run of those differences confirms my conclusions. I think they do well enough to give "an approximately true" idea of what we should find if we had the opportunity of discussing a much larger number of observations, and this was all that I claimed.

The remarks of "F. M. T." lead to two useful deductions. One is the desirability of checking, as soon as may be, the conclusions already reached, by discussing the observations that have since accumulated. The other is to improve, if possible, the method of measuring the height of head. The existing plan was adopted, after consultation with many competent persons, and many trials, as the best then available for making this very difficult measurement. I have, however, never ventured to introduce its use in my laboratory at South Kensington.

FRANCIS GALTON.

Intermittent Sensations.

IN a short notice in NATURE of May 23 (p. 86), calling attention to the intermittence of the intensity of some sensations, and more particularly to the experience of M. Couetoux as reported in the *Revue Scientifique*, the writer very properly remarks, that these sensorial fluctuations deserve more thorough study. It may interest him, therefore, to learn that the interrupted sensibility of the retina can be easily demonstrated, to anyone possessed of binocular vision.

Some years ago, on converging the eyes, so as to fuse the images of two squares, each square being composed of parallel lines 1 mm. broad with an equal interval between them, and the lines in one square being perpendicular to those of the others, I was astonished to find that instead of squares, which ought to have resulted from the perfect fusion of the two images, the field was occupied by a series of zig-zags, composed of portions of straight lines of each square, passing across the field sometimes from right to left, sometimes the contrary way, and too complex and transitory to admit of analysis.

Since your notice, while experimenting with my students with a stereoscope, we have obtained the same result in every case. But, in order to determine the rate of intermittence, the attention was fixed on a small mark made in the centre of one of the squares.

This mark was found, on an average of a number of experiments by different individuals, to be visible, with its accompanying lines, for from 6 to 8 seconds, and then completely extinguished; and the lines of the other square, appearing for an equal interval of time, thus completed the cycle of activity and rest in from 12 to 16 seconds.

On covering the eye not directed to the mark, this point was never entirely lost sight of, but went through a series of changes of brightness and degradation of the sensorial impression, corresponding in time with those of the previous experiment.

These experiments seem to show that the impression is not equally intense, at the same instant, over the surface of each retina, but occupies successive areas, in somewhat irregular patches, which appear to be supplemented by the other retina in binocular vision It is probably due to this that the imperfect images of objects formed on the retina are corrected, and our perceptions made more accurate than they would be if our sensations were not intermittent. THOMAS REID.

11 Elmbank Street, Glasgow.

The Aurora.

THE aurora in the Unites States is rarely seen at a single station for two nights in succession, but is usually reported from different stations for about four days at each manifestation. Recurrence at intervals of nearly twenty-six days is common.

During 1888 there were eighteen instances of this, in which the beginnings of the attendant magnetic perturbations, as shown by the self-recording magnetograph, were so abrupt that it was possible by this means to determine the time of the revolution of the sun, the average period thus found being twenty-six days and eight hours.

This behaviour of auroras and magnetic storms indicates that any solar disturbance which may originate them has this power during a limited portion only of its transit across the earthward side of the sun. From April 1886 to April 1889 inclusive, there were in this country 188 such characteristic outbreaks of the aurora. In twenty-six, observations were lacking; but in the remaining 162, in every instance, bright faculæ with or without dark spots are known to have been located upon the sun's eastern limb appearing by rotation. In those instances in which a disturbance appearing by rotation failed to originate an aurora, there was, as a rule, an increase in the number of stations reporting thunderstorms. Indeed, at such times there was always an increase of thunderstorms, although the aurora when at its height not unfrequently seemed to take their place, causing a temporary decrease. From this it follows that the appearance upon the sun by rotation of spots or faculæ is a condition upon which the appearance of the aurora or increase of thunderstorms to some extent depends. M. A. VEEDER.

Do Animals Count?

HAVING studied Sir J. Lubbock's interesting book, I remembered a fact observed by me, which, though it is not conclusive, seems worth mentioning. I was amused some years ago to observe the feeding of the young in a sparrow-house near an upper window of my house. The old sparrow alighted upon the small veranda of the sparrow-house with four living cankerworms in his beak. Then the four young ones put out their heads, with the customary noise, and were fed each with a caterpillar. The sparrow went off, and returned after a while again with four living cankerworms in his beak, which were disposed of in the same manner. I was so interested and pleased with the process that I watched it for some time and during the following days.

A fact which I have not seen noticed here in the extensive sparrow literature, is that for a number of years sparrows begin to build nests of dry grass and hay at the top of high trees. The first I saw were large irregular balls placed on the tripod of twigs. The entrance was on the inner side near the lower end of the balls. Last year, I observed another form of the nests. A strong rope formed of dry grass, as thick as a man's wrist and as long as the forearm, is fastened only with the upper end to strong branches at the top of high trees. The rope's end has a rather large ovoid shape with the entrance to the inside near the end. Of such nests I saw last winter about a dozen on the elms here in Main Street, near the College grounds, and similar ones in Putnam Avenue and other streets. A long pole near my house strongly covered by a vine (*Celastrus scandens*) had such a nest for three years, used every year.

In the sparrow-houses around my lodging the sparrows stay throughout the winter; commonly one male and three females in every house, till in spring the superfluous females are turned out. H. A. HAGEN.

The "Hatchery" of the Sun-fish.

THE fact that the "sun-fish" of the American lakes and streams prepares a place for the deposit of its eggs and guards them till hatched is widely known. Certainly is has long been known and is recorded in all recent American works on fishes. The first detailed statement of its nidification I know of was published by Dr. John D. Godman, in his "Rambles of a Naturalist," about 1830, and is reprinted with the third and succeeding editions of his "American Natural History," published in 1836, &c.

Another quite full account of its nest-building and care of the eggs was published, with an illustration, by the late Prof. L. Agassiz in the Proceedings of the American Academy of Arts and Sciences (vol. iii. pp. 329, 330, 1857). But the accounts of Godman and Agassiz, as well as all others, and my own observations, fail to agree with those recorded in NATURE (June 27, p. 202). The sun-fish, generally at least, simply clears a subcircular area whose diameter is usually about two or three times its own length, and therein the female deposits her eggs. It has generally been assumed that she alone or she and the male in turn guards the nest. The idea, however, is only the result of analogy from the observation of the higher vertebrates. It is quite likely that the male fish is usually the guardian of the nest, as in the case of the Gasterosteids, Cichlids, and Silurids.

It should be added that the American sun-fish, although called in some places roach and bream, is not at all related to the English fishes so named, but is the representative of a family (*Centrarchidæ*) peculiar to and quite characteristic of North America. This family is exemplified by about forty species, referred to ten or eleven genera. The only species observed in the Adirondack region is the *Eupomotis gibbosus*, generally known to European naturalists as *Pomatis vulgaris* or *auritus*. The family is closely related to the Percids, and is indeed considered to form a part of the latter by many naturalists, and has nothing to do with the Cyprinids, to which the roach and bream belong. THEO. GILL.

Washington, July 17.

Centrifugal Force and D'Alembert's Principle.

I agree so cordially with the greater part of Prof. Minchin's address to the Association for the Improvement of Geometrical Teaching, delivered on January 19, 1889, and reported in NATURE of June 6, p. 126, that I feel the more induced to enter a protest against his remarks on the subject of "centrifugal force."

I admit that the name is not well chosen, and is often misunderstood, but I contend that we want a name for certain forces which are now called centrifugal, and which, until a better name be suggested, we can do no better than to continue to call by that name.

If a train, passing round a curve at too great a rate, tears the rails from the sleepers, we want a name for the force producing this effect. When a train, running over a horizontal girder bridge, produces a deflection greater than that due to its weight, we want a name for the force producing this extra strain.

The popular mistake is in regarding centrifugal force as a force imparted *to* a body whose motion is being deflected, instead of being imparted *by* such a body.

When a wet mop is trundled, for example, the water does not fly from it owing to centrifugal force, but owing to want of sufficient centripetal force to keep it back.

Prof. Minchin says:—"If we imagine a stone to be attached to an elastic string, one end of which is tied to the hand, while the stone is projected vertically upwards, the hand would experience an *upward* pull. Are we thence to conclude that the stone is continually acted on by an *upward* force?"

From this illustration Prof. Minchin obviously objects to the term "centrifugal force" as meaning a force imparted *to* the body whose motion is being deflected. In this he is certainly right, but this is no objection against its legitimate use as a force imparted *by* such a body.

Clerk Maxwell ("Matter and Motion," p. 97), says that "in some popular treatises centripetal and centrifugal forces are described as opposing and balancing each other. But they are merely different aspects of the same stress." Just so. But because two classes of forces are different aspects of the same stress, why, if sufficiently common and important, should they not have distinctive names given them?

What I understand by centrifugal force is the reaction against a force deflecting a body's motion.

Knowing the objections which have been raised to the use of the term centrifugal as denoting such forces, I have endeavoured to find some unobjectionable equivalent for it. For *centripetal* force (which, strangely enough, is not generally objected to), I have found what seems to me a fair equivalent, viz. *normal force*, defining force as *normal* when it produces deflection only, and *tangential* when it produces change of rate only, but I have never been able to find a better name than centrifugal for the reaction against normal forces.

Prof. Minchin traces back what he considers to be the "fallacy" of centrifugal force to D'Alembert's principle, to which he objects as "unnatural and unnecessary." I do not think he will get many to agree with him in this view. The hypothetical reversal of the resultant forces in D'Alembert's principle may be unnecessary in the sense that we can do without it; but as it enables us to avoid the consideration of those changes in forces which are functions of the positions of their points of application, it is to be regarded rather as an ingenious device, unnecessary perhaps now that we have learned to distinguish power from work—that is, the fluxion from the fluent—but very useful when the ideas of power and work were confused together, as until lately they have been. At present it would perhaps be better to enunciate D'Alembert's principle as follows:—

"The algebraical sum of the powers of the external forces of a passive system is equal to the sum of the powers of the resultant forces." A *passive system*, for any motion, being defined as "one the sum of the powers of whose *internal* forces for that motion, is zero." F. GUTHRIE.

South African College, July 2.

"The Theorem of the Bride."

DR. ALLMAN would be doing a service if he could trace the *origin* of this term (see NATURE, July 25, p. 299). Its occurrence in the "Scholia" carries its use back to an early date, but hardly far enough. R. T.

RECENT RESEARCHES INTO THE ORIGIN AND AGE OF THE HIGHLANDS OF SCOTLAND AND THE WEST OF IRELAND.[1]

II.

III.—*The Silurian Period.*

AFTER the long interval of time represented by the elevation of the red sandstones into dry land, and their entire removal from some places by denudation, the north-west of Scotland, and probably a large tract lying around it, sank under the sea. The depression seems to have been slow and gradual, and to have continued until the site of the Cambrian basins and of the surrounding region was covered with a considerable depth of clear open sea-water. The records of this subsidence are contained in a series of strata having a total thickness of somewhere about 2000 feet, and divisible into two chief groups—a Lower, composed of quartzites, grits, and thin conglomerate, about 500 feet in total depth, and an Upper, consisting almost wholly of limestone. Perhaps the most striking feature in this series of stratified rocks is the abundance of their organic remains. The quartzites are crowded with the tubes formed by sea-worms when the material existed as soft white sand on the sea-bottom. The limestones are made up of the remains of calcareous organisms, among which the most conspicuous that now remain are chambered shells and Gasteropods. Throughout these limestones, worm-casts are present almost everywhere, and in such abundance as to show, as Mr. Peach has pointed out, that "nearly every particle of the calcareous mud must have passed through the intestines of worms." A large collection of fossils has been made by the Geological Survey from these limestones, which, though not yet specifically determined, amply confirm the original generalization of Salter, made more than thirty years ago, that the aspect or facies of organic remains in the limestones of the north-west of Scotland resembles that of the older parts of the Lower Silurian formations of Canada rather than that of the corresponding rocks in Wales. So marked is the resemblance to the American type as to indicate that some shore-line must once have stretched across the North Atlantic, in order to afford a platform for the free migration of marine life between the two areas. The contrast with the Welsh type has been explained by the probable existence of some barrier that separated the sea-bed over the north-west of Scotland from that of Southern Scotland, England, and Wales. That such a barrier existed is tolerably certain, and I shall presently refer to some indications of its probable position. At the same time it may be open to question whether the Durness limestones can be properly correlated as homotaxial equivalents of any Lower Silurian rocks in Wales. My own impression is that they may be older than the oldest Arenig rocks, and may be equivalent to some part of the "Primordial Silurian" or Cambrian series. This, however, is a question that must remain unsettled until a thorough critical examination of the fossils has been completed.

The area within which these Silurian quartzites and limestones can be certainly recognized forms a narrow belt extending for about 110 miles along the north-west coast of Scotland, from the northern coast of Sutherland to the south of the Island of Skye. Throughout that extent of ground the rocks exhibit remarkable persistence in the character and thickness of their several subdivisions, whence the inference may legitimately be drawn that the area within which they are now visible forms but a small part of the region over which they were originally deposited.

It was claimed by Murchison, and generally conceded by geologists, that the quartzites and limestones of the north-west pass upward into a younger series of schists, representing metamorphosed sedimentary rocks. This order of succession appeared to be established by the evidence of many clear natural sections along the whole tract from Durness to Skye. It was first adopted and afterwards opposed by Nicol, who in his later papers maintained that the supposed younger schists were merely the old or Archæan gneiss brought up again by great faults, and pushed over the younger formations. But he failed to account for the striking difference in petrographical character between the old gneiss and the younger schists, and for the remarkable coincidence between the general dip of the latter and that of the Silurian stratified rocks on which they seemed to rest conformably. During the last ten years, various geologists have renewed the investigation of the question, among whom I may specially mention Dr. Hicks, Prof. Bonney, Dr. Callaway, Prof. Lapworth, and the members of the Geological Survey, particularly Messrs. Peach, Horne, and Clough. The result of their labours has been, in the first place, the discovery of one of the most complicated pieces of geological structure at present known in any country; in the second place, the abandonment of all further controversy, and the attainment of complete harmony regarding the order of geological succession in the North-West Highlands.

Murchison's view that there is a regular upward passage from the quartzites and limestones into the upper schists is proved to be erroneous, while Nicol's contention that the old gneiss is brought up again above the Silurian rocks is found to be, so far, correct. But the structure is now seen to be infinitely more complex than Nicol imagined, while, on the other hand, Murchison's belief that the younger schists were evidence of a gigantic metamorphism later than Lower Silurian time is undoubtedly true, though in a sense very different from that in which he looked at the question.

Nowhere in the North-West Highlands can any rock be seen resting in its original and natural position above the limestones. The highest limestone of Durness is the youngest rock of that region about the geological position of which there is any certainty. At present we know absolutely nothing of other sedimentary strata which followed that limestone. That such strata continued to be deposited is certain, for the changes which the quartzites and limestones have undergone could not have taken place save under the pressure of a thick mass of overlying material. But this superincumbent mass has been entirely obliterated in the extraordinary series of terrestrial movements which I have now to describe.

[1] The Friday evening lecture delivered at the Royal Institution on June 7, by Dr. Archibald Geikie, F.R.S. Continued from p. 302.

IV.—*The Period of the Younger Schists.*

Without entering into details, which are only intelligible with the help of a large map and sections, and even with this aid involve much disquisition of a technical kind, I may briefly say that after the deposition of the limestone and of the missing strata, whatever these may have been, which covered them, the whole region was convulsed by a series of disturbances, to which there has since been no parallel within our borders. By a series of intermittent movements the terrestrial crust, for thousands of feet downward, over the North-West Highlands, was fissured and pushed bodily westward. The various geological formations of that district—Archæan, Cambrian, and Silurian—were disrupted and driven over each other. Thus masses of rock, not more than a few hundred feet thick, were piled up so as to appear multiplied tenfold. The youngest strata were doubled under the oldest, and large slices of the ancient Archæan gneiss were made to rest on the Silurian limestones.

Fortunately the strongly marked characters of the different members of the Silurian series, the striking contrast between them and the Cambrian sandstones and Archæan gneiss, and the manner in which all these rocks are now laid bare on coast cliffs and rugged hill-sides, have rendered possible the task of unravelling this labyrinthine structure. The large maps, on the scale of 6 inches to a mile, on which this structure has been worked out by the Geological Survey, are by far the most complicated which the Survey has yet produced; indeed, I am not aware that such mapping has ever before been attempted. [Some specimens of these maps were exhibited.]

On exposed rock-faces we see a thin group of strata repeated again and again by small reversed faults, the lower beds being made to rest on the higher till they occupy a great breadth of ground, and appear of considerable thickness. Further examination will generally show that they have been all pushed westwards, and that their truncated under ends rest upon a platform of undisturbed rock along which they have travelled. We may further observe them to be abruptly cut off at a higher level by a sharp line, on which perhaps stands another series of piled-up beds. This piling up and truncation of the rocks is followed by a still more gigantic displacement. Lower and lower portions of the geological series have been torn up and thrust westward until at last the Archæan platform has given way, and masses of it, many hundreds of feet in thickness and many miles in length, have been driven over the younger formations. The horizontal distance to which this removal has reached can sometimes be shown to have amounted to at least ten miles; perhaps it may have been sometimes even greater.

In studying this complicated system of dislocations we soon meet with evidence that the movements were not all effected at one time, but that on the contrary they took place at intervals, the earlier being disrupted by the later. The lines of maximum thrust override those of lesser size, and the most easterly of these lines passes successively across all the others till it rests directly on unmoved rocks. The period of terrestrial disturbance was probably a prolonged one, and this inference is strengthened by other evidence to be afterwards adduced.

The direction of movement has been on the whole from the east-south-east. Bordering the west coast of Sutherland and Ross there is a strip of ground about 10 or 15 miles broad and some 90 miles long, in which the rocks have not been displaced. East of that strip, along a belt of dislocation varying up to five or six miles in breadth, the disturbances become increasingly numerous and powerful towards the interior, until at last a gigantic thrust-plane is encountered, above and beyond which the rocks have been so crushed and altered, that it is for the most part no longer possible to tell what their original character has been. They are now flaggy schists—the younger "quartzose and gneissose flagstones" of Murchison, "the Moine schists" of the Geological Survey.

The enormous amount of fracturing, displacing, and crushing caused by these terrestrial disturbances has resulted in the development of regional metamorphism on an extensive scale. Every stage can be traced from a sandstone or conglomerate into a perfect schist, and from the most typical coarse Archæan gneiss into a fine laminated slate.

Where the feeblest amount of alteration has taken place, the rock has been merely somewhat crushed, its larger crystals or pebbles have been fractured, and the separated portions have been re-cemented. A further stage is shown where the fine material of the rock has been more comminuted and has been drawn out round the flattened and elongated crystals or pebbles. The latter give way in proportion to their power of resistance. The felspars and hornblendes are first left as "eyes," and then crushed down till they disappear in the general matrix. The harder quartz-pebbles of the conglomerates have resisted longer; but they too, in the planes of great movement, are found to be pulled out to twice or four times their length, or to be flattened out into mere thin plates like pennies. One of the most singular proofs of this internal movement of the component particles of even so obdurate a rock as quartzite is shown by the deformation of the worm-tubes. As these tubes come within the influence of the movement their vertical position changes into an inclined one, and they become gradually flatter and more drawn out, till at last, before they cease to be traceable, they appear as mere long ribbons on the surface of the rock, which then becomes a quartz-schist. Along the planes of intense crushing the original structure of a rock is entirely effaced, its crystals or grains are ground into fragments, and it acquires a streaked laminated structure like a shale or slate.

But for the most part, concomitant with the mechanical destruction of the various rocks, there has been a chemical and mineralogical re-arrangement of their particles. Out of their broken-down materials new minerals have crystallized, and this process of reconstruction has, in the most thoroughly altered masses, proceeded so far that the whole new structure is now crystalline. In this manner, mica, quartz, felspar, hornblende, and other minerals, have been developed, and have arranged themselves along the lines of movement in the crushed rock. These lines, approximating to the surfaces of the great thrust-planes, may be utterly discordant from the structure-lines, such as those of foliation or bedding, in the original mass. Rocks of this character are true schists, and I know of no internal or external signs by which, apart from field-evidence, they are to be distinguished from Archæan schists, as to the derivation of which we can only guess, and which, therefore, must in the meantime be considered as original rocks.

By the aid of the microscope, much assistance is obtained in tracing out the mineral transformations which have taken place in the course of this regional metamorphism. To show the larger features of the change, so far as they can be judged of in hand-specimens, I exhibit on the table a series of pieces of the crushed gneiss, quartzite, and conglomerate; and to illustrate the internal changes I show a selection of slides on the screen, photographed from thin slices of the rocks as seen under the microscope.

The importance of the discovery of this belt of extreme complication in the North-West Highlands can hardly be over-estimated. It gives us the key to the geological structure, not only of the Highlands, but of all the areas of younger crystalline schists in our own area, and will doubtless be found to explain much in the geological structure of Scandinavia. The lines of maximum thrust-planes can be followed for 100 miles, from the north of Sutherland into Skye; but this is only a small part of their extent. They can be picked up again in the west of Mayo and Donegal, a total distance of some 400 miles. That similar lines of movement have affected Scandinavia and produced the distinctive strike of the rocks there can hardly be doubted, so that the total length of disturbed country in North-Western Europe probably exceeds 1600 miles, trending in a general north-north east direction.

How far the influence of the great terrestrial movements extended eastwards from what now appears as the belt of maximum disturbance, and what effect it had upon the configuration of the surface, are questions to which as yet no satisfactory answer can be given. It is difficult to suppose that such colossal displacements and fractures of the crust should not have powerfully affected the superficial topography of the time. They may have produced a high mountain range, or a succession of parallel ranges, extending along the north-west of Europe. The existence of some such mass of land is needed to account for the vast piles of sediment of which the Palæozoic, Secondary, and Tertiary formations have been built up. So great, however, is the antiquity of these terrestrial movements, so continual and gigantic has been the denudation, and so repeated have been the oscillations of level, that the upheaved land has been reduced to the fragments that now form the Highlands and Islands of the west of Ireland, of Scotland, and of Scandinavia.

It is quite clear that during the disturbances in the north-west region the main thrust came from the eastward. It will be interesting to discover how far towards the east these disturbances affected the structure of the rocks beneath. That it reached across the whole breadth of the Scottish Highlands—that is, for a distance of 100 to 130 miles—can be conclusively proved. That it extended much further, and embraced within its area the whole of the Silurian regions of the three kingdoms can, I think, be shown to be highly probable.

To understand this part of the problem it is necessary to consider the structure of the ground immediately to the east of the belt of extreme complication in the North-West Highlands. I have said that the displacements and metamorphism increased in intensity from west to east, until at last, by a final gigantic thrust, a series of reconstructed schists has been driven over rocks whose origin can still be determined. Among these eastern schists it is occasionally possible to detect more or less reliable traces of the original rocks out of the crushing down of which they have been formed. Thus we find in the northern part of the area slices of Archæan and eruptive rocks, and in the south an increasing amount of material which has been derived from the destruction of the red Cambrian sandstones. It is tolerably evident that in the broad band of country which extends from the belt of complication eastwards to the Moray Firth and the line of the Great Glen, and embraces the mountainous tracts of Sutherland, Ross, Western Inverness-shire, and North-Western Argyllshire, the lower parts of the geological record are repeated again and again. It is mainly the Archæan platform, with its covering of Cambrian sandstones, and possibly the lower parts of the Silurian series, which have been broken up, plicated, crushed, and converted into the series of crystalline schists that form the picturesque heights of Ben Hope and Ben Klibric southward to the Moidart and Morven. Nevertheless, when this wild tract of country comes to be mapped out in detail, there will probably be found intercalated bands of higher formations which have here and there been caught in folds of the lower rocks.

But when we pass eastwards from the Great Glen into the mountains of Eastern Inverness-shire, Perthshire, and the South-Western Highlands, we encounter a totally different series of rocks. Though greatly plicated, dislocated, crushed, and metamorphosed, these rocks can be recognized as unquestionably, in the main, of sedimentary origin. They must be many thousands of feet in thickness, including among their members such rocks as conglomerate, pebbly grit, quartzite, black slate, andalusite slate, phyllite, mica-schist, fine flaggy gneiss, and limestone, together with intrusive sheets and bosses of various eruptive rocks. Some of the groups of this series can be followed and mapped for long distances with nearly as much ease as the members of a succession of unaltered Palæozoic or Secondary formations. There is a belt of limestone, for example, which has been traced by the Geological Survey almost continuously from the coast of Banffshire to the west of Argyllshire, through the very heart of the Highlands—a total distance of not much less than 200 miles. These limestones have for the most part become so thoroughly crystalline, that fossils can hardly be expected to be found in them, though there are occasional less altered portions of rock which may eventually prove to be fossiliferous. The limestones are associated with quartzites and schists, as unaltered limestones are with sandstones aud shales. I cannot myself doubt that they have been formed by the aggregation of the remains of calcareous organisms. The same rocks are prolonged into the north of Ireland, where one of the dark limestones at Culdaff has lately yielded certain bodies which some palæontologists have declared to be the remains of a coral (*Favosites*). The black slates which so closely resemble the dark Carbonaceous shales of the Lower Silurian region of South Scotland have afforded in Donegal some curious pyritous markings, strongly suggestive of Graptolites.

Out of this enormous mass of metamorphosed sedimentary strata the Scottish Highlands east of the Great Glen are built up, as well as the region which extends southwards across the north-west of Ireland as far as the centre of County Galway. The first question that requires an answer with regard to it has reference to its relation to the fossiliferous quartzites and limestones of the north-west. Murchison, who led the way in the investigation of the stratigraphy of the Highlands, believed that the quartzites and limestones of the Central Highlands lay towards the base of the whole series of post-Cambrian rocks, and were the south-eastward extensions of those of Sutherland. But recent investigations throw some doubt on this view, which at the time it was promulgated seemed so natural and simple. We know that the quartzites and limestones of the Central Highlands, so far from being near the bottom of the vast series of schists, are underlain by many thousand feet of other metamorphosed sedimentary strata, and that the actual base is nowhere reached in that region.

During the last two years, in concert with some of my colleagues of the Geological Survey, I have devoted some time to the task of endeavouring to find the bottom of these crystalline schists of Scotland and Ireland, as a necessary foundation for placing them on their true geological horizon, and at length, this spring, our efforts have been successful beyond our expectations. Last year, in the north-west of the Island of Islay, I found a group of scarcely altered shales, grits, and thin limestones emerging from beneath the black slates which underlie the schists, limestones, and quartzites of that region. So little have these strata suffered from the metamorphism which has affected the rocks lying above and to the east of them, that I quite anticipate that fossils will be found in them. This year, in company with Mr. C. T. Clough, I came upon a somewhat similar group of little-metamorphosed black slates and grits at the north-east end of the Island of Iona. I am hopeful that these strata will yield fossils; I myself found in them some short black limes, which at once recalled the form and condition of the fragments of the central rods of Graptolites so commonly met with in the black shales of the Southern Uplands of Scotland. The discovery of recognizable fossils in these strata would fix the geological age of the rocks of the Central Highlands and of the north-west of Ireland.

An interesting feature about these slates of Iona is that they lie at the very bottom of the series of younger schists. Immediately under them are a coarse grit (arkose) and conglomerate, formed out of the Archæan gneiss, which comes out in great force from underneath them, and forms the main part of the island.[1] The uprise of an axis of the old gneiss so far to the east of the line of great complication, and at the base of the vast sedimentary masses of the Central Highlands, is a fact of great importance. We seem to find here a fragment of the old barrier which separated the American province in which the Durness limestones were deposited, from the area of Western and Central Europe in which the other Silurian formations of Britain were laid down. Prolongations of the same ridge towards the north-east are possibly to be traced even as far as the mountains between the head of the Rivers Nairn and Findhorn, where some of my colleagues think that there is probably another core of the Archæan gneiss.

The search for a base to the same great series of schists as they are developed in the north-west of Ireland has been equally successful. Along the west of County Mayo, Archæan gneiss has been recognized by us,[2] exhibiting the typical characters of the same rock in the north-west of Scotland. In Achill Island we found the base of the quartzite and schist series in the form of a coarse quartz-conglomerate resting on the gneiss. But all these rocks have come within the influence of the intense regional metamorphism. The conglomerate in particular has had its quartz-pebbles pulled out in the direction of movement, and its paste has been converted into a fine kind of gneiss.

Having thus traced an original westward boundary to the younger crystalline schists of Ireland and Scotland, I saw that it would be important to follow their eastern boundary as far as it had not been concealed by later formations. In Galway we found that the quartzites, limestones, and schists are succeeded to the south by the large area of Archæan gneiss already referred to. But the boundary between the two groups of rock is one of extreme complication, somewhat like that of the North-West Highlands. Along a line running east and west through the heart of this county from Mannin Bay to Lough Corrib, the two groups have been so dislocated and so thrust between and over each other that much time and patience, with the use of large-scale maps, would be required to map out their respective areas. But the important fact is readily perceptible that in Galway the uprise of a large Archæan area gives us a southern limit for the basin in which the younger schists of the north-west of Ireland were deposited.

To the east and north-east of the Galway area the country has been overspread with Old Red Sandstone and Carboniferous strata, so that for a long space the older rocks are concealed. Far to the north-east, in Tyrone, on the southern borders of the great area of crystalline schists, a mass of dark hornblendic rocks was mapped some years ago by Mr. Nolan, of the Geological Survey of Ireland, and referred doubtfully to a pre-Cambrian age. A more recent examination of this mass, with the experience gained over so wide a region among the older crystalline rocks, has enabled us to identify it without hesitation as a characteristic portion of the Archæan gneiss. It rises as a long north-east ridge along the south-eastern margin of the chloritic schists of Londonderry which were deposited against and over it. We discovered, moreover, that these schists have at their base, resting on the old gneiss, a thick volcanic series consisting of amygdaloidal basic lavas, tuffs, and coarse volcanic agglomerates. The green chloritic material of the schists, not improbably represents the original magnesian silicates in the finer volcanic dust that mingled with the ordinary sediment of the sea-bottom.

From the evidence now adduced, it is, I think, manifest that the crystalline schists of the Scottish Highlands east of the Great Glen, as well as their continuation into the north-west of Ireland, cannot be regarded as merely the equivalents of the quartzites and limestones of Sutherland and Ross. They are enormously thicker and more varied in their component members than those north-western strata. Whether even any part of them represents the sedimentary rocks of the north-west seems to me open to serious doubt. My own impression is that they are probably younger than these rocks, and that they once stretched far to the north-west, and covered them to a depth of many thousands of feet. That the fossiliferous strata of the North-West Highlands were originally buried under a thick pile of other sediments I have already shown.

The last question on which I propose to touch is the geological date of the extraordinary terrestrial disturbances to which the crystalline schists of the Highlands of Scotland and the north-west of Ireland owe their characteristic structures. The limit of its antiquity is easily fixed. As these disturbances involve rocks containing fossils of Lower Silurian age, they must obviously have taken place after some part at least of the Lower Silurian period. In Scotland their chronological limit in the other direction is determined by the fact that the conglomerates of the Lower Old Red Sandstone are largely composed of the crystalline schists of the Highlands. They must consequently have occurred before the deposition of some part at least of the Lower Old Red Sandstone. Here, then, is a long geological interval within which the gigantic upthrusts and metamorphism began and ended.

But the evidence obtained in Ireland enables us to fill up this interval with a little more definiteness. In Southern Mayo and Northern Galway, as Prof. Hull has pointed out, the Upper Silurian rocks rest upon and contain abundant fragments of the younger crystalline schists which stretch into these counties from Donegal. And the inference has naturally been drawn that the great terrestrial disturbances and metamorphism occurred before the Upper Silurian period But a recent more critical examination of the ground has satisfied me that this inference, though to a certain extent correct, does not embrace the whole truth.

Those who have visited Connemara may remember the singular group of mountains which hem in the Killary fjords, and rise in Mweelrea and its neighbouring ridges to a height of more than 2600 feet above the sea that frets their base. These massive buttresses of rock owe their distinctive forms to the thick beds of coarse grit and conglomerate of which they are in great measure built up. An abundant series of fossils proves that this mass of deposits is of Upper Silurian age. It is the base of these exceedingly coarse sediments which along their southern margin can be seen to rest upon the upturned edges of the crystalline schists, and to be there largely made up of fragments derived from that metamorphic platform. The numerous bands of coarse conglomerate upon successive horizons serve to indicate considerable terrestrial disturbance during their deposition. That the commotion continued after that time is further shown by the remarkable way in which the rocks have been dislocated. These Upper Silurian sediments have been broken up into large mountainous blocks which have been thrown on end or actually pushed over each other. So violent

[1] The existence of a slight displacement at the actual junction does not obscure the evidence of the true relation of the rocks.

[2] In my recent traverses in the west of Ireland I had the advantage of the company and assistance of my colleagues, Mr. Peach, Mr. McHenry, and Dr. Hyland.

has the movement been along certain lines, that the bands of greywacke and shale have been intensely crumpled and puckered, and have actually been converted locally into fine micaceous schists.

Hence it seems tolerably certain that though in the west of Ireland the chief plications, fractures, and metamorphism were completed before Upper Silurian time, and though a vast interval must have elapsed during which the progress of denudation laid bare the younger schists, and thereby provided materials for the Upper Silurian conglomerates, the terrestrial disturbances nevertheless continued during the deposition of these conglomerates, and were renewed with increased vigour afterwards.

If we compare the geological structure of the Silurian tracts of England, Wales, and the south of Scotland, and the east of Ireland, with that of the areas of the younger crystalline schists, many points of resemblance will be seen to occur between them. Towards the north and north-west we find that the Archæan, Cambrian, and oldest Silurian rocks, now exposed there by the progess of denudation, have been subjected to the intensest mechanical deformation, and have assumed the most completely schistose structures. Coming southward, we trace the younger crystalline schists of the Central Highlands and of Donegal thrown into innumerable north-east and south-west folds, and becoming less and less metamorphosed as they are followed towards the lower grounds. Still further south the Lower and Upper Silurian rocks, plicated, crumpled, and dislocated, repeat the familiar structure of the Southern Highlands, but with only partial and feeble metamorphism. I am disposed to look upon the whole of these structures as the result of one great succession of terrestrial movements which began and reached their maximum of intensity during some part of Lower Silurian time, but which continued to repeat themselves at intervals with greater or less vigour through a long series of geological ages, down to the early part of the Old Red Sandstone period.

As the consequence of this prolonged disturbance, the Archæan and older Palæozoic rocks have been thrown into those north-east and south-west folds, which have in large part determined the trend of the land in the north-west of Europe. The shaping of our mountains into their present forms has been brought about by ages of subsequent sculpture, in which the agencies employed by Nature have operated mainly on the surface, but the carving of their features has been guided by the internal structures developed by those subterranean movements which we have been considering.

THE ENTIRE SKELETON OF AN ENGLISH DINOSAUR.

SOME years ago an article appeared in the columns of this journal (vol. xxviii. p. 439), in which a notice was given of the marvellously preserved skeletons of *Iguanodon* from the Wealden deposits of Bernissart, in Belgium, some of which are now exhibited in the Brussels Museum of Natural History. In that article the author very properly insisted upon the extreme importance of those specimens from an anatomical point of view, as exhibiting the whole of the bones of the skeleton in their natural juxtaposition. He was, however, probably then unaware (as the undermentioned specimen was not at that time exhibited to the public) that the British Museum possessed the skeleton of an English Dinosaur, which, although of smaller size than the Bernissart Iguanodons, belongs to the same sub-ordinal group, and exhibits equally clearly the mutual relations of the component bones. The English skeleton is, indeed, in some respects much more satisfactory than the Belgian specimens, inasmuch as its bones have not been flattened and crushed in the manner which so sadly disfigures those of the latter. Further, the English Dinosaur has an additional interest in that it is one of quite the earlier members of the group, its geological horizon being the Lower Lias of Dorsetshire.

This specimen, as being the only known example of the almost entire skeleton of a Dinosaur from English deposits, is so remarkable as to deserve especial attention from all those interested in the former inhabitants of our islands. In the first place, the history of its discovery is somewhat curious. Thus, some time previously to 1861, Mr. J. Harrison, of Charmouth, obtained from the Lower Lias of that neighbourhood portions of the hind-limb of a comparatively large Dinosaur, and, later on, a skull, lacking only the extremity of the muzzle. In the year mentioned, these specimens were described by Sir Richard Owen in the publications of the Palæontographical Society, under the name of *Scelidosaurus harrisoni*; the portions of the limb being taken as the type of the genus, and the skull referred to a smaller individual of the same species. Stimulated by the extreme interest aroused by the discovery of this skull, Mr. Harrison continued his excavations on the spot where the latter had been obtained, and was rewarded by finding the whole of the remainder of the skeleton, with the unfortunate exception of most of the vertebræ of the neck. The skeleton was extracted in several blocks, and these, after careful "development" of the bones, were fitted together so as to enable the whole skeleton to be exhibited.

Until the completion of the Natural History Museum at South Kensington, this magnificent skeleton was, however, from want of space, never exhibited to public view; and it was not until some three years ago that it was properly mounted and placed in its present position, where, in a handsome glass case which permits a view of both sides, it forms one of the chief treasures of the unrivalled gallery of fossil reptiles in that Museum. The bones being all firmly cemented together by matrix, and also more or less dislocated out of their normal places, it was, however, of course impossible to mount the skeleton in its natural position—which was probably a semi-erect one; and it is accordingly now placed with the axis of the vertebral column in a horizontal position. As thus mounted, the specimen is about 11 feet in length, but the absence of the cervical vertebræ renders it impossible to ascertain its true dimensions, the head being now placed much too near to the shoulder-girdle. The skeleton has been somewhat dislocated, and twisted over to the right side, so that the neural arches and spines of the vertebræ of the back and loins are seen on the right, and the under surface of their bodies, or centra, on the left side of the specimen. Both hind-limbs are entire, although the left one is thrust up by the twist, and has become placed near the tail. The haunch-bones (ilia) of the pelvis still nearly retain their normal position; and on the left side of the specimen we see the lower extremities of the left pubis and ischium lying crossed over the lower ends of the corresponding bones of the right side. A portion of that part of the pubis which lies in advance of the acetabulum is visible; and the post-acetabular portions of both the pubis and ischium lie in the original parallel position which is so characteristic of this group of Dinosaurs and of the Struthious birds. The left side of the shoulder-girdle is well preserved, and has the humerus and portions of the bones of the fore-arm in their original position; but the bones of the hands are wanting. The dermal scutes, with which the body and tail were protected, are seen arranged in longitudinal rows, which have, however, been somewhat thrown out from their original position. We would especially call the attention of those who may think it worth their while to visit the Museum, in order to study this unique specimen, to the marvellous preservation of the hind-limbs, which permits even the smallest bones of the toes to be fully exhibited on both sides. It may, however, be worth the consideration of the authorities of the Museum, whether this skeleton might not be more easily understood by the uninitiated if the various bones were labelled with their scientific, and perhaps also with their popular, names, since it is somewhat puzzling, even to the expert, to name them all at a glance.

As already mentioned, the skull of the skeleton was figured by Sir R. Owen in 1861, and the acquisition of the remainder of the skeleton enabled that eminent palæontologist to confirm his reference of the skull to the genus *Scelidosaurus*. The body-skeleton formed, indeed, the subject of a second memoir published by the Palæontographical Society in 1862, with eleven quarto plates; but we venture to say that these illustrations do not render justice to the specimen, since they only include separate portions. To fully illustrate this unrivalled skeleton would, indeed, require a double quarto plate, in which the whole specimen should be shown, with the individual bones duly labelled; and a task thus remains for some zealous palæontologist to fulfil.

The accompanying figure is an attempt at a restoration of the skeleton in the natural position of the animal. The presence of a predentary bone in advance of the mandibular symphysis is based on the occurrence of this element in *Iguanodon* and the allied *Stegosaurus;* while the five digits in the hand are likewise introduced from the evidence of the latter genus.

The importance of this specimen is that it is the only English Dinosaur, with the exception of the small *Hypsilophodon*, which shows all the bones of the skeleton in position; and although it is of course exceedingly easy to be wise after the event, yet we cannot help thinking that this skeleton might have afforded its describer the opportunity of being the first to determine the true nature and position of the bones of the pelvis in this group of Dinosaurs—a problem which was solved in a paper communicated to the Geological Society in 1876. The two parallel bones lying on the inferior aspect of the hinder part of the trunk of this specimen, and directed backwardly, could not, indeed, possibly have been taken for anything else but the pubis and ischium; and the resemblance of the latter bone to the problematical "*os cuvieri*," or so-called clavicle, of Mantell's imperfect skeleton of *Iguanodon*, which has for many years been in the Museum, might have suggested the homology of

Approximate restoration of the skeleton of *Scelidosaurus harrisoni*, from the Lower Lias of Charmouth. Greatly reduced. The vertebral column has been restored from *Iguanodon*, and the spines and chevrons of the vertebræ are, not improbably, too long: the ossified tendons are conjectural.

the two bones. Curiously enough, however, the pubis and ischium, which are certainly the most remarkable bones in the whole skeleton, are not figured, and apparently not even mentioned, in the original memoir.

Finally, it may perhaps interest some of our readers who do not follow the ever-changing classifications of the palæontologists, to mention that the genus *Scelidosaurus* is the type of a family referred by Prof. O. C. Marsh to his sub-order Stegosauria. Other authorities, however, consider that this sub-order is not really separable from the Ornithopoda of the same writer, which includes the Iguanodons. Accepting this emendation, the Ornithopoda will be a sub-order of Dinosauria, including all those forms in which the pelvis has a structure comparable to that of the Struthious birds; while the remaining members of that order may be classed in the sub-order Theropoda, as represented by *Megalosaurus*, and the Sauropoda, as represented by *Cetiosaurus* and *Pelorosaurus*. Recently, indeed, it has been proposed to abolish the name Dinosauria, and to group the Theropoda and Sauropoda together under the new name of Saurischia, and to apply the name Ornithischia to the Ornithopoda. The name Dinosauria has, however, become such a household word, that its suppression cannot be admitted; and if it be eventually found advisable to adopt the proposed division of these reptiles into two distinct orders, the preferable course would be to restrict the name Dinosauria to the so-called Saurischia, since *Megalosaurus* and *Cetiosaurus* were the forms first mentioned in the original notice of the order in 1840; while the earlier names, such as Ornithopoda, might be retained for the second order. In this connection we may, however, quote a remark made by an eminent man of science at a meeting of the Geological Society, to the effect that "he was inclined to think that the progress of knowledge tended rather to break down the lines of demarcation between groups supposed to be distinct, than to authorize the creation of fresh divisions."

R. L.

NOTES.

We print elsewhere the Technical Instruction Bill introduced into the House of Commons last week by Sir W. Hart Dyke. The Government is to be congratulated on having presented a measure which cannot fail to produce an excellent effect on the higher branches of technical education in England.

WE regret to have to announce the death of the Rev. J. M. Berkeley, the eminent cryptogamic botanist.

THE Professorship of Civil Engineering and Mechanics in the University of Glasgow is likely to be vacant by the resignation of Prof. James Thomson, on account of weak health. The appointment, which is supposed to be worth about £600 a year, is in the gift of the Crown.

THE eleventh Congress of the Sanitary Institute, which is to meet at Worcester from September 24 to 28, will be divided into three Sections, viz. Section I. Sanitary Science and Preventive Medicine; Section II. Engineering and Architecture; Section III. Chemistry, Meteorology, and Geology. Each Section will begin its work on a separate day. A Conference of Medical Officers of Health will be held during the Congress; and there will be a Health Exhibition in the Skating Rink and special additional buildings from September 24 to October 19. This Exhibition will include sanitary apparatus and appliances, and articles for domestic use and economy.

THE International Congress on Hygiene, which is to meet in Paris on Sunday, will be attended by nearly 600 members, representing twenty-five nationalities. The Paris Correspondent of the *Times* says that the members will be lavishly entertained at the Ministry of Public Instruction, at the Ministry of the Interior, at the Hôtel de Ville, and by the town of Rheims, where they will visit the important works for the treatment of sewage. Several European Governments will be officially represented, notably Belgium, Denmark, Spain, and Turkey. Brazil and nearly all the South American Republics send official delegates. Prof. Corfield, Mr. Shirley Murphy, Dr. Alfred Carpenter, and some other Englishmen interested in sanitary questions, propose to attend the meetings.

THE International Congress of Photography will meet in Paris from August 6 to 17. The rules relating to the proceedings of the Congress have been issued.

THE eighth Congress of Russian Naturalists will be opened at St. Petersburg on January 7, 1890, and will last a week.

THE Russian Chemical and Physical Society, as we learn from its Annual Report, has now 340 members. Its Journal contains every year a most valuable index of all that is published in Russia in the domain of chemistry and chemical technology.

THE monument erected by the Russian Consul at Kashgar, in memory of Adolph Schlagintweit, is reported to be ready. It is in the form of a pyramid with an iron cross on the top, and has been erected on the very place where the great German traveller was executed by order of the then ruler of Kashgar, Vali-khan-tyuria.

ON Thursday last, the new galleries and the new greenhouse of the Museum of Natural History of Paris were formally opened by the Minister of Public Instruction, who was accompanied by the Director, Prof. Frémy, and, among others, by M. de Quatrefages, M. Gaudry, M. Chauveau, and M. E. Blanchard. The new gallery is a fine building, three stories high, built of iron and stone. The collections have already been in part transferred to it. The greenhouse is a very ordinary one. Enormous substructures have been rendered necessary by the fact that it is on the side of a small hill. The building was begun ten years ago, and serves to show what progress has since been made in the art of iron-building.

ACCORDING to the Rome Correspondent of the *Daily News*, the Municipal Council of Rome has decided to devote a sum of money to the formation of a Pasteur Institute. Confidence in M. Pasteur's treatment of hydrophobia is increasing in Italy, as is shown by the fact that little by little all the principal towns are providing buildings for the treatment of the disease by inoculation.

ADMIRAL SIR ROBERT SPENCER ROBINSON, K.C.B., F.R.S., died at his residence, 61 Eaton Place, on July 27, in his eighty-first year. He was elected a Fellow of the Royal Society in 1869. Among his works was a treatise on the steam-engine for marine purposes.

MR. W. F. H. BLANDFORD succeeds Mr. A. E. Shipley, who has resigned the post of Lecturer on Economic Entomology at the Royal Indian Engineering College, Cooper's Hill.

AT the session of the Council of University College, London, on July 6, the title of Emeritus Professor of Engineering and Mechanical Technology was conferred on Prof. A. B. W. Kennedy, F.R.S.

THE Association for the Improvement of Geometrical Teaching has begun the formation of a library of reference of mathematical text-books. This should increase the usefulness of the Association to teachers of mathematics, especially to such as live in the neighbourhood of London. The library already contains a respectable assortment of works, contributed by various authors and publishers. It is, of course, intended chiefly for works of recent date, but it contains a loan collection of older works, lent by Mr. F. Hockliffe, of Bedford, among which may be mentioned Cocker's "Arithmetic," Tacquet's "Elementa Geometriæ," and D'Chales' "Elements of Euclid," The library is at present under the charge of Mr. C. V. Coates (2 Prince's Mansions, Victoria Street), who will be glad to receive donations of books, pamphlets, &c., on behalf of the Association.

IN the Report submitted to the general meeting of the Scottish Meteorological Society on June 24, the Council state that the preparation of No. VI. of the Society's Journal has been kept steadily in progress, and is now in type, and will shortly be issued to members. In this number a fuller account is given than heretofore of the storms which strike the Scottish coasts, drawn chiefly from the very full and accurate reports of storms from the northern lighthouses. These reports of storms may justly be regarded as the fullest accounts of storms made anywhere in the world by observers who record the phenomena night and day. The Council are of opinion that it is not possible to overrate the importance of these observations of storms in their bearing on the discussion of the Ben Nevis observations and the weather of North-Western Europe, which, it is proposed, will engage the whole time next year of the Secretary and such assistance as may be obtained. The photographing of meteorological phenomena continues in progress as opportunity offers, and at the next meeting of the Society the directors will be in a position to show to members a second series of these interesting and important photographs. This year the snow disappeared from the summit of Ben Nevis in the middle of May, being about a month earlier than any previous year, and seven weeks earlier than in 1885. Shortly thereafter, or in the beginning of June, the spring near the Observatory dried up; and during that month the water supply for the Observatory had to be carried on horseback, from a distance of two miles and a half. The directors have had under consideration a proposed systematic observation of the numbers of dust particles in the atmosphere with the instrument recently invented by Mr. Aitken, one of the directors, and they are of opinion that, for many reasons, the best place for most satisfactorily conducting the observations is the Ben Nevis Observatory. Mr. Aitken has kindly agreed to superintend the construction of the instrument, and to see to the placing of it in a suitable position. It has been resolved to apply for a grant from the Government Research Fund to aid in this novel and important inquiry. M. Mascart, Director of the Meteorological Service of France, has also resolved to carry on the same investigation in Paris.

IN a telegram from Yokohama, dated July 30, it is stated that the town of Kumamoto, on the Island of Kiou-Siou, near Nagasaki, had been visited by an earthquake, causing great loss of life and destruction of property.

SOME details with regard to the recent severe earthquake in Turkestan have been received at St. Petersburg. The first shock was felt at Vyernyi at 3.15 a.m. on July 12. Several houses were damaged and a great number of chimneys were destroyed. The same shock was felt at Jarkend, Pishpek, Ala-medyn, Prjevalsk (Kopal), Pavlodar, Lepsa, Semipalatinsk, Kulja, and on the Kashgar frontier. At Prjevalsk, all private houses on the shores of Lake Issyk-kul, as also the bridges, were destroyed; the shores bear many traces of landslips. The shock was so severe that people could hardly stand on their feet. At Pavlodar the direction of the earthquake was from south-west to north-east. At Semipalatinsk, the Irtysh was covered with heavy waves. The whole of the village Malovodnoie was destroyed, and in the canton of Koram seventeen men were killed. Several houses were destroyed in the villages of Zaitsevskoie, Mikhailovskoie, Lugovoie, Janghyz, and Karabulak, as also at Kulja. On July 14, three shocks were noticed at Jarkend, at 2, 4, and 10 p.m., and they were followed by several feebler shocks on July 15.

THE master of the *Argentina*, German mail steamer, which arrived at Lisbon from Pernambuco on July 19, reports that north of the Cape de Verd Islands heavy cross seas were experienced, in which the vessel pitched heavily. For four days the air was filled with reddish yellow dust, sometimes so thick that the sun could scarcely shine through it, and looked quite pale, although the sky was cloudless.

AMONG donations received at the meeting of the Royal Botanic Society on Saturday were seeds from the Parana River at Rosario, South America, collected by Mr. C. W. Sowerby. Mr. Sowerby announces his discovery of one of the habitats of *Pontedera azurea*, a very beautiful floating water-plant, which flowered some nine years ago in the Victoria House in the Society's Gardens, and has since been widely distributed. He states that masses of the plant were found floating down the river, and forming islands of one or two acres in extent, upon one of which a puma was seen.

AT the monthly meeting of the Royal Society of Queensland, on June 14, Mr. De Vis read a most interesting paper on *Prionodura newtoniana* (Meston's bower-bird) and *Acanthiza squamata*, recent additions to the Queensland avifauna. The former was minutely described. It was first found by Mr. K. Broadbent in the scrubs on the Tully River, but its true habitat is now ascertained to be the highlands north of Herberton, where it was observed by Mr. A. Meston in the course of a short visit to the top of Bellenden-Ker. Mr. Meston brought down the first skin of a male bird, but not in a condition to permit full recognition. Excellent specimens, male and female, were afterwards obtained by Mr. Broadbent near Herberton. Prionodura is emphatically a bower-bird. Both its observers in nature met with its bowers repeatedly, and agree in representing them as of unusual size and structure. The bower is usually built on the ground between two trees, or between a tree and a bush. It is constructed of small sticks and twigs, piled up almost horizontally round one of the trees, and rising to a height of from 4 to 6 feet. A similar pile about 18 inches high is then built round the foot of the other tree; the intervening space is arched over with stems of climbing plants; the piles are decorated with white moss, and the arch with moss interspersed with bunches of fruit resembling wild grapes. The birds, young and old, male and female, play merrily under and over the archway. The completion of the massive bower so laboriously attained is not sufficient to satisfy the architectural impulse of the bird, for scattered immediately around are numbers of dwarf hut-like structures—gunyahs they are called by Mr. Broadbent, who remarks that they give the spot exactly the appearance of a blacks' camp in miniature.

THE current number (vol. iii. No. 4) of the Journal of the Bombay Natural History Society contains a paper by Lieut. Barnes, on nesting in Western India, a district which, so far, appears to have been treated in an incomplete fashion in works on Indian oology. The writer seeks to collect, in as concise a form as possible, all information at present available on the subject, as a nucleus round which collectors may record their observations, and thus prepare the way for a complete knowledge of bird-life in Western India. Dr. Dymock writes on the means of self-protection possessed by certain plants, and Mr. Hart on certain branching palms, while Mr. Aitken discourses pleasantly on the natural history of a voyage from Liverpool to Bombay, and Mr. Oates has a short paper on the Indian and Burmese scorpions of the genus Isometrus, with a description of three new species. The Journal is almost always sure to contain one or two papers, half scientific, half sporting, from the pens of noted *shikarees*, which are sometimes of vivid interest. The present issue has a paper of this class on the habits of the sambhur, with personal reminiscences of sport in pursuit of it, by Mr. Reginald Gilbert, and a striking anonymous paper entitled "Mauled by a Panther." The illustrations, as usual, are numerous and of great beauty.

WITH regard to the question of the inheritance of injuries, a correspondent, "P. V.," writes to us about an Irish terrier bitch which had a litter by a mongrel terrier whose tail had been cut off with a hatchet. Of the litter, one dog puppy was without a tail. The Irish terrier belonged to "P. V.," and he says that she had had several litters before, none of which were in any way deformed.

PROF. FRANZ KLAPÁLEK, of Prague, has been investigating the rivers of Bohemia under the auspices of a committee formed for their physical exploration. In the course of his researches he was able to study the full life-history of *Agriotypus armatus*, Walker, a curious hymenopterous parasite on the aquatic larvæ of caddis-flies, chiefly of the genus *Silo*. The details are published in the *Entomologist's Monthly Magazine* for August, with illustrations. When these larvæ are attacked by the parasite, the cases have always a curious band-like appendage at one end. Formerly it was considered that this appendage was formed by the caddis-worm, but Prof. Klapálek proves that it is due to the larva of the parasite, and consists of the secretion from the salivary glands. What its precise use may be does not at present seem quite clear.

PROF. W. K. BURTON, of the College of Engineering, Imperial University, Tokio, writes to the *Japan Mail* that the Photographic Society of Japan has now been duly constituted, and that there are already nearly sixty members, of whom very nearly one-half are Japanese. There are a few professional photographers, but the great majority are amateurs. Viscount Enomoto, Minister of Education for Japan, has consented to be nominated as President. A meeting of the Society was held on June 7, when Mr. K. Ogawa gave a demonstration of the working of the platinotype printing process of Willis, from the coating of the paper to the completion of the print.

THE last monthly part of Mr. Samuel H. Scudder's "Butterflies of the Eastern United States and Canada, with especial reference to New England," will be issued on October 1. We have already called attention to the importance of this work. It makes three volumes, and contains seventeen plates of butterflies, six of eggs, eleven of caterpillars, two of the nests of caterpillars, three of chrysalids, two of parasites, thirty-three of structural details in all stages of life, nineteen maps and groups of maps to illustrate the geographical distribution of butterflies, and three portraits of early naturalists of America; in all about 2000 figures on ninety-six plates, of which forty-one are coloured. The text contains 2000 pages, including an introduction of 104 pages, and an appendix, of 150 pages, which contains descriptions of such species concerned as have not been found within the limits of New England, and also descriptions of all known parasites of North American butterflies, by Messrs. Howard and Williston.

THE City of London College Science Society has issued its Report for 1888–89. We are glad to see that the session was one of increased activity, and, as the Committee are able to add, of continued success. Papers on subjects of great scientific interest were read, and there were many excursions to places suitable for geological study and for the collection of botanical and zoological specimens. The Society now publishes a monthly journal.

MR. PERCY LINDLEY is editing a series of "Holiday Handbooks." One of those sent to us deals with the Hartz Mountains, another with the Ardennes. They cost only a penny each, and are well done. For the same price one may now get a very good little illustrated Guide to London. It is published by Mr. J. P. Murray.

THE tenth part of Cassell's "New Popular Educator" has been issued. It is well illustrated, and has a good map of British North America.

A REMARKABLE series of experiments illustrating an extreme case of "mass" or "catalytic" action are described by Messrs. Morse and White of the University of Pennsylvania, Philadelphia, in the current number of the *American Chemical Journal* (p. 348). The sulphides and oxides of zinc and cadmium, which are so difficultly volatilizable when heated alone, are found to be readily volatilizable in presence of their respective metals, zinc or cadmium, owing to alternate dissociation and recombination. The pure sulphides were first prepared by dissolving redistilled zinc or cadmium in hydrochloric acid and precipitating with sulphuretted hydrogen. The washed pr cipitates were next dried in the ordinary way, and then heated to 300° C. in a current of pure dry sulphuretted hydrogen. They were finally repeatedly treated with carbon bisulphide to remove any traces of free sulphur. The sulphides as thus prepared were found to be perfectly stable in a vacuum, the exhausted tubes containing them being heated until the glass softened and collapsed without any signs of volatility of the sulphides being apparent. About 15 grams of either of the sulphides were then mixed with 40 grams of the corresponding metal and placed at the sealed end of a combustion tube, the other end being connected with a Sprengel pump. The end containing the mixture was placed in a furnace, and after the exhaustion was completed as far as possible, was gradually heated. As the temperature rose the metal began to fuse, and a yellowish white film of sulphur was formed in the cool portion of the tube projecting out of the furnace. The formation of this deposit is due to the fact that while the tube is comparatively free from the metallic vapour, the sulphur liberated by the dissociation of the sulphide, having a higher rate of diffusion than the vapour of the metal, partly escapes recombination, and is deposited in the free state in the cooler portion of the tube just outside the furnace. As the temperature still rises this deposit becomes converted into sulphide, and eventually a long line of crystals of the sulphide is formed along the bottom of the projecting part of the tube. Cadmium sulphide was found to be transported much further along the tube than zinc sulphide, and the crystals could be seen to form and fall in a manner resembling a fine rain. Indeed, so ready is the dissociation of cadmium sulphide under the influence of metallic cadmium that by rapidly raising the temperature the experiment becomes dangerous, the dissociation occurring with almost explosive violence. On several occasions when the mixture was too tightly packed into the end of the tube, the whole contents were violently blown into the Sprengel pump. It is necessary to leave a very considerable free space along the top of the tube to insure a successful experiment. It was found that the oxides of zinc and cadmium behave similarly to the sulphides, oxide of zinc in this case dissociating most readily. The singular action of these metals in lessening the stability of their respective oxides and sulphides certainly forms one of the most extreme cases of "mass" or "catalytic" action on record; and that it is not a mere mechanical carrying action appears abundantly proved by the slight deposit of sulphur which is always noticed in the earlier stage of the experiment, and by the beautiful manner in which the sulphides themselves are afterwards deposited.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. F. Dobbs; a Common Otter *Lutra vulgaris*) from North Wales, presented by Mr. Chas. H. Wynn; two White Storks (*Ciconia alba*) from North Africa, presented by Mr. Thomas Hay; three Well-marked Tortoises *Homopus signatus* ♂ ♀ ♀), four Rufescent Snakes (*Leptodira rufescens*), a Many-spotted Snake (*Psammophylax multimaculatus*), a Spotted Slowworm (*Acontias meleagris*), a Puff-Adder (*Vipera arietans*) from South Africa, presented by the Rev. G. H. R. Fisk; a Tesselated Snake (*Tropidonotus tessellatus*) from Italy, presented by Mr. H. D. Brocklehurst; two Common Toads (*Bufo vulgaris*), British, presented by Dr. J. J. Pitcairn; a Common Zebra (*Equus zebra* ♀) from South Africa, two Black-eared Marmosets (*Hapale penicillata*) from South-East Brazil, a Tovi Parrakeet (*Brotogerys tovi*) from Columbia, a Red and Blue Macaw (*Ara macao*) from Central America, deposited; a Peba Armadillo (*Tatasua peba*), a Pretre's Amazon (*Chrysotis pretrii*), a —— Snake (*Helicops leopardinus*) from Brazil, a White-throated Capuchin (*Cebus hypoleucus* ♂) from Central America, a Senegal Touracou (*Corythaix persa*) from West Africa, six Spotted Tinamous (*Nothura maculosa*) from Buenos Ayres, a Tesselated Snake (*Tropidonotus tessellatus*) from Italy, purchased; two Mule Deer (*Cariacus macrotis*), two Crested Pigeons (*Ocyphaps lophotes*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A NEW COMET, 1889 *e*.—A telegram from Melbourne to Prof. Krueger announces the discovery of a bright comet by Mr. Davidson, of Queensland, on July 21. The following positions of this comet have been obtained:—

Place.	G.M.T. (h. m. s.)	R.A. (h. m. s.)	N.P.D. (° ′ ″)
Melbourne ...	July 22 23 3 50 ...	12 46 9·0 ...	122 29 6
Rome	July 27 8 37 4 ...	13 37 29·9 ...	110 19 2

The comet is therefore coming north very rapidly.

COMET 1889 *d* (BROOKS).—The following elements and ephemeris for this comet are by Dr. H. Oppenheim:—

$$T = 1889 \text{ August } 3{\cdot}40 \text{ G.M.T.}$$

$$\left.\begin{aligned}\pi &= 339^\circ\ 37' \\ \Omega &= 28\ 13 \\ \iota &= 5\ 56\end{aligned}\right\}\text{Mean Eq. } 1889{\cdot}0.$$
$$q = 0{\cdot}3627$$

The comet probably has a short period.

Ephemeris for Greenwich Midnight.

1889.	R.A. h. m.	Decl. ° ′	Brightness.

THE VIENNA OBSERVATORY.—We have received two volumes of the publications of this Observatory, viz. the Annals for 1885 and 1886 (*Annalen der k. k. Univ. Sternwarte in Wien, Währing*, Band v. and vi.). The former contains three sections, viz. (1) observations with the meridian circle in 1884, being Zones 119 to 198 of the observations of Santini's stars south of the equator; (2) corrections and notes to sundry catalogues, particularly to Oeltzen's catalogues of Argelander's zones and to the zone catalogues of Lamont and of the Washington Observatory; and (3) measures of double-stars made by Drs. Holetschek and Hepperger. The latter volume contains observations of minor planets and comets made with the Clark 11¾-inch refractor, the Fraunhofer 6-inch, and the great Grubb telescope of 27-inch aperture, and meteorological observations made in the years 1885 and 1886. There is an apparently unobserved erratum on p. 115 of the former section. The observation on 1885 October 3, said to be of Klymene (No. 104) is really of Ilsa (No. 249). It is given correctly under the latter planet.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *AUGUST* 4–10.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 4

Sun rises, 4h. 31m. ; souths, 12h. 5m. 50·1s. ; daily decrease of southing, 5·6s. ; sets, 19h. 41m. : right asc. on meridian, 8h. 58·8m. ; decl. 17° 8′ N. Sidereal Time at Sunset, 16h. 35m.

Moon (at First Quarter August 4, 13h.) rises, 12h. 50m. ; souths, 18h. 1m. ; sets, 23h. 1m. : right asc. on meridian, 14h. 55·1m. ; decl. 12° 8′ S.

THE NEWCASTLE MEETING OF THE BRITISH ASSOCIATION.

ACTIVE preparations are now being made for the Newcastle meeting of the British Association, and it is expected that the proceedings will be of more than usual interest. The meeting will be held from September 11 to 19. At the first general meeting, on September 11, at 8 p.m., Sir F. Bramwell, F.R.S., will resign the chair, and Prof. Flower, C.B., F.R.S., the President-elect, will assume the presidency, and deliver an address. The different Sections will assemble on the following morning for the reading and discussion of reports and other communications. The following are the Presidents of the Sections:—(A) Mathematical and Physical Science, Captain W. de W. Abney, R.E., C.B., F.R.S.; (B) Chemical Science, Sir I. Lowthian Bell, F.R.S.; (C) Geology, Prof. James Geikie, F.R.S.; (D) Biology, Prof. J. S. Burdon-Sanderson, F.R.S.; (E) Geography, Col. Sir F. De Winton, K.C.M.G.; (F) Economic Science and Statistics, Prof. F. Y. Edgeworth, M.A.; (G) Mechanical Science, Mr. William Anderson, M.Inst.C.E.; (H) Anthropology, Prof. Sir W. Turner, F.R.S.

On Thursday evening, September 12, there will be a *soirée*; on Friday evening, September 13, Prof. W. C. Roberts-Austen, F.R.S., will deliver a discourse on "The Hardening and Tempering of Steel"; on Saturday evening, September 14, Mr. B. Baker will deliver a discourse on "The Forth Bridge"; on Monday evening, September 16, Mr. Walter Gardiner will deliver a discourse on "How Plants Maintain Themselves in the Struggle for Existence"; on Tuesday evening, September 17, there will be a *soirée*; and the concluding meeting will be held on the afternoon of Wednesday, September 18.

Excursions to places of interest in the neighbourhood of Newcastle-on-Tyne will be made on the afternoon of Saturday, September 14, and on Thursday, September 19.

The first meeting of the General Committee will be held on Wednesday, September 11, at 1 p.m., for the election of the President and Sectional officers, and the despatch of business usually brought before that body. The General Committee will meet again on Monday, September 16, at 3 p.m., for the purpose of appointing officers for 1890, and of deciding on the place of meeting in 1891. The concluding meeting of this Committee will be held on Wednesday, September 18, at 1 p.m., when the Report of the Committee of Recommendations will be received. The Committee of Recommendations will meet at 3 p.m. on September 16 and 17, and (if necessary) on September 18, at 10 a.m.

The Local Secretaries for the Newcastle meeting are Prof. P. Phillips Bedson and Prof. J. H. Merivale.

The Reception Room will be opened on Monday, September 9, at 1 p.m., and on the following days at 8 a.m., for the issue of tickets to Members, Associates, and ladies, and for supplying lists and prices of lodgings, and other information, to strangers on their arrival. No tickets will be issued after 6 p.m. In the Reception Room there will be offices for supplying information regarding the proceedings of the meeting. The Journal, containing announcements of the arrangements for each day, will be laid on the table on Wednesday, September 11, and the following mornings, at 8 a.m., for gratuitous distribution. Lists of members present will be issued as soon as possible after the commencement of the meeting, and will be placed in the same room for distribution. The published volumes of the British Association can be ordered in this room, for Members and Associates only, at the reduced prices appointed by the Council. The tickets will contain a map of Newcastle-upon-Tyne, and particulars as to the rooms appointed for Sectional and other meetings. For the convenience of Members and Associates, a branch post office (which will be available also for communication between Members attending the meeting) will be opened in the Reception Room. Members and Associates may obtain information about local arrangements, and facilities afforded by the railway companies, on application to the Local Secretaries, Newcastle-upon-Tyne.

THE GOVERNMENT'S TECHNICAL INSTRUCTION BILL.

THE following is the Bill to Facilitate the Provision of Technical Instruction, introduced into the House of Commons by Sir W. Hart Dyke, and read a first time, on July 24:—

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

I. (1) A local authority may from time to time out of the local rate supply or aid the supply of technical or manual instruction, to such extent and on such terms as the authority think expedient, subject to the following restrictions, namely:—

(*a*) The local authority shall not out of the local rate supply or aid the supply of technical or manual instruction at an elementary school to scholars receiving instruction in the obligatory or standard subjects prescribed by the minutes of the Education Department for the time being in force; and

(*b*) The amount of the rate to be raised in any one year by a local authority for the purposes of this Act shall not exceed the sum of *one penny* in the pound.

(2) A local authority may, for the purposes of this Act, appoint a Committee consisting either wholly or partly of members of the local authority, and may delegate to any such Committee any powers exercisable by the authority under this Act, except the power of raising a rate or borrowing money.

II. (1) The managers of any school or other institution giving technical instruction in the district of a local authority may make an arrangement with the authority for transferring their school or institution to it, and the local authority may assent to any such arrangement.

(2) The provisions of Section 23 of the Elementary Education Act, 1870, with respect to arrangements for the transfers of schools, shall apply in the case of arrangements for the tranfers of schools or institutions in pursuance of this section, with this modification, that for the purposes of transfers to a local authority references to the School Board shall be construed as references to the local authority, and references to the Education Department as references to the Department of Science and Art.

III. The conditions on which Parliamentary grants may be made in aid of technical or manual instruction shall be those contained in the minutes of the Department of Science and Art in force for the time being.

IV. (1) For the purposes of this Act the expression "local authority" shall mean the Council of any county or borough, and any urban or rural sanitary authority within the meaning of the Public Health Acts.

(2) The local rate for the purposes of this Act shall be—

(*a*) In the case of a County Council, the county fund;

(*b*) In the case of a Borough Council, the borough fund or borough rate;

(*c*) In the case of an urban sanitary authority not being a Borough Council, the district fund and general district rate, or other fund or rate applicable to the general purposes of the Public Health Acts;

(*d*) In the case of a rural sanitary authority, the rate or rates out of which special expenses incurred in respect of any contributory place or places are payable under the Public Health Act, 1875.

(3) A County Council may charge any expenses incurred by them under this Act on any part of their county.

(4) A rural sanitary authority may charge any expenses incurred by them under this Act on any contributory place or places within their district.

(5) A local authority may borrow for the purposes of this Act—

(*a*) In the case of a County Council, in manner provided by the Local Government Act, 1888;

(*b*) In the case of a Borough Council, as if the purposes of this Act were purposes for which they are authorized by Section 106 of the Municipal Corporations Act, 1882, to borrow;

(*c*) In the case of an urban sanitary authority not being a Borough Council, or of a rural sanitary authority, as if the purposes of this Act were purposes for which they are authorized to borrow under the Public Health Acts.

V. In this Act—

The expression "technical instruction" shall mean instruction in the principles of science and art applicable to industries, and in the application of special branches of science and art to specific industries or employments. It shall not include teaching the practice of any trade or industry or employment, but, save as aforesaid, shall include instruction in the branches of science and art with respect to which grants are for the time being made by the Department of Science and Art, and any other form of instruction which may for the time being be sanctioned by that Department by a minute laid before Parliament and made on the representation of a local authority that such a form of instruction is required by the circumstances of its district.

The expression "manual instruction" shall mean instruction in the use of tools, and modelling in clay, wood, or other material.

VI. This Act shall not extend to Scotland or Ireland.

VII. This Act may be cited as the Technical Instruction Act, 1889.

PROFESSOR LOOMIS ON RAINFALL.[1]

THE subject of this chapter is the mean annual rainfall in all the different countries of the globe, with a discussion of the conditions favourable and unfavourable to rainfall, and an examination of individual cases of rainfall in the United States, Europe, and over the Atlantic Ocean, and the areas of low barometric pressure without rain.

To begin with, Prof. Loomis has compiled a list of 1427 stations, and arranged them in order of latitude. With each station is found its altitude, its mean annual rainfall, and the number of years of observation. This list would have been considerably larger if all the stations where the amount of rainfall is measured were quoted, for in England alone there are 2200 stations where rainfall is regularly measured, in the United States 2000, whilst the total number of stations in France is 1500. The plan adopted by the author has been to select a few stations from those countries which rejoiced in a plentitude of rain-gauges, but in regions where few stations exist all the measurements were used.

Following upon each enunciation of causes which affect rainfall is found a tabular statement demonstrating its truth.

The conditions favourable to rainfall, according to Prof. Loomis, begin with the fact that the north-east and south-east trade winds, on approaching the belt of calms near the equator, and being gradually deflected upward, are cooled by expansion, so that the aqueous vapour is condensed, and the belt of calms becomes a belt of rain. This equatorial rain-belt, of course, moves with the sun in declination, and some observations included in table lxxxiv. strikingly exemplify this movement by giving for twelve months respectively the number of rains in a hundred observations between latitudes 20° N. and 10° S., the maximum of falls moving with the sun.

A second cause for abundant rainfall is the influence of mountains, for when a strong wind meets a mountain it is forced up the side of the mountain, and elevated into a colder region, the result being that its vapour is precipitated by the cold of elevation. Table lxxxv. gives a comparison of the rainfall in two regions situated within twenty-five miles of each other, but of different altitudes, and from it the conclusion is deduced that the rainfall on a mountain from 4000 to 10,000 feet high is more than double that at neighbouring places near the sea-

[1] "Contributions to Meteorology," Chapter III., by Elias Loomis, LL.D., Professor of Natural Philosophy and Astronomy in Yale University, &c. Revised Edition. (New Haven, Connecticut, U.S., 1889.)

level. A third condition favourable to an abundant rainfall is proximity to the ocean, especially when the prevailing wind comes from the ocean. Capes and headlands projecting considerably into the ocean generally show a rainfall greater than interior stations only a few miles distant; and lastly, Prof. Loomis notes that the great and non-periodic depressions of the barometer are always accompanied by a considerable fall of rain, and that the average tracks of these depressions are marked by an excess of rainfall.

The following are some of the conditions unfavourable to rainfall. Fresh winds blowing in a nearly uniform direction throughout the year, such as prevail within a portion of the system of trade winds, especially in mid-ocean. The rainfall on Ascension Island is quoted as a case in point, observations for two years showing that the direction of the wind was south-east or very nearly so during the time, the rainfall during these two years being 2·31 and 4·30 inches respectively. This condition of things prevails over the Atlantic Ocean within the region where the trade winds blow with considerable force and are seldom interrupted.

A second condition unfavourable to rain is a position on the leeward side of a range of mountains running in a direction nearly at right angles to that of the prevalent wind. An illustration of this principle is seen on the Malabar coast of Hindustan. On the ocean side of the range of mountains the rainfall is 250 inches annually, whilst on the eastern side of the range the air is very dry, and the amount of the mean annual rainfall is less than 25 inches.

When there is a second range of mountains, parallel and within 100 or 200 miles of the first, the influence of this cause is considerably intensified, and this diminution is still more decided when a place is surrounded by mountains, or nearly so. Salamanca is so situated, and the mean annual rainfall there is less than 10 inches.

Elevated plateaus have generally less rainfall than insulated mountain peaks of an equal elevation; this is illustrated by the fact that Leh, being situated on that remarkable plateau of Tibet, has a mean annual rainfall of less than 3 inches. Another similar case is found in the tableland (the Punos) between two great chains of the Andes; and it is observed that the average height of the Sahara being over 1500 feet, this elevation may contribute in some degree to the smallness of the rainfall.

Another condition unfavourable to rainfall is the dryness of the atmosphere, under which head Prof. Loomis gives three special cases, viz. remoteness from the ocean, measured in the direction from which the prevalent wind proceeds, areas of high barometric pressure, and high latitudes. This last conclusion does not state that the average rainfall regularly diminishes as we go northwards, the same as the mean temperature; but if the mean annual fall be taken for every 10° of latitude the important influence on the amount of rainfall is very decided, and is emphatically exhibited in high latitudes. The general table of observations, arranged in order of latitude, which began this chapter, shows that for the four stations whose latitude exceeded 71° the mean annual rainfall was 7·44 inches, whilst the paucity of observations of the fall of rain or snow that have been made during the various Arctic expeditions also demonstrates the fact.

A review is next made of the regions which show a very small rainfall, and the causes inquired into where the observations of pressure, temperature, and humidity of the air, and the direction and force of prevailing winds rendered it possible to obtain some definite information as to the meteorological condition of the region.

Prof. Loomis has thoroughly investigated the conditions of rainfall in the United States, and from the tables of observations he arrives at the inference that the depression of the barometer accompanying extraordinary rainfalls is not very great, the average pressure at the low centre being 29·63 inches for the part of the United States north of latitude 36°, and the average pressure at the stations of greatest fall being 29·77 inches.

Table cxii. gives all the cases where the barometer fell below 29 inches at any station in the United States or Canada between September 1872 and June 1884, and also the station where the greatest rainfall occurred for the preceding twenty-four hours. The conclusion drawn from such a comparison is that a moderate depression of the barometer is as favourable to great rainfall as an extremely great depression, which would seem to indicate that rainfall has but little connection with barometric depression. It must, however, be remembered that the depression at the centre of a low area depends not merely upon the barometric gradient, but upon the geographical extent of the low area.

The following are some of the conclusions Prof. Loomis arrives at respecting the causes of rainfall in the United States. One of the most common causes of rain is an unstable condition of the atmosphere resulting from an unusually high temperature combined with unusual humidity. Another very common cause of rain frequently associated with this is a cold northerly or westerly wind in the western segment of the low area, and proximity to the ocean or to a large inland sea.

The investigation affords important evidence respecting the influence of rainfall upon areas of low pressure, viz.—

No great barometric depression with steep gradients ever occurs without considerable rainfall.

In great rain-storms the barometric pressure generally diminishes while the rainfall increases.

The greatest depression of the barometer generally occurs about twelve hours after the greatest rainfall.

A great fall of rain is favourable to a rapid progress of the centre of least pressure, while a small rainfall is generally attended by a less rapid progress.

It is also noted that some of the characteristics of areas of low pressure with little or no rain are:—

(1) Feeble barometric gradients.
(2) Moderate winds.
(3) Slow changes of barometric pressure.
(4) Slow progressive movement.

Whilst in similar areas of low pressure with excessive rainfalls all these conditions are reversed.

In order to study the influence of rainfall upon barometric pressure under different geographical influences, Prof. Loomis has compiled for Europe a similar set of tables to those concerning the United States. Of the 106 stations having a rainfall of not less than 2·5 inches in twenty-four hours, eighty-six are situated south of latitude 48°, and fifteen are north of latitude 48°, indicating that heavy rains are about six times as frequent in the south as in the north of that latitude. Prof. Loomis thinks that the summary of observations relating to Europe seems to indicate that great rains occur on the west side of the low centre more frequently than they do in the United States.

Tables have also been prepared showing the rainfall over the North Atlantic as far as observations permitted. An unexpected fact exhibited by these tables is the prevalence of rainfalls with the barometer somewhat above 30 inches.

A comparison of the results that have been obtained for the United States and for Europe brings Prof. Loomis to some important conclusions respecting the influence of local causes in modifying the relation of rainfall to barometric pressure.

The conclusions are, for stations east of the Rocky Mountains:—

(1) South of latitude 36°, a rainfall of 2½ inches in eight hours at any station occurs on the east side of a low area more frequently than on the west side in the ratio of 2·6 to 1.

(2) North of latitude 36°, a rainfall of 2 inches in eight hours at any station occurs on the east side of a low area more frequently than on the west side in the ratio of 2·8 to 1.

(3) A total rainfall of 9 inches in eight hours at all the stations east of the Rocky Mountains occurs on the east side of a low area more frequently than on the west side in the ratio of 6·2 to 1.

(4) Over the North Atlantic Ocean great rain areas occur on the east side of an area of low pressure more frequently than on the west side in the ratio of 2·6 to 1.

(5) In Europe a rainfall of 2½ inches in twenty-four hours at any station occurs on the east side of a low area more frequently than on the west side in the ratio of 2·0 to 1.

These results indicate that in the United States and Europe, as well as over the North Atlantic Ocean, great rainfalls are generally associated with a barometric pressure somewhat below the mean, and the precipitation occurs chiefly on the eastern side of a low area.

The relation of a rising to a falling barometer with rain points to the conclusions that at Philadelphia the amount of rain which falls while the barometer is descending is nearly three times as great as that which falls while the barometer is rising. The entire Atlantic coast of the United States north of latitude 36° exhibits results similar to those found for Philadelphia. Advancing westward from the Atlantic coast, the ratio of the precipitation when the barometer is falling, compared with that when the barometer is rising, changes somewhat rapidly, and before we reach the Mississippi River the ratio is reduced to 1·32.

In Great Britain the amount of rain with a falling is twice that with a rising barometer, but, advancing eastward, this ratio rapidly diminishes, and in Central Europe the precipitation is greater when the barometer is rising than when it is falling. Plates are appended, which exemplify in an emphatic manner all the facts that have been tabulated concerning rainfall. Five gradations of colour only have been used to indicate the rainfall of less than 10 inches to over 75 inches. By this means the main results have been rendered more prominent.

R. A. GREGORY.

THE SOURCES OF THE NITROGEN OF VEGETATION.[1]

NO problem relating to the nutrition of plants has given rise to so much discussion as that of the source of their nitrogen and the methods of its assimilation. It is obviously both a matter of the highest scientific interest, and also, owing to the high price of combined nitrogen in manures and the comparative ease with which it is washed out of the soil in the form of nitrates, one of great practical importance to the agriculturist and the community.

Ever since the discovery of the composition of atmospheric air by Priestley, Scheele, and Lavoisier, the question as to whether plants were able to absorb and utilize free nitrogen has attracted much attention. At the end of the last century, or beginning of this, Ingenhousz, Sennebier, Woodhouse, and De Saussure became interested in the subject.

Boussingault commenced his experiments in 1837; Ville, whose results conflicted with those of Boussingault, in 1849; and, shortly after, this last named investigator started a new series of experiments which confirmed his former conclusions that plants, under the conditions of the experiment, were not able to assimilate free nitrogen.

In 1857, experiments on the assimilation of free nitrogen by plants were started at Rothamsted; and in 1861 was published, in the Philosophical Transactions, the classical memoir of Lawes, Gilbert, and Pugh, on this subject.

In this earlier paper a brief history and summary of the results of other experimenters is given, and then the recent results obtained at Rothamsted. The conclusions arrived at were identical with those of Boussingault, that there is no evidence that plants assimilate nitrogen. Still the authors allowed that there were some difficulties with regard to the supply of nitrogen to leguminous plants, which assimilate from some source or another much more nitrogen than gramineous plants under similar conditions of supply of combined nitrogen.

It was admitted that, "if it be established that the processes of vegetation do not bring free nitrogen into combination, it still remains not very obvious to what actions a large proportion of the existing combined nitrogen may be attributed."

These views, that plants were unable to assimilate free nitrogen were widely and generally held for many years, though there have always been some dissentients.

In the meantime, however, the indefatigable investigators of Rothamsted have not been resting in the matter, but have added much to our exact knowledge of the supplies of combined nitrogen to the soil from the air, on the amount and nature of the combined nitrogen in soils and in crops, on the processes of nitrification in soils, and the amount of nitrogen removed from soils in crops and in drainage.

During the last few years the main question as to the availability of atmospheric nitrogen to plants has taken a somewhat different aspect: it is now often suggested that though the higher plants are unable to directly take up free nitrogen, yet indirectly it is brought under contribution in some way; the ways most generally favoured being either under the influence of electricity of low tension, or of microbes or some low forms of organisms; and by such means it is thought that nitrogen is brought into a form in which it is useful to the higher plants.

In Sir J. B. Lawes and Dr. Gilbert's new memoir they give a summary of some previously published Rothamsted results, chiefly relating to nitric acid in soils and subsoils; also of the results of Cameron, S. W. Johnson, Hampe, Wagner, and Wolff, on the assimilation of nitrogen by plants, from more or less complex organic bodies like urea, uric acid, hippuric acid, and tyrosine.

A number of new determinations of nitric acid in soils and subsoils, and of total combined nitrogen in the surface soils of the Rothamsted experimental plots are given; and also the results of numerous experiments with dilute solutions of organic acids on soils, to ascertain the action of such dilute acids, in some degree comparable to the acid sap of the roots of plants, on the organic nitrogenous matter of soils.

In the second part of the memoir are summarized the recent results and conclusions of other workers relating to the fixation of free nitrogen.

Probably the results of Berthelot, which have from time to time been published in the *Comptes rendus*, have influenced the opinions and the course of inquiry in recent years more than any others. In 1876 and 1877, Berthelot found that various organic compounds under the influence of the silent electric discharge, even of low tension, were able to fix free nitrogen, and concluded that such fixation of nitrogen takes place in ordinary soils under normal conditions. In 1885 he published results showing the fixing of free nitrogen by certain soils under conditions which led him to believe that the action must be due to the influence of micro-organisms, and to such action M. Berthelot seems now inclined to impute most influence in the matter. Although the gains in nitrogen, expressed in percentages, were very small, yet there was gain in all cases when the soils were exposed either in the open, or in a room, or in closed flasks, and no gain when the soils were sterilized. Unless there be some unrecognized source of error, such as might easily be imagined in the case of the freely exposed soils, one seems bound to accept Berthelot's conclusions. Dehérain's results at Grignon are next discussed; they are chiefly on the gains or losses occurring on experimental field plots, and are perhaps not of such a nature as to materially assist one at the present stage of the inquiry.

Joulie's results, as given in the *Bulletin de la Société des Agriculteurs de France* in 1886, showed exceedingly large gains of nitrogen, which he is inclined to ascribe to the action of microbes; here the gains of nitrogen were certainly more than take place in ordinary farm practice, and occurred with buckwheat, which is not usually considered as a "nitrogen collector."

Dietzell's experiments are mentioned; in all cases but one, in which there was a slight gain in nitrogen, the results are fully accordant with established facts. B. Frank, who has recently written a paper on the whole aspect of the question, has published some experiments of his own. He concluded, as have others, that two opposite actions are at work in the soil—one setting nitrogen free, and the other bringing it into combination, the latter being favoured by vegetation—but that there is no decisive evidence to show how this combination is brought about; it does not necessarily follow that the plant itself effects the combination. Some of Frank's experimental conditions, however, were considerably removed from those occurring in the ordinary course of farm practice.

The very important and most interesting experiments of Hellriegel and Wilfarth follow. The first of these were described at the Berlin meeting of the *Naturforscher-Versammlung*, in 1886; subsequent experiments were described at the Wiesbaden meeting in 1887, and they were further given in a paper by König, published in Berlin in 1887; but the full text and details of their work were not published in time for Messrs. Lawes and Gilbert to refer to. A paper on these results appeared last November in *Beilageheft zu der Zeitschrift des Vereins für die Rübenzucker-Industrie*, and the work of these investigators is described by M. Vesque in the January number of *Annales Agronomiques*.

The experiments date from 1883 onwards, and were on cereals, buckwheat, rape, and various leguminous plants. The plants were grown in pots in washed siliceous sand, to which the necessary cinereal constituents were added. In this all the plants grew normally until the nitrogen in the seed was used up; then the plants not belonging to the Leguminosæ ceased growing until supplied with some combined nitrogen, nitrate of soda was used, when growth was proceeded with almost exactly in proportion to the amount of nitrogen supplied. With the Leguminosæ the results were more eccentric: sometimes the plants died of nitrogen-hunger; sometimes after a time of such hunger they recovered and produced abundant growth. To

[1] "On the Present Position of the Question of the Sources of the Nitrogen of Vegetation, with some New Results, and Preliminary Notice of New Lines of Investigation." By Sir J. B. Lawes and Prof. J. H. Gilbert. Phil. Trans. 1889, clxxx. B. pp. 1–107.

the sterile soil with the young plants there was added in a large number of cases a small quantity of an extract of a garden soil; the extract used contained less than one milligramme of nitrogen; the oats, rape, and buckwheat remained undeveloped, but the leguminous plants soon became deep green and grew vigorously. If the soil extract were previously sterilized by heat, it produced no effect. Moreover the soil used in the preparation of the extract was of importance; with peas any soil extract answered, but not so with lupins and sainfoin; with these plants, to render success certain it was found necessary to use an extract of a soil which had previously grown the same plants. Some experiments were also made in large sealed flasks, to which carbon dioxide was admitted at intervals; in these the results were practically the same as in free air, showing that it was not the combined nitrogen of the air which was absorbed.

It was also found that whilst on the leguminous plants which developed well, either with or without the addition of soil extract, the characteristic tubercules of papilionaceous plants were well marked, on those which did not develop in the sterile soil, and also on plants grown in sterilized soil to which nitrate had been added, and which plants developed at the expense of the added nitrogen, but did not assimilate free nitrogen, there were no tubercules. Hence there is obviously some connection between the production of the tubercules and the assimilation of the free nitrogen. In all cases where free nitrogen is presumably assimilated by the plant, the soil is also enriched in nitrogen, the more so when the plant growth is more vigorous, and this excess of nitrogen in the soil is almost entirely in organic combination.

The general conclusions are that leguminous plants, though they are able to make use of combined nitrogen in similar forms to those the graminaceous plants utilize, yet differ from this latter order of plants in being able to use some other form of nitrogen, not that existing in the soil. This second source of nitrogen must be the free nitrogen of the air, which the Leguminosæ utilize through the agency of certain micro-organisms which are in symbiosis with them, and exist in the tubercules of the roots of this order of plants.

The results obtained by von Wolff at Hohenheim, from 1883 onwards, are mentioned. Wolff is not inclined to admit that plants assimilate free nitrogen, but thinks that the only remaining hypothesis is that certain plants can appropriate the combined nitrogen of the air, either directly through their leaves or more probably after absorption by the soil. A porous soil probably absorbs far more nitrogenous compounds from the air than an equal superficial area of dilute acid, as used in experiments by Schlœsing, Kellner, and Müller. He admits, however, that it is difficult to see why the grasses are unable to benefit by this equally with the legumes.

W. O. Atwater has published three papers on various aspects of the subject in the *American Chemical Journal*. In these papers he gives results of his own experiments and also discusses those of others. He concludes that in many of his experiments with peas, when the growth was normal, half or more of the total nitrogen of the developed plants was obtained from the air. In what way the nitrogen was acquired, the experiments do not show, but Atwater inclines to the idea that the plants themselves directly acquired the atmospheric nitrogen. The conclusion of this second part of the memoir gives some recent experiments and opinions of Boussingault on the subject. He remained strongly of the opinion that plants were unable to assimilate free nitrogen; although, as is here pointed out, some of his experiments in 1858 and 1859, with lupins, might be considered as leading to such a conclusion.

The third part of the memoir gives a summary and general considerations and conclusions.

Regarding the evidence relating to other sources than free nitrogen, Lawes and Gilbert have shown that the amount of nitric acid remaining in a soil is much less after the growth of a crop than under corresponding conditions without a crop. Also that nitrification in soils is more active where leguminous crops are grown than where gramineous plants only are present; and that deep-rooted leguminous plants like *Medicago sativa* or *Melilotus leucantha* take up more nitric acid from the soil than shallower-rooted leguminous plants like *Trifolium repens*. But the supply of nitric acid in some soils, such as clover-exhausted land or bean-exhausted land, is inadequate to account for the nitrogen taken up by other leguminous crops grown on such land. No very definite conclusions could be drawn from the Rothamsted experiments as to the power of the acid sap of roots to take up nitrogenous organic matter from the soil, though it is seen to be not improbable that green-leaved plants can "take up directly, and utilize, amide bodies rendered soluble within the soil by the action of their acid root sap."

Our authors in conclusion point out that, since experimenting in free air instead of in closed vessels, as in Boussingault's and their own researches, has become common, there has been a great accumulation of evidence tending to indicate the fixation of free nitrogen. The modes of explanation of the gain of nitrogen are: that it has been absorbed from the air, either by the soil or by the plant; that there is fixation of free nitrogen within the soil by the agency of porous and alkaline bodies; that there is fixation in the soil by the agency of electricity; that there is fixation by the plant itself; that there is fixation under the influence of micro-organisms within the soil. The balance of recorded evidence is undoubtedly in favour of the last-mentioned mode of explanation. "Indeed, it seems to us," say Lawes and Gilbert, "that, if there be not experimental error, there is fixation of nitrogen within the soil, under the influence of micro-organisms, or other low forms of life." But they think that final judgment must be held in abeyance for the present. Most of their own and Boussingault's previous experiments excluded, by their conditions, the action of electricity or of micro-organisms.

They then consider some of the facts of agricultural production in their bearing on the question as to how far the establishment of the reality of the fixation of free nitrogen is necessary to the solution of problems of agricultural production. They point out that the loss of nitrogen in ordinary farm practice is not so great as Berthelot and others have assumed; the annual loss of nitrogen by cropping in Great Britain, for example, is probably under 20 pounds per acre. The loss by drainage may in some cases be considerable, and in special cases there may be loss by evolution of free nitrogen. Probably the loss of free nitrogen from the plant itself during growth, which is assumed by some, does not occur. The accumulation of combined nitrogen which occurs in the surface soil of pastures is not conclusively explained, but it may have a subsoil origin, and this assumption has as much evidence in its favour as that it has an atmospheric origin. In the soil and subsoil of Rothamsted, to a depth reached by the deeper-rooting plants, there is 20,000 pounds of combined nitrogen per acre; in very many of the soils of this country there is more, though in some less than this: the accumulation of nitrogen in the surface soil may well be due to nitrogenous crop-residue, the nitrogen of which comes principally from the subsoil. Again the natural fertility of most soils is without doubt due to the accumulation of ages of natural vegetation with little or no removal; and the amount of nitrogen even now brought into combination under the influence of electricity, over a given area, would be sufficient, with growth and little or no removal, to account for the accumulations in natural prairie or forest lands even of the richest.

The Rothamsted experiments have shown that after growing crops for many years without nitrogenous manures there has always been a diminution of nitrogen in the top soil; this has been found to be the case with diverse crops, including gramineous, cruciferous, chenopodiaceous, and also leguminous crops, and with a four-course rotation of crops. There has not been compensation of nitrogen from the air, or at all events to the extent of the annual losses. "The agricultural production of the present age is, in fact, as far as its nitrogen is concerned, mainly dependent on previous accumulations; and as in the case of the use of coal for fuel there is not coincident and corresponding restoration, so in that of the use or waste of the combined nitrogen of the soil, there is not evidence of the coincident and corresponding restoration of nitrogen from the free to the combined state."

It is not yet conclusively proved that the whole of the nitrogen of leguminous plants comes from the subsoil; it is equally not proved that it comes from the air; though in the case of crops belonging to other natural orders it may be affirmed that atmospheric nitrogen is not the source. May it be that the development of organisms capable of bringing free nitrogen into combination within the soil is favoured by leguminous growth and crop-residue, as there can be little doubt is the case with the organisms which produce nitrification?

Frank has shown that on the roots of certain trees, especially the Cupuliferæ but also on willows and some Coniferæ, is a fungus-mantle which is believed to be in true symbiosis with the higher plant; and it may well be supposed that the fungus partly assists the tree by bringing the organic nitrogen of the soil into a form in which it becomes available to the chlorophyllaceous plant; much in the same way as has been observed by Gilbert in the case of fairy-rings, where the fungus, so to speak, prepares the nitrogenous nutriment for the grass. That the tubercules that are nearly always present on the roots of leguminous plants are in some way connected with the assimilation of nitrogen by the plants is an hypothesis that is gaining ground. Much study has of late years been devoted to the morphology and functions of these tubercules by, amongst others, Tschirch, Brunchorst, Frank, Van Tieghem, Lundström, and Marshall Ward; and still more recently by Bréal, Beyerinck, and Prazmowski. It seems almost certain that these tubercules contain micro-organisms, which are the proximate cause of the excrescences, and these may live in symbiosis with the legumes, and prepare their nitrogenous food possibly from free nitrogen. The tubercules are richer in nitrogen than the roots themselves, and some observers look upon them as being merely reservoirs of nitrogenous nutriment, not as manufactories. Beyerinck (*Botan. Zeitung*, 1888) has obtained and cultivated an organism which he calls *Bacillus radicicola*, from these tubercules, and studied some of its reactions. It seems very probable that further study of these tubercules of the Leguminosæ may put us on the right track for solving the mysteries of the nitrogenous nutrition of this order of plants.

In a postscript to the memoir the authors state that they have started some experiments with leguminous plants much on the same lines as those of Hellriegel and Wilfarth. The results of these experiments will be looked forward to with very great interest.

This memoir is a most welcome and solid contribution to a most important problem. It is quite obvious that the last word on the subject has not been said, and probably very much more work must be done before it is. The authors, from their own labours and thought on the subject, continued through so many years, are well able to criticize the work of others, and this they have here done, as far as most of the important papers published up to date are concerned, in an able and frank manner. If leguminous plants are able to avail themselves of the free nitrogen of the air, or if soils are able, through the agency of microbes or in other ways, to fix free nitrogen, the exact conditions necessary for the accomplishment of these ends is not yet known. The conditions of risk and exposure to accidental sources of nitrogen-gain in small experiments in the open air are very great, and experiments made under such conditions require very careful verification. Also the methods of nitrogen determination used should be subjected to rigorous investigation and control, as also the methods of taking the samples used in analysis, which in the case of a complicated body like a soil presents great difficulty in obtaining a perfectly homogeneous mixture. The exact limits of experimental error in the various determinations want investigation. The subject, from its important practical bearings, is worthy the attention of a scientific commission who could give undistracted attention to it. E. K.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination will be held at Queen's College, in the first week of October, to fill up at least two open Classical Scholarships for candidates proposing to commence residence this October, and one open Scholarship in Natural Science (Chemistry and Physics) for candidates proposing to commence residence in October 1890.

Classical candidates must not have exceeded nineteen years, and Natural Science candidates eighteen years, on October 10, 1889.

A further notice will be issued.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xi. No. 4 (Baltimore, July 1889).—Prof. Cayley opens the number with a resumption of his memoir on the surfaces with plane or spherical curves of curvature (pp. 293–306).—The circular cubic with double focus on itself is treated by Schröter and Durège (*Crelle*, Bd. v.). Mr. F. Morley, writing on the geometry of a nodal circular cubic (pp. 307–16), gives a geometrical account, illustrated by figures, of the case when the curve, in addition, is nodal. Some properties of the special case when the inflexion is at infinity are given by Dr. Booth (*Quarterly Journal*, vol. iii.) in his discussion of the logocyclic curve (cf. vol. i. of his "Collected Papers," cap. xxx.).—The next paper supplies a defect in MM. Briot and Bouquet's "Propriétés des fonctions définies par des équations différentielles" (*Journ. de l'École Pol.*, cap. xxxvi.): it is entitled, "On the Functions defined by Differential Equations, with an extension of the Puiseux polygon construction (see *Journ. de Math. pures et appliquées*, i. 15) to these equations" (pp. 317–28), and is written by Mr. H. B. Fine.—In the memoir "Sur les solutions singulières des équations différentielles simultanées" (pp. 329–72), M. Goursat extends results obtained by M. Darboux to simultaneous differential equations and to equations of higher order.—The number, and volume, concludes with a note by J. C. Fields, on the expression of any differential coefficient of a function of any number of variables by aid of the corresponding differential coefficients of any n powers of the function, where n is the order of the differential coefficient (pp. 388–96).—All these papers are, of course, purely mathematical: there is a physical paper (pp. 373–87) by Prof. H. A. Rowland, entitled "Electro magnetic Waves and Oscillations at the Surface of Conductors." The calculations are founded on Maxwell's equations. "In these equations occur two quantities, J and ψ. Maxwell has given the reasons for rejecting ψ, and has shown that neither J nor ψ enter into the theory of waves. In order, however, that there shall be no propagation of free electricity in a non-conductor, the components of the electric force must satisfy the equation of continuity, and this leads to components of the vector potential satisfying the same equation, and $J = 0$ therefore. I have satisfied myself that there is absolutely no loss of generality from these changes."

IN the *Nuovo Giornale Botanico Italiano* for July, Sig. A. Bottini has an interesting article on the structure of the olive, especially on that of the several layers of tissue of which the ripe fruit is composed. A disease to which the crop has been recently liable he believes to have been erroneously attributed to a parasitic fungus, *Septoria oleaginea*.—The greater part of this number is occupied by the proceedings of the meeting of the Botanical Society of Italy held in Florence.—Prof. Arcangeli gives an account of a series of experiments on the amount of heat due to the respiration of fungi. The greatest elevation of temperature he finds to amount to 1°·25 C. in the case of *Lepiota excoriata*. In all cases the elevation of temperature is most conspicuous about midday, or early in the afternoon.—The colouring-matter of the cones of *Abies excelsa* is stated by Sig. L. Macchiati to be due to a mixture of three distinct substances, two of them crystallizable, accompanied by a waxy substance.

Das Wetter for July contains:—(1) The second part of an explanatory discussion, by Dr. Wagner, of the recently published instructions for the observers of the Prussian Meteorological Institute. The points referred to relate especially to rainfall and thunderstorm observations. The author refers to the variability of rainfall values both as regards time and place, and to the necessity of stations near each other, to explain the irregularities of the yearly amounts. It is only since 1887 that such a system has been established in North Germany, where it is proposed to raise the number of stations to 2000, which will then only give one for about 77 square miles. The hours of observation are also discussed, the result being that the usual morning observation cannot be altered; but the instructions direct that the rainfall should be set down to the day upon which it is observed; this has generally been done in Prussia, whereas in other countries it is put down to the previous day. The author refers to the importance of the measurement of rain during the passage of thunderstorms, and also to the advantage to be derived from the more general use, at stations of the second and third order, of simple registering barometers and thermometers, similar to those of Richard Frères.—(2) A criticism of Herr Falb's weather predictions taken from an article in the *Göttingen Zeitung*. M. Falb bases his theory on the influence of the sun and moon upon the interior of the earth, and upon the surrounding media of air and water, and calculates certain "critical days" from the relative positions of these bodies. The author of the article has checked the predictions sent to the German agricultural Press since April 12, and points out that although the weather of May has been unusually warm, no mention of the fact was contained in the predictions, and concludes with the remark that a theory which shows such little success, as in the comparison in question, is useless to the agriculturist.—(3) A description, by Dr. Wagner, of the new popular Observatory, "Urania," opened on July 3, in Berlin, on the site of the Exhibition buildings. It contains a large equatorial, over 16 feet in length, with a lens of about 12½ inches in diameter, a large number of instruments and microscopes, and a spacious lecture theatre.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, June 20.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Observations on the melting-point of some salicylic and anisic compounds, by Dr. W. H. Perkin, F.R.S. The author, in 1867, described methylated and ethylated salicylaldehydes as colourless liquids which do not solidify when cooled in a freezing mixture, whereas Voswinckel states that methylated salicylaldehyde is a solid melting at 35° (*Ber. der deut. chem. Gesellsch.*, 1882, 2024). Further experiments show that although the methylated aldehyde does not readily crystallize in a freezing mixture it can be made to do so, but the crystals so obtained melt at 2°·7–3°. Prismatic crystals having the melting-point described by Voswinckel were once obtained on evaporating an ethereal solution of the aldehyde, and it is found that if the oily aldehyde is touched with one of these it immediately becomes a solid mass, having a melting-point of 35°; when these crystals are fused, and the resulting oil cooled in a freezing mixture, crystals melting at 2°·7–3° are again formed. It is therefore established that methylated salicylaldehyde forms crystals of two kinds, having melting-points differing by about 32°.—The action of propionyl and butyryl chloride on phenol, by the same. When phenol is acted upon by propionyl chloride, a secondary product, propionyl phenol, $C_3H_5O \cdot C_6H_4 \cdot OH$, is formed in addition to phenyl propionate. A corresponding reaction occurs when phenol is treated with butyryl chloride.—The nature of solutions as elucidated by a study of their freezing temperatures, by Mr. S. U. Pickering. By determining the freezing temperatures of mixtures of sulphuric acid and water, the author has obtained results which in his opinion confirm the existence in solution of the majority of the hydrates of sulphuric acid which have been indicated by a study of the densities, heat of dissolution, heat capacity, and electric conductivity of these solutions (cf. p. 166).—Note on the determination of the molecular weight of substances in solution, especially colloids, by Prof. H. E. Armstrong.—The correspondence between the magnetic rotation and the refraction and dispersion of light by compounds containing nitrogen, by Dr. J. H. Gladstone, F.R.S., and Dr. W. H. Perkin, F.R.S.—Note on the oxidation of paradiamines, by Prof. R. Meldola, F.R.S., and Mr. R. E. Evans. The authors find that the amido-groups of paraphenylenediamine are split off in the form of ammonia, when it is oxidized to quinone by the action of potassium bichromate.—Monobenzyl-derivatives of the phenylenediamines, by Prof. R. Meldola and Mr. J. H. Coste. Monobenzyl meta- and para-phenylenediamines have been prepared, and their oxidation products examined. The paradiamine, when oxidized with an equimolecular proportion of benzylaniline, yields an unstable greenish-blue indamine, and when oxidized with two molecular proportions of benzylaniline at the temperature of boiling water, forms an azine or benzylated saffranine which is of interest as being produced, in contradiction to the generally received view, from one molecule of a diamine, and two molecules of a secondary instead of a primary monamine.—Note on a yellow pigment in butterflies, by Mr. F. G. Hopkins. The colour effects on the wings of lepidopterous insects are for the most part probably due to purely physical causes, but in some cases pigments are undoubtedly present. A yellow pigment, which is found in its purest form in the common English brimstone butterfly, and may also be detected in the wings of a very large number of day-flying Lepidoptera, can be obtained from the wings by simple treatment with hot water, in which it is freely soluble, and may be identified by its yielding a marked murexide reaction, when evaporated with nitric acid, and afterwards treated with ammonia or potash. The common brimstone butterfly yields somewhat less than a milligram of pigment from each insect; larger foreign species, such as those belonging to the species *Callidryas*, may yield as much as 4–5 milligrams. Examination of the pigment reveals its near relationship to mycomelic acid, a yellow derivative of uric acid; and the author suggests that it may possibly be a condensation product of uric and mycomelic acids.—Zinc dextrosate, by Mr. A. C. Chapman.—β-bromonaphthalenesulphonic acids, by Mr. R. W. Sindall. It is found that dichloronaphthalenes are chiefly formed when the chlorides of the β-bromonaphthalenesulphonic acids are distilled with phosphorus pentachloride, the bromine atom becoming displaced by chlorine.—Isomeric change in the naphthalene series, No. 5; β-iodonaphthalenesulphonic acids, by Prof. H. E. Armstrong and Mr. W. P. Wynne. A further contribution to the study of isomeric change in the naphthalene series, in which additional evidence, derived from the investigation of the acids obtained on sulphonating β iodonaphthalene under varied conditions, is adduced in favour of the view that the β-derivatives of naphthalene are formed by isomeric change from α-derivatives and not by direct substitution.—The formation of sulphones on sulphonating naphthalene-derivatives by means of chlorosulphonic acid, by Mr. W. M. Heller.—Note on the hydration of cyanides, by Prof. H. E. Armstrong. Unlike the α-derivative, β-cyanonaphthalene cannot be sulphonated; if, however, it is dissolved in fuming sulphuric acid, and the solution poured into water, it is completely converted into the amide of naphthoic acid. In like manner trichloracetonitril, $CCl_3 \cdot CN$, slowly combines with sulphuric anhydride, forming a crystalline compound which on treatment with water undergoes immediate and complete conversion into trichloracetamide. These cases appear to afford striking evidence in favour of the view that hydrating and hydrolytic agents act by forming compounds directly attackable by water; they serve, in fact, to support the integration rather than the dissociation hypothesis of chemical change.—The existence of salicylic acid in certain genera of the *Liliaceæ*, by Dr. A. B. Griffiths. The author states that he has isolated salicylic acid from the leaves, stems, &c., of *Tulipa*, Yucca, and *Hyacinthus*.—On the oxidation products of acenaphthene, by Mr. T. Ewan and Dr. J. B. Cohen.—Schützenberger's process for the estimation of the oxygen dissolved in water, by Sir H. E. Roscoe, F.R.S., and Mr. J. Lunt.—Isomeric change in the phenol series (third notice), by Mr. A. R. Ling.

EDINBURGH.

Royal Society, July 1.—Dr. John Murray, Vice-President, in the chair.—Prof. Tait communicated a paper, by Dr. G. Plarr, on the determination of the curve, on one of the co-ordinate planes, which forms the outer limit of the positions of the point of contact of an ellipsoid of revolution which touches all three planes of reference. By considering an ellipsoid of revolution the number of the equations to be finally solved is reduced to two.—Mr. A. Crichton Mitchell read a paper on the thermal conductivity, and the specific heat, of manganese steel. The thermal conductivity is one-seventh of that of iron, and increases with rise of temperature, but only at half the rate at which the conductivity of iron increases. The specific heat is 1·008 times that of iron—both increasing at the same rate with rise of temperature.—Sir W. Turner described the placentation (zonary) of the halicore dugong.—Dr. W. Peddie discussed the question Does the co-efficient of absorption depend upon the intensity of light? So far as his experiments have gone the answer is (as has hitherto been assumed) in the negative. He used a diverging beam of light, the intensity varying from 1 to 50.—A paper, by Dr. A. B. Griffiths, on the renal organs of the Nematoidea, was submitted.

July 15.—Prof. Chrystal, Vice-President, in the chair.—Prof. Tait read a paper, by Captain P. Weir, on an azimuth diagram, and also read a note by himself on the same.—Two papers, by Sir W. Thomson, on molecular arrangement, and on electrification by flame, respectively, were submitted.—Dr. R. W. Felkin discussed the geographical distribution of some tropical diseases.—Prof. Tait read a note on the compressibility of solutions of sugar. Sugar in solution increases the internal pressure, but not to the same extent as common salt does.—Prof. Berry Haycraft read a paper written by himself in conjunction with Dr. C. W. Duggan, on the coagulation of serum albumen, serum globulin, egg albumen, and vitellin.—Dr. Alex. James discussed a new point in connection with the latent period of muscle contraction.—Prof. Tait read a paper on the time of impact as depending on the masses of the impinging bodies. In the substances experimented on the distortion is proportional to a power of the kinetic energy.—Dr. Alex. Bruce communicated a paper on the segmentation of the nucleus of the oculo-motor nerve, and he also read another on the upward continuation of the spinal cord.—Dr. P. J. White read a description of the skull and visceral arches of *Tæmargus microcephalus*.—Prof. Tait submitted a paper, by the Rev. M. M. U. Wilkinson, on the scalar equations which represent the relations connecting n points. He also read a paper by himself on some novel quaternion formulæ.—Prof. Crum Brown communicated a paper by Prof. Letts and Mr. R. F. Blake on benzyl phosphines and the action of alcohols upon a mixture of phosphorus and phosphorus iodide.—Prof. Tait communicated a paper, by Prof. C. N. Little, on the non-alternate ± knots of the eighth and ninth orders.—The Chairman gave a review of the session.

SYDNEY.

Royal Society of New South Wales, June 5.—Prof. Liversidge, F.R.S., President, in the chair.—The Chairman announced that the Council had awarded the Society's bronze medal and a money prize of £25 to Mr. Thomas Whitelegge, for his paper on the marine and fresh-water invertebrate fauna of Port Jackson and the neighbourhood.—The following papers were read:—Note on the composition of two sugar plantation soils, by W. A. Dixon; and the Australian aborigines, by W. T. Wyndham.—Three new meteorites were exhibited by Mr. H. C. Russell, viz. two from Barratta Station, thirty-four miles north of Deniliquin, weighing 31½ pounds and 48 pounds, sp. gr. 3·706 and 3·429 respectively, and one from Gilgoin Station, near Brewarrina, 67½ pounds, sp. gr. 3·857.—In the course of some remarks respecting the recent heavy rainfall, Mr. Russell (the Government Astronomer) stated that he had no hesitation in saying that if rain equal to that which fell in and around Sydney (*i.e.* 20 to 26 inches) had fallen generally over the catchment areas of Windsor, Richmond, the upper parts of the Hawkesbury, and in the valley of the Hunter, most if not all the towns on their banks would have been swept away.—Prof. Anderson Stuart exhibited (1) the kymoscope, an apparatus he had devised for showing the action of the heart upon the blood in the circulatory system, also the difference in the pulse beats; (2) an appliance or means of showing that the shape of the chest is largely due to gravitation.

PARIS.

Academy of Sciences, July 22.—M. Des Cloizeaux, President, in the chair.—Summary of the solar observations made at the Observatory of the Collegio Romano during the second quarter of the year 1889, by M. P. Tacchini. During this period the solar spots have continued to diminish in number, so that the minimum appears now to have been reached. The protuberances also show a perceptible decrease, their height and expansion being even inferior to those of the previous quarter.—Two solar eruptions, by M. Jules Fenyi. The forms are here reproduced of the two eruptive protuberances of September 5–6, 1888, described in the *Comptes rendus*, vol. cviii. No. 17.—Restoration of the meridian and curve of mean time traced by Monge on the wall of the Ecole de Génie at Mézières, now the Prefecture of the Ardennes, by M. Cochard. At the request of the Mayor of Mézières, the author has carefully restored this interesting monument of the illustrious geometrician, which appears to have been executed by him some time between the years 1780 and 1784. Monge's dial is 5·20 m. high, distance taken on the meridian between the two solstices.—On the variations in the intensity of the current during the process of electrolysis, by M. N. Piltschikoff. In continuation of his previous note on the initial phase of electrolysis (*Comptes rendus*, March 25, 1889), the author here describes a curious phenomenon of transformation of molecular into electric energy, which he has observed in the course of his researches.—On the double elliptical refraction of quartz, by M. F. Beaulard. In a previous communication (*Comptes rendus*, vol. cviii. p. 671), the author described a new method of studying the phenomenon of double elliptical refraction presented by quartz at a direction oblique to the axis. Here he gives the first results of his researches carried on by means of this method.—On the zinc and cadmium chromites, by M. G. Viard. By modifying M. Gerber's process the author has succeeded in obtaining the crystallized chromites of zinc and cadmium which are here described. Their respective densities are 5·29 at 13° and 5·79 at 17°.—On the formation of crystallized alkaline and alkaline-earthy platinates at high temperatures, by M. G. Rousseau. The author here deals with the platinates of baryta and soda, which are shown to be as stable as the manganates and ferrites. They offer a fresh example of the formation of compound bodies at a temperature higher than that at which they are destroyed.—Quantitative analysis of the bicarbonate of soda in milk, by M. L. Padé. During his researches into the causes of the disappearance of the greater part of the alkaline element in the soluble ashes of milk, to which the bicarbonate of soda has been added, the author has discovered an exact method of effecting the analysis of this salt. During combustion about two-thirds of the carbonate of soda are transformed to the phosphate of soda and the carbonate of calcium by reacting on the phosphate of calcium contained in the milk. According to this transformation the phosphate of soda is contained in the ashes of a milk to which the carbonate of soda has been added. But the soluble ashes of a pure milk being but slightly alkaline, and containing only traces of phosphoric acid, in order to ascertain exactly the quantity of bicarbonate of soda that has been added, all that is needed is to take the alkalinity of the ashes and analyze the phosphoric acid contained in them.—Study of a molar of an elephant and of the process by which it is fixed in the maxillary, by M. V. Galippe. The recent death of an elephant in Paris has afforded the author an opportunity of studying the general structure of the gum in this animal, as well as certain pathological lesions, the analysis of which is here given in detail.—Papers were contributed by M. J. Macé de Lépinay, on the interference fringes produced by extended luminous sources; by M. Ad. Carnot, on the ammonio-cobaltic tungstates and vanadates; by M. E. Duvillier, on α-diethyl-amido-propionic acid; by M. J. Courmont, on a new bacillary tuberculosis of bovine origin; and by M. H. Wild, on the earthquake of Werny indicated by the magnetic and electric registering apparatus of Pavlovsk.

THURSDAY, AUGUST 8, 1889.

EMPIRICAL LOGIC.

The Principles of Empirical or Inductive Logic. By John Venn, Sc.D., F.R.S., Fellow and Lecturer in the Moral Sciences, Gonville and Caius College, Cambridge. (London: Macmillan and Co., 1889.)

THOSE familiar with Dr. Venn's previous logical writings felt sure that his new contribution would at least be something very different from an ordinary text-book. There is a novelty, perhaps something of a quaint peculiarity, in the manner of viewing and illustrating his subject, which gives to the author's works an appearance of originality which might be easily confused with that which is due, as in the case of such a treatise as Mill's "Logic," to a radically new conception. And to say this in these days, when logical text-books are multiplied, and, as some would think, all the old problems have been finally threshed out, is no small praise. In the less frequently explored fields already traversed by Dr. Venn—the logic of probability and symbolic logic—there was, of course, more room for such fresh treatment. This freshness is, however, just as conspicuous in the new treatise, which goes over the well-trodden ground of common logic. If anybody is stupid enough to think that logic is necessarily a dry subject, he may be recommended to look into Dr. Venn's last treatise. It is brimfull of shrewd observation, of apt illustration taken from the least conventional sources; more than this, it has humour, and it has fancy—a logician's, of course, but of a genuine quality.

In his general stand-point the author is, as the title of his book tells the expert, and as he fully discloses in his introductory chapter, not far from that of Mill. That is to say, he is an out-and-out materialist. Logic is not, as the formalist says, concerned only with the mind's thought and its normal forms, but occupies itself about the relation of this thought to objective fact or existence—that is, about objective truth. Hence here, as with Mill, we find the reference to reality running through the whole treatment of the subject. This emphasizing of the objective aspect is made sufficiently plain by the fact that, in his first chapter, before taking up the common topics, terms, propositions, &c., he deals at great length with the "physical foundations of inference," the assumptions with respect to the nature of the external world with which the logician sets out. In some directions, indeed, Dr. Venn carries this objective reference further than Mill, and with good results. Particularly valuable is the account of the meaning of reality or objective truth in the case of fictitious ideas, as "dragon." At the same time, our author is very far from making logic a purely objective science in the sense in which the physical sciences are objective. Having to give an account of and to provide rules for inference, it must at every step take into account the subjective aspect as well. Thus it has to consider facts so far as they are known, and, whilst it insists that names are representative of real things, it no less clearly contends that these names sum up and embody the amount of knowledge we happen to possess of the realities at any particular time. The steady grasp of this twofold aspect of the subject-matter of logic gives Dr. Venn a great advantage in the treatment of details. This is strikingly illustrated in his whole account of the connotation of names, and the related subject, definition. What a common name, *e.g.* "gold," means is of course a group of qualities known to exist in certain real things; but a glance shows us that these are not all the qualities that exist in the things, but only a certain portion of these conventionally selected. So again, in dealing with hypothetical propositions, the author turns his recognition of the double aspect to good account. A hypothetical statement, of the form, "If the summer is hot, the supply of water will be diminished," has at once a reference to clear objective fact, and to the mind's doubt or ignorance. The mind's attitude of doubt is seen in the very form of the supposition, "*If* the summer is hot," the objective certainty reveals itself in the inference confidently drawn from the supposition. One may add that it is this same just recognition of the equal rights of subject and object in logic which accounts for his taking a more modest view of induction than Mill. He tells us in his preface that the title "Empirical Logic" is intended to show that "no ultimate objective certainty, such as Mill, for instance, seemed to attribute to the results of induction, is attainable by any exercise of the human reason." Mill's confident repose on a system of universal law has been rudely handled by writers like the late Prof. Green, who denied his right to reach such universality on his purely empirical or Humean basis. And now we have scientific men like the late Profs. Clifford and Jevons, and Dr. Venn, urging from Mill's own empirical stand-point that experience can never guarantee such perfect universality.

In the case of a work like the present one it is difficult for the reviewer to give, by means of a few typical references, the scope and gist of the argument. As already hinted, it is not in any sense a new logical system. Indeed, it can hardly be called a complete system at all. It does not take us in an orderly, systematic manner through all the well-recognized divisions of the subject. Thus a large part of the domain of the common syllogistic logic is very slightly dealt with, if at all; no reference being made to the so-called laws of thought, or the axioms which underlie the thinking process so far as this is merely self-consistent. Nor even if we view it as a treatise on inductive logic can Dr. Venn's work be called complete, since some of the most important matters appertaining to induction—for example, experiment in relation to observation, the deductive method, scientific hypothesis—are altogether passed by, or only just referred to. In fact, Dr. Venn's volume, which he tells us embodies the substance of courses of lectures, must be regarded as a series of discussions of some of the more important or more neglected points of logic, having a certain connection from the fact that they imply one *manière de voir*, and the same fundamental principles. This being so, one must try to indicate the quality of the work by a reference to one or two of the more important matters dealt with.

To begin with the first chapter, which is an excellent compact statement of the main pre-suppositions of material logic, Dr. Venn has done good service in showing how much work of the mind has gone to the construction of the world of objects with which the logician sets out. All that he says here about the work of analysis and synthesis might perhaps be translated by a Kantian or even a Hegelian into his own philosophical dialect. What our author, however, is concerned to bring out is the practical motive that underlies our common thought-distinctions. He shows in a striking manner that there is something arbitrary in our way of demarcating "things" or "objects," though this is justified by practical exigencies. The recognition of this elasticity in our conception of a thing enables the writer later on to handle with good effect the common distinction between concrete and abstract terms. These, says our author, are not absolute, but relative designations. "Hardly any object, as objects are regarded by us, can be selected, which is not to some extent a product of our powers of abstraction, and the more or less of this faculty called into play in any particular case hardly warrants us in labelling the instances respectively with such distinct designations."

Somewhat similar considerations are applied to collective terms. "There is nothing," writes Dr. Venn in his most ingenious vein, "to hinder us from taking a 'scratch lot' of things, to use the slang phrase, and giving a name to the lot with the caprice which we show in naming a yacht or a dog," *e.g.* the persons who happen at a particular moment to be in a given space in Fleet Street. This idea of the arbitrary limits of our common distinctions is made good use of in the treatment of the relation of the subject and predicate in propositions where, as too rarely happens in English works on logic, adequate recognition is taken of impersonal propositions. With reference to this last topic, however, it should be said that Dr. Venn's treatment, though fresh and suggestive, is hardly adequate. He seems to start from the supposition that logicians resolve all forms of predication into attribution of qualities to things (the subjects). This is to ignore the careful analysis of the import of propositions carried out by Mill, Bain, and others.

In a work on inductive logic the mode of dealing with causation may be said to be conclusive as to the writer's competence. Dr. Venn's account forms one of the most valuable portions of his work. Very happy and fruitful in simplification and the dispelling of confusion is his idea that the logician in dealing with the relation of cause and effect stands midway between the point of view of every-day practical sense and that of a rigorously scientific or speculative intelligence. The popular view is practical, and is subordinated to the production of (desirable) effects. The logician improves on this, first of all by enumerating the antecedents more completely, and secondly by "screwing up the cause and effect into close juxtaposition,"—that is, into an approximately immediate sequence. At the same time, he does not aim at absolute completeness in either respect, for this, as the writer shows, would be to defeat his end. He retains something of the popular practicality of view, and this is ingeniously illustrated in the common logical doctrine that, whereas the same antecedent can only be followed by one consequent, the same consequent can be preceded by different antecedents (plurality of causes). Perhaps Dr. Venn is a little hard on Mill and logicians generally for their way of formulating the causal relation. No doubt, as he contends, every concrete event is a highly complex group of elements, followed by another complex group. But the logician is dealing with causation for purposes of induction. He assumes that the investigator must generalize, and generalize as far possible, if he wishes to attain his goal, viz. comprehensive principles or laws. A general statement, such as "Friction produces heat," is, no doubt, in a sense highly elliptical. There must of course be, in every case, a definite set of circumstances in which the friction acts and the heat is developed. But there is no need to refer to these in stating the general truth; on the contrary, this statement, just because it is a large principle available for guidance in a vast number of diverse cases, must be an abstraction. Historically considered, moreover, it may be said that Dr. Venn makes too much of the practical impulse in the genesis of our idea of causation. Primitive man, as soon as he could form an idea about cause at all, was presumably already beginning to ask about the origin of things, and to work out a crude cosmogony of his own.

On the nature of inductive processes, and the well-known methods formulated by Mill, our author is distinctly in advance of his predecessors. With his customary caution he points out the difficulties that have to be got over before generalization can begin. Combining in a manner the views of Mill, Whewell, and Jevons, he regards a complete process of inductive discovery as consisting of three steps, viz. (1) a stroke of insight or creative genius in order to detect the property to be generalized (and possibly also the class); (2) the formal process of generalization; and (3) the final stage of verification (apparently by way of deduction). The chapter on the methods is judiciously critical, and may with advantage be compared with Mr. Bradley's less discriminating treatment. The way is prepared for a study of the complex problems of physical induction by the selection of a simple artificial example, viz. the case of a man in an hotel office, who has to determine what room rings a particular bell. This case is dealt with by purely formal considerations, similar to those which guide us in the problems of symbolic logic. It is then shown that such purely formal treatment is inappropriate in the case of physical investigations, and the special methods of induction are thus introduced as a *pis aller*. The author is most original in dealing with the Joint Method, which every careful reader of Mill's "Logic" must have felt was very far from clear.

There are other features in Dr. Venn's scheme of induction which deserve careful notice. Among these may be named the account of co-existences as distinguished from sequences (chapter iii.); the description of the nature and function of units and standards (chapters xviii. and xix.), which is less technical and more suitable to a logical treatise than that given by Jevons; the highly characteristic chapter on the possible extension of our general powers of observation (chapter xxiii.), where the bold idea is entertained of our being able some day to spread out an event in time just as the telescope and the microscope enable us to spread out an object in space; and, lastly, the discussion in the concluding chapter of the effect of our practical tendencies in modifying a strictly logical or speculative view of the world.

Any one of these might well call for detailed remark if space permitted. They show the author at his best, finely observant of overlooked points, subtly ingenious in devising new, quaint, and even startling possibilities. But the reader must be referred to the volume itself for a fuller appreciation of these qualities.

When one has gained much pleasure and profit from a work, it seems almost shabby to begin to find fault. Yet no critical reader of Dr. Venn's treatise can fail to perceive its defects. It is as if the author had boldly set them before our very eyes challenging criticism. The want of close connection has already been touched on. There seems, indeed, a surprising lack of systematic arrangement, as if the author had sat down to write without a clear plan before him. Poor formal logic gets badly treated. Thus we have an account of terms, propositions, including hypotheticals and disjunctives, but no account of the syllogism. Nor can it be said that the writer has introduced just as much of the common syllogistic logic as is needed for setting forth the processes of induction. Much given us under terms and propositions cannot well be regarded as needed in a treatise on the logic of induction. Sometimes, indeed, the author wanders into the mystic region of symbolic logic. Again and again he opens up in a tantalizing way views which he does not stop to establish. One may instance the point touched on (p. 43), whether the converse of a particular proposition is in substance a new proposition. This depends on our view of the import of a proposition, which, as already pointed out, is not adequately dealt with. Again, the author seems to deny the existence of a negative disjunctive of the type "Either A is not B or C is not D," but he does not trouble to prove the point, or indeed to make clear what he precisely means. It is surprising, again, to find Dr. Venn discussing the functions of the syllogism not only without giving any preliminary sketch of it, but without the barest reference to the nature of the axiom which underlies it. On the other hand, a good deal that is known to the general student from previous works (including the author's own) is needlessly repeated, and helps sadly to swell the size of the volume. Another feature that will strike every careful reader, and which is strongly suggestive of defective plan, is the frequency of the forward reference, as "we shall see by and by," and so forth. This is apt to be very confusing. In noting this, together with the comparative infrequency of the backward reference, one cannot help thinking of the author's remark on the popular view of causation, that it looks forward rather than backward.

A number of the author's statements seem to the present writer open to dispute. It must be surely a slip which makes him write of the classifications of natural history as made up of *collective* terms (p. 170). The Dicotyledons are surely not a collection in the sense in which the House of Commons is a collection. The limitation of the denotation of terms to present existences (p. 179) strikes one not only as highly capricious, but as inconsistent with what is said about differences of time in connection with predication. Once more, one would like to challenge the strong statement that the only easily discoverable instance of a purely verbal dispute is that about the "sameness" of a thing (p. 296). In one place, at least, the writer's ingenuity seems to carry him too far. Writing of logical definition by genus and differentia (p. 302, by a slip written genus and species), Dr. Venn tries to show that this is perfectly rational on the supposition (which logic is bound to make) that we all know the meaning of our terms, or, since the very need of defining a term shows that there is one term of which this cannot be supposed, of all terms but one. But it is obvious that this consideration would equally suggest or justify an inverse process of definition, viz. by naming a lower species, and subducting its differentia. Such slight blemishes as these are probably inseparable from Dr. Venn's manner of work, and it can safely be said that they detract but little from the general and lasting impression of masterful competence which his volume is certain to leave on the student's mind.

JAMES SULLY.

REMSEN'S "INORGANIC CHEMISTRY."

Inorganic Chemistry. By Ira Remsen, Professor of Chemistry in the Johns Hopkins University. (London: Macmillan and Co., 1889.)

THIS book is of interest from the circumstance that it is the first of its kind in the language of any pretensions which is based upon the periodic law. It is further characterized by the fulness with which general relations are discussed. The attempt is made to present the facts of inorganic chemistry in such a manner as to bring out their analogies and connections, with a view of elucidating the broad general principles of the science. Details of experiments, either as showing the origin and modes of preparation of products, or as illustrating their leading properties, are for the most part omitted, or are relegated to an appendix containing special directions for laboratory work. The book is put together in a plain, straightforward manner, with no attempt at any literary airs and graces; indeed, we may add that at times the style verges on a simplicity which is perilously near being puerile. Having said this much in commendation of the general plan of the work, we have said all we can say in its praise. For, however excellent may be the plan of a treatise of chemistry, its main value, after all, must depend upon the accuracy and completeness of its statements; and, as we proceed to show, there is much in this book which is both inaccurate and incomplete. From the style in which it is issued, and its price, we presume that the work is intended for the benefit of comparatively advanced students —at all events for a higher grade than that for which the author's well-known smaller books were prepared. Indeed, we are distinctly informed that the earlier works were intended to form a series of which the present volume is the most advanced member. Now, whilst it may be convenient for the purpose of elementary teaching not to tell the whole of what is known about a thing, the advanced student, if he has any scientific instinct at all, insists on knowing the truth, the whole truth, and nothing but the truth. Unfortunately, he does not always get that from this work. Prof. Remsen is admirable in his introductory books. In these there is a reticence of statement and a subordination of facts which make the books excellent for the purposes of school-teaching. But in the larger book it appears to us that the author suffers from the defects of his excellencies: what is a merit in the "Briefer Courses" becomes a positive blemish in the advanced work. Indeed, the volume before us seems to be nothing but the smaller work on inorganic chemistry "writ large," since in point of knowledge the student is not carried very much further than he is in that book. Take, for example, the statement respecting the mode of preparing hydrogen, given on pp. 26 and 27. We read that, when sulphuric acid acts upon zinc, the chemical change is represented both qualitatively and quantitatively by the equation $Zn + H_2SO_4 = ZnSO_4 + 2H$. This is stated without a word of qualification, in a long paragraph on the complex nature of the changes which take place in a chemical reaction; and yet every teacher knows that this equation does not express the truth, the whole truth, and nothing but the truth about the matter. Again, too, on p. 30, in the account of the mode of preparing oxygen, we have the conventional methods of representing the decomposition of potassium chlorate into equal parts of perchlorate and chloride, and the subsequent decomposition of the perchlorate into chloride, whereas Teed, and, subsequently, Frankland and Dingwall, showed some years ago that these equations altogether fail to represent what actually occurs.

McLeod's work on the part played by the admixed manganese dioxide in facilitating the evolution of oxygen from potassium chlorate is perhaps too recent to have received notice in the very meagre account given of the supposed modes of action of this substance; but the space occupied by the description of "gnomium," which is still more recent, might, we think, have been more profitably employed by some mention of Mercer's theory of "catalysis." This poverty of statement is, at times, almost exasperating. The account of Lavoisier's work, on p. 5, would have seriously jeopardized the chances of a London University matriculant if given in an examination paper. Nine out of ten average students would gather from this account that Lavoisier made chemistry what it is to-day by proving why it was that, "whenever water is boiled for a time in a glass vessel, a deposit of earthy matter is formed." With respect to the etymology of the term oxygen, it is stated that "the name is at present somewhat misleading," which might imply that it may possibly become less so in the future. On p. 298 we are told that "it was in an examination of urine for the purpose of discovering the philosopher's stone that phosphorus was first discovered in 1669." On p. 383 it is stated that "the name soda-water had its origin in the fact that the carbon dioxide used in charging the water is frequently made from primary or acid sodium carbonate." Are we to infer also that lithia and potash waters are prepared from carbonic acid evolved from the carbonate of the respective metals? On p. 141 we read that Lavoisier "considered chlorine to be an oxygen compound of some undiscovered element which was called *murium*. . . . The acid was accordingly called *muriatic acid*. . . ." If this implies that the term "muriatic acid" was derived from *murium*, it is contrary to Lavoisier's own account of the origin of the name. On pp. 60 and 61 of his "Traité Élémentaire de Chimie," partie 1, chap. iii. ("Œuvres de Lavoisier," Imprimerie Impériale), "De la Nomenclature des Acides en général, et particulièrement de ceux tirés du salpêtre et du sel marin," he says:—

"Rien ne nous a été plus facile que de corriger et de modifier l'ancien langage à l'égard de ces acides; nous avons converti le nom d'acide vitriolique en celui d'acide sulphurique, et celui d'air fixe en celui d'acide carbonique; mais il ne nous a pas été possible de suivre le même plan à l'égard des acides dont la base nous était inconnue. Nous nous sommes trouvés alors forcés de prendre une marche inverse, et, au lieu de conclure le nom de l'acide de celui de la base, nous avons nommé, au contraire, la base d'après la dénomination de l'acide. C'est ce qui nous est arrivé pour l'acide qu'on retire du sel marin ou sel de cuisine. . . . Nous avons nommé cette base inconnue *base muriatique*, *radical muriatique*, en empruntant ce nom, à l'exemple de M. Bergman et de M. de Morveau, du mot latin *muria*, donné anciennement au sel marin."

And in the index it is given: "*Acide muriatique*—son nom dérivé du mot latin *muria*, 61." As a matter of fact, the term was employed by Bergman and Scheele some years before the Lavoisieran nomenclature was published.

Loose, imperfect, or partial statements are, in fact, to be found on every other page. The word *eudiometer* is derived from εὔδια, calm air, and μετρον, a measure, "because it is used for the purpose of measuring gases (p. 51)." On p. 61, dissociation is defined to be "the gradual decomposition of a chemical compound by heat." Contrary to the statement on p. 44, hydrogen has *not* been liquefied. If this gas does not unite with oxygen at ordinary temperatures (p. 45), how is the action of platinum foil and of the Döbereiner lamp explained? The well-known process of extracting silver from argentiferous lead is called *Pattison's* method (p. 598). On p. 304 it is stated that phosphine unites with hydrochloric acid to form phosphonium chloride, and the statement is made that the reaction is perfectly analogous to that which takes place between hydrochloric acid and ammonia. It is nothing of the kind: phosphine and hydrochloric acid only combine under pressure, and the compound is dissociated, at ordinary temperatures, when the pressure is released. To judge from the statement on p. 281, the author is ignorant of the work of Tilden on the oxychlorides of nitrogen. The rusting of iron (p. 693) is *not* due to moisture in the air: iron does not rust in moist air in the absence of carbonic acid, as every tin-plate worker knows, and as Crace-Calvert, years ago, conclusively demonstrated. On p. 121 we have an account of chlorine trioxide, although Garzarolli-Thurnlackh, more than eight years since, working under Pebal's direction, showed that the substance so designated is a mixture of the dioxide with varying quantities of free chlorine and oxygen. The author still believes, apparently, in the existence of the ammonium-amalgam, and wholly ignores the work which shows that it is nothing but a metallic froth. He incorrectly describes the action of sulphuric acid upon potassium permanganate (p. 683), and tells us that no oxygen compound of fluorine is known, in spite of the existence of an oxyfluoride of phosphorus. The argument as to the valency of fluorine and the constitution of fluosilicic acid (p. 416), based on the supposition that hydrofluoric acid has the molecular formula H_2F_2, falls to the ground in view of the recent work of Thorpe and Hambly. These by no means exhaust all the errors we had noted, but the list is sufficiently long to show that the book has apparently been hastily and somewhat carelessly put together. It has, however, certain good points, and by a judicious overhauling might be made into a good book, for it is precisely one of those works that would have been better if the author had taken more pains.

THE MIDDLE LIAS OF NORTHAMPTONSHIRE.

The Middle Lias of Northamptonshire. By Beeby Thompson, F.G.S., F.C.S. Pp. 150. (London: Simpkin, Marshall, and Co., 1889.)

THE sub-title of this work explains that the subject is considered stratigraphically, palæontologically, economically, as a source of water supply, and as a mitigator of floods.

The author commences with some account of the beds grouped as Middle Lias, there being considerable difference in the classifications adopted by geologists, from the fact that the distinction between Middle and Lower Lias is mainly dependent on fossils. In considering this matter we have to deal with a series of clays, exhibiting a succession of organic remains, intimately connected, and yet characterized at different horizons by certain species of Ammonites. There are no stratigraphical planes of demarcation for our guidance, and it is merely a matter of convenience (or inconvenience as the case may be) to adopt a divisional line. The subject was discussed at some length in NATURE (vol. xv. p. 113) and we may therefore pass on to say that Mr. Thompson includes in his Middle Lias the zones of *Ammonites margaritatus* and *A. spinatus*, in this respect following the plan adopted by the Geological Survey.

As with the junction of the Middle and Lower Lias, so with that of the Middle and Upper Lias, there is, at any rate in Northamptonshire, evidence of intimate connection. We find, in fact, a "transition bed" between Middle and Upper Lias; and this, although but a few inches thick, has furnished a large number of fossils to Mr. T. Beesley, Mr. E. A. Walford, and the author of this work. Much interest attaches to this transition bed, from the fact that it contains an admixture of Middle and Upper Lias fossils, although a larger proportion of the former. Among the Upper Lias Ammonites found in it are *A. communis*, *A. annulatus*, and *A. Holandrei*; and it is noteworthy that *A. communis* and *A. crassus* are recorded also from the Marlstone below (zone of *A. spinatus*). All these species are very closely connected, and the abundance of *A. communis* in the lower beds of the Upper Lias of some parts of England, serves to show that its value as a zonal species in the uppermost beds is very local. We note that Mr. Thompson speaks of "falcifer" Ammonites—a mode of expression with which we fully sympathize, for the species, unfortunately, are becoming so much subdivided that before long no one but a specialist in Ammonites will dare to identify any particular form.

The work before us well illustrates the progress made in our knowledge of the details of British formations. The author has evidently laboured long and earnestly at his subject, and indeed no one but a resident geologist could have given us such particulars of the subdivisions of the Middle Lias and the fossils that occur in the different layers, for some sections yielding valuable information are open but for a short time, and the geologist who spends but a few weeks in a district may fail to find exposures of every zone. Moreover, now increasing attention is given to the biological history of species, the precise position they occupy in the series of strata is of the greatest importance. Hence the work is of value not merely from a local point of view, but as contributing much material that will help towards a full knowledge of the Lias of Britain.

Summarizing his results, Mr. Thompson catalogues 94 genera and 273 species from the Middle Lias, including, however, but few of the Foraminifera. Vertebrate remains are scarce, but the conditions of deposit, as remarked by the author, were to a large extent shallow water and littoral marine—conditions that appear to be generally unfavourable to the preservation of the fishes and reptiles of the Lias.

The economic products of the Middle Lias are duly noted by the author. These are practically confined to building-stone and brick earth. The valuable iron ores found in some localities hardly come into the area, although some beds were at one time worked at King's Sutton.

Considerable attention has been given by the author to the question of water-supply, and in 1881 he suggested that the supply for the town of Northampton might be increased by the formation of a number of dumb-wells. In this way he anticipated that the surface drainage might be conducted underground through the Upper Lias, so that the porous beds of the Middle Lias would be utilized as a natural reservoir, while at the same time the liability to floods would be lessened. The scheme was brought before the Town Council, but, as the author candidly admits, the Water Committee, after consulting Sir Robert Rawlinson, were fully justified in rejecting it. It is, however, far from apparent that the scheme was faulty in theory. The natural storage of water has been advocated by several authorities, and it has been put into practice in India. The whole subject is worthy of close attention, and we can commend this portion of Mr. Thompson's book to those interested in the questions of water-supply and drainage. H. B. W.

OUR BOOK SHELF.

A Dictionary of Explosives. By Major J. P. Cundill, R.A. Published by the Royal Engineers Institute. (Chatham: Mackay and Co., 1889.)

IT is impossible to look at this list of explosive substances prepared by Major Cundill without coming to the conclusion that the chemist has had little to do with the most of them. Mixtures are things which do not delight the chemical mind either in an explosive substance or anything else. It places too much reliance on some mechanical operation, mixing or something of that kind, to give the chemical notion of exactness in its composition.

A theoretically perfect explosive would be a substance like hexanitro-benzene, $C_6(NO_2)_6$, but this has not yet been made. The variety and curious nature of substances and mixtures, many of them solemnly patented, described in this book, are most interesting. One, amongst several, is a mixture of carbonate of lime, chloride of sodium, and urine evaporated with charcoal. It seems pretty harmless as an explosive. Not so, however, many other mixtures containing potassium chlorate for which safety is claimed. It is really quite incomprehensible how people with the slightest knowledge of chemistry can propose mixtures containing potassium chlorate and organic substances, and in many cases even sulphur as well.

By drawing the attention of chemists to the amount of nonsense palmed off on the Patent Office, this little book will se ve a good turn; but it is also of practical value, as extracts from the specifications are given in many cases which may save much seeking.

Some advice at the end of the book is useful, especially to those interested in explosives in a professional way, but who are not sufficiently chemists to be able to deduce it for themselves. Possibly it is the fault of the specifications, and not the author, that benzene is written in several ways, benzole, benzine, &c.

On p. 68 there is an equation to represent the products of gun-cotton when detonated, to which perhaps some exception may be taken, but after all but slightly, for there is still much ignorance on the matter. It is

$$2C_6H_7O_2 3NO_3 = 9CO + 3CO_2 + 7H_2O + N_6.$$

It is very doubtful indeed whether any of these nitrates can be burnt under any conditions without yielding a considerable quantity of oxides of nitrogen as end products; probably NO in the first instance, which takes up oxygen from the air, and is undoubtedly the greatest drawback in the use of gun-cotton, glycerol nitrate, and similar substances.

Some advice is given about nitro-glycerine on p. 39. "Any indication of acid fumes or tinge of green should be followed by their prompt destruction with suitable precautions." It would have been well here to give some precautions even at the risk of repetition, for it is not safe to play with nitro-glycerine when in this state. The author might have added that an addition of aniline at this stage renders the destructive operations much safer.

Under the heading of smokeless and "noiseless" gunpowder, little more could be said at the present time than the author has ventured upon. We do not quite believe that a "noiseless" explosive will be so easily found as a smokeless one. Such a substance belongs almost to the category of explosives that act in "one direction only," or have no recoil.

We think the book will be useful in several ways. Blank pages are inserted for further additions to our stock of explosives, safe and unsafe, as they are published.

W. R. H.

Gaseous Fuel. By B. H. Thwaite. (London: Whittaker and Co., 1889.)

THIS little book of forty-six pages contains the substance of a popular lecture delivered by the author, under the auspices of the Manchester and Salford Noxious Vapours Abatement Association. It gives an account of the principles which underlie the economical consumption of fuel in general, and of the various forms of "gaseous fuel" in particular, and more especially of those forms in which the lecturer is professionally interested. The book, of course, makes no pretensions to deal with the subject exhaustively: its main object, apparently, is to direct attention to the advantages of smokeless fuel as compared with coal as ordinarily burnt. The author is occasionally to be found tripping in his chemistry and physics, and there are, now and then, a few awkward turns of expression. Thus, we read that fire-damp "is a light carburetted hydrogen, one of the gaseous paraffines or methane, its principal formula being chiefly CH_4"! (p. 15). The inventor of the well-known laboratory burner is styled "Baron Bunsen." On p. 34 we read: "The principle of the development of motive power by the instantaneous combustion of gaseous fuel rests in the laws of Charles Gay Lussac and Boyle—*ergo*, that the pressure exerted by a gas varies directly as its volume." The author seems to imply that the idea of using the fire-damp at Hebburn Colliery, near Newcastle, originated in a suggestion made by him some two years ago in *Engineering*. In reality, the idea is due to the younger Buddle. Indeed, as a matter of fact, blowers which have been encountered in the process of working have been frequently utilized either for heating or illuminating purposes; notable examples are at Llwynypia and at Pandy, in the Rhondda Valley.

A Treatise on Spherical Trigonometry, and its Application to Geodesy and Astronomy. With Numerous Examples. By Dr. J. Casey, F.R.S. (London: Longmans, 1889.)

THIS is a sequel to the large "Plane Trigonometry" by the same writer, and is naturally drawn up on the same plan. Its size is handy, and yet it contains a very large amount of matter. Much of this the author claims to be original, and a great deal, as in the case of the "Plane Trigonometry," has been collected from the foreign mathematical journals. The first three chapters cover familiar ground, with here and there a new feature inserted. Chapter iv., entitled "Various Applications," gives properties of transversals, of isotomic and isogonal conjugates, of the Lemoine and symmedian points, and of some other lines with which recent plane geometry has made us familiar—more especially our author's own "Sequel to Euclid." Chapter v. discusses the spherical excess, and in chapter vi. we have a full account of small circles on the sphere. The subject of inversions is discussed in chapter vii., and in chapter viii. we have full details of the polyhedra. The last chapter gives an account of numerous applications of the subject, as to geodesy and astronomy. It would be almost impossible, we should say, to light upon a theorem elsewhere which is not contained here. More than 500 exercises afford scope for practice. As in the case of the "Plane Trigonometry," the author's great indebtedness to Prof. Neuberg, of Liége, is suitably acknowledged, for it is through this gentleman's courtesy the book is brought so thoroughly into touch with Continental sources of information.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coronæ round a Light produced by a Peculiar St ucture in the Eye.

FOR some years past I have been aware that a bright light on a dark background appeared to be surrounded by faint coloured rings, and that these rings were due to something in the eye itself. But I gave them little attention, for I imagined they were formed in the same way as the coronæ seen when the sun or moon is covered by a thin cloud; opaque particles in the cornea, or little elevations or depressions of its surface, playing the part of the drops of water in the cloud. This is the view taken in Verdet's great work on the wave-theory of light. "Les cercles irisés, qu'à la suite de certaines inflammations de la conjonctive on aperçoit autour des corps lumineux, se rattachent à la même cause que les couronnes; ces apparences sont dues à l'existence de granulations très-petites et sensiblement égales dans la portion de la conjonctive qui se trouve en avant de la cornée transparente" (Verdet, "Leçons d'Optique Physique," § 79). I have lately discovered, however, that the phenomenon in my own case must be due to quite a different cause.

A leading characteristic of the diffraction phenomena produced by a number of equal obstacles, *irregularly spaced*, is the bright disk surrounding the light, which is for the most part nearly white. Near the light it is bluish, while the outer border passes through yellow to red. To the red succeeds purple, blue, green, yellow, red, &c., the colours resembling those of Newton's rings. The central disk is far the brightest part, and there is no real break in the colours, though the first purple is a good deal darker than its neighbours. The easiest way to see these colours is to sprinkle a slip of glass with Lycopodium seed and look through it at a bright point of light. The above description applies equally well whether the obstacles are spherical or cylindrical. The latter form is nearly approached in Nature by the fine needles of ice of which many clouds must be largely composed. With other forms of obstacle the colours would be more or less blurred, but in any case the bright central disk would survive.

When recently engaged in investigating such phenomena, I noticed that the rings formed in my eye were of an utterly different character. There are two narrow rings, apparently in contact—the inner green, the outer red; the apparent breadth of each being about 20′, and the radius of the intermediate circle about 2° 30′. Within the green ring is a broad dark space, and then comes the ordinary colourless haze surrounding the light. The rings are not quite continuous, and certain short arcs are much brighter than the rest. But the arrangement of these arcs seems quite irregular, and is different in the two eyes. With this exception the two eyes behave alike. The green and red, though faint, are of good quality, not unlike a very faint prismatic spectrum. They are rather capricious in their appearance, requiring a dark background and a moderately bright light. A small arc light some thirty yards from my window generally shows them well, though they vary a good deal in brightness, and at times I cannot see them at all.

The question was, how the colours were produced. After pondering the matter for some time, and rejecting one explanation after another, the true solution suddenly flashed upon me. The colours are the first spectrum of a diffraction grating, and the ring form is due to the bars of the grating lying in different directions in different parts of the eye. The idea was readily put to the test. Cutting a small hole, one-tenth of an inch square, in a piece of paper, I held it in front of the eye. When the aperture was in the centre, the coloured rings vanished; when it was drawn to one side to the very edge of the pupil, two bright spots appeared on the circle, one above, the other below the light. The rest of the circle was invisible. As the aperture was moved round the outside of the pupil, the two bright spots revolved round the circle, preserving their angular distance of 90° from the aperture. This shows that the bars of the grating radiate from the centre of the pupil and are only found near its edge. From the dimensions of the rings we may deduce that the lines are spaced at the rate of about 75 to the millimetre, or 1900 to the inch. Since the coloured ring is not uniformly bright, the grating must be imperfectly developed behind some parts of the outer edge of the pupil. But trial with the diaphragm left no doubt that the structure was present to some extent all round. I then compared the coloured rings with the spectra seen on looking at a light through an ordinary diffraction grating of 3000 lines to the inch. The appearance was very similar, though in the latter case of course the red and green were much brighter, and were accompanied by a comparatively faint violet band. The breadth of the red and green bands relatively to their distance from the light agreed very well with the measurements given above.

Another evening I prepared some diaphragms with annular apertures of which three, A, B, C, had the inner and outer diameters respectively 10·7 and 8·6 mm., 9·9 and 7·6 mm., 8·1 and 6·1 mm. In A the central stop was large enough to hide the light and of course extinguish the rings too. With B when held centrically the rings were very plain—indeed yellow could be made out between the green and red—while the light was distorted and enlarged by both spherical and chromatic aberration. With C the rings were visible but not distinct. I found too that with B I could see the rings round the naked flame of a bright paraffin lamp only two or three feet away, for the pupil enlarged till it cleared the stop. But with C, I had to move two or three yards away before the rings appeared. These experiments show the diffracting structure to exist in a ring, whose diameter lies between 8·1 mm. and 7·6 mm., and that it does not extend far inside the lower limit. Further, the diameter of the pupil when the rings are visible may be decidedly less than 8·6 mm. The structure is not on the inner edge of the iris, but it may lie either in the cornea or in the crystalline lens. The latter is known to be built up of closely-packed radial fibres from 0·0056 mm. to 0·0112 mm. in breadth (Helmholtz, "Physiologische Optik," § 5). It seems probable that some modification of these near the edge of the lens form the diffracting layer. I have since found that at a distance of a hundred yards from the electric light the pupil can be made to clear the central stop of A. There is then seen a narrow circle of light, too faint to show colour. I was not able to get a good enough measure of its diameter to decide whether it was smaller than before.

I can hardly fancy this curious structure in the eye to be a rare peculiarity. One of my friends saw the green ring well defined round the electric light one evening, and with practically the same radius as I. He was not sure about the red. Inside the green he described the colour as very dark purple, almost black. Probably this was a contrast effect, but possibly it was the violet of the spectrum. In Sir John Herschel's "Meteorology" I find the following passage. After speaking of coronæ round the sun, he says: "Occasionally the cornea of the eye itself becomes filmy by the diffusion over it of minute particles, which (such at least is our personal experience) exhibit round a candle two or three beautiful coronas, the second of 17° 57′ in diameter, of vivid colours and most perfect definition." This description makes me feel suspicious that the rings were of the same class as mine. It suggests separate spectra such as are produced by a diffraction grating. Further, the accuracy of the measurement implies a tolerably narrow ring, whereas in ordinary coronæ, if the second green had a diameter 18°, the second blue and second red would have diameters 15° and 23° respectively. His dimensions do not agree with mine, but imply bars or lines at distances of about 0·007 mm. Fibres of this breadth are found in the crystalline lens. JAMES C. MCCONNEL.

Davos, Switzerland.

Use or Abuse of Empirical Formulæ, and of Differentiation, by Chemists.

As I believe that I am one of the "ingenious and clear-sighted" chemists who, Prof. Lodge suggests, may be "run away with by a smattering of quasi-mathematics and an over-pressing of empirical formulæ," I hasten to assure him that he is quite wrong in his surmises.

With every word of Prof. Lodge's remarks on the proper method of examining curves I heartily agree; with his strictures on the abuse of formulæ I more than agree: I should advise chemists not even to use them.

The method of examining the continuity of any curve by plotting out the experiments themselves, and then differentiating the curves representing them, is the method which I have applied in nearly every case, and applied it, I believe, for the first time to questions of a chemical nature. The only difference between my *modus operandi* and that which Prof. Lodge suggests is that, instead of differentiating the curves by a mechanical integrator, I take readings from them at definite intervals, and find the differences between these readings arithmetically.

I do not consider, however, that this is the safest method of examining results. The method which was introduced to the notice of chemists by Mendeleeff, which was used subsequently by Crompton, and on which I have placed my chief reliance, consists of differentiating the experimental numbers themselves, and not the curves which may be drawn to represent them. If s_1 and s_2 be the densities of p_1 and p_2 per cent. solutions, $\frac{dp}{ds}$ at a percentage $\frac{p_1 + p_2}{2}$ is given by $\frac{s_1 - s_2}{p_1 - p_2}$.

Each of these two methods has its own special advantages, but the balance is generally strongly in favour of the last one. It does not necessitate the drawing of the original curve, which drawing may often be considerably modified by the "taste" of the drawer; it will sometimes bring about the recognition of breaks which might be overlooked in the original curve, for though the differential curve can show no breaks which do not exist in the original curve, it may often, as a consequence of its very nature, show breaks clearly, which would be recognized only with difficulty in the original curve; and, lastly, the proper depiction of the original curve is often a practical impossibility, as, for instance, with the densities of sulphuric acid solutions, where the scale which would have to be adopted to give the experimental error a fairly visible magnitude would involve dealing with a curve some 3000 inches long.

Prof. Lodge could, no doubt, have told us more than he has done of the difficulties and dangers of differentiation in any form, and, perhaps, the extensive practical experience which I have had in the process has made me more alive to these dangers than even he is. I need only say here that I have not yet come across a case where I should feel warranted in stating that a break existed on the evidence of one curve only where the break depended on differentiation for being clearly visible. In my own work I have never considered any breaks as being more than "suggested" unless they were shown by at least two different properties of the substance under examination; the majority of the breaks which I insist on are shown by more than two, in some cases by as many as seven different properties.

As to the examination of the curves by means of empirical formulæ, nothing of the sort has been done, and it is difficult to understand how Prof. Lodge, even though he speaks under correction, should have so misunderstood the methods adopted. If Mendeleeff's paper may have been open to misinterpretation, Crompton's certainly was not, for he gives in a tabular form the results of the direct differentiation of the experimental numbers themselves; an abstract only of my own paper has as yet appeared, and I have not got it by me to refer to, but I do not think that the terms "formula" or "equation" occurred throughout it. The impossibility that seems to exist of getting either chemists or physicists to understand that the method of examining curves which we have employed does *not* involve the use of any equation at all is indeed extraordinary. My own opinion on the use of equations will be best illustrated by the following extract from my paper:—"It is necessary to say a word at starting to correct an erroneous opinion which is prevalent as to the method of examining curves which I have adopted. . . . It is imagined by many that this method consists in fitting sundry equations to the curves, and, on the strength of their concordance with these equations, to conclude that they are continuous or otherwise. Now, it is quite true that if a curve differentiates into a straight line after a certain number of differentiations, an equation of a certain form must represent that curve, and if it yields several straight lines there must be as many different equations applicable to different parts of it; but it is one thing to find equations empirically, and prove (?) their truth by a display of those most fallacious of arguments known as tables of 'found' and 'calculated' values, and another thing to apply an ordinary process of mathematical analysis to the curves, letting them speak for themselves, and tell us whether they are continuous or not. On the former of these methods I would place absolutely no reliance, and so far have I been from making use of it, that I have not found the equation for any single curve here depicted, and have purposely avoided finding any. The mathematical argument on which this work depends is, that a curve, if it be continuous, will on differentiation give either a straight line or another continuous curve, whereas, if it be not continuous, but be made up of different curves, will yield on differentiation a series of straight lines or curves. This, I think, is an incontestable fact."

That the majority of chemists are not mathematicians I willingly admit; this painful fact is shown only too clearly by their blind acceptance as gospel truth of everything which is "proved" mathematically. But Prof. Lodge must do us the justice to admit that we have occasionally some glimmers of common-sense, glimmers which would be inconsistent with our assuming that a certain curve was a parabola, and then being pleased, or even surprised, that it behaved after the manner of parabolas.

However much I may envy the powers of a mathematician, and however firmly I may believe that chemical facts will eventually be translated into mathematical expressions, I feel that at the present day the introduction of mathematical formulæ into chemistry almost invariably involves the exclusion of common sense. It is curious that Prof. Lodge's letter should have been immediately followed by an article on chemical affinity, which, I think, will be found to give a striking illustration of this dictum. What may be termed the x and y theory of chemical action, studied on paper by Guldberg and Waage, and followed up in the laboratory by Ostwald, has led unfortunate chemists into a labyrinth of cumbrous mathematical expressions for erroneous facts, where the common-sense of Berthollet would have given them a simple explanation of all the true facts of the case (see Trans. Chem. Soc., 1889, 26).

Harpenden, July 22. SPENCER PICKERING.

P.S.—Since writing the above I have obtained the most absolute justification of my method of differentiation which could possibly be obtained. I have isolated in the solid crystalline form a new hydrate of sulphuric acid, the existence of which I had predicted from an examination of the density and heat results of solutions of the acid. A few further details on the subject will, I believe, be found in the last issue of the *Chemical News*. S. P.

Ilfracombe, August 4.

PHOTOGRAPHIC STAR-GAUGING.

THE mere equal-surface counting of the stars visible with the same instrument in different sections of the sky gives results open to misinterpretation. Admirable in itself, the method fails because it encounters what we may call "systematic errors" in the distribution of the stars. With incidental anomalies it is fully competent to deal; they should, on a large average, be mutually compensatory; but it breaks down before the clustering tendency which pervades, more or less markedly, the entire sidereal system. Not only are certain parts of space more crowded than others, but the crowded parts are related according to an obvious plan. They do *not* occur casually. Their effect is then heightened, instead of being eliminated, by multiplied observations.

The present resources of science, however, seem to offer the means of discriminating, to some extent, between real crowding and the simple extent of star-strewn space. Although the total number of the stars visible in each case with the same telescope might be precisely the same, their relative numbers, counted by magnitudes, would in all probability be very different. In a stratum, supposing the distribution of the stars equable, and their size uniform, their numbers should be nearly quadrupled at each descent of a magnitude. This of course is an ideal law of progression which we cannot expect to find anywhere strictly obeyed; but even approximate conformity to it must be held to indicate with tolerable certainty that the lessening ranks of the stars are, on the whole, at distances from us corresponding with their light. Now it *is* approximately conformed to by the stellar multitude down to about 8·9 magnitude over the general expanse of the sky, as well as over the zone of the Milky Way. But in that zone, stars of the ninth and higher magnitudes very much exceed their due numerical proportions; in other words, they are physically, no less than optically, condensed.

From these circumstances two very important inferences may be derived: first, that the lower margin of the galactic aggregations lies at a distance from us corresponding roughly to the mean distance of a ninth magnitude star, costing light some fourteen hundred years of travel; next, that the aggregated objects are average stars, neither larger nor smaller than those in our nearer neighbourhood. Both conclusions seem inevitable should the facts turn out, on closer investigation, to be as above stated. A regular increase in the numbers of the successive photometric orders of stars, tallying with the increased cubical contents of the successive spheres of which the radii are the theoretical mean distances of those same orders, affords strong, if not demonstrative, evidence of a corresponding real penetration of space.[1] And since the sequence continues unbroken down just to the ninth magnitude, we see that the galactic condensations of ninth magnitude stars cannot be situated nearer to us than their brightness would lead us to suppose—cannot, in other words, be stars on a lower than the ordinary level of lustre.

It is tolerably certain, however, that the denser star-clouds of the Milky Way lie far beyond ninth magnitude distance. The ground for this assertion is not the apparent minuteness of their components, but the singular fact, adverted to by Argelander, that, in the divided Milky Way, running from Cygnus to the Centaur, the

[1] The idea of determining distance by distribution seems to have presented itself to Dr. Gould in 1874. See *American Journal of Science*, vol. viii.

shining branches are nearly on a par with the dark rift separating them as regards the distribution of stars even fainter than the ninth magnitude. The nebulous effect to the eye distinguishing the branches is, then, presumably due to more remote collections. As to the further limits of these, we know as yet nothing, except that Herschel's gauge-numbers left it to be inferred that "thinning-out" had become marked before the attainment of fourteenth magnitude distance. On these, and similar subjects, enlightenment may be hoped for through the judicious use of means already at hand.

For simple star-counts, we have only to substitute star-counts by magnitudes over selected areas of the sky.[1] The relative numbers of the photometric ranks can hardly fail to give highly valuable indications as to real distribution; provided only that the assumption of a general uniformity in the brightness of the stars be valid. Not, it need scarcely be said, of a uniformity such as to preclude any extent of individual variety; all that need be supposed is, that the average size of a star remains constant throughout sidereal space. This hypothesis has far more probability in its favour than any other which could be set up instead of it; though it may receive corrections as our inquiries advance.

The photometric classification of small stars is one of the many branches of sidereal science which will henceforth be prosecuted only with the assistance of the camera. Visual methods are inadequate and insecure. Those by photography, it is true, have also their difficulties, not yet completely vanquished: they will, however, evidently prove manageable. Prof. Pickering is tentatively establishing methods in photographic photometry which will doubtless before long be brought to perfection. They depend mainly upon comparisons of stellar impressions upon any given plate, exposed under known conditions, with standard impressions of standard stars obtained with varied exposures or apertures. For the purpose we have in view, accidental errors of estimation, even if very large in amount, are of no importance. What is essential is, that the integrity of the series should be preserved—that the proportionate change of light from one magnitude to the next should remain invariable from the first term to the last. The realization of this aim, now virtually attained, is one of the most weighty services rendered to astronomy by the sensitive plate.

We may now describe the process of photographic star-gauging. It consists in the enumeration, by magnitudes or half-magnitudes, of the stars down, say, to the fifteenth magnitude, self-pictured from distinctively situated patches of the sky. Each such area should be wide enough to insure the elimination of minor irregularities in distribution; but a single large field would often suffice to show the characteristic grouping of the smaller telescopic stars.

The Milky Way would naturally be the first subject of inquiry; and the comparison of several plates taken in different sections of its course might be expected to yield data of great significance as regards its constitution. From simply calling over the muster-roll by orders of brightness of the stars contained in them, answers may be derived to the following questions:—

(1) How far does the regular sequence of increasing numbers extend? That is, down to what grade of brightness do the stars continue nearly to quadruple with each additional magnitude?

(2) Is the progression interrupted by defect or excess, or by each alternately? In other words, does the stellar system embrace systematic vacancies, as well as systematic groupings?

(3) Supposing an accumulation of stars to set in at a definite stage of space-penetration, where does it stop? Down to what magnitude is the augmented ratio of increase maintained?

(4) Are there symptoms of approaching total exhaustion of the stellar supplies beyond?

These should be found in a concurrent decrease of density with brightness, "density" being understood as the proportion of the numbers present to the space *theoretically* available for stars of a given magnitude. For one of two things seems certain: either the thinning fringe of stars is composed of really small objects interspersed among larger ones; or of average stars at average distances from us, but further and further apart from each other. In the first case, the system ends abruptly; in the second, it is, as it were, shielded by outliers from the absolute void.

Particular attention should be paid to the differences of stellar distribution upon plates of the Milky Way proper, and of the dark aperture between its cloven portions. That this really forms an integral part of the galaxy is shown by the far greater profusion of small stars there than in the general sky at the outer margins of the galactic branches—a fact in itself fatal to the "spiral theory," by which the rift was interpreted as a *chink* of ordinary sky-background left by the interlacing, to the eye, of two great streams of stars, one indefinitely more remote than the other. From photographs we may now hope to learn what is the nature of the distinction between rift and branches—what are the magnitudes, relative numbers, and presumable mean distances, of the clustering stars present in the latter, but absent from the former.

Gauges taken in the neighbourhood of the southern "coal-sack" ought to prove instructive as to the nature of the nebulous stratum out of which it seems as if *scooped*. If the Milky Way be there shallower than elsewhere, a greater uniformity of lustre may be looked for among the stars composing it. No background profusely stored with lessening ranks will come into view, and stars below the average of those grouped in bright masses, representing their genuine companions, will be but scantily present.

Outside the Milky Way, two points suggest themselves as likely to be settled by photographic gauges. Argelander found that the faintest stars in the *Durchmusterung* were everywhere in excess of their due proportion.[1] Even at the galactic pole, their increase, as compared with the class next below, was sextuple instead of quadruple; in the undivided galactic stream it was 9½, in the rift 8½ times. If this semblance of crowding *in all directions* at about the mean distance of a ninth magnitude star be no accident of enumeration, then the Milky Way is only the enhancement of a phenomenon universally present, and the fundamental plan of the sidereal system must be regarded as that of a sphere with superficial condensation intensified in an equatorial ring. The counts, to settle this question, will have to extend over a considerable area.

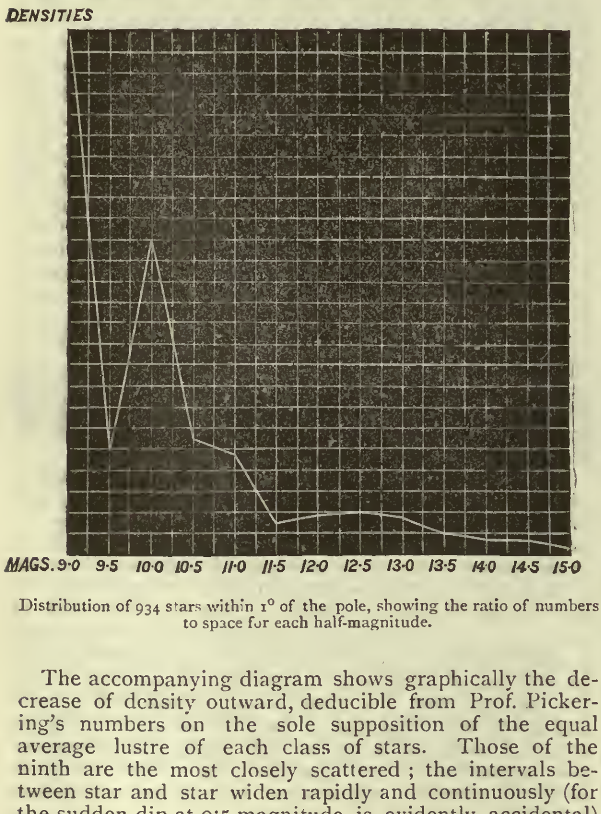
The second point for photographic investigation refers to the limits of the system towards the galactic poles. There is reason to believe them comparatively restricted. M. Celoria, of the Milan Observatory, using a refractor capable at the utmost of showing stars of eleventh magnitude, obtained for a "mean sounding," at the north pole of the Milky Way, almost identically the same number given by Herschel's great reflector.[2] That is to say, *no additional stars were revealed by the larger instrument.* Should this evidence be confirmed, the boundary of the stellar scheme should here be placed at a maximum remoteness of 3500 years of light-travel.

As a specimen of a photographic gauge-field on a small scale, we may take Prof. Pickering's Catalogue, from the Harvard plates, of 947 stars within 1° of the north celes-

[1] This plan was first suggested by Prof. Holden in 1883, as a mode of investigating the composition of star-groupings ("Washburn Publications," vol. ii. p. 113). Counts with varied telescopic apertures gave him the numbers in the successive photometric ranks. We believe that a photographic method of determining them has since been adopted by him.

[1] *Bonner Beobachtungen*, Bd. v. "Einleitung."
[2] *Memorie dell' Istituto Lombardo*, t. xiv. p. 86.

tial pole.[1] The region examined lies about 27° from the zone of the Milky Way, but is nearly reached by a faint extension from it Since only one eighth magnitude star, and none brighter, are included in it, the study of distribution, for which it offers some materials, may be said to begin with the ninth magnitude. A single glance at the synoptical table suffices to show that the numerical representation of the higher magnitudes is inadequate. The small stars are overwhelmingly too few for the space they must occupy if of average brightness; and they are too few in a constantly increasing ratio. Either, then, the diminishing orders form part of a heterogeneous collection of stars of all sizes at nearly the same distance from us (about that corresponding to ninth magnitude); or they belong to attenuated star-layers stretching to a much vaster distance. A criterion might be supplied by Prof. Holden's plan[2] of charting separately stars of successive magnitudes over the same area, and judging of their connection or disconnection by the agreement or disagreement in the forms of their groupings.



Distribution of 934 stars within 1° of the pole, showing the ratio of numbers to space for each half-magnitude.

The accompanying diagram shows graphically the decrease of density outward, deducible from Prof. Pickering's numbers on the sole supposition of the equal average lustre of each class of stars. Those of the ninth are the most closely scattered; the intervals between star and star widen rapidly and continuously (for the sudden dip at 9·5 magnitude is evidently accidental) down to 11·5 magnitude, when a slight recovery, lasting to the thirteenth magnitude, sets in. How far these changes are of a systematic character, can only be decided from far wider surveys. A. M. CLERKE.

TWO AMERICAN INSTITUTIONS.

I.—THE SMITHSONIAN INSTITUTION.

IN 1826, Mr. James Smithson, F.R.S., an English gentleman (a natural son of the first Duke of Northumberland), in a fit of pique at the action of the Committee of the Royal Society, who had declined to accept a scientific paper he had submitted, bequeathed to the United States of America a large sum of money, (£105,000), "to found at Washington under the name of the Smithsonian Institution, an establishment for the increase and diffusion of knowledge among men."

The question of how knowledge might be best increased and diffused with £105,000 then arose for discussion.

The President of the United States applied to a number of persons, "versed in science and familiar with the subject of public education, for their views as to the mode of disposing of the fund best calculated to meet the intentions of Smithson and be most beneficial to mankind."

The President of Brown University (Prof. Wayland) proposed a University to teach languages, law, and mental philosophy (Arts), without Science. Dr. Thomas Cooper, of South Carolina, proposed a University to teach science only, and to exclude Latin and Greek, literature, law, and medicine. Mr. Richard Rush proposed a Museum with grounds attached sufficient to reproduce seeds and plants for distribution; a press to print lectures, &c., and courses of lectures on physical and moral science, and on government and public law. The Hon. John Quincy Adams proposed the establishment of an astronomical Observatory, with instruments, and a small library. Prof. W. B. Johnson proposed the establishment of an institution for experimental research in physical science. Mr. Charles L. Fleischman proposed the establishment of an agricultural school and farm. The Hon. Asher Robbins proposed a literary and scientific institution; and memorials were presented to Congress in favour of appropriating the fund for annual prizes for the best original essays on the various subjects of the physical sciences; for the establishment of a system of simultaneous meteorological observations throughout the Union; for a National Museum; and for a Library.

For ten years the Congress of the United States wrestled with the interpretation of the words "the increase and diffusion of knowledge among men." The discussions were numerous and irritating; and it was repeatedly proposed to send the money back to England. Finally Congress was wise enough to aknowledge its own ignorance, and authorized a body of men to find some one who knew how to settle the question. Joseph Henry was chosen. His idea was accepted and acted upon. "To *increase knowledge* men were to be stimulated to original research by the offer of rewards for original memoirs on all subjects of investigation; to *diffuse knowledge* the results of such research were to be published;" and in addition it was decided to issue a series of reports giving an account of new discoveries in science, and of the changes made from year to year in all branches of knowledge not strictly professional; as well as to publish occasionally separate treatises of general interest; and all these were to be distributed amongst the public institutions of the world.

In the result the Smithsonian Institution was established for the promotion of original research, and the diffusion of the same, and it now distributes to 3700 public institutions in Europe, Asia, Africa, and America, the following publications:—

"The Smithsonian Contributions to Knowledge," of which twenty-six volumes in a quarto series have been issued, comprising memoirs and records of original investigations; researches in what are believed to be new truths; efforts to increase human knowledge. "The Smithsonian Miscellaneous Collections," an octavo series, already numbering thirty-four volumes, containing reports on the present state of our knowledge of particular branches of science; instructions for digesting and collecting facts and materials for research; lists and synopses of species of the organic and inorganic world; reports of explorations; aids to bibliographical investigations, &c. "The Annual Reports of the Board of Regents of the

[1] *Harvard Annals*, vol. xviii. p. 138.
[2] Recommended in the *Century Magazine* for September 1888, as well as in "Washburn Publications," vol. ii. p. 113.

Smithsonian Institution" (thirty-two volumes), containing also very valuable records, catalogues, and memoirs.

Another part of the income was applied in accordance with the requirements of the Act of Congress to the gradual formation of a library and a museum. But in 1866 the library was amalgamated with the Library of Congress and lodged in the Capitol. The Library, however is, open throughout the year with equal facilities for students, including the free use of the books of both collections. In 1852, Mr. Henry established what is known as the "Smithsonian system of exchanges," whereby, in exchange for those of America, the scientific publications of Societies and individuals throughout the civilized world are made accessible without cost to the students of science in America. This system has added to the Library almost complete series of the Transactions of many of the older Societies of England, France, and Germany, which it would now be difficult if not impossible to replace. They comprise hundreds of works which, like those of the Societies in question, can be obtained in no other way than by exchange. The collection is now the best in existence.

In his evidence before the Royal Commission on Scientific Instruction (English), June 1870, Mr. Henry said:—

"This is considered a very important part of the plan of operations. Not only are books distributed, but the Institution has commenced the practice of distributing specimens of natural history over the world and getting others in exchange. As an interesting fact in connection with this system, I may mention that all the lines of steamers convey the Smithsonian packages free of cost, and also that they are admitted through all Custom houses without being opened, and free from all duties in all countries."

This generous system is still in operation, and has been very much extended.

In 1858 the United States Government transferred the National Museum (established 1842) to the custody of the Smithsonian Institution with the same amount of annual appropriation ($4000) which had been granted to the United States Patent Office when in charge of it; but this annual appropriation has now been increased to about $40,000. A new Museum was built at a cost of $350,000.00, and at the last session of Congress a Bill appropriating $500,000.00 for the construction of a second Museum building passed the Senate, but was not brought to vote in the House of Representatives. The Secretary has no doubt, however, but that in a year or two a building much larger than the present one will be supplied.

The National Museum is in three divisions—the Museum of Record, the Museum of Research, and the Educational Museum—and there are departments, with twenty-four curators and sub-curators, of arts and industries, ethnology, antiquities, mammals, birds, fishes, comparative anatomy, mollusks, insects, marine invertebrates, invertebrate fossils, plants, minerals, lithology and physical geology, metallurgy and economic geology. There are, in addition, chemical and natural history laboratories, and a bureau of ethnology.

"So rapidly were the treasures of the Museum increased by the gathered fruits of various Government explorations and surveys, as well as by the voluntary contributions of the numerous and widespread tributaries of the Institution, that the policy was early adopted of freely distributing duplicate specimens to other institutions where they would be most appreciated and most usefully applied. And in this way the Smithsonian became a valuable centre of diffusion of the means of investigation. The clear foresight which announced that the Museum must soon outgrow the entire capacity of the Smithsonian resources was amply vindicated; but the strong desire of Joseph Henry to see established in Washington a *National* Museum he did not live to see gratified" ("Memorial of Joseph Henry," discourse of W. B. Taylor, p. 285). He died May 13, 1878.

An extensive system of meteorological observations was instituted in 1849. About six hundred observers, scattered over the United States and the Territories, became voluntary correspondents of the Institution. This department was transferred in 1872 to the newly-established Meteorological Department established by the Government under the Signal Office of the War Department. The digested observations have been published in the "Contributions to Knowledge."

The memoirs in the quarto volumes of the "Contributions to Knowledge" (over 120) are universally recognized as valuable original authorities on their respective topics. There is no restriction as to the subject of research, and they consist of archæological, anthropological, botanical, geological, palæontological, meteorological, magnetical, physical, physiological, and philological observations, investigations on the solar system, the laws of atmospheric circulation, and systems of consanguinity and affinity. They have undoubtedly tended "to increase and diffuse knowledge."

The thirty-odd volumes of the "Smithsonian Miscellaneous Collections" are of a more technical character than the "Contributions," including systematic and statistical compilations, scientific summaries, and valuable accessions of tabular "constants." Scientific men generally have applauded the value and acknowledged their indebtedness to publications comprised in this series, which include such scientific classics as Clark's "Constants of Nature," Guyot's "Meteorological and Physical Tables," Watson's "North American Botany," Binney and Tryon's "Land and Fresh-water Shells of North America"; North American "Coleoptera" by Le Conte, "Diptera" by Loew, "Lepidoptera" by Morris, and "Neuroptera" by Hagen.

All these are distributed over every portion of the civilized and colonized world, and constitute a monument to the memory of James Smithson, such as never before was built on the foundation of one hundred thousand pounds.

II.—The Johns Hopkins University, Baltimore.

Johns Hopkins, a merchant of Baltimore, who died in 1873, in the seventy-ninth year of his age, bequeathed a large part of his fortune to two institutions which perpetuate his name—the Johns Hopkins University and the Johns Hopkins Hospital. Each foundation received an endowment of not far from three and a half million dollars, or about £700,000. The two institutions are separate corporations, but are closely affiliated. The University has just concluded its thirteenth year of work. Since its opening, in 1876, it has issued frequent statements of the development of its plans in the form of Annual Reports.

The Johns Hopkins University is an unsectarian foundation. There is no test for the assent of students or Professors. This is the especial privilege of the new institutions for higher education that have sprung up of late years. "No hungry tradition treads them down." They approach the problem of education untrammelled by customary practice; yet, utilizing the experience gained by the older Universities, they make more independent and original attempts at its solution.

Universities as a rule have grown from an aggregation of Colleges; the University, in process of time, being evolved as a supplement to collegiate training. The Johns Hopkins University is an exception to this rule. In accordance with the terms of the gifts, the institution started with the idea of the University, in the higher conception of that word, as a universal school and a fostering mother. Not merely a place in which degrees are granted in the Faculties of Arts, Sciences, Divinity, Law, or Medicine, but as an organized force for the education of the community of the district in which it is placed, for deepening, purifying, and strengthening all good influences on the men, and the alliance of the men with the institutions. Institutions remain, but the men pass away—

"The individual withers, and the world is more and more."

According to the thirteenth Annual Report of the University (September 1887 to September 1888), it appears that the academic staff included 57 Professors, Associate Professors, and Lecturers. There were 420 students; 199 were residents of Maryland, 196 came from other States of the Union, and 25 from foreign countries; 231 had already graduated, 127 had matriculated for the degree of B.A., and 62 were admitted as special students to pursue courses of study for which they seemed fitted, without reference to graduation. The University does not provide lodging or board.

There are seven distinct and parallel courses of College instruction adapted for matriculation, and the various elective groups for the degree examinations in the University. The subjects of the Professors and Lecturers last session were: history, political economy, mathematics, astronomy, physics, chemistry, mineralogy, geology, biology, psychology, pedagogics, pathology, Greek, Latin, Sanskrit, Indo-European philology, Shemitic languages, Romance languages, Teutonic languages, Anglo-Saxon, and English. The large and well-appointed physical, chemical, and biological laboratories of the University have already been detailed in NATURE (vol. xxxiii. p. 237).

Two degrees only are granted—the Bachelor of Arts and the Doctor of Philosophy; and since degrees were first conferred in 1878, 177 have attained the Baccalaureate degree, and 131 have been advanced to the degree of Doctor of Philosophy.

There are twenty Fellowships of $500 each. The examination for these is, in a certain sense, competitive, but not with uniform tests, nor by formal questions submitted to the candidates. The applicants' previous record, and the Professors' record, is taken into consideration.

"Those who are appointed are expected to proceed to the degree of Doctor of Philosophy. The appointments are not made as rewards for good work already done, but as aids and incentives to good work in the future; in other words, the Fellowships are not so much honour and prizes bestowed for past achievements, as helps to further progress and stepping-stones to honourable intellectual careers. They are not offered to those who are definitely looking forward to the practice of any one of the three learned professions (though such persons are not formally excluded from the competition), but are bestowed almost exclusively on young men desirous of becoming teachers of science or literature, or proposing to devote their lives to special branches of learning which lie outside of the ordinary studies of the lawyer, the physician, or the minister. Appointments are rarely, if ever, made of graduates of more than five years' standing."

There are also twenty graduate scholarships of $200 each for those who have taken the baccalaureate degree. There are also thirty-eight ordinary and honorary Hopkins Scholarships ($250 annually and free tuition) for promising young men.

Courses of public lectures, designed primarily for the members of the University, and supplementary to the regular class-room work, are given each session. The admission of the public is by ticket, to be previously obtained free. The courses for 1887-88 included: ten lectures on some of the problems of great cities; six lectures on the local study of natural history; nine lectures on the history of the science of electricity and magnetism; eleven lectures on the causes which led to the French Revolution; four lectures on Greek lyric poetry; eight lectures on the topography of Athens.

The University Library consists of 35,000 volumes. And it is lately reported that the valuable scientific collection of the Maryland Academy of Sciences has been presented to the University.

But the great point of this institution is its efforts in the direction of the endowment of scientific research. Prof. Newcomb, one of the Professors of the University, said in 1876 of America what is very true of Great Britain: "We are deficient in the number of men actively devoted to scientific research of the higher types; in public recognition of the labours of those who are so engaged; in the machinery for making the public acquainted with their labours and their wants; and in the preliminary means for publishing their researches." The Johns Hopkins University has encouraged scientific research, and the publication of its results, to a large extent; not only by training young men in the methods of exact science, and fitting them for the scientific service of the Government, for scientific and technical laboratories, and for the teaching profession, but also by the publication of journals and monographs detailing the results of scientific study. The trustees, determining to encourage the heads of departments and other qualified scholars to contribute each in his own way to the advancement of the science which he professed, started five periodicals, conducted by Professors and graduates, and aided by the University chest, namely: *The American Journal of Mathematics*, 10 vols., edited by Prof. Newcomb; *The American Chemical Journal*, 10 vols., edited by Prof. Remsen; *The American Journal of Philology*, 9 vols., edited by Prof. Gildersleeve; *Studies from the Biological Laboratory*, 4 vols., edited by Prof. Martin and Dr. Brooks; and the *Johns Hopkins University Studies in Historical and Political Science*, edited by Prof. H. B. Adams, the seventh series of which is in progress. All of these publications are considered on both sides of the Atlantic to be of the greatest value. *The American Journal of Psychology*, *Modern Language Notes*, and *Contributions to the Study of Archæology*, are also edited by members of the academic staff, and there are University Societies on all these subjects.

The University also publishes *University Circulars* monthly, containing scientific notes in biology, chemistry, history, political science, mathematics, physics, philology, philosophy, logic, &c., besides the usual Annual Reports and special publications, such as the "Reports of the Chesapeake Zoological Laboratory." This is a laboratory of about fifty individuals at ten stations, and the results of their work at the sea-shore, in the study of natural laws in their simplest manifestations, from 1879 to 1886 include ninety-nine titles.

Dr. Gilman, the President of the University, reported at the tenth anniversary that 176 former students were known to be engaged in the work of teaching, mostly in colleges; and that among the former pupils are eighty physicians, thirty-eight ministers, and thirty-four lawyers. There were no exact statistics of those engaged in scientific pursuits.

Such are the beginnings of the Johns Hopkins University. Those engaged in the work of higher education in this country will appreciate fully the fortunate circumstances in the inception of the institution: a benefaction of £700,000 for endowment; carefully selected trustees, to whose wisdom, moderation, and far-sightedness much is due; a wisely organized constitution; able Professors and teachers, gauged by the standard of work done and success achieved; and foundations to assist all these contributed by a critical and discerning public. The institution started full of promise, and it is redeeming its promise with a rapidity unparalleled in the history of academic institutions.

J. TAYLOR KAY.

THE MEETING OF THE BRITISH ASSOCIATION AT NEWCASTLE-ON-TYNE.

THE arrangements of the Local Committee are nearly completed for the reception of the British Association on the occasion of its fifty-ninth annual meeting, which, as our readers are aware, is to be held in Newcastle-on-Tyne, and will commence on September 11. This will be the third occasion on which the Association has held its annual Congress in Newcastle-on-Tyne, the last being in 1863—a meeting memorable as being the largest gathering of members and friends of the Association, which has only been once exceeded in point of numbers, viz. by the Manchester meeting of 1887. No efforts have been spared on the part of the Committee to make preparations for a meeting which, it is hoped, will prove as successful and interesting to the members as the former meeting proved; and in their endeavours to do this, the work of the Committee has been greatly facilitated by the many notable additions, in the shape of buildings suitable for the purposes of the Association, which have been erected since 1863.

The reception-rooms, occupying a central position with respect to the various Section rooms, will be located in the new buildings of the University of Durham College of Medicine, Bath Road, in which building a writing-room and ladies' drawing-room will be provided, also special rooms for the use of the officers of the Association. The Cambridge Drill Hall, near the reception-room, is to be fitted up for a luncheon-room. Sections A and B will meet in the new buildings of the College of Science, opened in November last by H.R.H. Princess Louise; and in the chemical laboratory of this College it is intended to bring together a series of exhibits illustrating the chemical and allied manufactures of the district. The general meetings of the Association will be held in the St. George's Drill Hall.

The Natural History Museum, opened by H.R.H. the Prince of Wales in 1884, in which building is Mr. Hancock's unique collection of British birds, will be used for the two *soirées;* the first is to be given by the Mayor and Corporation, and the second by the Local Committee.

A guide-book, arranged in three sections, has been prepared for the occasion of the Association's visit, dealing respectively with the history and topography, the geology and natural history, and the industries of the district. The first section is edited by the Rev. J. Collingwood Bruce; the second by Prof. Lebour; and the third by Mr. Wigham Richardson.

The Durham, Northumberland, and Newcastle-on-Tyne Botanical and Horticultural Society has arranged to hold its autumn show during the time of the meeting, and on Wednesday, September 11—the first day of the show—it will be open to members free on presentation of their tickets.

On the Saturday, half-day excursions have been arranged to the following places of interest: Morpeth, Wallington, Seaton Delaval, Hexham, Marsden, Prudhoe, Durham, and an excursion down the river. The Senate of the University of Durham proposes to hold a special Convocation on the Saturday for the purpose of conferring honorary degrees on the President and other officers of the Association. Convocation will be followed by a luncheon, to which 200 members of the Association will be invited, after which there will be a special service in the Cathedral.

Thursday, the last day of the meeting, is to be devoted to whole-day excursions to the following places: Alnwick, Cragside (the seat of Lord Armstrong), Middlesbrough, Berwick, Lanercost, Beal, Little Mile, Belford, Raby, Bardon Mill, and Middleton-in-Teesdale.

The principal works in Newcastle and on the Tyne will be thrown open to members for inspection during the meeting.

The railway company is prepared, during the meeting, to issue tickets at reduced rates to and from places in the neighbourhood, and to run special trains, so that members, should they wish to do so, will be able to reside in the country or on the coast, and get to and fro conveniently. Through the kindness of the authorities of University College and of Hatfield Hall, Durham, the Local Committee are enabled to place the students' rooms in these buildings on their hotel and lodgings list, which list will also be found to contain the addresses of several places in Tynemouth, Cullercoats, and Whitley, on the coast.

THE NEW BUILDINGS OF THE SORBONNE.

IN England we are still fighting about the question whether London is or is not to have a teaching University. It is significant that Frenchmen have no soit of doubt as to the necessity of such an institution in Paris. During the long and splendid history of the Sorbonne they have had ample experience of the value of a great teaching body in the capital; and the result is that this is one of the institutions in which men of all parties take a common pride.

So long ago as 1855 it was decided that new buildings for the Sorbonne should be erected, but the scheme was not really complete until 1881. It was then estimated that the expense would be 22,000,000 francs—a formidable enough sum, but one which caused no serious difficulty, as the city readily undertook to contribute half of it. The foundation was laid in 1885, and now a considerable part of the work is finished. This was opened on Monday, in the presence of the Head of the State, and the ceremonies on the occasion may be regarded as affording fresh evidence of the enthusiasm felt by educated Frenchmen for all that represents and tends to develop the highest intellectual life of the nation. Every University had been asked to send delegates elected by the students to the celebration; and the State, and the City of Paris, agreed to look upon them as their guests during the ten days of festivity in honour of science. "This part of the programme," says the Paris Correspondent of the *Daily News*, "has been well carried out, arrangements having been made with different hotels to board and lodge the foreign visitors at the expense of the Hôtel de Ville and the Ministry of Public Instruction. Russia and Germany have not accepted invitations, but the Universities of Great Britain, of the Scandinavian countries, of Belgium, Holland, Greece, Switzerland, Italy, Spain, and the United States are represented. There are about 700 delegates from these countries, besides a large number who have come at their own expense."

The *fêtes* began on Sunday evening with a gala performance of "Faust" at the Opera House, which the President attended. On Monday, 3000 persons assembled in the new amphitheatre, an immense hall adorned with frescoes. Each delegation had a standard-bearer carrying the flag of his nation, and the members of the various groups were warmly greeted by the public as they advanced to the places appointed for them. At 3 o'clock M. Carnot arrived, and took his seat on the platform, surrounded by Ambassadors, statesmen, and Academicians. M. Ferry, as the Minister who made the arrangements for the enlargement, was much cheered.

M. Gréard, Rector of the Academy, made the first speech. He sketched the history of the Paris University, extolled the events of 1789, and described study as a common Fatherland, which had brought together delegates from nearly all the European and American Universities. M. Hermite next reviewed the mathematical teaching of the Sorbonne since 1808. M. Chautemps, President of the Municipality, vindicated democracy from the imputation of indifference to culture, and claimed credit for the body represented by him for having founded a Chair of French Revolution History and a Chair of Evolution. M. Fallières, Minister of Education, dwelt on the efforts and sacrifices of the Republic for the diffusion of culture. He referred to the moribund condition of the Universities on the eve of the Revolution, and the want of cohesion between the colleges afterwards established, and eulogized the individuality now developed by the provincial Universities.

NOTES.

AT the annual graduation ceremony at the close of the summer session of the University of Edinburgh, last week, Prof. T. R. Fraser intimated that the important Cameron Prize in Therapeutics, the recipient of which might be selected from any country, had been awarded to M. Pasteur, a Doctor of Laws of Edinburgh University, in recognition of the high importance and great value in practical therapeutics of the treatment of hydrophobia discovered by him.

THE fifty-seventh annual meeting of the British Medical Assotion will begin at Leeds on Tuesday, the 13th inst., and go on until the 16th, under the presidency of Mr. C. G. Wheelhouse. The President's address will be delivered on the evening of the 13th. On the 14th, an address in medicine will be given by Dr. Hughlings Jackson, F.R.S., and afterwards the Stewart Prize will be presented to Dr. Klein, F.R.S., for his work in bacteriology and scarlet fever. On the 15th, an address in surgery will be given by Dr. Pridgin Teal, F.R.S., and on the 16th, Sir James Crichton Browne, F.R.S., will deliver an address in psychology.

AT the Academy of Medicine, Paris, in the grand amphitheatre, a numerous and distinguished audience gathered on Sunday for the first sitting of the International Congress of Hygiene. The chair was taken by Prof. Brouardel, with Dr. Chautemps, President of the Paris Municipal Council, and Sir Douglas Galton as Vice-Presidents. Sir Douglas Galton returned thanks on behalf of the various English Sanitary Societies, represented at the Congress by ten English delegates. He promised a hearty welcome to the French hygienists, who, he hoped, would in great numbers attend the next International Congress, to be held, as arranged, in London in 1891. The work of the Congress began in earnest on Monday, and among the subjects discussed was a proposition submitted by Dr. Jablowski, the Russian delegate, to the effect that children suffering from tuberculosis of the lungs, or even only suspected to have this complaint, should be sent back from school to their families. This proposal was rejected, but it was considered that the school doctor should exclude such pupils as by the dangerous character of their expectorations might spread the specific germ of pulmonary consumption. On Tuesday there was a discussion on the inspection of unwholesome dwellings; and in connection with "the dust-bin grievance" the Congress unanimously passed a resolution that kitchen refuse should never be kept in the house over night, that it should be placed outside in metallic boxes, and that it should be removed every twenty-four hours.

IN his interesting speech on the Education Estimates on Monday, Sir W. Hart Dyke had much to say about the new Code, the enforcing of which he has been obliged to postpone. He showed that it would "open and widen the curriculum," and referred especially to the advantages it would confer on small schools in the midst of a scattered agricultural population. The mass of our agricultural schools in England and Wales did nothing but just pass their scholars through the elementary subjects. Both sides of the House regarded that as a most deplorable thing. Questions had been put to him from time to time as to teaching agriculture in the rural schools. Knowing something of rural school life, he should do nothing so absurd as to attempt to turn out first-rate agriculturists from our elementary schools. But there was a vast difference between that and turning children out knowing nothing of plants or botany or of insect life, and what was useful and what was injurious to agriculture. A vast deal of good might be done by training in regard to these matters. What they proposed to do was to provide that any scholar might attend elementary science classes at district centres. At present, in towns as well as in agricultural districts, more combination was required between schools to enable them to carry out different kinds of teaching. What one school was unable to do, a group of three or four, with little trouble and with an economy of expenditure, might readily carry out. Sir John Lubbock and Sir Henry Roscoe expressed much regret that the new Code had been for the present withdrawn, and hoped that it would be introduced again next session.

THE committee of the national association for the promotion of technical education have issued their second annual report. They think they may fairly congratulate the members on the progress made by the movement during the past year. On May 1, 1888, an anonymous donor offered to contribute £500 to the funds of the association, provided £1000 were raised from other sources before May 1, 1889. The support received from the public has been such that the committee have secured this donation. They refer with especial satisfaction to the support received from representative bodies of working men. No fewer than thirty-one working men's Co-operative Societies have given donations or subscriptions during the year, and many more are in complete accord with the aims of the association. The committee hope that with the resources now at their disposal they may be able to extend their work, particularly in the department of secondary education, but they appeal for a larger number of annual subscriptions. Nothing has occurred to weaken their belief in the magnitude and urgency of the work which needs to be carried out to improve, develop, and harmonize, and bring into close relations one with another, the elementary, secondary, and technical education of the country.

THE establishment of a technical school at Frankfort-on-Maine for young artisans and mechanics was planned long since by different corporations in that city, and from a statement made lately by the mayor, it appears that all the expenses in connection with the school are to be borne by the city, which will also give the rooms and see to the appointment of the teachers. The lessons will be given on Sundays and in the evening on week days. The pupils will be charged a very moderate tuition fee only. Great energy is displayed in order to open this school very shortly, says the British Consul in his last Report, as the accomplishment of the scheme will be hailed with great satisfaction throughout the city.

THE death of Mr. C. Spence Bate, F.R.S., at Plymouth, is announced. He was the author of the "Report of the Crustacea Macrura dredged by H.M.S. *Challenger*, during the years 1873–76." He was also the author of the "Catalogue of the Specimens of Amphipodous Crustacea in the Collection of the British Museum"; and of a work on "The Pathology of Dental Caries." In conjunction with Mr. J. O. Westwood, Mr. Bate wrote "A History of the British Sessile-eyed Crustacea."

DURING last week Mr. John Aitken visited the Ben Nevis Observatory in connection with the proposed investigation into the number of dust particles in the atmosphere. From observations made by him and Mr. Omond, the numbers varied from 350 per cubic centimetre about noon to 500 at 3 p.m. The purest air previously examined by Mr. Aitken was on the Ayrshire coast, and gave 1260 dust particles to the cubic centimetre. It is, of course, premature to draw conclusions from these observations, but it may be suggested that extended observation will in all probability establish the fact of the singular purity of the air at this height, as compared with that at lower levels; and that the numbers of dust particles will be greatest at the Observatory in that part of the day when the ascending currents up the heated sides of the mountain are strongest.

REFERENCE was made in our last issue (p. 326) to the drought on the top of Ben Nevis in June last. In that month the hours of sunshine registered by the sunshine recorder were 250, a number considerably in excess of any previous month, the highest having been 206 hours in June 1887. With the early disappearance of the snow and strong sunshine of June, such vegetation as is found at these heights is well forward. On July 22, fine specimens of *Silene maritima*, about 8 inches in height, well grown, with abundant flowers, many of them in seed well matured, were gathered on Cairn Dearg, one of the lower heights of the mountain, at a height of 3800 feet above the sea. In Hooker's "Flora of the British Islands," the limiting height of this plant is given at 3000 feet.

THE Report of the Director of the Hong Kong Observatory, for 1888, has been issued. It is an interesting and exhaustive document. In reference to thunderstorms in the colony during the past five years, Dr. Doberck states that they are most frequent in May, and that they have not occurred in November, December, and January. They seldom happen in February. With reference to the daily variation, they are more frequent at night than during the day-time in the proportion of three to two. They appear to be most abundant about 1 a m., and least so about 8 a.m., in the proportion of about two to one. During the past year the temperature was on an average higher than in previous years, and rose higher than before on hot days. This appears to have been at least partly due to a more southerly direction of the wind, but the temperature has been rising on the whole since 1884. Whether this is periodical remains to be investigated. The Director thinks there are fair prospects of finding it is so. The past year was more damp than usual, the rainfall was heavy, and the mean barometer below the average. The amount of sunshine was less, and the cloudiness greater than usual. It is generally considered to have been an unhealthy year.

Science says that in 1887–88 the courses in astronomy at the Johns Hopkins University were so extended as to justify its being chosen as a principal subject by candidates for the degree of Doctor of Philosophy. A small observatory has been erected, and is fitted up with a meridian circle by Fauth and Co., a portable transit instrument by Troughton, a clock, a chronograph, and other subsidiary apparatus. In the dome of the physical laboratory is mounted an equatorial of 9½ inches aperture, so fitted that the student can learn to make the usual determinations with the largest instruments of that class. The work in astronomy consists of a study of the history and practice of the subject, supplemented by instruction in the use of the instruments, and exercises in astronomical computation. During the year 1889–90 the courses are intended to cover a wider range of individual subjects than usual.

THE Royal Society of New South Wales offers its medal and a money prize for the best communication (provided it be of sufficient merit) containing the results of original research or observation upon each of the following subjects. To be sent in not later than May 1, 1890:—The influence of the Australian climate (general and local) in the development and modification of disease—the Society's Medal and £25; on the silver ore deposits of New South Wales—the Society's Medal and £25; on the occurrence of precious stones in New South Wales, with a description of the deposits in which they are found—the Society's Medal and £25. To be sent in not later than May 1, 1891:—The meteorology of Australia, New Zealand, and Tasmania—the Society's Medal and £25; anatomy and life-history of the Echidna and Platypus—the Society's Medal and £25; the microscopic structure of Australian rocks—the Society's Medal and £25. The competition is in no way confined to members of the Society, nor to residents in Australia, but is open to all without any restriction whatever, excepting that a prize will not be awarded to a member of the Council for the time being; neither will an award be made for a mere compilation, however meritorious in its way. The communication, to be successful, must be either wholly or in part the result of original observation or research on the part of the contributor.

AT a recent meeting of the Genevan Society of Physics and Natural History, M. Mallet exhibited two balls of almost perfect sphericity, about 4 inches in diameter, one black, and of vegetable origin, the other white, and of mineral origin, but both produced by a mechanical movement. The black ball had been found with another in a piece of oak which had long served as the shaft of a mill-wheel. A cavity having formed in the wood, through disease or the work of some insect, the dust of the wood, with acquired moisture, had been rolled into this spherical form, growing in size, like a snowball (a slow process of many years probably, as the wheel was very old). The white ball, a calcareous pebble, was found with many others in a grotto traversed by a torrent which flowed into the Rhone.

FOUR years ago a light-ship was stationed in the Baltic, between the Islands of Bornholm and Rügen, and the currents there have been measured on 294 days in a year, every two hours, with interesting results (described by Herr Dinklage in the *Annalen der Hydrographie*). It is found that the currents vary most irregularly in direction, strength, and duration, but in most cases follow the prevailing winds (of which the westerly are the most frequent). Currents which did not diverge more than 90° from the wind's direction being counted as similar in direction, 86 per cent. were of this nature. The relation becomes more pronounced when only winds and currents above a certain limit of force are considered. A sudden change in direction of wind is soon followed by a change in that of current. The effect of wind direction on current direction is certainly apparent the first day, and to a depth of at least 5 metres. The direction of current rarely coincides exactly with that of wind, and divergence to the right is distinctly more frequent than divergence to the left. As this cannot be attributed to the form of neighbouring coasts or to the circulation of winds (for winds in our latitudes turn mostly the other way), the author regards the effect as due to the rotation of the earth.

THE Northern Lighthouse Board have adopted Priestman's oil engines for blowing fog signals in preference to steam or gas engines. A great saving is thus effected in first cost, no chimney being required as in the case of a steam engine, nor gas works, which would be needful if a gas engine were adopted.

THE first part of the Journal of the College of Science of the Imperial University of Japan, which has just been published, contains two papers illustrated by numerous excellent plates. The first is by Prof. Matsujiro Yokoyama, on the subject of "Jurassic Plants from Kaga, Hida, and Echizen," three provinces on the west coast of Japan. It is a valuable contribution to our knowledge of the fossil flora of Japan, a subject hitherto little investigated. Prof. Yokoyama's specimens were collected, for the most part, by the Geological Survey of Japan.

His descriptions and classification show a thorough acquaintance with the subject. The conclusion he arrives at is that the "Jurassic flora of Kaga, Hida, and Echizen belongs to the same geological horizon as the flora of Siberia, Spitzbergen, and Yorkshire—namely, to the Bathonian stage of the Inferior Oolite with special relations to the flora of Siberia." The second paper is by Prof. Yasushi Kikuchi, on "Pyroxenic Components in certain Volcanic Rocks from the Bonin Islands."

IN his Annual Report on Education in Hong Kong, Dr. Eitel, the Government Inspector of Schools, says that the total number of educational institutions of all descriptions known to have been at work in the colony of Hong Kong during the year 1888 amounts to 206 schools, with a grand total of 8717 scholars. More than three-fourths of the whole number of scholars—that is to say, 6728—attended schools (99 in number) which are subject to Government supervision, and either established or aided by Government in some form or other. The remainder—viz. 107 schools, with 1989 scholars—are private institutions entirely independent of Government supervision, and receiving no aid from public funds, except that they are exempt from payment of rates and taxes.

M. TAUPIN, who was recently despatched by the Governor-General of French Indo-China to the Laos States on an exploration, has presented a report of the results, which he sums up as follows:—"I have studied the language and system of writing of the Laos—that is, of the only population in the world possessing a graphic-alphabetical system. Of this there has been up to the present no positive knowledge. It was only known that the Laotian language and writing were somewhat similar to those of Siam. The language is spoken by about four millions of people. I have collected interesting information relating to the natural history of these regions, and much commercial information. . . . I have made numerous meteorological observations, and taken a large number of anthropometrical measurements according to the Broca system."

IN the *Izvestia* of the Moscow Society of the Friends of Natural Science, vol. lxiii., there is an exhaustive work, by M. Kharuzin, on the Kirghizes. The anthropological data relative to the great Bukéeff stem are fully presented, and illustrated by sixteen photographs. The writer also describes the religious beliefs of the Kirghizes, their religious festivities and worship, and their customary law. An appendix contains the results of the excavation of thirty-six *koorgans* in the Kirghiz Steppe.

THE Governor of Jamaica, in his Report regarding the progress of the colony during the past year, says that the Department of Public Gardens and Plantations has done much useful work, and that the distribution and collection of valuable economic plants have been actively carried on. The Hope Gardens, which are intended to take the place of those at Castleton, as the head botanical station, have made good progress, but as they are young, and the authorized annual expenditure limited, some time must elapse before they will be complete. Although they are 19 miles from Kingston, they attract a large number of visitors. At the cinchona plantation actual cultivation has ceased so far as planting operations are concerned, but the establishment of a hill garden there has been attended to. No cinchona bark was shipped during the year, but bark has been supplied to the Government analytical chemist for preparation of a liquid extract of a febrifuge manufactured according to a method adopted by Mr. Hooper, Government Quinologist in the Nilgiris, and which is to be tested by the Medical Department of the colony. Attention is directed to the propagation at Castleton of the Manilla hemp plant with a view to its introduction into different parts of the island, and it is pointed out that even if the fibre is not utilized as an article of export, it may supply a local demand for rope, and so save such a valuable timber-tree as the "mahoe," of which large numbers are annually destroyed by the peasantry by being stripped of their bark, which is twisted into ropes. Another interesting circumstance alluded to is the successful experiment of grafting the mangostien (which, although growing at Castleton for many years, has only recently reached the fruiting stage) upon the gamboge tree of common growth.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. H. J. Cunnington; a Peregrine Falcon (*Falco peregrinus*), captured at sea, presented by Captain Watson; an Indian Fruit Bat (*Pteropus medius* ♂) from India, presented by Mr. Tholen; an Ocelot (*Felis pardalis*) and a Brazilian Cariama (*Cariama cristata*) from South America, presented by Captain W. Heathorn Lacy; a Tuberculated Iguana (*Iguana tuberculata*) from Brazil, presented by Mr. H. E. Blandford; three Palm Squirrels (*Sciurus palmarum*) from India, purchased; an Indian Python (*Python molorus*) from India, deposited; and ten Gold Pheasants (*Thaumalea picta*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *AUGUST* 11–17.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 11

Sun rises, 4h. 41m.; souths, 12h. 4m. 56·3s.; daily decrease of southing, 9·7s.; sets, 19h. 28m.: right asc. on meridian, 9h. 25·5m.; decl. 15° 9′ N. Sidereal Time at Sunset, 16h. 50m.

Moon (Full on August 11, 5h.) rises, 19h. 36m.*; souths, 23h. 58m.*; sets, 4h. 28m.: right asc. on meridian, 21h. 16·5m.; decl. 18° 54′ S.

GEOGRAPHICAL NOTES.

We regret to learn of the death of Lieutenant Tappenbeck in the Cameroons. He, with Lieutenant Kund, had been doing good work in the Cameroons interior, as they had before done in the Congo region. Lieutenant Kund has returned to Berlin, and has been describing the results of his second journey into the interior. In general, he and his companions followed the same route as on the previous expedition, and were received in quite a friendly way by the natives who had before attacked them. Very interesting observations were made as to the ethnological conditions of the South Cameroons region. A spot was selected for a station, of which the late Lieutenant Tappenbeck was to have been chief. The region is close to the limit of distribution of the Bantus, and there is a considerable variety of ethnological mixtures. Within the limits of the primæval forest, which lies behind the narrow coast stretch, the explorers came upon an almost dwarfish tribe, with yellow skins, hunting in scattered hordes, and building only temporary shelters for themselves. On the plateau, again, the explorers met with a free and friendly population of large, strong, and handsome men, with a well-organized social system. Quite different from the degraded coast people and the decaying forest people, these highland tribes have preserved the original good features of their race; and among them, Lieutenant Kund thinks, the scientific and industrial development of the Cameroons might be carried out.

Everyone interested in geographical exploration will be sorry to hear of the death, apparently by assassination, of M. Camille Douls, while on his way across the Sahara towards Timbuctoo. M. Douls was born at Bordes, in Aveyron, in 1864. In 1881 he visited the Antilles and Central America; and four years afterwards he spent some time in Morocco, studying the language and manners of the Arabs. In 1887 he explored the unvisited western regions of the Sahara; and last year he started on the journey which was destined, unhappily, to be his last.

Mr. Ernest Favenc describes in the August number of the Proceedings of the Royal Geographical Society, the results of a recent exploring journey in West Australia, in the country situated about 24° S. lat. The result of the trip was the discovery of several large tributary rivers of the Ashburton, running through magnificent pastoral country. Mr. Favenc found the physical features of the country different entirely to the conjectural ones placed on some of the maps of West Australia. Still there is a very great scarcity of water, many of the river beds being quite empty. The geological formation of the Ashburton is against the likelihood of any valuable mineral deposits being discovered in the future. There seem, however, to be indications of a gold reef at the head of the Gascoyne.

Colonel Antonio R. P. Labre, a Brazilian gentleman, has for some time been doing important exploring work in the region between the Beni and Madre de Dios rivers and the Purus. These great South American rivers have been often enough followed along their courses, but no one had attempted to penetrate through the primæval forests that separate their courses. This is what Colonel Labre has done, his leading object being to explore the india-rubber resources of the region. There are many rubber stations along these rivers, mainly occupied by Bolivians. The principal journey of Colonel Labre was undertaken for the purpose of crossing westward from the india-rubber settlements on the Madre de Dios to the nearest navigable point on the Aquiry tributary of the Purus, and ascertaining if the distance and the nature of the ground presented facilities for the construction of a road, and ultimately of a railway. He ascended the Madeira from the Amazons, and although this is the only route by which the considerable trade to and fro between the Amazons and Bolivia is carried on, it took Colonel Labre, with a large and well-equipped expedition, thirty-four days to accomplish the 161 miles between San Antonio at the foot of the long series of falls, and the town of Villa Bella at the mouth of the Beni. During the overland journey several tribes of Indians were met with, about whom little or nothing is known. The people are mostly Araunas, and seem to have a well-organized social system, with temples and some form of worship. The women, some of them light-coloured, are not allowed to enter the temples. The idols are not of human form, but are geometrical figures made of wood and polished. Several other tribes were met with. The general result of Colonel Labre's expedition was to open up a route of communication between the large towns of the Amazons and the whole of Northern Bolivia, a route which may be extended to Southern Peru by the navigation of the Madre de Dios to the province of Pancastambo and the rich and populous province of Cuzco. Colonel Labre believes that the Purus and its affluents contain about 40,000 indigenes speaking forty or more different languages.

Dr. H. Meyer has arrived at Zanzibar for the purpose of making another attempt to ascend to the highest summit of Kilimanjaro. He will afterwards proceed to explore Mount Kenia.

According to *Petermann's Mitteilungen*, Prof. A. Wichmann has recently returned to Europe from his journey to the Dutch East Indies. On the little island of Samauw, lying off the coast of Timor, he found numerous mud volcanoes. On the island of Rotti, at the south-west end of Timor, he discovered upon the slopes, in two mud volcanoes, some ammonites and belemnites, the first Jurassic fossils which have been found in this archipelago. Prof. Wichmann crossed from Palos, on the island of Celebes, to the Bay of Tomine, on the east coast. The route lay over a mountain range about 3000 feet high, covered with primæval forests, and uninhabited. These mountains are composed of gneiss, crystalline slate, and granite.

M. H. Coudreau recently described to the Paris Geographical Society the results of his last expedition to the Tumuc-Humac Mountains (Guiana), which were only very imperfectly explored by the late M. Crevaux. M. Coudreau effected a survey on the scale of 1 : 100,000 of 2500 miles of route, 1625 miles of which lay along river-courses, and the remaining 875 among the mountains. A complete survey was executed of the courses of the Maroni, Oyapock, and Maroni, from their mouths to their sources. M. Coudreau penetrated into the trackless part of the forest, where a passage had to be hewn out. Measurements were made of 150 summits, and the sources of nearly all the water-courses of both slopes of the range were fixed. The climate of these highlands is healthy, the mean temperature being about 72° F. Immense forests cover a large belt of country at the foot of the mountains. From an ethnographical point of view, M. Coudreau's mission has resulted in the careful study of the manners, customs, and dialects of the score or so of Indian tribes inhabiting this region.

M. Borelli, who for three years has been exploring in the Shoa region and the Galla country, tracing the course of an important River Omo, is convinced that this river falls into Lake Samburu, the Prince Rudolf Lake of Count Teleki; and that therefore the Omo does not belong to the Nile basin, but to an entirely distinct inland lake system, which has no outlet. M. Borelli has brought home hundreds of photographs of the people of the region he has been exploring, and large collections of specimens of the products of the country which will be deposited in the Trocadero.

General Strelbitzky has just published a new edition of his work, "The Superficies of the Russian Empire and the Neighbouring States of Asia." He has incorporated in this edition all the new data, accumulated since 1875, relating to the measurement of the superficies of Russia and her Asiatic possessions. Detailed data as to the superficies of interior seas and lakes, islands, and drainage-areas of separate rivers are added; and the writer presents the first trustworthy information as to the superficies of China, Persia, Afghanistan, Bukhara, Khiva, Corea, and Japan. All figures are given in geographical miles, kilometres, and Russian versts.

AN ATTEMPT TO APPLY TO CHEMISTRY ONE OF THE PRINCIPLES OF NEWTON'S NATURAL PHILOSOPHY.[1]

NATURE, inert to the eyes of the ancients, has been revealed to us as full of life and activity. The conviction that motion pervaded all things, which was first realized with respect to the stellar universe, has now extended to the unseen world of atoms. No sooner had the human understanding denied to the earth a fixed position and launched it along its path in space, than it was sought to fix immovably the sun and the stars. But astronomy has demonstrated that the sun moves with unswerving regularity through the star-set universe at the rate of about 50 kilometres per second. Among the so called fixed stars are now discerned manifold changes and various orders of movement. Light, heat, electricity—like sound—have been proved to be modes of motion; to the realization of this fact modern science is indebted for powers which have been used with such brilliant success, and which have been expounded so clearly at this lecture-table by Faraday and by his successors. As in the imagination of Dante the invisible air became peopled with spiritual beings, so before the eyes of earnest investigators, and especially before those of Clerk Maxwell, the invisible mass of gases became peopled with particles: their rapid movements, their collisions, and impacts became so manifest that it seemed almost possible to count the impacts and determine many of the peculiarities or laws of their collisions. The fact of the existence of these invisible motions may at once be made apparent by demonstrating the difference in the rate of diffusion through porous bodies of the light and rapidly moving atoms of hydrogen and the heavier and more sluggish particles of air. Within the masses of liquid and of solid bodies we have been forced to acknowledge the existence of persistent though limited motion of their ultimate particles, for otherwise it would be impossible to explain, for example, the celebrated experiments of Graham on diffusion through liquid and colloidal substances. If there were, in our times, no belief in the molecular motion in solid bodies, could the famous Spring have hoped to attain any result by mixing carefully dried powders of potash saltpetre, and acetate of soda, in order to produce, by pressure, a chemical reaction between these substances through the interchange of their metals, and have derived, for the conviction of the incredulous, a mixture of two hygroscopic though solid salts—nitrate of soda and acetate of potash?

In these invisible and apparently chaotic movements, reaching from the stars to the minutest atoms, there reigns, however, an harmonious order which is commonly mistaken for complete rest, but which is really a consequence of the conservation of that dynamic equilibrium which was first discerned by the genius of Newton, and which has been traced by his successors in the detailed analysis of the particular consequences of the great generalization,—namely, relative immovability in the midst of universal and active movement.

But the unseen world of chemical changes is closely analogous to the visible world of the heavenly bodies, since our atoms form distinct portions of an invisible world, as planets, satellites, and comets form distinct portions of the astronomer's universe; our atoms may therefore be compared to the solar system, or to the systems of double or of single stars, for example, ammonia (NH_3) may be represented in the simplest manner by supposing the sun nitrogen surrounded by its planets of hydrogen; and common salt ($NaCl$) may be looked upon as a double star formed of nitrogen and chlorine. Besides, now that the indestructibility of the elements has been acknowledged, chemical changes cannot otherwise be explained than as changes of motion, and the production by chemical reactions of galvanic currents, of light, of heat, of pressure, or of steam power, demonstrate visibly that the processes of chemical reaction are inevitably connected with enormous though unseen displacements, originating in the movements of atoms in molecules. Astronomers and natural philosophers, in studying the visible motions of the heavenly bodies and of matter on the earth, have understood and have estimated the value of this store of energy. But the chemist has had to pursue a contrary course. Observing in the physical and mechanical phenomena which accompany chemical reactions the quantity of energy manifested by the atoms and molecules, he is constrained to acknowledge that within the molecules there exist atoms in motion, endowed with an energy which, like matter itself, is neither being created nor is capable of being destroyed. Therefore, in chemistry, we must seek dynamic equilibrium not only between the molecules but also in their midst among their component atoms. Many conditions of such equilibrium have been determined, but much remains to be done, and it is not uncommon, even in these days, to find that some chemists forget that there is the possibility of motion in the interior of molecules, and therefore represent them as being in a condition of death-like inactivity.

Chemical combinations take place with so much ease and rapidity, possess so many special characteristics, and are so numerous, that their simplicity and order was for a long time hid from investigators. Sympathy, relationship, all the caprices or all the fancifulness of human intercourse, seemed to have found complete analogies, in chemical combinations, but with this difference, that the characteristics of the material substances—such as silver, for example, or of any other body—remain unchanged in every subdivision from the largest masses to the smallest particles, and consequently their characteristics must be a property of its particles. But the world of heavenly luminaries appeared equally fanciful at man's first acquaintance with it, so much so that the astrologers imagined a connection between the individualities of men and the conjunctions of planets. Thanks to the genius of Lavoisier and of Dalton, man has been able, in the unseen world of chemical combinations, to recognize laws of the same simple order as those which Copernicus and Kepler proved to exist in the planetary universe. Man discovered, and continues every hour to discover, *what* remains unchanged in chemical evolution, and *how* changes take place in combinations of the unchangeable. He has learned to predict, not only what possible combinations may take place, but also the very existence of atoms of unknown elementary bodies, and has besides succeeded in making innumerable practical applications of his knowledge, to the great advantage of his race, and has accomplished this notwithstanding that notions of sympathy and affinity still preserve a strong vitality in science. At present we cannot apply Newton's principles to chemistry, because the soil is only being now prepared. The invisible world of chemical atoms is still waiting for the creator of chemical mechanics. For him our age is collecting a mass of materials, the inductions of well-digested facts, and many-sided inferences similar to those which existed for astronomy and mechanics in the days of Newton. It is well also to remember that Newton devoted much time to chemical experiments, and while considering questions of celestial mechanics, persistently kept in view the mutual action of those infinitely small worlds which are concerned in chemical evolutions. For this reason, and also to maintain the unity of laws, it seems to me that we must, in the first instance, seek to harmonize the various phases of contemporary chemical theories with the immortal principles of the Newtonian natural philosophy, and so hasten the advent of true chemical mechanics. Let the above considerations serve as my justification for the attempt which I propose to make to act as a champion of the universality of the Newtonian principles, which I believe are competent to embrace every phenomenon in the universe, from the rotation of the fixed stars, to the interchanges of chemical atoms.

In the first place, I consider it indispensable to bear in mind that, up to quite recent times, only a one-sided affinity has been recognized in chemical reactions. Thus, for example, from the circumstance that red-hot iron decomposes water with the evolution of hydrogen, it was concluded that oxygen had a greater affinity for iron than for hydrogen. But hydrogen, in presence of red-hot iron scale, appropriates its oxygen, and forms water, whence an exactly opposite conclusion may be formed.

During the last ten years a gradual, scarcely perceptible, but most important change has taken place in the views, and consequently in the researches, of chemists. They have sought everywhere, and have always found systems of conservation or dynamic equilibrium substantially similar to those which natural philosophers have long since discovered in the visible world, and in virtue of which the position of the heavenly bodies in the universe is determined. There, where one-sided affinities only were at first detected, not only secondary or lateral ones have been found, but even those which are diametrically opposite, yet among these, dynamical equilibrium establishes itself, not by excluding one or other of the forces, but regulating them all. So the chemist finds in the flame of the blast-furnace, in the formation of every salt, and, with especial clearness, in double salts, and in the crystallization of solutions, not a fight ending in the victory of one side, as used to be supposed, but the conjunction of forces; the peace of dynamic equilibrium resulting

[1] The Friday evening lecture delivered at the Royal Institution of Great Britain, on May 31, 1889, by Prof. D. Mendeleeff, Professor of Chemistry in the University of St. Petersburg.

from the action of many forces and affinities. Carbonaceous matters, for example, burn at the expense of the oxygen of the air, yielding a quantity of heat and forming products of combustion, in which it was thought that the affinities of the oxygen with the combustible elements were satisfied. But it appeared that the heat of combustion was competent to decompose these products, to dissociate the oxygen from the combustible elements; and therefore, to explain combustion fully, it is necessary to take into account the equilibrium between opposite reactions, between those which evolve and those which absorb heat.

In the same way, in the case of the solution of common salt in water, it is necessary to take into account, on the one hand, the formation of compound particles generated by the combination of salt with water, and, on the other, the disintegration or scattering of the new particles formed, as well as of those originally contained. At present we find two currents of thought, apparently antagonistic to each other, dominating the study of solutions: according to the one, solution seems a mere act of building up or association; according to the other, it is only dissociation or disintegration. The truth lies, evidently, between these views; it lies, as I have endeavoured to prove by my investigations into aqueous solutions, in the dynamic equilibrium of particles tending to combine and also to fall asunder. The large majority of chemical reactions which appeared to act victoriously along one line have been proved capable of acting as victoriously even along an exactly opposite line. Elements which utterly decline to combine directly may often be formed into comparatively stable compounds by indirect means, as, for example, in the case of chlorine and carbon; and, consequently, the sympathies and antipathies, which it was thought to transfer from human relations to those of atoms, should be laid aside until the mechanism of chemical relations is explained. Let us remember, however, that chlorine, which does not form with carbon the chloride of carbon, is strongly absorbed, or, as it were, dissolved by carbon, which leads us to suspect incipient chemical action even in an external and purely surface contact, and involuntarily gives rise to conceptions of that unity of the forces of Nature which has been so energetically insisted on by Sir William Grove and formulated in his famous paradox. Grove noticed that platinum, when fused in the oxyhydrogen flame, during which operation water is formed, when allowed to drop into water decomposes the latter and produces the explosive oxyhydrogen mixture. The explanation of this paradox, as of many others which arose during the period of chemical renaissance, has led, in our time, to the promulgation by Henri St. Claire Deville of the conception of dissociation and of equilibrium, and has recalled the teaching of Berthollet, which, notwithstanding its brilliant confirmation by Heinrich Rose and Dr. Gladstone, had not, up to that period, been included in received chemical views.

Chemical equilibrium in general, and dissociation in particular, are now being so fully worked out in detail, and applied in such various ways, that I do not allude to them to develop, but only use them as examples by which to indicate the correctness of a tendency to regard chemical combinations from points of view differing from those expressed by the term hitherto appropriated to define chemical forces—namely, "affinity." Chemical equilibria dissociation, the speed of chemical reactions, thermo-chemistry, spectroscopy, and, more than all, the determination of the influence of masses and the search for a connection between the properties and weights of atoms and molecules; in one word, the vast mass of the most important chemical researches of the present day, clearly indicates the near approach of the time when chemical doctrines will submit fully and completely to the doctrine which was first announced in the "Principia" of Newton.

In order that the application of these principles may bear fruit, it is evidently insufficient to assume that statical equilibrium reigns alone in chemical systems or chemical molecules: it is necessary to grasp the conditions of possible states of dynamical equilibria, and to apply to them kinetic principles. Numerous considerations compel us to renounce the idea of statical equilibrium in molecules, and the recent yet strongly supported appeals to dynamic principles constitute, in my opinion, the foundation of the modern teaching relating to atomicity, or the valency of the elements, which usually forms the basis of investigations into organic or carbon compounds.

This teaching has led to brilliant explanations of very many chemical relations and to cases of isomerism, or the difference in the properties of substances having the same composition. It has been so fruitful in its many applications and in the foreshadowing of remote consequences, especially respecting carbon compounds, that it is impossible to deny its claims to be ranked as a great achievement of chemical science. Its practical application to the synthesis of many substances of the most complicated composition entering into the structure of organized bodies, and to the creation of an unlimited number of carbon compounds, among which the colours derived from coal tar stand prominently forward, surpass the synthetical powers of Nature itself. Yet this teaching, as applied to the structure of carbon compounds, is not on the face of it directly applicable to the investigation of other elements, because in examining the first it is possible to assume that the atoms of carbon have always a definite and equal number of affinities, while in the combinations of other elements this is evidently inadmissible. Thus, for example, an atom of carbon yields only one compound with four atoms of hydrogen and one with four atoms of chlorine in the molecule, while the atoms of chlorine and hydrogen unite only in the proportions of one to one. Simplicity is here evident, and forms a point of departure from which it is easy to move forward with firm and secure tread. Other elements are of a different nature. Phosphorus unites with three and with five atoms of chlorine, and consequently the simplicity and sharpness of the application of structural conceptions are lost. Sulphur unites only with two atoms of hydrogen, but with oxygen it enters into higher orders of combination. The periodic relationship which exists among all the properties of the elements, such, for example, as their ability to enter into various combinations, and their atomic weights, indicate that this variation in atomicity is subject to one perfectly exact and general law, and it is only carbon and its near analogues which constitute cases of permanently preserved atomicity. It is impossible to recognize as constant and fundamental properties of atoms, powers which, in substance, have proved to be variable. But by abandoning the idea of permanence, and of the constant saturation of affinities—that is to say, by acknowledging the possibility of free affinities—many retain a comprehension of the atomicity of the elements "under given conditions"; and on this frail foundation they build up structures composed of chemical molecules, evidently only because the conception of manifold affinities gives, at once, a simple statical method of estimating the composition of the most complicated molecules.

I shall enter neither into details, nor into the various consequences following from these views, nor into the disputes which have sprung up respecting them (and relating especially to the number of isomers possible on the assumption of free affinities), because the foundation or origin of theories of this nature suffers from the radical defect of being in opposition to dynamics. The molecule, as even Laurent expressed himself, is represented as an architectural structure, the style of which is determined by the fundamental arrangement of a few atoms, while the decorative details, which are capable of being varied by the same forces, are formed by the elements entering into the combination. It is on this account that the term "structural" is so appropriate to the contemporary views of the above order, and that the "constructors" seek to justify the tetrahedric, plane, or prismatic disposition of the atoms of carbon in benzole. It is evident that the consideration relates to the statical position of atoms and molecules, and not to their kinetic relations. The atoms of the structural type are like the lifeless pieces on a chess-board: they are endowed but with the voices of living beings, and are not those living beings themselves; acting, indeed, according to laws, yet each possessed of a store of energy, which, in the present state of our knowledge, must be taken into account.

In the days of Haüy, crystals were considered in the same statical and structural light, but modern crystallographers, having become more thoroughly acquainted with their physical properties and their actual formation, have abandoned the earlier views and have made their doctrines dependent on dynamics.

The immediate object of this lecture is to show that, starting with Newton's third law of motion, it is possible to preserve to chemistry all the advantages arising from structural teaching, without being obliged to build up molecules in solid and motionless figures, or to ascribe to atoms definite limited valencies, directions of cohesion, or affinities. The wide extent of the subject obliges me to treat only a small portion of it—namely, of *substitutions*, without specially considering combinations and decompositions—and, even then, limiting myself to the simplest examples, which, however, will throw open prospects embracing all the natural complexity of chemical relations. For this reason, if it should prove possible to form groups similar, for example, to H_4 or CH_6 as the remnants of molecules CH_4 or C_2H_6, we shall not pause to consider them, because, as far as we know, they fall asunder into two parts, $H_2 + H_2$ or $CH_4 + H_2$, as soon as they are even temporarily formed, and are capable of separate existence, and therefore can take no part in the elementary act of substitution. With respect to the simplest molecules which we shall select—that is to say, those of which the parts have no separate existence, and therefore cannot appear in substitutions—we shall consider them according to the periodic law, arranging them in direct dependence on the atomic weight of the elements.

Thus, for example, the molecules of the simplest hydrogen compounds—

HF	H_2O	H_3N	H_4C
Hydrofluoric acid	Water	Ammonia	Methane

correspond to elements the atomic weights of which decrease consecutively—

$$F = 19, \ O = 16, \ N = 14, \ C = 12.$$

Neither the arithmetical order (1, 2, 3, 4 atoms of hydrogen) nor the total information we possess respecting the elements will permit us to interpolate into this typical series one more additional element; and therefore we have here, for hydrogen compounds, a natural base upon which are built up those simple chemical combinations which we take as typical. But even they are competent to unite with each other, as we see, for instance, in the property which hydrofluoric acid has of forming a hydrate—that is, of combining with water; and the similar attribute of ammonia, resulting in the formation of a caustic alkali, NH_3H_2O, or NH_4OH.

Having made these indispensable preliminary observations, I may now attack the problem itself, and attempt to explain the so-called structure, or rather construction of molecules—that is to say, their constitution and transformations—without having recourse to the teaching of "structionists," but on Newton's dynamical principles.

Of Newton's three laws of motion, only the third can be applied directly to chemical molecules when regarded as systems of atoms among which it must be supposed that there exist common influences or forces, and resulting compounded relative motions. Chemical reactions of every kind are undoubtedly accomplished by changes in these internal movements, respecting the nature of which nothing is known at present, but the existence of which the mass of evidence collected in modern times forces us to acknowledge as forming part of the common motion of the universe, and as a fact further established by the circumstance that chemical reactions are always characterized by changes of volume or the relations between the atoms or the molecules. Newton's third law, which is applicable to every system, declares that "action is always associated with reaction, and is equal to it." The brevity and conciseness of this axiom was, however, qualified by Newton in a more expanded statement: "The actions of bodies one upon another are always equal, and in opposite directions." This simple fact constitutes the point of departure for explaining dynamic equilibrium—that is to say, systems of conservancy. It is capable of satisfying even the dualists, and of explaining, without additional assumptions, the preservation of those chemical types which Dumas, Laurent, and Gerhardt created unit types, and those views of atomic combinations which the structionists express by atomicity or the valency of the elements, and, in connection with them, the various numbers of affinities. In reality, if a system of atoms or a molecule be given, then in it, according to the third law of Newton, each portion of atoms acts on the remaining portion in the same manner and with the same force as the second set of atoms acts on the first. We infer directly from this consideration that both sets of atoms forming a molecule are not only equivalent with regard to themselves, as they must be according to Dalton's law, but also that they may, if united, replace each other. Let there be a molecule containing atoms A B C, it is clear that, according to Newton's law, the action of A on B C must be equal to the action of B C on A, and if the first action is directed on B C, then the second must be directed on A, and consequently then, where A can exist in dynamic equilibrium, B C may take its place and act in a like manner. In the same way the action of C is equal to the action of A B. In one word every two sets of atoms forming a molecule are equivalent to each other, and may take each other's place in other molecules, or, having the power of balancing each other, the atoms or their complements are endowed with the power of replacing each other. Let us call this consequence of an evident axiom "the principle of substitution," and let us apply it to those typical forms of hydrogen compounds which we have already discussed, and which, on account of their simplicity and regularity, have served as starting-points of chemical argument long before the appearance of the doctrine of structure.

In the type of hydrofluoric acid, HF, or in systems of double stars, are included a multitude of the simplest molecules. It will be sufficient for our purpose to recall a few: for example, the molecules of chlorine, Cl_2, and of hydrogen, H_2, and hydrochloric acid, HCl, which is familiar to all in aqueous solution as spirit of salt, and which has many points of resemblance with HF, HB_2, HI. In these cases division into two parts can only be made in one way, and therefore the principle of substitution renders it probable that exchanges between the chlorine and the hydrogen can take place, if they are competent to unite with each other. There was a time when no chemist would even admit the idea of any such action; it was then thought that the power of combination indicated a polar difference of the molecules in combination, and this thought set aside all idea of the substitution of one component element by another.

Thanks to the observations and experiments of Dumas and Laurent fifty years ago, such fallacies were dispelled, and in this manner this same principle of substitution was exhibited. Chlorine and bromine, acting on many hydrogen compounds, occupy immediately the place of their hydrogen, and the displaced hydrogen, with another atom of chlorine or bromine, forms hydrochloric acid or bromide of hydrogen. This takes place in all typical hydrogen compounds. Thus chlorine acts on this principle on gaseous hydrogen—reaction, under the influence of light, resulting in the formation of hydrochloric acid. Chlorine, acting on the alkalies, constituted similarly to water, and even on water itself—only, however, under the influence of light, and only partially because of the instability of HClO—forms, by this principle, bleaching salts, which are the same as the alkalies, but with their hydrogen replaced by chlorine. In ammonia and in methane, chlorine can also replace the hydrogen. From ammonia is formed in this manner the so-called chloride of nitrogen, NCl_3, which decomposes very readily with violent explosion on account of the evolved gases, and falls asunder as chlorine and nitrogen. Out of marsh gas, or methane, CH_4, may be obtained consecutively, by this method, every possible substitution, of which chloroform, $CHCl_3$, is the best known, and chloro-carbonic acid, CCl_4, the most instructive. But by virtue of the fact that chlorine and bromine act in the manner shown on the simplest typical hydrogen compounds, their action on the more complicated ones may be assumed to be the same. This can be easily demonstrated. The hydrogen of benzole, C_6H_6, reacts feebly under the influence of light on liquid bromine, but Gustavson has shown that the addition of the smallest quantity of metallic aluminium causes energetic action, and the evolution of large volumes of bromide of hydrogen.

If we pass on to the second typical hydrogen compound—that is to say, water—its molecule, HOH, may be split up in two ways: either into an atom of hydrogen and a molecule of oxide of hydrogen, HO, or into oxygen, O, and two atoms of hydrogen, H; and therefore, according to the principle of substitution, it is evident that one atom of hydrogen can exchange with oxide of hydrogen, HO, and two atoms of hydrogen, H, with one atom of oxygen, O.

Both these forms of substitution will constitute methods of oxidation—that is to say, of the entrance of oxygen into the compound—a reaction which is so common in Nature as well as in the arts, taking place at the expense of the oxygen of the air or by the aid of various oxidizing substances or bodies which part easily with their oxygen. There is no occasion to reckon up the unlimited number of cases of such oxidizing reactions. It is sufficient to state that, in the first of these, oxygen is directly transferred, and the position, the chemical function, which hydrogen originally occupied is, after the substitution, occupied by the hydroxyl. Thus ammonia, NH_3, yields hydroxylamine, $NH_2(OH)$, a substance which retains many of the properties of ammonia.

Methane and a number of other hydrocarbons yield, by substitution of the hydrogen by its oxide, methylic, $CH_3(OH)$, and other alcohols. The substitution of one atom of oxygen for two atoms of hydrogen is equally common with hydrogen compounds. By this means alcoholic liquids containing ethyl alcohol, or spirits of wine, $C_2H_5(OH)$, are oxidized till they become vinegar or acetic acid, $C_2H_3O(OH)$. In the same way caustic ammonia, or the combination of ammonia with water, NH_3H_2O, or $NH_4(OH)$, which contains a great deal of hydrogen, by oxidation exchanges four atoms of hydrogen for two atoms of oxygen, and becomes converted into nitric acid, $NO_2(OH)$. This process of conversion of ammonia salts into saltpetre goes on in the fields every summer, and with especial rapidity in tropical countries. The method by which this is accomplished, though complex, though involving the agency of all-permeating micro-organisms, is, in substance, the same as that by which alcohol is converted into acetic acid, or glycol, $C_2H_4(OH)_2$ into oxalic acid, if we view the process of oxidation in the light of the Newtonian principles.

But while speaking of the application of the principle of substitution to water, we need not multiply instances, but must turn our attention to two special circumstances which are closely connected with the very mechanism of substitutions.

In the first place, the replacement of two atoms of hydrogen by one atom of oxygen may take place in two ways, because the hydrogen molecule is composed of two atoms, and therefore, under the influence of oxygen, the molecule forming water may separate before the oxygen has time to take its place. It is for this reason that we find, during the conversion of alcohol into acetic acid, that there is an interval during which is formed aldehyde, C_2H_4O, which, as its very name implies, is "alcohol dehydrogenatum," or alcohol deprived of hydrogen. Hence aldehyde combined with hydrogen yields alcohol, and, united to oxygen, acetic acid.

For the same reason there should be, and there actually are, intermediate products between ammonia and nitric acid, $NO_2(HO)$, containing either less hydrogen than ammonia, less oxygen than nitric acid, or less water than caustic ammonia. Accordingly we find, among the products of the de-oxidization of nitric acid and the oxidization of ammonia, not only hydroxylamine, but also nitrous oxide, nitrous and nitric anhydrides. Thus, the production of nitrous acid results from the removal of two atoms of hydrogen from caustic ammonia and the substitution of the oxygen for the hydrogen, $NO(OH)$; or by the substitution, in ammonia, of three atoms of hydrogen by hydroxyl, $N(OH)_3$, and by the removal of water; $N(OH)_3—H_2O = NO(OH)$. The peculiarities and properties of nitrous acid, as, for instance, its action on ammonia and its conversion, by oxidation, into nitric acid, are thus clearly revealed.

On the other hand, in speaking of the principle of substitution as applied to water, it is necessary to observe that hydrogen and hydroxyl, H and OH, are not only competent to unite, but also to form combinations with themselves, and thus become H_2 and H_2O_2; and such are hydrogen and the peroxide thereof. In general, if a molecule AB exists, then molecules AA and BB can exist also. A direct reaction of this kind does not, however, take place in water, therefore undoubtedly, at the moment of formation hydrogen reacts on the peroxide of hydrogen, as we can show at once by experiment; and further, because the peroxide of hydrogen, H_2O_2, exhibits a structure containing a molecule of hydrogen, H_2, and one of oxygen, O_2, either of which is capable of separate existence. The fact, however, may now be taken as thoroughly established, that, at the moment of combustion of hydrogen or of the hydrogen compounds, peroxide of hydrogen is always formed, and not only so, but in all probability its formation invariably precedes the formation of water. This was to be expected as a consequence of the law of Avogadro and Gerhardt, which leads us to expect this sequence in the case of equal interactions of volumes of vapours and gases; and in the peroxide of hydrogen we actually have such equal volumes of the elementary gases.

The instability of peroxide of hydrogen—that is to say, the ease with which it decomposes into water and oxygen, even at the mere contact of porous bodies—accounts for the circumstance that it does not form a permanent product of combustion, and is not produced during the decomposition of water. I may mention this additional consideration that, with respect to the peroxide of hydrogen, we may look for its effecting still further substitutions of hydrogen by means of which we may expect to obtain still more highly oxidized water-compounds, such as H_2O_3 and H_2O_4. These, Schönbein and Bunsen have long been seeking, and Berthelot is investigating them at this moment. It is probable, however, that the reaction will stop at the last compound, because we find that in a number of cases the addition of four atoms of oxygen seems to form a limit. Thus, OsO_4, $KClO_4$, $KMnO_4$, K_2SO_4, Na_3PO_4, and such like, represent the highest grades of oxidation.[1]

As for the last forty years, from the times of Berzelius, Dumas, Liebig, Gerhardt, Williamson, Frankland, Kolbe, Kekulé, and Butlerow, most theoretical generalizations have centred round organic or carbon compounds, so we will, for the sake of brevity, leave out the discussion of ammonia derivatives, notwithstanding their simplicity in respect to the doctrine of substitutions; we will dwell more especially on its application to carbon compounds, starting from methane, CH_4, as the simplest of the hydrocarbons, containing in its molecule one atom of carbon. According to the principles enumerated, we may derive from CH_4 every combination of the form CH_3X, CH_2X_2, CHX_3, and CX_4, in which X is an element, or radical, equivalent to hydrogen—that is to say, competent to take its place or to combine with it. Such are the chlorine substitutes mentioned already, such is wood-spirit, $CH_3(OH)$, in which X is represented by the residue of water, and such are numerous other carbon derivatives. If we continue, with the aid of hydroxyl, further substitutions of the hydrogen of methane, we shall obtain successively $CH_2(OH)_2$, $CH(OH)_3$, and $C(OH)_4$. But if, in proceeding thus, we bear in mind that $CH_2(OH)_2$ contains two hydroxyls in the same form as peroxide of hydrogen, H_2O_2 or $(OH)_2$, contains them—and, moreover, not only in one molecule, but together, attached to one and the same atom of carbon—so here we must look for the same decomposition as that which we find in peroxide of hydrogen, and accompanied also by the formation of water as an independently existing molecule; therefore $CH_2(OH)_2$ should yield, as it actually does, immediately water and the oxide of methylene, CH_2O, which is methane with oxygen substituted for two atoms of hydrogen. Exactly in the same manner out of $CH(OH)_3$ are formed water and formic acid, $CHO(OH)$, and out of $C(OH)_4$ is produced water and carbonic acid, or directly carbonic anhydride, CO_2, which will therefore be nothing else than methane with the double replacement of pairs of hydrogen by oxygen. As nothing leads to the supposition that the four atoms of hydrogen in methane differ one from the other, so it does not matter by what means we obtain any one of the combinations indicated—they will be identical; that is to say, there will be no case of actual isomerism, although there may easily be such cases of isomerism as have been distinguished by the term metamerism.

Formic acid, for example, has two atoms of hydrogen, one attached to the carbon left from the methane, and the other attached to the oxygen which has entered in the form of hydroxyl, and if one of them be replaced by some substance, X, it is evident that we shall obtain bodies of the same composition, but of different construction, or of dfferent orders of movement among the molecules, and therefore endowed with other properties and reactions. If X be methyl, CH_3—that is to say, a group capable of replacing hydrogen because it is actually contained with hydrogen in methane itself—then by substituting this group for the original hydrogen, we obtain acetic acid, $CCH_3O(OH)$, out of formic, and by substitution of the hydrogen in its oxide or hydroxyl, we obtain methyl formiate, $CHO(OCH_3)$. These bodies differ so much from each other physically and chemically that, at first sight, it is hardly possible to admit that they contain the same atoms in identically the same proportions. Acetic acid, for example, boils at a higher temperature than water, and has a higher specific gravity than it, while its metamer, formo-methylic ether, is lighter than water, and boils at 30°—that is to say, it evaporates very easily.

Let us now turn to carbon compounds containing two atoms

[1] Because more than four atoms of hydrogen never unite with one atom of the elements, and because the hydrogen compounds (*e.g.* HCl, H_2S, H_3P, H_4Si) always form their highest oxides with four atoms of oxygen, and as the highest forms of oxides (OSO_4RO_4) also contain four of oxygen, and eight groups of the periodic system, corresponding to the highest basic oxides R_2O, RO, R_2O_3, RO_2, R_2O_5, RO_3, R_2O_7, and RO_4, imply the above relationship, and because of the nearest analogues among the elements—such as Mg, Zn, Cd, and Hg; or Cr, Mo, W, and U; or Si, Ge, Sn, and Pt; or F, Cl, Br, and J, and so forth—not more than four are known, it seems to me that in these relationships there lies a deep interest and meaning with regard to chemical mechanics. But because, to my imagination, the idea of unity of design in Nature, either acting in complex celestial systems or among chemical molecules, is very attractive, especially because the atomic teaching at once acquires its true meaning, I will recall the following facts relating to the solar system. There are eight major planets, of which the four inner ones are not only separated from the four outer by asteroids, but differ from them in many respects, as, for example, in the smallness of their diameters and their greater density. Saturn with his ring has eight satellites, Jupiter and Uranus have each four. It is evident that in the solar systems also we meet with these higher numbers, four and eight, which appear in the combination of chemical molecules.

of carbon to the molecule, as in acetic acid, and proceed to evolve them from methane by the principle of substitution. This principle declares at once that methane can only be split up in the four following ways:—

(1) Into a group CH_3 equivalent with H. Let us call changes of this nature methylation.

(2) Into a group CH_2 and H_2. We will call this order of substitutions methylenation.

(3) Into CH and H_3, which commutations we will call acetylenation.

(4) Into C and H_4, which may be called carbonization.

It is evident that hydrocarbon compounds containing two atoms of carbon can only proceed from methane, CH_4, which contains four atoms of hydrogen by the first three methods of substitution: carbonizing would yield free carbon if it could take place directly, and if the molecule of free carbon—which is in reality very complex, that is to say, strongly polyatomic, as I have long since been proving by various means—could contain only C_2 like the molecules O_2, H_2, N_2, and so on.

By methylation, we should evidently obtain from marsh gas, ethane, $CH_3CH_3 = C_2H_6$.

By methylenation, that is, by substituting group CH_2 for H_2, methane forms ethylene, $CH_2CH_2 = C_2H_4$.

By acetylenation, that is, by substituting three atoms of hydrogen, H_3, in methane, by the remnant CH, we get acetylene $CHCH = C_2H_2$.

If we have applied the principles of Newton correctly, there should not be any other hydrocarbons containing two atoms of carbon in the molecule. All these combinations have long been known, and in each of them we can not only produce those substitutions of which an example has been given in the case of methane, but also all the phases of other substitutions, as we shall find from a few more instances, by the aid of which I trust that I shall be able to show the great complexity of those derivatives which, on the principle of substitution, can be obtained from each hydrocarbon. Let us content ourselves with the case of ethane, CH_3CH_3, and the substitution of the hydrogen by hydroxyl. The following are the possible changes:—

(1) $CH_3CH_2(OH)$: this is nothing more than spirit of wine, or ethyl alcohol, $C_2H_5(OH)$, or C_2H_6O.

(2) $CH_2(OH)CH_2(OH)$: this is the glycol of Wurtz, which has shed so much light on the history of alcohol. Its isomer may be $CH_3CH(OH)_2$, but as we have seen in the case of $CH(OH)_3$, it decomposes, giving off water, and forming aldehyde, CH_3CHO, a body capable of yielding alcohol by uniting with hydrogen and of yielding acetic acid by uniting with oxygen.

If glycol $CH_2(OH)CH_2(OH)$ loses its water, it may be seen at once that it will not now yield aldehyde, CH_3CHO, but its isomer, $\underset{O}{CH_2CH_2}$, the oxide of ethylene. I have here indicated in a special manner the oxygen which has taken the place of two atoms of the hydrogen of ethane taken from different atoms of the carbon.

(3) $CH_3C(OH)_3$ decomposed as $CH(OH)_3$, forming water and acetic acid, $OH_3CO(OH)$. It is evident that this acid is nothing else than formic acid, $CHO(OH)$, with its hydrogen replaced by methyl. Without examining further the vast number of possible derivatives, I will direct your attention to the circumstance that in dissolving acetic acid in water we obtain the maximum contraction, and the greatest viscosity when to the molecule $CH_3CO(OH)$ is added a molecule of water, which is the proportion which would form the hydrate $CH_3C(OH)_3$. It is probable that the doubling of the molecule of acetic acid at temperatures approaching its boiling-point has some connection with this power of uniting with one molecule of water.

(4) $CH^2(OH)C(OH)^3$ is evidently alcoholic acid, and indeed this compound, after losing water, answers to glycolic acid, $CH_2(OH)CO(OH)$. Without investigating all the possible isomers, we will note only that the hydrate $CH(OH)_2CH(OH)_2$ has the same composition as $CH_2(OH)C(OH)_3$, and although corresponding to glycol, and being a symmetrical substance, it becomes, on parting with its water, aldehyde of oxalic acid, or the glyoxal of Debus, $CHOCHO$.

(5) $CH(OH)_2C(OH_3)$, from the tendency of all the preceding, coresponds to glyoxylic acid, aldehyde acid, $CHOCO(OH)$, because the group $CO(OH)$, or carboxyl, enters into the compositions of organic acids, and the group CHO defines the aldehyde function.

(6) $C(OH)_3C(OH)_3$, through the loss of $2H_2O$, yields the bibasic oxalic acid $CO(OH)CO(OH)$, which generally crystallizes with $2H_2O$, following thus the normal type of hydration characteristic of ethane.[1]

Thus, by applying the principle of substitution, we can, in the simplest manner, derive not only every kind of hydrocarbon compound, such as the alcohols, the aldehyde alcohols, aldehydes, alcohol acids, and the acids, but also combinations analogous to hydrated crystals which usually are disregarded.

But even these unsaturated substances, of which ethylene, CH_2CH_2, and acetylene, CHCH, are types, may be evolved with equal simplicity. With respect to the phenomena of isomerism, there are many possibilities among the hydrocarbon compounds containing two atoms of carbon, and without going into details it will be sufficient to indicate that the following formulæ, though not identical, will be isomeric substantially among themselves: CH_3CHX_2 and CH_2XCH_2X, although both contain $C_2H_4X_2$, or CH_3CX_2 and CHXCHX, although both contain $C_2H_2X_2$, if by X we indicate chlorine or generally an element capable of replacing one atom of hydrogen, or capable of uniting with it. To isomerism of this kind belongs the case of aldehyde and the oxide of ethylene, to which we have already referred, because both have the composition C_2H_4O.

What I have said appears to me sufficient to show that the principle of substitution adequately explains the composition, the isomerism and all the diversity of combination of the hydrocarbons, and I shall limit the further development of these views to preparing a complete list of every possible hydrocarbon compound containing three atoms of carbon in the molecule. There are eight in all, of which only five are known at present.[2]

Among those possible for C_3H_6 there should be two isomers, propylene and trimethylene, and they are both already known. For C_3H_4 there should be three isomers: allylene and allene are known, but the third has not yet been discovered; and for C_3H_2 there should be two isomers, though neither of them are known as yet. Their composition and structure is easily deduced from ethane, ethylene, and acetylene, by methylation, methylenation, by acetylenation and by carbonization.

(1) $C_3H_8 = CH_3CH_2CH_3$ out of CH_3CH_3 by methylation. This hydrocarbon is named propane.

(2) $C_3H_6 = CH_3CHCH_2$ out of CH_3CH_3 by methylenation. This substance is propylene.

(3) $C_3H_6 = CH_2CH_2CH_2$ out of CH_3CH_3 by methylenation. This substance is trimethylene.

(4) $C_3H_4 = CH_3CCH$ out of CH_3CH_3 by acetylenation or from CHCH by methylation. This hydrocarbon is named allylene.

(5) $C_3H_4 = \underset{CH_2}{CHCH}$ out of CH_3CH_3 by acetylenation, or from CH_2CH_2 by methylenation, because $\underset{CH}{CH_2CH} = \underset{CH_2}{CHCH}$. This body is as yet unknown.

(6) $C_3H_4 = CH_2CCH_2$ out of CH_2CH_2 by methylenation. This hydrocarbon is named allene, or iso-allylene.

(7) $C_3H_2 = \underset{C}{CHCH}$ out of CH_3H_3 by symmetrical carbonization, or out of CH_2CH_2 by acetylenation. This compound is unknown.

(8) $C_3H_2 = \underset{CH_2}{CC}$ out of CH_3CH_3 by carbonization, or out of CHCH by methylenation. This compound is unknown.

[1] One more isomer, $CH_2CH(OH)$, is possible, that is secondary vinyl alcohol, which is related to ethylene, CH_2CH_2, but derived by the principle of substitution from CH_4. Other isomers of the composition C_2H_4O, such, for example, as $CHCH_3(OH)$, are impossible, because it would correspond to the hydrocarbon $CHCH_3 = C_2H_4$, which is isomeric with ethylene, and it cannot be derived from methane. If such an isomer existed, it would be derived from CH_2, but such products are up to the present unknown. In such cases the insufficiency of the points of departure of the statical structural teaching is shown. It first admits constant atomicity, and then rejects it, the facts serving to establish either one or the other view; and therefore, it seems to me that we must come to the conclusion that the structural method of reasoning, having done a service to science, has outlived the age, and must be regenerated, as, in their time, was the teaching of the electro-chemists, the radicalists, and the adherents of the doctrine of types. As we cannot now lean on the views above stated, it is time to abandon the structural theory. They will all be united in chemical mechanics, and the principle of substitution must be looked upon only as a preparation for the coming epoch in chemistry, where such cases as the isomerism of fumaric and maleic acids, when explained dynamically, as proposed by Le Bel and Van 't Hoff, may yield points of departure.

[2] Conceding variable atomicity, the structurists must expect an incomparably larger number of isomers, and they cannot now decline to acknowledge the change of atomicity, were it only for the examples HgCl and $HgCl_2$, CO and CO_2, PCl_3 and PCl_5.

If we bear in mind that for each hydrocarbon serving as a type in the above tables there are a number of corresponding derivatives, and that every compound obtained may, by further methylation, methylenation, acetylenation, and carbonization, produce new hydrocarbons, and these may be followed by a numerous suite of derivatives and an immense number of isomeric bodies, it is possible to understand the limitless number of carbon compounds, although they all have the one substance, methane, for their origin. The number of substances is so enormous, that it is no longer a question of enlarging the possibilities of discovery, but rather of finding some means of testing them, analogous to the well-known two which for a long time have served as gauges for all carbon compounds.

I refer to the law of even numbers and to that of limits, the first enunciated by Gerhardt forty years ago, with respect to hydrocarbons—namely, that their molecules always contain an even number of atoms of hydrogen. But by the method which I have used of deriving all the hydrocarbons from methane, CH_4, this law may be deduced as a direct consequence of the principle of substitutions. Accordingly, in methylation, CH_3 takes the place of H, and therefore CH_2 is added. In methylenation the number of atoms of hydrogen remains unchanged, and at each acetylenation it is reduced by two, and in carbonization by four atoms—that is to say, an even number of atoms of hydrogen is always added or removed. And because the fundamental hydrocarbon, methane, CH_4, contains an even number of atoms of hydrogen, therefore all its derivative hydrocarbons will also contain even numbers of hydrogen, and this constitutes the law of even numbered parts.

The principle of substitutions explains with equal simplicity the conception of limiting compositions of hydrocarbons, C_nH_{2n+2}, which I derived, in 1861,[1] in an empirical manner from accumulated materials available at that time, and on the basis of the limits to combinations worked out by Dr. Frankland for other elements.

Of all the various substitutions the highest proportion of hydrogen is yielded by methylation, because in that operation alone does the quantity of hydrogen increase; therefore, taking methane as a point of departure, if we imagine methylation effected $(n-1)$ times we obtain hydrocarbon compounds containing [the highest quantities of hydrogen. It is evident that they will contain

$$CH_4+(n-1)\,CH_2, \text{ or } C_nH_{2n+2},$$

because methylation leads to the addition of CH_2 to the compound.

It will thus be seen that by the principle of substitution—that is to say, by the third law of Newton—we are able to deduce, in the simplest manner, not only the individual composition, the somerism, and relations of substances, but also the general laws which govern their most complex combinations, without having recourse either to statical constructions, to the definition of atomicities, to the exclusion of free affinities, or to the recognition of those single, double, or treble ties which are so indispensable to structurists in the explanation of the composition and construction of hydrocarbon compounds. And yet, by the application of the dynamic principles of Newton, we can attain to that chief and fundamental object—the comprehension of isomerism in hydrocarbon compounds, and the forecasting of the existence of combinations as yet unknown, by which the edifice raised by structural teaching is strengthened and supported. Besides, and I count this for a circumstance of special importance, the process which I advocate will make no difference in those special cases which have been already so well worked out, such as, for example, the isomerism of the hydrocarbons and alcohols, even to the extent of not interfering with the nomenclature which has been adopted, and the structural system will retain all the glory of having worked up, in a thoroughly scientific manner, the store of information which Gerhardt had accumulated about the middle of the fifties, and the still higher glory of establishing the rational synthesis of organic substances. Nothing will be lost to the structural doctrine, except its statical origin; and as soon as it will embrace the dynamic principles of Newton, and suffer itself to be guided by them, I believe that we shall attain, for chemistry, that unity of principle which is now wanting. Many an adept will be attracted to that brilliant and fascinating enterprise, the penetration into the unseen world of the kinetic relations of atoms, to the study of which the last twenty-five years have contributed so much labour and such high inventive faculties.

D'Alembert found in mechanics, that if inertia be taken to represent force, dyamic equations may be applied to statical questions which are thereby rendered more simple and more easily understood.

The structural doctrine in chemistry has unconsciously followed the same course, and therefore its terms are easily adopted; they may retain their present forms provided that a truly dynamical—that is to say, Newtonian—meaning be ascribed to them.

Before finishing my task and demonstrating the possibility of adapting structural doctrines to the dynamics of Newton, I consider it indispensable to touch on one question which naturally arises, and which I have heard discussed more than once. If bromine, the atom of which is eighty times heavier than that of hydrogen, takes the place of hydrogen, it would seem that the whole system of dynamic equilibrium must be destroyed.

Without entering into the minute analysis of this question, I think it will be sufficient to examine it by the light of two well-known phenomena, one of which will be found in the department of chemistry, and the other in that of celestial mechanics, and both will serve to demonstrate the existence of that unity in the plan of creation, which is a consequence of the Newtonian doctrines. Experiments demonstrate that when a heavy element is substituted for a light one, in a chemical compound—an atom of magnesium in the oxide of that metal, for example, for mercury, the atom of which is $8\frac{1}{3}$ times heavier—the chief chemical characteristics or properties are generally though not always preserved.

The substitution of silver for hydrogen, than which it is 108 times heavier, does not affect all the properties of the substance, though it does some. Therefore chemical substitutions of this kind, the substitution of light for heavy atoms, need not necessarily entail changes in the original equilibrium; and this point is still further elucidated by the consideration that the periodic law indicates the degree of influence of an increment of weight in the atom as affecting the possible equilibria; and also what degree of increase in the weight of the atoms reproduces some, though not all, the properties of the substance.

This tendency to repetition, these periods, may be likened to those annual or diurnal periods with which we are so familiar on the earth. Days and years follow each other; but, as they do so, many things change; and in like manner chemical evolutions, changes in the masses of the elements, permit of much remaining undisturbed, though many properties undergo alteration. The system is maintained according to the laws of conservation in Nature, but the motions are altered in consequence of the change of parts.

Next, let us take an astronomical case, such for example as the earth and the moon, and let us imagine that the mass of the latter is constantly increasing. The question is, what will then occur? The path of the moon in space is a wave-line similar to that which geometricians have named epicycloidal, or the locus of a point in a circle rolling round another circle. But in consequence of the influence of the moon, it is evident that the path of the earth itself cannot be a geometric ellipse, even supposing the sun to be immovably fixed; it must be an epicycloidal curve, though not very far removed from the true ellipse, that is to say, it will be impressed with but faint undulations. It is only the common centre of gravity of the earth and the moon which describes a true ellipse round the sun. If the moon were to increase, the relative undulations of the earth's path would increase in amplitude, those of the moon would also change, and when the mass of the moon had increased to an equality with that of the earth, the path would consist of epicycloidal curves crossing each other, and having opposite phases. But a similar relation exists between the sun and the earth, because the former is also moving in space. We may apply these views to the world of atoms, and suppose that, in their movements, when heavy ones take the place of those that are lighter, similar changes take place provided that the system or the molecule is preserved throughout the change.

It seems probable that in the heavenly systems, during incalculable astronomical periods, changes have taken place and are still going on similar to those which pass rapidly before our eyes during the chemical reaction of molecules, and the progress of molecular mechanics may—we hope will—in course of time, permit us to explain those changes in the stellar world which have more than once been noticed by astronomers, and which are

[1] "Essai d'une théorie sur les limites des combinaisons organiques," par D. Mendeleeff, 2/11 août 1861, *Bulletin de l'Académie i. d. Sc. de St.-Pétersbourg*, I. v.

now so carefully studied. A coming Newton will discover the laws of these changes. Those laws, when applied to chemistry, may exhibit peculiarities, but these will certainly be mere variations on the grand harmonious theme which reigns in Nature. The discovery of the laws which produce this harmony in chemical evolutions will only be possible, it seems to me, under the banner of Newtonian dynamics which has so long waved over the domains of mechanics, astronomy, and physics. In calling chemists to take their stand under its peaceful and catholic shadow, I imagine that I am aiding in establishing that scientific union which the managers of the Royal Institution wish to effect, who have shown their desire to do so by the flattering invitation which has given me—a Russian—the opportunity of laying before the countrymen of Newton an attempt to apply to chemistry one of his immortal principles.

BABYLONIAN ASTRONOMY.[1]

IV.

THE nightly motion of the stars from east to west appears to have been the only one known to the Babylonian astronomers. The inclination of the equator on the ecliptic brought, however, a few of the austral stars over the horizon at certain times of the year for a short period, and in a few cases, as in that of the star *Sukudu* (Sirius), these stars were used to determine certain periods or festivals. The complicated motion of the planets never was known to them, and the planets were accordingly regarded as evil spirits which disturbed the harmony of Nature. A similar view is taken in the Zend-Avesta. After a cosmical year of 360,000 ordinary years, the series of heavenly and consequently terrestrial events was to begin again.

While the Semitic religion had emerged from tribal monotheism, the Akkadians followed a sect professing Mazdeism—that is, a religion admitting two principles, one good and one bad; but they thought that, as the good gods would not hurt them, it was wise to propitiate the bad ones, and propitiation easily led to worship. That is how the seven planets, the disturbers of heavenly harmony, became their chief deities. For the same reason all disturbing causes, apparent or real, were subjects of their special attention, pestilence, thunder, comets, &c. Eclipses (which they could not predict) were at first also of bad omen, but by a curious reversion they became happy signs.

The ignorance of the Babylonians with regard to astronomy might have been gathered from the statements of classical authors, if they had been examined with an unprejudiced mind. Diodorus Siculus says positively that their notions about astronomy, fixed at an early date, never changed, and that they could not predict the solar eclipses. We also know from a fragment of Berosus, preserved by Vitruvius, that the Babylonians believed the moon to be a globe half incandescent and half dark, the lunar phases and eclipses being produced by its own motion. The errors and contradictions of the Greek and Latin authors, which misled us also, came from the fact that they borrowed their information from the Alexandrian astronomers, who, they thought, derived their science from Babylon. This was true, indeed, but only to a very small extent, as we shall see.

When, after the conquest of Alexander, the Greeks established themselves in Babylon, they imported with them all their scientific knowledge. The Babylonians, who had to learn Greek, soon discovered the accuracy of their new masters in science, and, exactly as did the Chinese astronomers after the settlement of the Jesuits in China, adopted the discoveries of the West.

This is put beyond doubt by the tablets of this period, the Seleucidian, which give tables of the motions of the moon and planets, and mention solar and lunar eclipses without any omens. The Seleucidian astronomers, wishing to use the older observations, made search for old records and tabulated them; these tablets are of the highest interest from the astronomical point of view. The British Museum possesses, for instance, a tablet, written 100 years B.C., giving the list of nineteen lunar cycles of eighteen years—that is, a table combining the Metonic cycle with the *saros*. This *saros*, or cycle of the lunar eclipses, must have been discovered after the settlement of the Greeks; it was called the "king" (*sar* in Babylonian, hence *saros* in Greek) just as the Metonic cycle was called "golden."

The first care of these astronomical innovators was, no doubt, to reform the very defective calendar of former times. They also divided the ecliptic into twelve parts, corresponding to the months, and chose twelve cuneiform signs to represent in their tablets the twelve zodiacal constellations. They then devised the Græco-Babylonian calendar, whence was derived the Jewish one of the time of the Maccabees.

This reform was not made, however, without causing a certain confusion in the star nomenclature, and even in the calendar itself; for, as the older Babylonians used to connect the various parts of the year with the stars or constellations according to their acronic rising, there was a certain hesitation in the choice made by the reformers. Probably this was what caused the parallel use of two calendars, one beginning with Nisan and the other with Tisrit. This hesitation has also left traces in the signs chosen to designate the zodiacal constellations; for instance, the sign representing the month Tisrit in older Babylonian was used to represent the constellation connected with the month Nisan.

It was from this new focus of astronomical science that the Alexandrian astronomers borrowed much of their information. Unfortunately, the old Babylonian superstitions had a most injurious influence on the rising Alexandrian astronomy. Jewish, Syrian, and Babylonian emigrants, fleeing from the Seleucidian tyranny, flocked to Egypt, bringing with them their superstitions and love for allegories. The Alexandrian astronomers accepted with the Babylonian nomenclature all the ideas of influences attributed to planets and stars, and, being able to predict conjunctions, tried to predict events supposed to be due to star influences. Astrology was then born, for astrology, it must be remembered, requires an accurate knowledge of the motions of stars and planets.

In conclusion, it may be said that we owe very little to the old Babylonian astronomers, and if the astronomical work of Berosus had been preserved, it would have given no scientific information, but only long lists of omens drawn from the rising and conjunctions of stars and planets, and also from their colour and other accidental aspects. The loss of such a work is not much to be regretted.

THE THREE CRUISES OF THE "BLAKE."

The Three Cruises of the "Blake." Two Vols. By Alexander Agassiz. *Bulletin of the Museum of Comparative Zoology at Harvard College*, Vols. XIV. and XV., Cambridge, Mass. (Boston and New York: Houghton, Mifflin, and Co., 1888.)

IN these profusely illustrated volumes there is presented to the general reading public the best and most comprehensive account of recent oceanographical investigations and speculations that has as yet been attempted. These volumes have, moreover, a special value for all who interest themselves in deep-sea researches, from the descriptions that are given of the work carried on with so much ability and industry by Mr. Agassiz and his fellow-countrymen on the eastern and southern sea-boards of the United States and in the West Indian seas. The volumes abound with novel and ingenious views bearing on nearly all the physical and biological phenomena of the ocean; and, whether we agree with the writer or not, his opinions are none the less welcome and suggestive, coming as they do from one who has for many years taken a large part in the practical work connected with the observations which he here undertakes to describe and discuss. It does not seem possible to over-estimate the credit due to the Government and the men who initiated and have carried through this excellent and extensive hydrographical survey of the deeper waters surrounding the eastern shores of North America, nor to value too highly the resulting additions to human knowledge. These positive additions to our knowledge of the ocean will be fully acknowledged and appreciated by all who desire to trace the causes that have led to the development of the surface features of the earth and the existing conditions of life on our globe.

After an attentive reading of the twenty-three chapters into which this publication is divided, it is possible to point out some errors; but slips cannot be avoided in a work dealing with such a wide range of subjects. It is difficult to follow the author in all his speculations, or to agree with him in all the deductions drawn from his excellent and extensive observations, but such agreement was in no way to be expected in these wide fields of research. Almost all the writings and opinions of previous and contemporaneous workers are in some way noticed, and discussed in an appreciative spirit. Mr. Agassiz is in every respect to be congratulated on the completion of this praiseworthy contribution to the growing science of oceanography. So many subjects are presented for discussion and remark that the reviewer is at a loss to know which may with most advantage be touched upon within the limits of a short notice. An attempt may at all events be made to point out the arrangement of the work, and the nature of the varied investigations treated of in the several chapters.

An introduction gives a brief sketch of the cruises of the *Blake*, the extent of the work undertaken, and indicates the localities in which these were conducted. Acknowledgment is duly recorded for the assistance obtained from naturalists in all parts of the world in working out the results of the dredgings. By arrangement the specimens were as far as possible sent to the same specialists as were engaged in describing the *Challenger* collections.

The first chapter deals with the equipment of the ship, which has already been made known through Captain Sigsbee's publication. Mr. Agassiz, from his engineering training in the copper mines of the West, was able to render very valuable assistance in modifying the apparatus for deep-sea work. To him we owe the introduction of wire dredging rope, improvements in the trawl, tow-net, and other apparatus. The use of tangles on rocky ground was very successful, as it was when used in similar places by the *Challenger*. The tow-net for intermediate depths is ingenious, but the experiments with it are in no way sufficient to prove that no living animals are to be found at intermediate depths, as is sometimes asserted. The *Challenger* experiments clearly showed that when tow-nets were dragged for considerable distances at depths of 1000 and 500 fathoms, they always contained animals (Challengeridæ and other Radiolarians and fishes, &c.) never taken in the nets dragged down to 100 fathoms from the surface. While the great development of life in the ocean is in the surface and sub-surface waters, where Algæ abound, and at and near the bottom, where the organic matters are settling on the mud or ooze, yet it appears to me that the *Challenger* has also shown that there is no intermediate lifeless region.

A short chapter gives a fair and impartial historical sketch of deep-sea work, with special reference to the work off the American coast; and a longer chapter gives a very complete account of the origin, development, and present condition of the Florida reefs—the most thorough account of a series of coral reefs to be found in the literature of the subject. Mr. Agassiz successfully explains the phenomena without calling in subsidence, indeed, he found Mr. Darwin's theory quite inapplicable. He rightly places stress on the vigorous growth of the reefs in all situations where they are bathed by currents coming directly from the ocean, and traces this vigorous growth to the abundant pelagic food brought to the reef-forming corals by these oceanic currents. He also dwells on the formation of submarine banks by the dead shells of these pelagic and other marine organisms. Speaking of the Pacific, he says: "It is difficult to account for the great depth of some of the lagoons—40 fathoms—on any other theory than that of subsidence." It appears to me that these depths are only found in very extensive atolls and barrier reefs, and that marine animals, other than the ordinary reef-building species, can build up submerged banks from much greater depths than 40 fathoms. Buchanan, on such a bank in the Atlantic, found *Lophohelia prolifera* growing in large quantities, together with Polyzoa, Crinoids, and other lime-secreting organisms. Besides, in the central parts of the lagoon of completely formed atolls, like Collomandu or Suadiva atolls, the solution of lime by the sea-water probably exceeds in quantity that secreted by organisms, and this process would of itself result in a deepening of the lagoon.

The topography of the Caribbean Sea, Gulf of Mexico, and eastern coasts of North America are illustrated by the admirable hydrographic charts of the Coast Survey. With a thorough knowledge of the various basins, their depths, currents, passages, and contour lines, Mr. Agassiz is well qualified to enter on a discussion of the relations of the American and West Indian fauna and flora, which he does in a most suggestive and instructive chapter. He says :—

"The deep soundings south of Cuba, between that island and Yucatan and Jamaica, do not lend much support to the theory of an Antillean continent as mapped out by Wallace, nor is it probable that this continent had a much greater extension in former times than now, judging from the depths found on both sides of the West Indian Islands. This would tend to prove the want of close connection between the West Indian Islands and the adjoining continent. It leads us to look for the origin of the fauna and flora of those islands to causes similar to those which have acted upon oceanic islands. The proximity of these islands to a great continent has, moreover, intensified the efficiency of these causes."

Since the return of the *Challenger*, the existence of Tertiary continents in the Atlantic, Indian, and Pacific Oceans does not appear to have been seriously advocated. These views have been generally replaced by that which looks upon the continents and ocean basins as holding positions of great permanence on the surface of the earth. Mr. Agassiz adopts this latter view, and illustrates it by special reference to the geological structure of the American continent and its adjoining oceans. In discussing this matter, he expresses the opinion that the "Blake Plateau" was once within the 100-fathom line, and that it has been cut away to its present depth of 500 or 600 fathoms "by the action of the Gulf Stream acting upon the 'Blake Plateau' from a geological time which we can trace with a certain degree of accuracy." This is a most important conclusion, but I cannot think it will be accepted till more evidence of the action of oceanic currents at these depths can be produced. The deposits I have examined from the bed of the Gulf Stream are principally composed of the shells of pelagic Foraminifera, Pteropods, and other organisms living in the present seas of the region, together with much glauconite and many phosphatic concretions. These would lead one to think that the bed of the Gulf Stream was now growing upwards by these accumulations, rather than being washed away.

All the new and valuable observations on the temperatures of the West Indian seas and on the Gulf Stream are presented to the reader with a wealth of illustration in the way of diagrams and maps that leaves little to be desired, and the chapters on these subjects give to the physical geographer many much-needed data.

Mr. Agassiz has long been known to the scientific world for his special researches on the pelagic animals of the eastern North American coasts, conducted chiefly at Newport since 1866. It was therefore to be expected that his observations in this direction would be attractive and important. Nearly all the principal organisms met with in the tow-nets are illustrated in the long chapter devoted to this subject, and the naturalist will here find much new matter and many novel views concerning the origin of this fauna. He says :—

"It seems most natural to look upon the pelagic fauna of to-day and that of former geological periods as made up of embryonic types removed from the influences necessary for their full development, even after a time reproducing themselves as other larval forms are now capable of doing. But to consider that the littoral forms were developed from pelagic types, as has been suggested by Moseley, does not seem to be warranted by the embryological history of marine invertebrates."

The chapters on marine formations, deep-sea deposits and deep-sea fauna contain the latest information and views as to their origin, and the first volume is concluded with a chapter on the physiology of deep-sea life, dealing with the gases in sea-water, the effects of pressure and temperature, phosphorescence, effects of the absence of sunlight, colours of deep-sea animals, source of their food, and other kindred relations.

It is now recognized that the inhabitants of the abysmal regions differ more from the shore species than they do from one another. Perhaps the most striking characteristic of deep-sea species is that they live in a region where there is no plant-life, and that their food consists primarily of the dead remains that fall to the bottom from the surface. All these animals, therefore, either live by eating the mud or ooze of the bottom, or by devouring each other. It appears to me probable that these deep-sea animals are derived from the shore ones, some species descending into these deep regions and establishing a home there at each geological period, while the forms from which they were derived have died out in the shallower waters.

This and all similar questions Mr. Agassiz discusses in his second volume, where he deals specially with the West Indian fauna of the deep sea. He writes :—

"We may safely assume that but little will hereafter be added to our notions of the association of the sponges, polyps, corals, echinoderms, crustacea, and mollusks, comprising the West Indian deep-sea fauna, and making it in certain groups by far the richest in the world. The number of new forms from the West Indian region constitutes such a vast addition to our knowledge of the principal classes of invertebrates of that fauna as to revolutionize our ideas of geographical as well as of bathymetrical distribution. No other region of the ocean has yielded so abundant a harvest."

I should think that in proportion to the number of dredgings, the regions in the Southern Ocean investigated by the *Challenger*, or off the north of Scotland worked over by the *Porcupine* and *Triton*, might be held to be quite as rich as those of the West Indian Islands. It is to be hoped that this will be shown before long by an expedition thoroughly equipped for examining the deep waters around Britain.

In a series of nine chapters in his second volume Mr. Agassiz attempts for the first time to give a general account of the deep-sea fauna in the areas explored by the *Blake*, commencing with the fishes, and ending with the Protozoa. In this he has been remarkably successful by the help of numerous illustrations. For details the reader must be referred to the volumes themselves, which will be widely consulted, and will well repay all who give them attentive study.

JOHN MURRAY.

KANT'S "KRITIK."

Kant's Critical Philosophy for English Readers. By J. P. Mahaffy and J. H. Bernard. (London: Macmillan and Co., 1889.)

THE abundance of Kantian literature within recent years shows no signs of abating. In Germany itself there is quite a school of students who have taken for their motto "We must go back to Kant," while in England the able commentaries of Prof. Caird and Prof. Watson have been succeeded by the studies of Dr. Hutchinson Stirling, Prof. Max Müller, and Dr. Mahaffy. The old translation of Mr. Meiklejohn still holds its own, though Mr. Belfort Bax and others have tried their hands on Kant, and made many improvements in detail. It is clear that the famous "Kritik of Pure Reason" is still regarded as a necessary element in all philosophic education, and as likely to continue longer in fashion than the more brilliant but less solid speculations of Schopenhauer and Von Hartmann, as well as of the more legitimate descendants of the Königsberg school.

There are certain well-known difficulties in Kant's philosophy to which the reader naturally turns when he has in his hands a new commentary on the "Kritik." Is any fresh light thrown on the schematism of the categories, or on the number and derivation of the categories themselves? Are we enabled to understand better the precise value of the principle of causation, or the principle of the permanence of substance? Above all, shall we be satisfied to accept the second and first editions of the "Kritik" as alike containing the true gospel of Kantianism, or are we to be left to suppose that there is a serious divergence between the earlier and later edition, especially in reference to idealism and the refutation of Berkeley? These are a few salient points out of many others on which we look for guidance to some fresh commentator. In the case of one of these, we have for some time been aware of Dr. Mahaffy's opinion. We know that in his early version of Kuno Fischer's "Commentary" he was dissatisfied with that philosopher's treatment of Kant on the subject of idealism. Dr. Mahaffy returns to the charge in the present edition (in which he has the collaboration of Mr. Bernard), perhaps in some measure stirred to resume the controversy by the discovery that Kuno Fischer in his recent "Critique of Kant" (1882) had not found reason to alter his original views. As the point is an important one, and as Dr. Mahaffy would probably himself select its treatment as the most characteristic contribution which his new edition has to offer to the better comprehension of Kant, we shall attempt as briefly as possible to lay the question at issue before our readers.

It was Schopenhauer who decisively stigmatized the second edition of the "Kritik" as inferior to its predecessor. Kant, he declared, had become alarmed at the idealistic conclusions which had been drawn from his principles, and proceeded to mutilate the earlier version of his doctrines by suppression of some passages, and alteration of others. There was one paragraph especially, inserted into the deduction of the categories, which stated in the most explicit terms that the "matter" of our intuitions is derived from a source independent of the understanding; and there was the comparatively long excursus introduced under the heading of a "Refutation of Idealism," which seemed expressly intended to reassure those who thought that Kant had taken up the position of Berkeley. Hence the conclusion was drawn that Kant, "in the weakness of old age," had compromised with the Realists, and that the second edition, in consequence, was by no means so clear and consistent an exposition of Kant's own opinions as the one it was intended to supersede. It is this opinion (which others besides Schopenhauer have entertained) which Dr. Mahaffy sets himself to oppose. He draws attention, in the first place, to Kant's own words in his preface, which contain the most unqualified statement of the practical identity of the two editions. "In the positions themselves," says Kant, "and in the grounds of proof, as well as in the form and completeness of the plan, I have found nothing to alter;" and again, "my present exposition, in substance, as regards the propositions, and even in their method of proof *changes absolutely nothing*, while it varies from the former here and there in the method of the exposition in such a manner as could not be managed by interpolation." These words are certainly explicit enough, and if we are to venture to disregard them, as Kuno Fischer has done, it can only be because on such a question the opinion of the author himself is perhaps not wholly trustworthy, or at all events ought not to be allowed to overbalance the evidence derived from a comparison of the editions. Such a comparison Dr. Mahaffy himself undertakes, and is thereby led to the conclusion that Kant's own judgment was right, and that of his critics was wrong. On the whole, it may be conceded that Dr. Mahaffy makes out his case, but even he would probably allow that the general tendency of the second edition is to accentuate Kant's avoidance of the idealistic position, and to effect, by a not too successful criticism of Berkeley, a reconciliation with the realistic position. Such a tendency is undoubtedly absent in the first edition. Indeed, Dr. Mahaffy admits, in a note on p. 23, that "it may be that Kant was somewhat frightened at the charge of Berkeleianism"; and the history of the controversy on this point given by Dr. Stirling in the eighth volume of *Mind* entirely confirms the opinion that in some fashion the effect produced by the first edition was one which Kant set himself to alter.

One of the important passages is, of course, the "Refutation of Idealism," which, although it was not wholly new, but had already been outlined in the first edition among the "paralogisms," still deserved the attention which the German critics gave to it because of the new position and importance which it assumed in the revised version. Is it the case, as the Idealists assumed, that the intimations of the inner sense (internal experience) are more trustworthy than the intimations of the outer sense (external experience)? May we rightly argue from sensations to the percipient who is the subject of the sensations, although we are debarred from arguing from sensations to the "matter" or external object to which the sensations are referred as their cause? According to the "Refutation of Idealism," Berkeley is clearly wrong: both inner sense and outer sense have precisely the same validity, inasmuch as both yield us "phenomena" of the same value: while it is also suggested that were it not for the *permanent* object of sensation, no sense of change, no sequence in the intimations of the inner sense, would be possible at all. Dr. Mahaffy devotes a chapter (chap. xiv.) to the discussion of this question, and we venture to think that there is no part of his work which more deserves an attentive perusal. We would especially point to the passages in which he discusses the precise meaning of Kant's principle of permanence (pp. 212 *et seq.*). Berkeley's polemic against matter was a disproof of the supposed substratum of qualities. But, according to Kant, Berkeley confused matter as a substratum of qualities with matter as a thing *per se*. No doubt we can never prove the existence of matter as a thing *per se*. On the other hand, the notion of a substratum is necessary in our knowledge in order to account for that permanence without which there would be for us no real world at all. This permanent substratum is itself *phenomenal*, because we can form no notion of permanence *except in space*, and space is a form of sensible intuition. Hence Kant would be the last to sanction any speculations on the permanence of unknown things *per se*: he is no materialist in the vulgar sense of the word; but he is, to the extent above explained, a problematical realist, in so far as he accepts the necessary principle of a permanent phenomenal substratum. If we further ask, Whence do we obtain this notion of permanence? Kant answers that we derive it "from the fact that all our experience is comprised in one time, which time cannot be perceived in itself, but only when occupied by some perception. Hence we infer the permanence of the matter of experience, of phenomenal substance, the changing states of which correspond to the various portions of changing time comprised in the one great complex of time. Thus we represent to ourselves the permanent, even though we have no permanent representation; and as an empirical criterion of this permanence in time, we use impenetrability, or modes of resistance in space" (p. 213).

Kant was, however, not content with merely indicating the equal authority of external experience as compared with internal experience. He advances to a still bolder position. While both external and internal experience, although they can give us no information concerning, objects *per se*, are equally immediate and equally certain Kant thinks that it can also be proved that in some respects external experience is the more important of the two. For internal experience is, after all, only possible if we presuppose external experience. Internal experience is subject to the form of time; it is made up of changing modes of consciousness. But change can only be understood if we already have the notion of permanence ("only the permanent can change," says Kant), and the notion of permanence is to be found in that permanent substratum which underlies all our external experience. Hence it is so little true that internal experience is more certain than external that the reverse is almost the case. Without external experience there would be for us no possibility of internal. Where Kant's critics have generally gone wrong is in assuming that where Kant speaks of a permanent substratum he means a thing *per se*. But this is not the case. What he means is a phenomenal substratum, the non-recognition of which is the fatal error of Berkeley.

We have spent so much time and space over this point that we have left ourselves but little opportunity to speak of others. But we do not think we are wrong in assuming it as the point of capital importance in Dr. Mahaffy's new edition, especially as it is at once the most original and the most effective part of his polemic against Kuno Fischer and other German critics. But there are many other features which deserve attention, although we can do no more than refer to them. We would especially direct the reader to the following. Let him observe Dr. Mahaffy's clear explanations of Kant's passage from the ordinary table of logical judgment to that of the categories (pp. 80 *et seq.*), his treatment of the categories themselves (pp. 88 *et seq.*), as well as his vindication of Kant against Mansel, Fichte, and other critics of the categories (pp. 100 *et seq.*). Chapter vii., on the deduction of the categories, is an important one, especially as it compares the "Prolegomena" with the "Kritik." If Dr. Mahaffy has not been able to bring into clearer light the difficult and unsatisfactory treatment which Kant has given to his principle of causality (pp. 180 *et seq.*), he at all events has effectively criticized Schopenhauer's carpings at the Kantian categories and schemata (pp. 151 *et seq.*). Mr. Bernard's contributions to the commentary begin with chapter xvii., and deal with Kant's "Dialectic of the Pure Reason," but we believe that for most students the chief interest of this new edition will be found to be concentrated in the commentary on the "Analytic." It should be added that the second volume is a translation of Kant's "Prolegomena," and contains also, in the appendix, the suppressed passages of the first edition of the "Kritik." The whole edition forms a striking and valuable version of the logical views of Kant, and we can imagine no more helpful text-book both for older and younger students of Kant's immortal "Kritik." W. L. COURTNEY.

OUR BOOK SHELF.

Monograph of the Marine and Fresh-water Ostracoda of the North Atlantic and of North-Western Europe. By Dr. G. S. Brady and Rev. A. M. Norman. (London: Williams and Norgate, 1889.)

ABOUT twenty-one years ago Dr. G. S. Brady published, in the Transactions of the Linnean Society of London, a monograph of recent British Ostracoda. The present monograph is to some extent a supplement to the former one, but as it embraces the description of the forms belonging to a greatly extended area, it may be regarded in the light of a new work, in the publication of which the authors have been ably assisted by the contributions of most of those zoologists interested in this group of Crustacea. The present memoir deals only with the section of the Podocopa. The geographical area embraces the Arctic Seas, the North Atlantic Ocean, and North-Western Europe. The North Atlantic area is fixed at 35° N., thus excluding the tropical species of the West Indies and the Gulf of Mexico; the Mediterranean is not included, as the doing so would have too greatly extended the limits of the work; and the North-Western European area embraces Austria, Germany, France, Belgium, Holland, Denmark, Scandinavia, and the British Islands. The distribution of the living species, as far as known, is recorded. One hundred and eighty-eight species inhabiting salt water are recorded, and sixty-one fresh-water forms, and yet it is certain that the record is still very incomplete. While the marine species of Norway and Sweden have been in part studied, little has been done with respect to the marine species of Denmark and Germany. The knowledge of the Dutch marine forms has been derived from some dredgings in the Rivers Maas and Scheldt. Those of the Belgian and French coasts are also but little known, and the same may be said of the truly Arctic species, while nothing is known of the forms inhabiting the coasts of the United States or Canada.

The fresh-water Ostracods of Norway and Sweden have been more or less investigated by G. O. Sars and Lilljeborg; in Denmark by no one since the time of O. F. Müller (1785); in Holland not at all; in Belgium only by Plateau: in Germany by Koch, W. Müller, and Zaddach, whose type species were very generously intrusted to Brady and Norman by Prof. Seeliger, of Königsberg. In France, the species have only quite recently been investigated by Moniez. Those of Great Britain are the only ones at all extensively worked out.

This monograph, which consists of 200 quarto pages, is illustrated with fifteen plates, and is published as Part II. of the fourth volume of the Transactions of the Royal Dublin Society.

The Harpur Euclid. Books I.—IV. By E. M. Langley and W. S. Phillips. (London: Rivington, 1889.)

THIS is an edition of the "Elements" "revised in accordance with the Reports of the Cambridge Board of Mathematical Studies, and the Oxford Board of the Faculty of Natural Science." The favourable impression made upon us by the two previous instalments of Books I. and II. is thoroughly confirmed by the additional matter now before us. We are not going to say that it is the best edition we have seen, for lately we have had under our notice two or three excellent works on much the same lines, but it is certainly not inferior to any of these, whilst for the arrangement of the text, the variety of type, and boldness and *correctness* of the figures, it is admirably adapted for school purposes. The editors, following on the lines of Mackay's interesting edition, have supplied ample store of illustration and historical matter, which will render the study of "Euclid" interesting to the intelligent boy. Not content with embracing within their net an account of Simson's line and the nine-point circle, Mr. Langley, in an article on the principal circles of a triangle, has given an excellent though brief description of the properties of symmedian lines and of the Brocard, cosine, and other modern circles, thus bringing the teaching of these circles within the range of the school curriculum. The exercises now reach the respectable total of 677, and to many of them useful hints for their solution are appended. We await the completion of the authors' task with interest, for a good work on elementary solid geometry is not altogether superseded by Nixon's admirable manual.

An Elementary Treatise on Mechanics. Part I. Statics. By Rev. J. Warren. (London: Longmans, Green, and Co., 1889.)

THIS is an elementary treatise intended for the use of schools and University students. The arrangement and methods of reasoning are best adapted for students who have made some acquaintance with trigonometry. At the same time a considerable portion of the book may be read by those students not possessing such mathematical knowledge. Each chapter contains a good selection of examples, some of which are worked out. This feature, together with the fact that the various theorems and results are very clearly established, will help to render the book a useful one. An experimental proof only is given of the parallelogram of forces, other proofs of which will be found in the second part of the work, which is devoted to dynamics. G. A. B.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Earlier Eruptions of Krakatão.

AT the time when a Committee of the Royal Society entrusted me with the preparation of a sketch of the geological facts bearing upon the great volcanic eruption of Krakatão in 1883, I was quite unaware that any reliable records concerning the early history of the East Indian Archipelago were in existence. I stated, therefore, that authentic history commenced only about three centuries ago, when the district began to be visited by the Dutch and Portuguese navigators; and that the earliest eruption of which we have any detailed account was that of 1680, described by Vogel and Hesse.[1]

At the same time, however, I pointed out that the study of the geological structure of the district—so well described by Mr. Verbeek and by MM. Bréon and Korthals—especially when that structure was considered in the light afforded by other volcanic areas that have been investigated by vulcanologists, led to very definite conclusions as to what must have been the early history of the great volcano.

It was shown that Krakatão is situated on a fissure traversing the Sunda Strait and running at right angles to the great band of volcanic activity which traverses the islands of Java and Sumatra; and it was inferred that at a very early period a volcano of great height and bulk was built up at the point marking the intersection of the two lines of fissure; it was then stated that—

"At some unknown period this volcano became the scene of an eruption, or series of eruptions, which, judging from the effects they have produced, must have been on even a far grander scale than that which four years ago attracted so much interest. By these outbursts the whole central mass of the volcano seems to have been blown away, and only an irregular crater-ring left behind. The great crater thus formed must have had a diameter of three or four miles, and its highest portions could have risen but a few hundreds of feet above the present level of the sea."

After pointing out that this crater-ring became to a great extent filled up by a succession of smaller eruptions, I proceeded to say:—

"Whether the tract now constituting the Strait of Sunda was then dry land uniting the islands of Java and Sumatra, we have no means of determining; but I may point out that there are some grounds for believing that the formation of the depression occupied by the straits was subsequent to the evisceration of the volcano."

After stating what these grounds are, I added:—

"It seems not improbable that the depression between the islands of Java and Sumatra may have resulted from subsidences accompanying or following the ejections taking place at the great central volcanic focus of Krakatão" (*loc. cit.*, pp. 7–8).

I am greatly indebted to Mr. C. Baumgarten, of Batavia, who, through Dr. R. Rost, the Librarian to the India Office, has called my attention to some ancient records that seem to confirm, in a singularly striking manner, these conclusions arrived at by scientific reasoning.

Mr. Baumgarten writes as follows:—

"In a Javanese book called 'Pustaka Raja,' the 'Book of Kings,' containing the chronicles of the island, kept secret during centuries in the Royal Archives, and only recently made public, we find the following interesting and curious account of an eruption of the mountain Kapi:—

"'In the year 338 Saka [*i.e.* A.D. 416], a thundering noise was heard from the mountain Batuwara,[2] which was answered by a similar noise coming from the mountain Kapi, lying westward of the modern Bantam. A great glaring fire, which reached to the sky, came out of the last-named mountain; the whole world was greatly shaken, and violent thundering, accompanied by heavy rains and storms, took place; but not only did not this heavy rain extinguish the eruption of fire of the mountain Kapi, but it augmented the fire; the noise was fearful, at last the mountain Kapi with a tremendous roar burst into pieces and sunk into the deepest of the earth. The water of the sea rose and inundated the land. The country to the east of the mountain Batuwara, to the mountain Kamula,[3] and westward to the mountain Raja Basa,[4] was inundated by the sea; the inhabitants of the northern part of the Sunda country to the mountain Raja Basa were drowned and swept away with all their property.

"'After the water subsided the mountain Kapi and the surrounding land became sea and the Island of Java[5] divided into two parts.

[1] "The Eruption of Krakatão and Subsequent Phenomena," Report of the Krakatão Committee of the Royal Society (1888).

[2] "Now called Pulosari, one of the extinct volcanoes in Bantam, and the nearest to the Straits of Sunda."

[3] "Now called the 'Gedé' mountain."

[4] "The most southern volcano of Sumatra, and situate in the 'Lampung' country."

[5] "The Sanskrit *Yawa-dwipa.*"

"'The city of Samaskuta, which was situate in the interior of Sumatra, became sea, the water of which was very clear, and which was afterwards called the lake Sinkara.[1] This is the origin of the separation of Sumatra and Java.'"[2]

Whether we are justified in accepting this date (A.D. 416) as that at which the very grand eruption of Krakatão, and the accompanying subsidence which led to the separation of Java and Sumatra, actually took place, I am not prepared to say. It may be that, as in many similar cases, the floating traditions of a grand catastrophe attached themselves to a subsequent event of a similar character. It is certainly very interesting to learn, however, that in the fifth century very grand volcanic outbursts were taking place in the district in question; and that a belief existed in the former connection of the islands of Java and Sumatra. Nor is it unimportant to discover that tradition is in complete harmony with scientific reasoning in assigning the separation of the two islands to actions occurring concurrently with great volcanic outbursts.

In concluding this note, I must express my great obligations to Mr. Baumgarten and Dr. Rost for bringing these important records under my notice. JOHN W. JUDD.

On some Effects of Lightning.

PROF. MCMILLAN'S interesting letter in NATURE of July 25 (p. 295) contains some minute details of the effects of a lightning-stroke on a house near Calcutta, on June 8 last. I agree with the writer that such cases are of value to electrical science, especially when reported by a competent observer. In Prof. McMillan's excellent letter there is one word to which I object, and that is "vagaries," as applied to electricity at high potential. When lightning enters a house, it is as much subject to law as when it flashes from the cloud to the earth, and does not behave with the whim, caprice, or freak implied by the word "vagary." In the absence of continuous conductors, the electrical discharge drags into its path light, conducting substances, which assist its progress, and by means of which it can strike through considerable distances and in various directions, as in the case before us. As to the effect of the discharge on the air of the house, Mr. McMillan appears to have made a real advance towards the solution of a difficult problem—namely, What is the origin of the powerful odour produced by a lightning-discharge within an inclosed space, such as a room or a ship? In most cases, the odour is compared to that of burning sulphur—"the ship seemed to be nothing but sulphur," was entered in the log of the *Montague*, after having been struck by lightning. Now as far back as 1785, Cavendish's famous experiment proved that electrical discharges in a confined mass of air lead to the formation of nitric acid, and Liebig found that acid in seventeen samples of rain-water collected during thunder-storms. Nevertheless, with these facts before him, Snow Harris wrote: "From whence this odour arises is still an interesting problem in physics," and he declines to discuss "those chemical views which some able philosophers have entertained of the nature of the odour emitted." Arago also states that the odour is generally compared to that of burning sulphur; but he adds: "others compare it to phosphorus, others to nitrous gas"; and significantly remarks: "L'odeur de gaz nitreux serait le plus facile à expliquer." Now, Prof. McMillan has shown that nitrogen teroxide, more or less diluted with air, was sufficient in the case so ably reported by him, to account for the colour and odour of the atmosphere produced within the house by the electric discharge. "The whole house seemed to be filled with an orange-coloured gas, mixed with clouds of dust affecting the breathing like fumes of burning sulphur," is the description given by the occupier of the house.

Another point of interest in this valuable communication is the introduction of ball-lightning. Arago is sceptical as to the existence of ball-lightning (*éclairs en boule*), or that which moves through the air at a comparatively slow rate, appearing like a luminous ball or globe of fire. Faraday is also equally sceptical. But the well-attested cases of what we name ball-lightning, and the Germans *Kugelblitz*, are so numerous that they can no longer be termed, in Arago's language, "a stumbling-block (*pierre d'achoppement*) for meteorologists." Snow Harris properly describes these luminous balls as a kind of brush or glow discharge. In the well-known case of the *Montague*, the luminous ball was seen rolling on the surface of the water towards the ship from to windward; evidently a brush discharge, or St. Elmo's fire, produced by some of the polarized atmospheric particles, yielding up their electricity to the surface of the water. On nearing the ship, the point of discharge became transferred to the head of the mast, and, the striking distance being thus diminished, the whole system returned to its normal state—that is to say, a disruptive discharge ensued between the sea and the clouds, producing the usual phenomena of thunder and lightning, described by the observers as "the rising of the ball through the mast of the ship." In Prof. McMillan's case I do not understand his remark that "no second ball was seen to enter from the opposite side to meet the first, and so produce the apparent explosion." Surely a second ball was not necessary to produce the effect described—namely, "an intensely brilliant ball of yellow fire, about 6 or 7 inches in diameter, which passed from one end of the room to the other at a pace just sufficiently slow to allow it to be readily followed by the eye: it appeared to be momentarily checked, then burst with a deafening report, which shook the whole house." In other words, it passed from a brush into a disruptive discharge.

Lastly, we have another remarkable confirmation of the fact that a lightning-conductor does not afford protection to surrounding objects. According to the French theory, a lightning-rod affords protection over a circle equal to twice its radius. But there are numerous cases to prove that no such radius of protection exists. The *Endymion* frigate, at Calcutta, in March 1842, was furnished with a chain conductor on the mainmast, but the lightning struck the foremast, shivered the topgallant and topmast, and damaged the lower mast. The mast struck was not above 50 feet from the mainmast. A somewhat similar accident happened to the *Etna* in Corfu, in January 1830. So also in the case that excited so much discussion at the time, the Board-house at Purfleet was struck on May 12, 1777, at a point about 40 feet from the conductor. A similar case occurred at the Poor-house at Heckingham in June 1781. So also in the recent Calcutta case, there was a conductor at one end of the building, projecting 8 or 9 feet above the roof-level. But the lightning entered the house by an iron-covered hatchway, 70 feet from the conductor, and near to a shell factory, which bristled with conductors.

Prof. McMillan properly attaches great value to such cases as the one he reports, leading as they do to the conditions which should govern the protection of buildings. In the course of a long experience, I have noticed that the profession which should be the best instructed on the subject, is—I hope I may say was—the worst. When the new buildings for the Cholmeley School at Highgate were being erected, the head master consulted me as to the erection of a lightning conductor, and asked me to see the architect. That gentleman called on me and said, "We never put up these things; we don't approve of them. I never erected one in my life, and don't know how." I once visited a church in Rutlandshire, that had been restored by Sir Gilbert Scott. The rector took me to one of the gable ends, and said, "You see, we have a lightning conductor, properly insulated by means of glass rings." I replied that on visiting the granite lighthouse at the end of the Plymouth breakwater, I noticed that Faraday, in fixing a lightning conductor, had caused a spiral groove to be cut inside the shaft from top to bottom, for the insertion of a massive copper band, so as to make the conductor an integral part of the building. Snow Harris's method of protecting a ship applies also to a building. At whatever part of the ship or building the lightning may strike, it ought to find an easy metallic path to the sea, or to the earth. The late Prof. Clerk Maxwell, writing to me as to the best method of securing a building, proposed to inclose it with a network of good conducting material, such as a copper wire, No. 4 British wire gauge, to be carried round the foundation of the house, up each of the corners and gables, and along the ridges. Further details would occupy too much space on the present occasion.

Highgate, N., August 1. C. TOMLINSON.

SOME weeks ago, two trees were struck by lightning near St. Albans, in Hertfordshire, the effects of which are most unusual. The two trees stood near each other in a wood called Symonds Hyde Wood. Assuming that the lightning struck downwards, it is easy to see in one case where the damage began—namely, at a place where a branch had by some means been broken off formerly, leaving a ragged break, into which no doubt water had soaked. Thence for some feet downward the effect was

[1] "The well-known Lake of the 'Menang-Kebo' country."
[2] See the "Krakatão Eruption and the Javanese Chronicles" in *Trübner's Record* for August 1889 (third series, vol. i. pt. 3).

apparently merely to split the bark in the usual way. But, at a height of about 20 feet from the ground (as I judged), something in the nature of an explosion must have taken place. Not only is the bark stripped absolutely clean off in large sheets from the level of the ground up to a height of about 30 feet, some of the sheets having been shot to a considerable distance, but where the explosion seems to have occurred, and for a considerable height above and below, the solid timber is burst open and broken into shivers, and the tree, which was a very fine one, is broken short across at the point where the greatest amount of splintering has taken place. Here, too, a considerable branch seems to have been wrenched off by the explosion.

The other tree is at a distance of perhaps 30 yards, and was, if anything, a still finer one. The appearances here are precisely similar, except that the lightning, which I imagine was conducted along the wet surface of the twigs and smaller branches at the top of the tree down to the junctions of the main branches with each other and the stem, here appears to have struck into the wood, tearing the bark up into rough filaments, which still remain attached to the surrounding bark. Most of this tearing occurs at the angles where the main branches join; but I noticed two places, each about the size of a five-shilling piece, each of which was at some distance above an angle. One such "bruise" appears also in the first-mentioned tree, some distance above the broken bough where the main body of the electricity appears to have entered. The "explosion" in the second tree was at a less height than that in the other.

It has been suggested that a good deal of the splintering may have been caused by the trees, weakened by the stroke, having been broken short off by the storm of wind which presumably raged at the time. I do not think this a probable explanation, for the following reasons. The trees are well within a considerable wood, where the effect of such a gale would not be fully felt, while the two tops are now lying almost at right angles to one another; not parallel as one would expect if the same gale of wind had overthrown them. It appears most probable that a violent explosion occurred, not exactly in the middle of the stem, but rather to the side remote from that to which the tops have fallen. I think it will be found that all the appearances agree with this explanation.

The destructive nature of the strokes cannot be adequately described by words: long splinters, of wedge-shaped section, are sticking up everywhere at the place of fracture, while many feet below it a pen-knife can be inserted easily in numbers of crevices which run up and into the stem along the radial lines which are always formed in the growth of oak timber, and which have here been split open.

Some black stains on the soil at the foot of the trees are pointed out as the effect of the "fire." It will be seen, however, that these are caused by the tannin in the oak sap staining the iron-impregnated clay soil.

I have seen numbers of lightning-struck trees, but have never seen anything to compare with these, and I much hope that some one, with more knowledge of lightning and its effects than I have, will take the train to St. Albans, with a photographic apparatus, and see and judge for himself, and give us some explanation. If he will write to my father (Rev. Dr. Griffith, Sandridge Vicarage, St. Albans, Herts), with a couple of days' notice or so, he will be happy to do all in his power to help, and will no doubt drive him to the spot.

Readers of NATURE may possibly remember a former letter of mine, written, if I recollect aright, in the autumn of 1879, describing a sparrow and her nest, flung out of a crevice in a chimney struck by lightning—the bird almost entirely plucked. The bird I placed in spirits, and deposited in the Cavendish Museum at Cambridge. The barking of these trees reminded me of the plucking of that bird.

A Brilliant Rainbow.

FROM the veranda of this Club, several of the members, including myself, have, within five minutes of the time of writing this (6.30 p.m.), witnessed a phenomenon the parallel to which we have never seen before—a most brilliant rainbow, the usual parallel reflection, and another rainbow *or* reflection quite as brilliant as the ordinary and usual reflection, at an angle which I sketched at the moment, but which, as I have no compasses, I cannot draw semicircular. The tide is out, and nothing but little puddles of sea are left.

E. BURTON DURHAM.

Alexandra Yacht Club, Southend-on-Sea, August 11.

THE 1851 COMMISSIONERS' ESTATE AT KENSINGTON.

A NEW light has been thrown upon the proposals of the Commissioners of 1851, to make grants for provincial Museums, and to found Scholarships of science and art, which were discussed in NATURE of July 18 (p. 265). As was then explained, the carrying out of these proposals would necessitate the sale of a considerable portion of the Commissioners' estate at Kensington Gore. We also showed that public protests had been raised during the last three months against any such sale; further, that State aid in co-operation with local effort has provided the country with a system of science and art Scholarships and grants for provincial institutions, and that the Commissioners are not in a position also to launch and administer a corresponding system of grants and Scholarships themselves, for the benefit of the country. But as the Commissioners have published a notification of their intention to proceed with their scheme, it is perhaps but natural that, when it is attacked, they should defend their position as ably as may be. The attack which has been made upon their scheme is twofold in character, but it aims chiefly at the preservation of the inner gardens of the estate from the degradation of being sold for and used as a common site for private houses, to the unavoidable detriment of the institutions upon the estate.

As regards the scheme for grants and Scholarships, Mr. Samuelson, M.P., gave notice of a question in the House of Commons to Sir Lyon Playfair, the gist of it being whether, in formulating their scheme, the Commissioners had examined, and taken account of, the scheme (identical in direction) which has been for years and is in operation under the Science and Art Department. Sir Lyon Playfair transferred the answering of this question to the Home Secretary, who stated accordingly that the Commissioners' scheme was being prepared, and would be printed in due course and laid before the House of Commons. Under these circumstances, we may postpone further remarks upon the Commissioners' grants and Scholarships scheme until it is printed in a complete form and submitted as promised.

In the meantime, however, we must take notice of another incident connected with the Commissioners and their proposals. On July 19, Mr. Bartley, M.P., gave notice of a question to be asked of Sir Lyon Playfair on July 22. The question was, whether Sir Lyon would, as a Commissioner of 1851, state the names of the different persons, public bodies, and institutions which had sent protests to the Commissioners for the Exhibition of 1851, against the proposed sale of part of the inner gardens of their estate at Kensington Gore for private buildings. Sir Lyon Playfair, however, was not in his place when the question should have come on on the 22nd. It was postponed to the 23rd; and when the printed notice paper for that day appeared, it was found that an arrangement had been made for the question to be answered, not by Sir Lyon Playfair, but by his brother Commissioner, the Home Secretary. The question was therefore asked of that Minister, and, before the answer to it could be given, Sir Lyon Playfair got up and asked whether the right hon. gentleman was aware that a deputation of the Mayors of nearly all the largest towns in England and Wales, representing a population of more than 3,000,000, had waited on the Commissioners to urge that the property in South Kensington should be sold and realized, in order to be applied to provincial Museums. Mr. Matthews replied to both the questions in one answer.

There had, he said, been protests from public bodies and towns against the sale of the estate, and it was also the case, as indicated in the question of Sir Lyon Playfair, that a deputation had waited on the Commissioners and urged the sale. The impression thus conveyed was, that the Commissioners had quite recently been between two fires, and had given way under the hottest. This would be a poor enough plight for a body of public men, who, up to within the last three or four years, had been consistent and strong enough to adhere to the main lines of a policy traced out for them in 1852, when they were charged with a public trust. But it is worse than a poor plight when considered, as it has to be, in conjunction with matured opinions and resolutions published by that same body of men in 1878.

The deputation to which Sir Lyon Playfair directed attention waited on the Commissioners, not, as was imagined, quite recently, but as long ago as 1877. The deputation was received at Marlborough House on June 20, 1877, and was headed by Mr. Chamberlain. The Prince of Wales made a very brief reply to it; and Lord Granville delivered a full exposition of the Commissioners' reasons for disagreeing with the views of the deputation. The deputation "proposed, as the best method of dealing with the Commissioners' trust: (1) the realization of the estate to as great an extent as possible; and (2) the application of the realized funds, in grants to provincial Museums for buildings, and for the purchase of suitable objects for exhibition therein." Amongst other statesmanlike views of their responsibilities towards their trust and to the public at large, Lord Granville, on behalf of the Commissioners, pointed to the importance, in the founding of provincial Museums, of voluntary subscriptions, and to the "danger of stopping the flow of them if you [the deputation] get a great central body supplying everything. There is the consideration how far even a large sum would go." The possibility of realizing a portion of the estate was mentioned; but it should be clearly stated that that portion of the estate was a site lying to the *south* of the present Imperial Institute. No portion of the inner gardens, upon which the Albert Hall abuts, was to be put up for sale.

It will be useful to now give extracts from the Sixth Report of the Commissioners published in 1878, shortly after the deputation above referred to had waited on them.

"The claim of the provincial towns to share in the application of our funds was supported by two considerations. In the first place, it was said that the support which enabled the Exhibition of 1851 to be held was obtained, to a large extent, from our great manufacturing centres. As a fact, the metropolis subscribed £35,108 16*s.* 11*d.*, and the provinces £34,057 12*s.* 8*d.* The second consideration urged was the difficulty which is felt in provincial towns in raising, by means of rates, amounts adequate to meet the expenses of building and maintaining scientific museums and galleries of art.

"That we are not insensible to the claims of the provinces to a share of the benefits to be derived from the resources at our command will be seen from the resolutions at which we have arrived, but as to the form in which such benefit should accrue we hold different views from those expressed by the deputation. In the first place, we consider that the proposal to capitalize the whole of our property cannot be entertained, because, apart from all other reasons, it is sufficient for our present purpose to observe that it would clearly be at variance with the appropriation of the land originally contemplated, and a reversal of the whole past policy of our body.[1]

"The object with which, under the guidance of the Prince Consort, we purchased the estate was to provide a remedy for the want so often felt in this country of an extensive site for the development of great institutions for the promotion of industrial art and science amongst the manufacturing population. The South Kensington Museum and the Museum of Natural History are two great monuments of the prudence of the course adopted, and, so long as the wants of technical education are so inefficiently provided for in this country as they are at present, we think that we ought to keep in our hands the means of meeting the possible requirements of institutions for that purpose. . . .

"The suggestion that the resources at our command might be applied to the promotion of local Museums of Science and Art, by grants in aid of buildings or collections of suitable objects, had received our full consideration before the deputation of provincial municipal representatives, already referred to, pressed this course upon us. The establishment of local Museums is an object which has long commended itself to us. In the original scheme, drawn up in the year 1868, for the series of annual International Exhibitions, it was proposed that 'a sum of money might be annually devoted to make purchases of remarkable objects, which might be sent to local Museums throughout the country.' If this scheme had proved permanently successful, we might have been able to supply, by degrees, each of the principal centres of industry with collections of objects illustrating the manufactures in which they are chiefly interested. But, in the present condition of our trust, we see several objections to the promotion of local institutions as a method of applying our resources. Firstly, the amount of the funds at our disposal is very limited, as compared with the numerous demands which might legitimately be made upon us in case we announced our readiness to make grants in favour of local institutions. Secondly, we fear the risk that the knowledge that a central body was ready with funds to assist local objects would have the effect of decreasing rather than stimulating private local subscriptions, and of producing a lukewarmness in local efforts which would far more than counterbalance the moderate amount of assistance which a share of our funds would provide. Thirdly, and chiefly, it is evident that such grants, while exhausting our funds, would result in mere temporary help to science and art."

The above extracts relate to the deputation to which Sir Lyon Playfair has drawn attention, and upon whose views, very distinctly controverted by the Commissioners, he seems to rely for justification in setting aside the protests made within the last three months against a sale such as the Commissioners have been opposed to.

It is therefore difficult to escape from some such conclusion as this: that the projected sale of the inner gardens of the estate for private building speculations will be an autocratic act utterly ruinous to the character of the Commissioners; and that the Commissioners persist in defending and urging this act by pleas and arguments stoutly opposed by themselves twelve years ago.

[1] "The following is an extract from our Second Report, dated in 1852:—'A large number of suggestions and applications, in reference to the d.sposal of the surplus, have been made to the Commissioners. . . . The answer which the Commissioners have returned to the different applications submitted to them has been to show, by reference to their preliminary Report to Her Majesty, of the 6th of November of last year, that they do not feel themselves to be in a position to comply with proposals which involve the surplus being applied to purposes of a limited, partial, or local character, or to returning to the different localities, in order to be there appropriated to local public objects connected with the progress of art, science, and education, the amount of subscriptions originally raised in each place, which subscriptions were at the time made on the clear understanding that they must be "absolute and definite." The Commissioners would call especial attention to the memorials from the important manufacturing and commercial towns of Birmingham, Bristol, Halifax, Hull, Oldham, Sheffield, and the Staffordshire Potteries, which are appended to this Report, and indicate clearly the strong feeling entertained by those well entitled to form an opinion on this subject, of the importance of establishments for instructing those engaged in trade and manufacture in the principles of science and art on which their respective industries depend.' The towns mentioned presented memorials praying for the establishment of a Central Institution of Arts and Manufactures."

THE INTERNATIONAL CHEMICAL CONGRESS.

AN International Chemical Congress has just been held in Paris under the presidency of M. Berthelot. The Congress was composed of some 300 members, including the most eminent French chemists, and a certain number of distinguished foreigners. It was much regretted that foreign countries should not have been more numerously represented, and it was explained that owing to the protracted illness of M. Hanriot, Secretary of the Paris Chemical Society and of the Congress, the invitations were not sent out till very late, and still further delay was caused by their passage through the Ministry of Public Instruction. Much credit is due to M. Fauconnier, who undertook to replace M. Hanriot at the last moment.

The opening meeting was held on the 29th ult. at the Conservatoire des Arts et Métiers, the proceedings being of a purely formal character. M. Berthelot, who occupied the chair, said that a large number of communications had been received by the organizing Committee, and that from the nature of these communications it had been found expedient to divide the Congress into four Sections, which he proceeded to enumerate, together with the list of Sectional Presidents and Secretaries proposed by the Committee :—

Section I. Analysis of Food-Products : President, M. Riche ; Secretary, M. Bishop.

Section II. Analysis of Agricultural Products : President, M. Joulie ; Secretary, M. Demoussy.

Section III. Analysis of Pharmaceutical Products : President, M. Petit ; Secretary, M. Bocquillon.

Section IV. Unification of Chemical Nomenclature : President, M. Friedel ; Secretary, M. Bouveault.

The Sectional meetings took place in the day-time ; the evenings of July 30, August 1, 2, and 3, being reserved for the discussion of the reports presented by the various Sections.

Section I.—The Section discussed a certain number of methods used in the analysis of flour, bread, wine, coffee, &c. At the general meeting the following resolutions were passed :—

(1) That the Government be requested to inspect regularly the factories of salted meats, as at present the brines used are added to constantly, but never changed (report by M. Combes).

(2) That the Government be requested to inspect all teas on their entry into France.

(3) That not more than 0·3 per cent. of lead should be permitted in the alloy used for "tinning," nor more than 5 per cent. in the alloy for tin vessels.

(4) That it is desirable that the methods of wine analysis should be verified and codified.

Section II.—After discussion of the methods at present in use for the analysis of earths, manures, &c., it was resolved that in the case of judicial disputes no single method should in any case be obligatory,[1] but that the fullest latitude should be allowed to the experts.

Section III.—It was resolved that a certain number of permanent Commissions should be appointed for the inspection of some of the most important substances used in pharmacy—quinine, morphine, chloroform, phenol, salicylic acid, analgesine, &c. The Commissions should endeavour to investigate and improve the methods of analysis used for these substances.

Section IV.—Section IV. was the one of by far the greatest general interest, as was testified by the presence of Profs. Alexeieff (Kiew), Calderon (Madrid), Franchimont (Leyden), Graebe (Geneva), Istrati (Bucharest), Noelting (Mulhouse), Boukowski Bey (Constantinople), and Colonel da Luz (Rio Janeiro), who were elected Vice-Presidents.

[1] The Comité Consultatif des Stations Agronomiques et des Laboratoires Agricoles has issued a code of the methods of analysis of manures, and these are at present obligatory.

The following is a short account of the discussions held at the Sectional meetings :—

The Nomenclature of Unsaturated Hydrocarbons.—M. Calderon read a paper, in which he proposed to replace the present arbitrary names of the hydrocarbons by a series of names derived from the fundamental terms of each series. He proposes to name paraffins, *proto-methane*, *deuto-methane*, &c., the olefines *deuto-ethylene*, *trito-ethylene*, &c. The radicles are derived from the hydrocarbons by the insertion of Latin numerals between the Greek numeral and the generic name ; thus, methyl becomes *proto-uni-methane*, &c. The author advocated these changes as calculated to facilitate the teaching of organic chemistry.—MM. Friedel, Grimaux, Graebe, and Maquenne expressed the view that it was impossible to make changes so radical, and that Hofmann's nomenclature was quite sufficient so far as the normal hydrocarbons are concerned.

M. Béhal presented a report to the Section on a system for the nomenclature of complex open-chain compounds. He regards them as formed by the addition of characteristic groups (*groupements fonctionnels*),[1] in which certain atoms of hydrogen are replaced by various radicles. These radicles are given in the order of the number of carbon atoms they contain, starting with the lowest. To denote different isomers the Greek letters, α, β, γ, δ, are employed. One or two examples may be given. The body

$$CH_3{-}CO{-}C{\equiv}C{-}CH_2{-}CHO$$

would be called acetyl-acetylene-ethaldehyde (acétyl-acétylène aldéhyde éthylique). The body

$$\begin{matrix} CH_3{-}CH_2{-}CO\diagdown & & \diagup COOH \\ & C{=}C{=}C & \\ CH_3{-}CO\diagup & & \diagdown CH_3 \end{matrix}$$

would be called acetyl propionyl allene[2] methyl formic acid.—Many objections were raised to M. Béhal's proposition by MM, Friedel, Graebe, Grimaux, and others, and it was finally decided to refer it to the Permanent Committee.

Derivatives of Ethylene and Urea.—M. Graebe proposed to denote the two atoms of carbon in ethylene derivatives, united by the double bond, by the letters *a* and *b*. If two similar radicles are introduced into the ethylene molecule, as, for example, in dimethyl ethylene, the two isomers would be called *ab*-dimethyl ethylene and dimethyl ethylene, or for greater clearness *a*-dimethyl ethylene. In the case of trisubstituted compounds it should be understood that the first two radicles were linked to the same carbon atom.—M. Franchimont proposed to adopt the same nomenclature for the urea derivatives. —Attention was drawn to the possibility of new isomers, if Wislicenus's extension of the Van 't Hoff-Lebel hypothesis should be proved to be of general application, but it was decided for the present not to number the four atoms of hydrogen in ethylene, and M. Graebe's proposition and M. Franchimont's rider were adopted.

Aldehydes.—M. Grimaux proposed a resolution recommending that in future aldehydes should be named after the corresponding alcohols, and not after the acids. He pointed out that this usage was consistent with the etymological origin of the word, and that the practice of giving the same name to alcohols and their corresponding acids would give rise to confusion in the names of the acid and hydrocarbon radicles which they contain ; the names corresponding to ethyl and acetyl, to benzyl and benzoyl, would become identical if we used the names

[1] In France the word function is used in the following sense. Methyl alcohol gives rise by substitution to compounds whose chemical behaviour is similar to its own, and are therefore said to have the same chemical *function*. The group $CH_2 . OH$ is thus characteristic of the *primary alcohol function* ; similarly, the group $C{=}C$ of the ethylene function, the group $H . C{=}O$ of the aldehyde function, &c., &c.

[2] Or isoallylene.

ethylic alcohol, ethylic acid, benzoic alcohol, benzoic acid. —M. Grimaux's proposition was adopted.

The Use of the Prefixes bi- and di-.—M. Bouveault proposed, in the name of M. Hanriot, that the prefix *bi* should be reserved for the denomination of bodies formed by the duplication of organic radicles; the words dipropargyl, diphenyl, dinaphthyl to be replaced by bipropargyl, biphenyl, binaphthyl.[1] M. Maquenne preferred to use *di* instead of *bi* for these double radicles; but it was pointed out that there were only about twelve bodies whose names would need to be changed to be in harmony with M. Hanriot's proposition, whereas the converse proposition would be much more difficult of adoption.—M. Grimaux thought that in any case it would be difficult to alter existing nomenclature at once, but proposed that the Congress should express a wish that M. Hanriot's system of nomenclature should be adopted for all new bodies, and should gradually replace the existing one.—M. Grimaux's modification of M. Hanriot's proposition was adopted.

The Use of the Suffix -ol.—M. Grimaux proposed that the suffix *-ol* should be restricted as far as possible to the alcohols, and that the names of all hydrocarbons should contain the letter *n*. He proposed that the ending *-ene* employed by English chemists, should be made use of for the aromatic hydrocarbons. *Benzine* and *naphtaline* in French, *benzol* in German, would be replaced by the English terms benzene and naphthalene.—M. Graebe warmly supported this proposition, and further suggested the abbreviation of naphthalene to *naphthene.*—M. Grimaux's proposition was adopted.

Ketones.—M. Friedel pointed out the ambiguity which exists in the French nomenclature of the acetones. Dimethyl acetone might mean either the body $CO(CH_3)_2$ or else $CH_3-CH_2-CO-CH_2-CH_3$ (or its isomer). He proposed to adopt the German notation for these bodies, and in general to replace the word *carbonyl* by the word *cetone* (this form being more adapted to the French language than ketone). Dimethyl cetone is then ordinary acetone. —The proposition was adopted.

The Group —C☰N.—M. Bouveault proposed to name this group *carbazil.*—M. Calderon and other members of the Congress were in favour of this name. It was also proposed to use the word *nitrile* universally.—M. Grimaux then pointed out that, as we made no distinction of nomenclature between the molecule and the half-molecule of chlorine, it would be unnecessary to do so in the case of cyanogen, and he proposed that the group —C☰N be denoted by the name cyanogen.—M. Grimaux's proposition was adopted.

The Sulphur Compounds.—M. Chabrié read a report on the sulphur compounds. He complained that a certain number of chemists used the term *sulphine* for compounds containing no oxygen, and which should properly be termed sulphides. He proposed that the name sulphine should be reserved for compounds of the formula $(SO)R_2$, sulphones for compounds $(SO_2)R_2$, derived respectively from sulphurous and sulphuric acids. This nomenclature is used by Beilstein in his invaluable compilation. It is naturally applicable to corresponding selenium and tellurium compounds.—It was decided to refer M. Chabrié's report to the Permanent Committee.

Ring Formulæ containing Nitrogen.—M. Bouveault read a long report on the subject. He proposed to adopt Widmann's nomenclature, with certain modifications in the details.—A protracted discussion ensued, and finally M. Graebe proposed that M. Bouveault's report should be printed and widely distributed, so as to elicit the opinion of all the chemists who had specially devoted themselves to the study of these compounds, and this was agreed to.[1]

Naphthalene.—M. Noelting read a report on the nomenclature of the naphthalene derivatives. He began by describing the various notations of Beilstein, Graebe and Noelting, Meldola, Weinberg, and the Swedish chemists. He proposed to denote the carbon atoms of the naphthalene ring by figures and to extend this system to anthracene, phenanthrene, &c. M. Noelting's proposal was adopted after discussion. The figures will be found below in the summary of the resolutions of the Congress. —It was agreed, on the suggestion of M. Auger, that when it was known that the radicles of a given di-substituted compound were in different rings, but their exact position was uncertain, they should be denoted by the symbol AB.

Benzene.—M. Combes read a report on the numeration of substituted benzene derivatives. He proposed to assign the place (1) to the hydrocarbon radicle containing the smallest number of atoms of carbon: in the absence of a hydrocarbon radicle he proposed to begin with the group having the lowest "molecular weight."—M. Combes gave as the reason for choosing the simplest hydrocarbon for the position (1) that it was this one which was generally attacked last by oxidizing agents.

M. Alexeieff pointed out that the oxidation of paracymene, $C_6H_4 . CH_3 . C_3H_7$, by the action of air and caustic soda, gives rise to cuminic acid, $C_6H_4 . CO_2H . C_3H_7$, and that in this case the position (1) would be changed, although there was no transposition in the molecule.[2]

M. Combe's report was referred to the Permanent Committee.

The general meeting for the discussion of the report of Section IV. was held under the presidency of M. Friedel, in the absence of M. Berthelot.

The following resolutions were adopted:—

(1) That an International Committee, with power to add to its number, be formed, whose object shall be to promote uniformity of chemical nomenclature.

The following gentlemen were nominated to serve on the Paris Committee:—MM. Berthelot, Friedel, Gautier, Grimaux, Jungfleisch, Béhal, Bouveault, Combes, Fauconnier.

That the Committee shall immediately request the following gentlemen to join them:—MM. Alexeieff (Russia), Armstrong (England), Baeyer (Germany), Beilstein (Russia), Boukowski Bey (Turkey), Calderon (Spain), Clève (Scandinavia), Franchimont (Holland), Graebe (Switzerland), Istrati (Roumania), Lieben (Austria-Hungary), Noelting (Germany), Paternò (Italy), Ira Remsen (United States).

(2) The two carbon atoms in ethylene, and the two hydrogen atoms in urea, shall be distinguished by the letters *a* and *b* (proposed by MM. Graebe and Franchimont).

(3) The aldehydes shall be named after their corresponding alcohols (proposed by M. Grimaux).

(4) The word carbonyl shall be replaced by the word cetone[3] (proposed by M. Friedel).

(5) The group —C☰N in organic compounds shall be called cyanogen, instead of nitrile (proposed by M. Grimaux).

(6) The suffix *-ol* shall be reserved as far as possible for alcohols. In the hydrocarbons it is to be replaced by the ending *-ene* (proposed by M. Grimaux).

(7) The prefix *bi-* shall in future be reserved for bodies formed by the union of two radicles such as biphenyl $(C_6H_5)_2$, bipropargyl $(C_3H_3)_2$, and the Congress expresses

[1] It may be mentioned that whereas in England the use of the prefix bi- has been almost entirely abandoned, in France it is still employed, though no rules for its use have hitherto been given; the terms *di-nitro benzine* and *benzine bi-nitré* denote the same body.

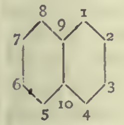
[1] The nomenclature of the pyridine and quinoleine derivatives agreed to by the Section was afterwards referred back to the Committee.

[2] It may be remarked that this difficulty is inherent to the case, since the oxidation of paracymene by chromic acid gives rise to paratoluic acid.

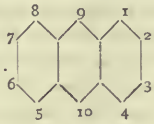
[3] This applies only to French nomenclature.

the desire that this nomenclature may be gradually adopted for bodies already known; the prefix *di-* to be used as at present, to denote bodies formed by double substitution (proposed by M. Hanriot).

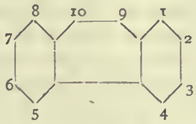
(8) The different carbon atoms of naphthalene anthracene, phenanthrene, fluorene, carbazol, acenaphthene, acridine, shall be numbered as follows:—



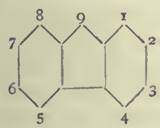
Naphthalene.



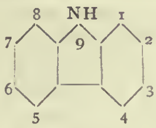
Anthracene.



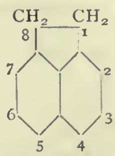
Phenanthrene.



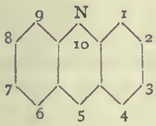
Fluorene.



Carbazol.



Acenaphthene.



Acridine.

(Proposed by M. Noelting.)

(9) The proposition to denote the carbon atoms of quinoleine by *α*, *β*, *γ* for the pyridine ring, and *o*, *m*, *p*, *a* (ortho, meta, para, ana) in the benzine ring,[1] which had been voted at the Sectional meeting, was adjourned by a vote of 42 against 26, and referred to the Permanent Committee.

After the carrying of the resolutions, M. Friedel made a short speech, in which he thanked especially the foreign members for their attendance and help. Some people might, he said, think that the Section had accomplished but little; that, however, was not his opinion: their aim had been to help workers in their work, and nothing could be more conducive to this aim than the use of the same language among the chemists of all countries. He felt sure that their efforts would prove fruitful in the future, and he hoped that by next year the International Committee would be able to report such serious progress as to justify the summoning of another Congress.

Thus terminated the formal proceedings of the Section and Congress, which had been marked throughout by the greatest good feeling among the *savants* of the various nations represented. On Sunday the Congress was brought to a final close by a banquet offered to the foreign members at the Terminus Hotel.

[1] Lellmann's notation.

THE REV. M. J. BERKELEY.

THE death of our great English mycologist has followed very close upon that of our great English lichenologist. Both of them were country clergymen of the Church of England, both were over eighty, and the career of both as botanical authors has extended over half a century.

The Rev. Myles Joseph Berkeley, M.A., F.R.S., was born at Biggin, in the parish of Oundle, in the year 1803. He was a descendant of the old historic family of that name. He was educated at Rugby, and at Christ's College, Cambridge, and graduated as fifth Senior Optime in the year 1825. After holding a curacy at Margate, he was appointed, in 1833, incumbent of two small parishes near Wansford, in his native county. Here he remained for thirty-five years, actively engaged in the performance of his parochial work. His stipend was small and his family large, and he had to supplement his clerical income by taking private pupils. This of course absorbed a great deal of his leisure, but his industry and force of character were so great that he got through, in addition, an enormous amount of scientific work. In 1868 he was appointed to the more valuable living of Sibbertoft, near Market Harborough, which he held until his death, on July 30. During the last ten years his health has failed, and in 1879 he presented his botanical collections to Kew, and, since that time, has published scarcely anything.

His attachment to botany must have begun very early in life, for I remember him saying, when we were speaking about a certain botanical examination, that he had not set any questions that he could not have answered when he was six years old. His friends thought he would have taken a higher degree at Cambridge if he had not given so much attention to natural history. His first book, "Gleanings of British Algæ," appeared in 1833. It deals mainly with minute microscopic types. The book which made his reputation was his "Monograph of the British Fungi," which forms the third volume of Hooker's "British Flora," published in 1836 This was the only hand-book of the British species in existence up to 1871, so that for thirty-five years it was the indispensable companion of every worker. The "Systema Mycologicum" of Fries, which summarized most ably all that was then known about genera and species, came out —the three volumes from 1821 to 1829, its "Supplement" in 1830, and the "Elenchus" in 1828; so that these were just in time to serve Berkeley as a foundation to build upon. From 1836 to 1870 he was the universal referee for everyone in this country who wanted information about fungi. Collections poured in upon him from home and abroad, and he described many thousands of genera and species, a large proportion of which were new, in Hooker's "Antarctic Floras," Hooker's *Journals of Botany*, the Transactions and Journal of the Linnean Society, and in the *Annals of Natural History*. During the latter part of the time he worked a great deal in conjunction with the late Mr. C. E. Broome, of Bath, who had abundant leisure and industry, combined with an unconquerable disinclination to publish on his own account, and in every Fungus-list "Berk. et Broome" is an often-quoted authority. Beginning with *Oidium Tuckeri*, he gave special attention to the fungoid pests of agriculture and horticulture; and it was, more than anything else, his papers on the potato disease that obtained for him the small pension that was granted to him during the last twenty years of his life. In 1857 he published a general "Introduction to Cryptogamic Botany," which has had a wide circulation. There has been no other book of a similar scope in the English language till this present year. His "Outlines of British Fungology," published in 1860, contains twenty-four plates, illustrating a series of about 150 typical forms. The text deals specially with the Hymenomycetes, and, for the other orders, does not go much beyond a catalogue of the British genera and species. His "Hand-book of the British Mosses," published in 1863, contains descriptions and plates of all the species then known in Britain. In the same year he was awarded the Biological Gold Medal of the Royal Society, of which he was elected a Fellow in 1879. But by this time his working days were over, and in that year he presented to Kew his entire fungus herbarium, followed, not long after, by his books. His herbarium contains specimens of upwards of 10,000 species, duly named and classified; and it has been estimated by Mr. G. E. Massee that it contains type specimens of 4866 species described by himself, and that the full number of new species which he described will not fall far short of 6000.

For many years he acted as one of the botanical examiners of the University of London, generally in conjunction with Sir J. D. Hooker and the late Dr. Thomson; and he acted also in the same capacity for the University of Cambridge and the Apothecaries' Company.

From the commencement of the *Gardener's Chronicle*, in 1841, till his health failed, he was a regular contributor to its pages. His most important papers were a series of articles on vegetable pathology, commenced in 1854 and continued at intervals till 1857. He also contributed a series of articles on the diseases of plants to the "Cyclopædia of Agriculture." He was one of the first to lay special stress upon the need for studying the full life-history of a fungus in order to understand it properly, the carrying out of which in the last generation has so completely changed many of our old ideas.

After the death of Lindley he acted for many years as botanical referee and general counsellor to the Royal Horticultural Society, a post for which he was well fitted, from his thorough knowledge of vegetable physiology and his acquaintance with practical gardening. It was in the Journal of this Society that his papers on the potato disease appeared. He was an excellent classical scholar, and read through all the proof-sheets of Bentham and Hooker's "Genera Plantarum," specially as linguistic critic. He was a man full of geniality, always willing to impart freely his wide store of information, and will be greatly missed by those that had the pleasure of his personal acquaintance. He had a commanding presence and a robust physique. His portrait, painted in oil by Peel in 1878, now hangs in the rooms of the Linnean Society, and a capital full-page engraving, by Mr. Worthington Smith, has twice appeared in the *Gardener's Chronicle*.

J. G. B.

NOTES.

We mentioned last week the *fêtes* in connection with the opening of the new Sorbonne, to which students from all the Universities of Europe had been invited. The following is a complete programme of the ten days' festivities—held under the auspices of the Association Générale des Étudiants de Paris—in which all the students of Paris, as well as their foreign guests, were invited to take part:—August 4, gala performance at the Opera. August 5, inauguration of the Sorbonne; reception by M. Fallières, Minister of Public Instruction. August 8, reception by the Municipality of Paris at the Hôtel de Ville. August 9, *matinée* at the Comédie Française; reception by M. Yves Guyot, Minister of Public Works; reception of the English and American students by M. Beljame, Professor of English at the Sorbonne. August 10, speeches by the chiefs of the foreign delegations; performance at the Gaîté Theatre. August 11, presentation of the chiefs of the foreign delegations to M. Carnot. August 12, ascent of the Eiffel Tower; excursion to Meudon; banquet on the terrace, under the presidency of M. Janssen. The *fêtes* have been throughout a magnificent success, and the students of all countries must carry away with them the most pleasant of remembrances of their French comrades. The Government and the City of Paris had voted a sum of about £3500 to the Association Générale des Étudiants, and it is to the organizing powers of the President, M. Chaumeton, and his devoted lieutenants, that the success of the meeting is due. At the Meudon banquet, at which there were nearly 2000 covers, M. Lavisse, Professor of Modern History at the Sorbonne, in an eloquent speech, declared that the principle of the future must be, not cosmopolitanism, but "*le respect de chaque patrie par toutes les patries.*"

The Congress of Physiological Psychology was held in Paris last week, and the meeting is considered to have been very successful. It was decided that a second meeting should be held in 1892, either in London or in Cambridge, during the month of August.

The Hygiene Congress at Paris brought its labours to a close on Saturday last. Among the subjects discussed during the week was that of the pollution of rivers. The Congress decided that the pollution of underground watercourses and of rivers by the residue of factories should in principle be forbidden, and that water from factories should not flow into a stream till it had been proved to be absolutely free from all injurious substances. The Congress was strongly of opinion that the most perfect method of purification was by irrigation. This, of course, must, in certain cases, be preceded by such mechanical and chemical processes as would render the water fit for agricultural purposes. It was related that many manufacturers had benefited by the application of the law, as in their efforts to prevent the pollution of watercourses they had made discoveries enabling them to utilize waste products. The difficulty was with the smaller manufacturers, who were not rich enough to take the necessary measures. The Congress decided that where persistent resistance was displayed the authorities should themselves execute the works prescribed for the purification of the water and compel the persons interested to pay the cost.

Arrangements are being made by the local committee of the American Association at Toronto for an excursion, starting September 3 or 4, to the Huronian district. Particulars will be given in a circular, which is to be issued by the American Geological Society. There will also be an excursion to the Pacific Coast.

Some time ago the Berlin Academy of Sciences received from Count Loubat, of New York, about £1150, with a request that a prize might be founded for the encouragement of North American studies. At the same time he sent £120, which was to be offered as a special prize. It has now been decided that a prize of £150 shall be awarded in July 1891, to the author of the best printed work on the settlement of civilized colonies in North America and their later history. The works to be submitted must have appeared between July 1, 1884, and July 1, 1889; and the authors must communicate to the Berlin Academy before July 1, 1890, their intention to compete. The language of the books may be German, English, French, or Dutch. In 1896 there will be another prize of similar amount for a work on the North American aborigines. Every five years a prize of £150 will be offered, the subjects being aboriginal and civilized history, chosen alternately. The money for the first of this series of prizes will be obtained by the addition of the special sum of £120 to the interest on the larger and permanent fund.

The Royal Danish Academy of Sciences invites research on the following among other subjects:—Compounds of alcohol radicals with copper, silver, or gold, and compounds of polyvalent alcohol radicals with metals (all unknown at present). Prize a gold medal. The fatty acids in the fat of butter; to be isolated and determined, and relations indicated especially between the quantities of oleic acid and those of palmitic acid and their higher homologues. Prize about £32. The Mycorhizæ of the beech. Are they different in different kinds of humus? Does the structure of the mycelium give a basis for classification? Is there a reciprocal symbiosis, the fungus preparing food for the plant, &c., &c. Prize about £32. Memoirs to be sent to Prof. Zeuthen, of Copenhagen, before October 31, 1890, except in the last case, for which the date is October 31, 1891.

The twelfth annual meeting of the Midland Union of Natural History Societies will be held at Oxford on the afternoon of Monday, September 23. An inaugural address, on heredity, will be delivered by the President, Mr. E. B. Poulton, F.R.S. This will be followed by a discussion, after which the meeting will transact all necessary business. In the evening there will be a *conversazione* in the Museum, and the Oxfordshire

Natural History Society and Field Club has arranged for exhibitions of objects of great interest. On the following day members will drive to Shotover Hill, and a lecture will be delivered by the President on "the geology of the district." Afterwards there will be a lunch in Christ Church dining hall. Special arrangements will be made for members to visit, on this and also on Monday afternoon, the following places:—Museum, Ashmolean Museum, Radcliffe Observatory, Botanic Gardens, Bodleian Library, and Clarendon Printing Press. The Oxford Society cordially invites members of natural history societies, and their friends, to the meetings of the Union; and no doubt so pleasant a programme will attract a very large number of visitors. Further information may be obtained from the Secretary, Mr. H. M. J. Underhill, 7 High Street, Oxford.

A useful little volume relating to the approaching meeting of the British Association has been issued at Newcastle. It contains, in addition to the programme and other information, memoirs (reprinted from the *Newcastle Daily Chronicle*) of the President, the Presidents of Sections, and the lecturers. The volume costs threepence, and will, of course, be widely circulated. There has also been issued, for the use of those who propose to attend the meeting, a list of the hotels, apartments, and furnished houses, with a plan of Newcastle.

Mr. George Phillips Bevan, F.G.S., died on the 3rd inst. at Yaldhurst, Lymington, in his sixtieth year. He was the author of many popular hand-books and guide-books. He also wrote industrial geographies of Great Britain, France, and the United States, and edited a series of works on "British Manufacturing Industries."

The American *Botanical Gazette* announces the death of Mrs. Lydia S. Bennett, a well-known botanist at Fisk University, Tennessee.

On August 12, about 3 o'clock a.m., a rather severe shock of earthquake was felt at Poitiers. Clocks were stopped, and furniture was displaced. No one was injured.

The German edition of the Report of the International Meteorological Committee meeting at Zürich, in September last, contains a preface by Dr. Neumayer, relating to the development of meteorological research in Germany, which, prior to the Congress of Vienna (1873), was almost at a standstill, very little attention having been paid to what was passing in other countries. But the impulse given by that Congress and various meetings of the Committee, together with the establishment of the Deutsche Seewarte at Hamburg and the Meteorological Institute at Berlin, have made the German-speaking countries rank among the foremost and most active promoters of meteorology, all now working together on one uniform plan. The Report contains also a very useful index to all the German editions of the publications of the International Meteorological Committee since the Congress of Rome (1879). A mere glance at this index shows the generality and usefulness of the labours of the Committee, exclusive of the meetings in some way connected with it, among which may be specially mentioned those of the Polar Committee (Hamburg, 1879), and the Conference for Agricultural Meteorology (Vienna, 1880). The preparation of meteorological bibliographies, the establishment of stations in remote parts of the world and upon high mountains, the preparation of elaborate meteorological conversion tables (not yet published) for use in all countries, and uniformity of methods, are but a few of the principal results arrived at in the last sixteen years.

One of the latest novelties in the application of electricity consists of an electric reading-lamp, which is being fitted to the carriages on the main line of the South-Eastern Railway. It is on the principle of the "put a penny in the slot" automatic machines. The apparatus is situated immediately over the passenger's head, and under the rack, and is contained in a small box 5 inches by 3. The light is of five-candle power, and is obtained by the introduction of a penny at the top of the box, and by a subsequent pressure of a knob, and will last for half an hour, extinguishing itself at the end of that time automatically. If the light be required for an indefinite period, a penny every half an hour will suffice. The light can be extinguished at any moment by means of a second button provided for the purpose. One of the special features of the invention is that, if the instrument is out of order, the penny is not lost, as it is in the present machines. It drops right through, and comes out at the bottom of the box, so that it can be recovered, and the same result happens in the case of any coin other than a penny. Each carriage is fitted with an accumulator which supplies the electricity. This invention will add greatly to the comfort of passengers during night journeys.

Some new light on the subject of indirect vision (*i.e.* vision with the lateral parts of the retina), is thrown by recent experiments made by Kirschmann. The common idea, that the sensitiveness of the retina diminishes outwards to the periphery, appears to be incorrect. There is an objective diminution of light-action, when a source of light is moved away laterally from the middle of the field of vision; for the mass of penetrating light gets less. Hence, were the diminishing sensitiveness a fact, a luminous surface should seem to lose brightness when moved to the side; but it does not (though it appears less distinct in outline and modified in colour). Kirschmann placed two rotatory disks made up of moveable black and white sectors (giving any degree of brightness), before the observer; who shut one eye, and looked at the middle of one disk, about a metre and a half from him, while he gave his attention to comparing the brightness of the second disk, seen at different angles, by indirect vision. The figures from numerous experiments prove that, in the horizontal meridian, the sensibility to brightness has a maximum at 22° to 25° from the centre, while in the vertical direction the maximum is at 12° to 15°. The growth of sensibility is much greater in the horizontal than in the vertical direction, and the upper part of the retina is superior in this respect to the lower. This corresponds to the needs of vision. Indirect vision with lateral parts of the retina is more important than that with the upper and lower regions; and the upper half is more important than the lower.

Messrs. Macmillan have issued a new volume of the "Nature Series"—"Timber and some of its Diseases," by H. Marshall Ward, F.R.S. Until the author's articles appeared in this journal, the subject, as he says in his preface, was almost unknown in England.

A suggestive paper, on "The Ta Ki, the Svastika, and the Cross in America," by Dr. Daniel G. Brinton, is printed in the new number of the Proceedings of the American Philosophical Society. He holds that all these symbols are graphic representations of the movements of the sun with reference to the figure of the earth, as understood by primitive man everywhere, and hence that these symbols are found in various parts of the globe without necessarily implying any historic connections of the peoples using them.

The Geological and Natural History Survey of Minnesota has issued its sixteenth Annual Report, dealing with such results of its work as are capable of being put into a shape fit for publication. Mr. Winchell, State Geologist, says in an introductory statement that investigations are being carried forward in the lithology of the crystalline rocks and in the palæontology of the fossiliferous ores, which are not yet sufficiently far advanced to be dealt with in a Report.

In a valuable paper, included in the Annual Report of the United States Department of Agriculture for 1888, on the plum

Curculio, Messrs. C. V. Riley and L. O. Howard state that this insect has brought about an almost entire abandonment of plum culture in many parts of America within the last twenty years; but it is by no means confined to this fruit. It breeds in great numbers in cherries, peaches, apricots, nectarines, and other stone fruits, including the Persimmon, and also infests many varieties of apples, crabs, and haws. It prefers, however, smooth-skined fruits. It is also a common inhabitant of the fungus growth of plum and cherry known as "Black Knot" (*Plowrightia morbosa*), from which it was first reared by Peck in 1818. Under the headings, "Habits and Natural History," "Natural Enemies," and "Remedies," the authors of the paper (which has just been reissued separately) give full information as to the pest to which they have devoted so much attention.

THE "Catalogue of the Moths of India," on which the compilers, Colonel C. Swinhoe and Mr. E. C. Cotes, have been engaged for three years, is completed; and an elaborate index has now been published. The compilers claim that the "Catalogue" comprises all the known moths of the Indian region, including Burma and Ceylon.

THE *Madras Journal of Literature and Science*, for the session 1888–89, contains, besides various other papers, the second part of an elaborate treatise, by Gustav Oppert, on the original inhabitants of India. In the first he treated of the Dravidians; here he deals with the other aboriginal tribes, whom he classes together under the name of the Gaudians. In the third part he proposes to set forth various conclusions to be drawn from this inquiry, supported by as much trustworthy evidence as he may be able to collect.

THE University Correspondence College, Cambridge, has sent us a copy of its latest "Matriculation Directory." The volume is full of information that will be useful to persons who propose to pass the matriculation examination of the London University. In the parts relating to text-books, much excellent advice is offered to candidates.

THE Mason Science College, Birmingham, has issued its syllabus of day classes for the session 1889–90.

THE Agricultural Society of the Gironde, as quoted in a recent British Consular Report, has published a statement showing the average costs incurred last year by proprietors in this department in employing the best-known remedies, viz. (1) against the *Phylloxera*, sulphuretted carbon; (2) against mildew, the so-called *Bouillie Bordelaise*, a mixture of three pounds of sulphate of copper with one pound of slaked lime and twenty-two gallons of water; (3) against *Oïdium*, sulphur; and (4) against *Antrachnosis*, a mixture of eighty pounds of sulphate of iron and ten pounds of sulphate of copper. The total cost of using all these remedies is said to have amounted on an average to about 31*s*. per acre, an expense which cannot be called excessive, especially when it is added that their application served at the same time as a preventive against snails and slugs, which also often do much damage to vines.

Globus contains an abstract of a paper read lately before the German Scientific Association of Santiago, on the inhabitants of Tierra del Fuego, by the Rev. C. Aspinall, an English missionary who has laboured long among them. The particular tribe amongst which the Ooshonia mission was established has received from Mr. Bridges the name of Jahgan, from a place to the south of Beagle Channel frequented by the tribe. The people usually go naked, save for a small skin thrown over the shoulders, but they smear their bodies with a mixture of train-oil and red earth as a protection against the cold. They support themselves by hunting, and at the worst feed on shell-fish. Certain disorders of the digestion, arising from the latter, they cure by a fungus diet. For the most part they move about from place to place, without any fixed abode, in bark canoes, in the centre of which a fire always burns. Each canoe contains a family, the wife rowing while the husband is always on the watch with his javelin. He always carries three kinds of spears with him, one for birds, the second for fish, and the third for crabs. On landing, the woman has first of all to carry her husband ashore, he holding the fire carefully above water, and then she begins the erection of their primitive hut. The men are rarely able to swim, but the women invariably, and this, together with their constant work at rowing, gives them extraordinary muscular power. To maintain their position as lords of creation the men have recourse to mysterious rites, from which the women are excluded. The men have usually two wives, an older and a younger one. Without writing of any kind, they yet preserve many rules and customs, mainly relating to the chase. They are good-natured and helpful, not addicted to lying or theft, but tenacious in the defence of their rights. They have many amiable traits of character. They love long stories and conversations, and in these a good part of their time is spent. One of their tales, of an extraordinary strong man who was made of stone, and ultimately was killed by a thorn entering a vulnerable spot in his heel, recalls the story of Achilles. Devoid of all religious ideas and duties, they have a vague idea of the spirits of the departed wandering about in the world, and greatly to be feared.

THE additions to the Zoological Society's Gardens during the past week include a Gazelle (*Gazella dorcas* ♂) from Egypt, presented by Mr. Umberto Arbib; a Cinereous Vulture (*Vultur monachus*) from Central Spain, presented by Lord Lilford; two Vinaceous Turtle Doves (*Turtur vinaceus*) from West Africa, presented by Mrs. Ffoulkes; two Alligators (*Alligator mississippiensis*) from Florida, presented by Mr. J. W. Bannehr; twenty-two Gold Fish (*Carassius auratus*), four Carp (*Cyprinus carpio*), British fresh waters, presented by Mr. A. H. Hastie; a Cinereous Vulture (*Vultur monachus*) from Central Spain, a Grey Parrot (*Psittacus erithacus*) from West Africa, twenty-four Teydean Chaffinches (*Fringilla teydea*) from the Canary Islands, deposited; a Globose Curassow (*Crax globicera*), two Triangular Spotted Pigeons (*Columba guinea*), two Cambayan Turtle Doves (*Turtur senegalensis*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 AUGUST 18–24.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 18

Sun rises, 4h. 52m.; souths, 12h. 3m. 35·1s.; daily decrease of southing, 13·3s.; sets, 19h. 15m.: right asc. on meridian, 9h. 51·8m.; decl. 12° 58′ N. Sidereal Time at Sunset, 17h. 4m.

Moon (at Last Quarter August 18, 11h.) rises, 22h. 18m.*; souths, 5h. 39m.; sets, 13h. 13m.: right asc. on meridian, 3h. 26·4m.; decl. 14° 48′ N.

THE CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

THE sixty-second Congress of German Naturalists and Physicians will be held, as we have already announced, at Heidelberg, from September 18 to 23; and the meeting promises to be one of great interest. Dr. G. Quincke and Dr. W. Kühne, by whom the various necessary arrangements are being made, have issued a programme, and take the opportunity to say that all naturalists, physicians, and students of the natural sciences, who may choose to attend the meeting, will be cordially welcomed. Although by its statutes the Congress consists only of Germans, foreign investigators, by being present and taking part in the proceedings, give much pleasure to their German colleagues.

The three general meetings will be held in the great hall of the Heidelberg Museum on September 18, 20, and 23. To the second of these general meetings, on September 20, a scheme embodying new statutes will be submitted for consideration. This scheme has been worked out by a committee in consequence of resolutions passed at the Congress held last year at Cologne.

According to the old statutes of 1822, still in force, the Congress consists of members and associates, but only the former have the right of voting. Everyone who has written a book on natural science or on medicine is regarded as a member. No one, however, who has merely written an inaugural dissertation can be considered as an author. Admission as associates is open to all who have occupied themselves scientifically with natural science and medicine. The ordinary ticket costs 12 marks; and the same ticket may be obtained for ladies at half the price. In return for an annual subscription of 5 marks, paid in accordance with the decisions of the Cologne Congress last year, the members receive a special member's ticket. The tickets will often have to be shown, so that members and associates ought to have them always ready.

Resolutions can be passed only at a general sitting; and everything is decided by the votes of a majority of the members. Resolutions with regard to scientific theses are not adopted either at the general sittings or in the Sections. The Sections elect their own Presidents, and may, in addition to the Secretary previously appointed, nominate, if necessary, a second or a third Secretary.

In connection with the meeting, there will be an exhibition of scientific apparatus, instruments, and preparations. It will be held in the town gymnastic hall (*Turnhalle*), Grabengasse, 22. Arrangements are being made for this exhibition by a special committee, the president of which is Herr Stadtrath Leimbach, 59 Gaisbergstrasse, Heidelberg, to whom all communications relating to the exhibition should be addressed. The ordinary ticket secures admission to the exhibition, which will be open daily, to members and associates only, from 8 to 11 o'clock a.m. During these hours, explanations will, if desired, be given by exhibitors or their representatives. After 11 o'clock the exhibition will be open to the public, who will have to pay for admission. A catalogue will be provided for members and associates.

The Directors of the Museum and of the Harmonic Society have placed their rooms at the disposal of the Congress; and through the kindness of the civic authorities, and of the Society to which the Museum belongs, it has been arranged that a concert shall be given in the town garden on September 18, and a festival in the Castle grounds on September 20; that the Castle shall be illuminated on the evening of September 23; and that a ball shall be given in the Museum on September 21. Tickets for the dinner in the great hall of the Museum, on September 19, will be issued at the Reception Room on Tuesday and Wednesday, September 17 and 18. The Reception Room and Inquiry Office will be on the ground floor of the Bayrischer Hof, 2 Rohrbacher Strasse, near the railway station.

Applications for lodgings will be received by Herr Rathschreiber Webel (Rathhaus, Heidelberg), Secretary of the Lodgings Committee. A representative of this Committee will be present in the Reception Room.

A daily Bulletin will be issued during the sitting of the Congress. Every morning it will be found in the Reception Room, with a list of members and associates; also with the orders of the day in the Sections, &c. Reports of papers can only be printed afterwards in the scientific part of the Bulletin. Papers which are intended for publication must be written plainly, and handed in not later than October 8.

A post and telegraph office will be open in the ground floor of the University from 8 a.m. to 8 p.m., and a room will be set apart for the writing of letters. Dr. Quincke and Dr. Kühne have not been able to induce the railway companies to issue tickets at a reduced price.

On Sunday, September 22, the following excursions will be made:—

(1) Through the Valley of the Neckar to Neckarsteinach, Hirschhorn, Eberbach, Ernstthal.

(2) By the Bergstrasse to Weinheim, Bensheim, Auerbach, Zwingenberg, Jugenheim.

(3) In the Palatinate, to Speyer, Neustadt, Annweiler, Dürkheim.

(4) To Mannheim, for the examination of the collections there, and for a visit to the opera.

All members and associates (even those who may already have their tickets) are requested to write their names on the list in the Reception Room, and at the same time to give their cards, with name, titles, and place of residence.

The following is the general order of the day:—

Tuesday, September 17: 9 a.m., opening of the Exhibition; 8 p.m., friendly meeting in the Museum.

Wednesday, the 18th: 9 a.m., first general meeting in the great hall of the Museum. (1) Opening of the Congress: Speeches. (2) Lecture by Geh. Rath von Meyer (Göttingen-Heidelberg), on "Chemical Problems of the Present Day." (3) Lecture by Dr. G. H. Otto Volger (Frankfort), on the "Life and Achievements of Dr. K. Schimper."

Midday: Assembling and formation of the Sections.

Afternoon: Sittings of the Sections.

7 p.m.: Concert in the Town Garden.

Thursday, the 19th: Sittings of the Sections; 5 p.m., dinner in the great hall of the Museum.

Friday, the 20th: 9 a.m., second general meeting in the great hall of the Museum. (1) Lecture by Prof. Hertz (Bonn), on "The Relations between Light and Electricity." (2) Consideration of the scheme of new statutes, under the presidency of Dr. Virchow, as Chairman of the Committee by which the scheme was drawn up. (3) Election (*a*) of the new Committee, (*b*) of the next place of meeting, (*c*) of the business managers of the next meeting.

Afternoon: Sittings of the Sections.

6.30 p.m.: Festival at the Castle.

Saturday, the 21st: Sittings of the Sections. 7.30 p.m., ball in the Museum.

Sunday, the 22nd: Excursions in the neighbourhood.

Monday, the 23rd: 9 a.m., third general meeting in the great hall of the Museum. (1) Lecture by Prof. Th. Puschmann (Vienna), on "The Significance of History for Medicine and the Natural Sciences." (2) Lecture by Prof. Brieger (Berlin), on "Bacteria."

Afternoon: Sittings of the Sections.

7.30 p.m.: Illumination of the Castle.

We append a list of the Sections:—(1) Mathematics and Astronomy; (2) Physics; (3) Chemistry; (4) Botany; (5) Zoology; (6) Entomology; (7) Mineralogy and Geology; (8) Ethnology and Anthropology; (9) Anatomy; (10) Physiology; (11) General Pathology and Pathological Anatomy; (12) Pharmacology; (13) Pharmacy and Pharmacognosis; (14) Medicine; (15) Surgery; (16) Gynæcology; (17) Children's Diseases; (18) Neurology and Pyschiatry; (19) Diseases of the Eye; (20) Diseases of the Ear; (21) Laryngology and Rhinology; (22) Dermatology and Syphilis; (23) Hygiene; (24) Medical Jurisprudence; (25) Medical Geography; (26) Military Sanitation; (27) Dentistry; (28) Veterinary Medicine; (29) Agricultural Chemistry; (30) Mathematics and the Natural Sciences in Relation to Education; (31) Geography; (32) Philosophical Instruments.

THE PROGRESS OF SCIENCE AS EXEMPLIFIED IN THE ART OF WEIGHING AND MEASURING.[1]

TWO centuries ago the world was just beginning to awaken from an intellectual lethargy which had lasted a thousand years. During all that time the children had lived as their parents before them, the mechanical arts had been at a standstill, and the dicta of Aristotle had been the highest authority in science. But now the night of mediævalism was approaching its end, and the dawn of modern progress was at hand. Galileo had laid the foundation for accurate clocks by discovering the isochronism of the simple pendulum; had proved that under the action of gravity light bodies fall as rapidly as heavy ones; had invented the telescope, and with it discovered the spots on the sun, the mountains on the moon, the satellites of Jupiter, and the so-called triple character of Saturn; and, after rendering himself immortal by his advocacy of the Copernican system, had gone to his grave aged, blind, and full of sorrows. His contemporary, Kepler, had discovered the laws which, while history endures, will associate his name with the theory of planetary motion, and he also had passed away. The first Cassini was still a young man, his son was a little child, and his grandson and great-grandson, all of whom were destined to be directors of the Paris Observatory, were yet unborn. The illustrious Huyghens, the discoverer of Saturn's rings and the father of the undulatory theory of light, was in the zenith of his powers. The ingenious Hooke was a little younger; and Newton, towering above them all, had recently invented fluxions, and on April 28, 1686, had presented his "Principia" to the Royal Society of London, and given the theory of gravitation to the world. Bradley, who discovered nutation and the aberration of light; Franklin, the statesman and philosopher, who first drew the lightning from the clouds; Dollond, the inventor of the achromatic telescope; Euler, the mathematician who was destined to accomplish so much in perfecting algebra, the calculus, and the lunar theory; Laplace, the author of the "Mécanique Céleste"; Rumford, who laid the foundation of the mechanical theory of heat; Dalton, the author of the atomic theory, upon which all chemistry rests; and Bessel, the greatest of modern astronomers—these and others almost as illustrious, whom we cannot even name to-night, were still in the womb of time.

Pure science first felt the effects of the new intellectual life, and it was more than a century later before the arts yielded to its influence. Then came Hargreaves, the inventor of the spinning-jenny; Arkwright, the inventor of the cotton-spinning frame; Watt, who gave us the condensing steam-engine; Jacquard, the inventor of the loom for weaving figured stuffs; Murdock, the originator of gas-lighting; Evans, the inventor of the high-pressure steam-engine; Fulton, the father of steam navigation; Trevithick, who ranks very near Watt and Evans in perfecting the steam-engine; and Stephenson, the father of railroads. If now we add the names of those who have given us the telegraph, to wit: Gauss, the eminent physicist and the greatest mathematician of the present century; Weber, Wheatstone, and Henry—all famous physicists—and Morse, the inventor and engineer; we have before us the demi-gods who have transformed the ancient into the modern world, given us machinery which has multiplied the productive power of the human race many-fold, annihilated time and space, and bestowed upon toiling millions a degree of comfort and luxury which was unknown to kings and emperors of old.

The discoveries and inventions of the last two centuries have so far exceeded all others within historic times that we are amply justified in calling this an age of phenomenal progress, and under the circumstances a little self-glorification is pardonable—perhaps even natural. The weekly and monthly records of scientific events which appear in so many newspapers and magazines are the immediate result of this, and the great increase of ephemeral scientific literature has led multitudes of educated people to believe that such records represent actual progress. The multiplication of bricks facilitates the building of houses, but does not necessarily improve architecture. Similarly, the multiplication of minor investigations improves our knowledge of details, but rarely affects the great philosophic theories upon which science is founded. The importance of human actions is measured by the degree in which they affect human thought, and the only way of permanently affecting scientific thought is by modifying or extending scientific theories. The men who do that are neither numerous nor do they require weekly paragraphs to record their deeds; but their names are honoured by posterity. Even in this golden age the advance of science is not steady, but is made by spasmodic leaps and bounds. Mere scientific brick-making, commonly called progress, is always the order of the day until some genius startles the world by a discovery affecting accepted theories. Then every effort is directed in the new line of thought until it is measurably worked out, and after that brick-making again resumes its place. While the progress in two centuries has been immense, the progress in a week or a month is usually almost *nil*. Optimism has its uses in many departments of human affairs, but science should be cool and dispassionate, having regard only for the truth. To make a trustworthy estimate of the actual state of the whole vast realm of science would be a task beyond the powers of any one man; but perhaps it will not be amiss to spend the time at our disposal this evening in briefly reviewing the recent progress and present condition of the fundamental processes upon which the exact sciences rest—I allude to the methods of weighing and measuring.

Physical science deals with many quantities, but they are all so related to each other that almost every one of them can be expressed in terms of three fundamental units. As several systems of such units are possible, it is important to select the most convenient, and the considerations which guide us in that respect are the following:—

(1) The quantities selected should admit of very accurate comparison with other quantities of the same kind.

(2) Such comparisons should be possible at all times, and in all places.

(3) The processes necessary for making such comparisons should be easy and direct.

(4) The fundamental units should be such as to admit of easy definitions and simple dimensions for the various derived units.

Scientific men have long agreed that these requirements are best fulfilled by adopting as the fundamental units a definite length, a definite mass, and a definite interval of time. Length is an element which can be very accurately measured and copied, but it must be defined by reference to some concrete material standard, as, for example, a bar of metal; and as all substances expand and contract with changes of temperature, it is necessary to state the temperature at which the standard is correct. A standard of mass, consisting of a piece of platinum, quartz, or other material not easily affected by atmospheric influences, probably fulfils the conditions set forth above better than any other kind of magnitude. Its comparison with other bodies of approximately equal mass is effected by weighing, and as that is among the most exact of all laboratory operations, very accurate copies of the standard can be made, and they can be carried from place to place with little risk of injury. Time is also an element which can be measured with extreme precision. The immediate instruments of measurement are clocks and chronometers, but their running is checked by astronomical observations, and the ultimate standard is the rotation of the earth itself.

It is important to note that the use of three fundamental units is simply a matter of convenience and not a theoretical necessity, for the unit of mass might be defined as that which at unit distance would generate in a material point unit velocity in unit time; and thus we should have a perfectly general system of measurement based upon only two fundamental units—namely,

[1] Annual Address of Dr. William Harkness, President of the Philosophical Society of Washington, delivered on December 10, 1887.

those of space and time. Such a system is quite practicable in astronomy, but cannot yet be applied with accuracy to ordinary terrestrial purposes. According to the law of gravitation,

$$\text{Mass} = \text{Acceleration} \times (\text{Distance})^2;$$

and as in the case of the earth we can measure the quantities on the right-hand side of that equation with considerable accuracy, we can satisfactorily determine the earth's mass in terms of the supposed unit. That suffices for the needs of astronomy, but for other scientific and commercial purposes a standard of mass having a magnitude of about a pound is necessary, and as two such masses can be compared with each other from five to ten thousand times more accurately than either of them can be determined in terms of the supposed unit, three fundamental units are preferable to two.

The Chaldeans, Babylonians, Persians, Greeks, and Romans, all seem to have had systems of weights and measures based upon tolerably definite standards, but after the decline of the Roman Empire these standards seem to have been forgotten, and in the beginning of the sixteenth century the human body had so far become the standard of measurement that the units in common use—as, for example, the foot, palm, &c.,—were frequently taken directly from it. The complete table of measures of length was then as follows: the breadth (not the length) of four barley-corns make a digit, or finger-breadth; four digits make a palm (measured across the middle joints of the fingers); four palms are one foot; a foot and a half is a cubit; ten palms, or two feet and a half, are a step; two steps, or five feet, are a pace; ten feet are a perch; one hundred and twenty-five paces are an Italic stadium; eight stadia, or one thousand paces, are an Italic mile; four Italic miles are a German mile; and five Italic miles are a Swiss mile. It was then the practice to furnish standards of length in books by printing in them lines a foot or a palm long, according to the size of the page, and from these and other data it appears that the foot then used on the continent of Europe had a length of about ten English inches.

In England, the first attempts at scientific accuracy in matters of measurement date from the beginning of the seventeenth century, when John Greaves, who must be considered as the earliest of the scientific metrologists, directed attention to the difference between the Roman and English foot by tolerably accurate determinations of the former, and also attempted the investigation of the Roman weights. He was followed by Dr. Edward Bernard, who wrote a treatise on ancient weights and measures about 1685, and towards the end of the century the measurements of the length of a degree by Picard and J. D. Cassini awakened the attention of the French to the importance of rigorously exact standards. In considering the progress of science with respect to standards of length, we may safely confine our inquiries to the English yard and the French toise and metre, for during the last two hundred years they have been almost the only standards adopted in scientific operations.

The English measures of length have come down from the Saxons, but the oldest standards now existing are the Exchequer yards of Henry VII. (1490) and Elizabeth (1588). These are both brass-end measures, the former being an octagonal rod about half an inch in diameter, very coarsely made, and as rudely divided into inches on the right-hand end and into sixteenths of a yard on the left-hand end; the latter a square rod with sides about half an inch wide, also divided into sixteenths of a yard, and provided with a brass bed having end-pieces between which the yard fits. One end of the bed is divided into inches and half-inches. Francis Baily, who saw this Elizabethan standard in 1836, speaks of it as "this curious instrument, of which it is impossible, at the present day, to speak too much in derision or contempt. A common kitchen poker, filed at the ends in the rudest manner by the most bungling workman, would make as good a standard. It has been broken asunder; and the two pieces have been dove-tailed together: but so badly that the joint is nearly as loose as that of a pair of tongs. The date of this fracture I could not ascertain, it having occurred beyond the memory or knowledge of any of the officers at the Exchequer. And yet, till within the last ten years, to the disgrace of this country, copies of this measure have been circulated all over Europe and America, with a parchment document accompanying them (charged with a stamp that costs £3 10*s.*, exclusive of official fees), certifying that they are true copies of the English *standard*."

In the year 1742 certain members of the Royal Society of London, and of the Royal Academy of Sciences of Paris, proposed that, in order to facilitate a comparison of the scientific operations carried on in the two countries, accurate standards of the measures and weights of both should be prepared and preserved in the archives of each of these Societies. This proposition having been approved, Mr. George Graham, at the instance of the Royal Society, had two substantial brass rods made, upon which he laid off, with the greatest care, the length of 3 English feet from the standard yard kept at the Tower of London. These two rods, together with a set of troy weights, were then sent over to the Paris Academy, which body, in like manner, had the measure of a French half-toise set off upon the rods, and keeping one, as previously agreed, returned the other, together with a standard weight of two marcs, to the Royal Society. In 1835, Baily declared this copy of the half-toise to be of little value because the original *toise-étalon* was of iron, and the standard temperature in France differed from that in England. In his opinion the French should have sent over an iron half-toise in exchange for the English brass yard; but this criticism loses much of its force when it is remembered that in 1742 neither England nor France had fixed upon a temperature at which their standards were to be regarded as of the true length. On the return of the rod from Paris, Mr. Graham caused Jonathan Sisson to divide the English yard and the French half-toise each into three equal parts, after which the rod was deposited in the archives of the Royal Society, where it still remains. Objection having been made that the original and legal standard yard of England was not the one at the Tower, but the Elizabethan standard at the Exchequer, the Royal Society requested Mr. Graham to compare his newly-made scale with the latter standard, and on Friday, April 22, 1743, he did so in the presence of a Committee of seven members of the Royal Society. In the following week the same gentlemen compared the Royal Society's scale with the standards at Guildhall and the Tower, and also with the standard of the Clockmakers' Company. These comparisons having shown that the copy of the Tower yard upon the Royal Society's scale was about 0·0075 of an inch longer than the standard at the Exchequer, Mr. Graham inscribed upon the Royal Society's scale a copy of the latter standard also, marking it with the letters Exch., to distinguish it from the former, which was marked E. (English), and from the half-toise which was marked F. (French).

In the year 1758 the House of Commons appointed a Committee to inquire into the *original* standards of weights and measures of England; and, under instructions from that Committee, the celebrated instrument-maker, John Bird, prepared two brass rods, respecting which the Committee speak as follows in their Report: "And having those rods, together with that of the Royal Society, laid in the same place, at the receipt of the Exchequer, all night with the standards of length kept there, to prevent the variation which the difference of air might make upon them, they the next morning compared them all, and, by the means of beam compasses brought by Mr. Bird, found them to agree as near as it was possible." One of these rods was arranged as a matrix for testing end-measures, and the other was a line measure which the Committee recommended should be made the legal standard of England, and which has since been known as Bird's standard of 1758. Respecting the statement that after lying together all night the rods were *all* found to agree as near as it was possible, Baily says: "This is somewhat remarkable, and requires further explanation, which unfortunately cannot now be accurately obtained. For it is notorious that the measure of the yard of the Royal Society's scale differs very considerably from the standard yard at the Exchequer. . . . Owing to this singular confusion of the lengths of the measures, which does not appear to have been unravelled by any subsequent Committee, it has happened that the Imperial standard yard . . . has been assumed nearly 1 ÷ 140 of an inch longer than the ancient measure of the kingdom." There is little difficulty in surmising what Bird did. The Exchequer standard consisted of a rod and its matrix. The Royal Society's Committee assumed the rod to be the true standard of 36 inches, and upon that assumption Graham's measurements gave for the length of the matrix 36·0102 inches, and for the length of the Royal Society's yard 36·0075 inches. The Parliamentary Committee of 1758 probably assumed the standard to consist of the rod and matrix together, which seems the better view; and by laying the rod in its matrix, and measuring to the joint between them, Bird would have got a length of about 36·0051 inches. The mean between that and 36·0075 would be 36·0063, which differs very little from the length of Bird's standard resulting from Sir George Shuckburgh's measurements. Thus the Committee's statement is justified, and there has been no falsification of the ancient standards.

On December 1, 1758, Parliament created another Committee on Weights and Measures, which, in April 1759, repeated the recommendation that Bird's standard of 1758 should be legalized, and further recommended that a copy of it should be made and deposited in some public office, to be used only on special occasions. The copy was made by Bird in 1760, but, owing to circumstances entirely unconnected with the subject, no legislation followed for sixty-four years.

The Royal Commission appointed during the reign of George III. to consider the subject of weights and measures, made its first Report on June 24, 1819, and therein recommended the adoption of the standard of length which had been used by General Roy in measuring the base on Hounslow Heath; but in a second Report, made July 13, 1820, they wrote:—"We . . . have examined, since our last Report, the relation of the best authenticated standards of length at present in existence, to the instruments employed for measuring the base on Hounslow Heath, and in the late trigonometrical operations; but we have very unexpectedly discovered that an error has been committed in the construction of some of these instruments. We are therefore obliged to recur to the originals which they were intended to represent, and we have found reason to prefer the Parliamentary standard executed by Bird in 1760, which we had not before received, both as being laid down in the most accurate manner, and as the best agreeing with the most extensive comparisons which have been hitherto executed by various observers, and circulated through Europe; and in particular with the scale employed by the late Sir George Shuckburgh."

Accordingly, when in 1824 Parliament at length took action, Bird's standard of 1760 was adopted instead of that of 1758. The former being a copy of a copy, its selection as a national standard of length seems so singular that the circumstances which brought about that result should scarcely be passed over in silence. Bird had a very accurate brass scale 90 inches long, which he used in all his dividing operations, whether upon circles or straight lines, and which Dr. Maskelyne said was 0·001 of an inch shorter on 3 feet than Graham's Royal Society yard E. In the year 1792, or 1793, the celebrated Edward Troughton made for himself a 5-foot scale, which conformed to Bird's, and which he afterwards used in laying down the divisions of the various instruments that passed through his hands. This was the original of all the standard scales he ever made, and at the beginning of the present century he believed these copies, which wete made by the aid of micrometer microscopes, to be so exact that no variations could possibly be detected in them, either from the original or from each other. Among the earliest of the scales so made by Troughton was the one used by Sir George Shuckburgh in 1796–98 in his important scientific operations for the improvement of the standards. Subsequently, the length of the metre was determined by comparison with this scale and with the supposed facsimile of it made by Troughton for Prof. Pictet, of Geneva; and thus it happened that on the continent of Europe all measures were converted into English units by a reference to Sir George Shuckburgh's scale. The Royal Commission of 1819 believed Bird's standard of 1760 to be identical with Shuckburgh's scale, and they legalized it rather than the standard of 1758, in order to avoid disturbing the value of the English yard, which was then generally accepted for scientific purposes.

There are yet four other scales of importance in the history of English standards—namely, the brass 5-foot scale made for Sir George Shuckburgh by Troughton in 1796; two iron standard yards, marked 1A and 2A, made for the English Ordnance Survey Department by Messrs. Troughton and Simms in 1826–27; and the Royal Society's standard yard, constructed by Mr. George Dollond, under the direction of Capt. Henry Kater, in 1831.

Bearing in mind the preceding history, the genesis of the present English standard yard may be thus summarized. In 1742, Graham transferred to a bar made for the Royal Society a length which he intended should be that of the Tower yard, but which was really intermediate between the Exchequer standard yard of Elizabeth and its matrix. That length he marked with the letter E, and, although destitute of legal authority, it was immediately accepted as the scientific standard, and was copied by the famous instrument-makers of the time with all the accuracy then attainable. Thus it is in fact the prototype to which all the accurate scales made in England between 1742 and 1850 can be traced. Bird's standard of 1758 was compared with the Exchequer standard and with the Royal Society's yard E., and was of a length between the two. Bird's standard of 1760, legalized as the Imperial standard, in June 1824, was copied from his standard of 1758. After becoming the Imperial standard, Bird's standard of 1760 was compared with Sir George Shuckburgh's scale by Capt. Kater, in 1830, and by Mr. Francis Baily, in 1834; with the Ordnance yards 1A and 2A, in 1834, by Lieut. Murphy, R.E., Lieut. Johnson, R.N., and Messrs. F. Baily and Donkin; and with Kater's Royal Society yard by Capt. Kater, in 1831. On October 16, 1834, the Imperial standard (Bird's standard of 1760) was destroyed by the burning of the Houses of Parliament, in which it was lodged; and very soon thereafter the Lords of the Treasury took measures to recover its length. Preliminary inquiries were begun on May 11, 1838; and on June 20, 1843, they resulted in the appointment of a Commission to superintend the construction of new Parliamentary standards of length and weight, among whose members the Astronomer-Royal (now Sir George B. Airy), Messrs. F. Baily, R. Sheepshanks, and Prof. W. H. Miller, were prominent. The laborious investigations and experiments carried out by that Commission cannot be described here, but it will suffice to say that for determining the true length of the new standard Mr. Sheepshanks employed a provisional yard, marked upon a new brass bar designated "Brass 2," which he compared as accurately as possible with Sir George Shuckburgh's scale, the two Ordnance yards, and Kater's Royal Society yard. The results in terms of the lost Imperial standard were as follows:—

Brass bar 2 = 36·000084 from comparison with Shuckburgh's scale, 0–36 in.
36·000280 ,, ,, ,, ,, 10–46 in.
36·000303 from comparison with the Ordnance yard, 1A.
36·000275 ,, ,, ,, ,, 2A.
36·000229 from Capt. Kater's Royal Society yard.

Mean = 36·000234

Respecting this mean, Mr. Sheepshanks wrote:—"This should be pretty near the truth; but I prefer 36·00025, if in such a matter such a difference be worth notice. I propose, therefore, in constructing the new standard to assume that—

Brass bar 2 = 36·00025 inches of lost Imperial standard at 62° F."

And upon that bar is the standard now in use was constructed.

Turning now to the French standards of length, it is known that the ancient *toise de maçons* of Paris was probably the toise of Charlemagne (A.D. 742 to 814), or at least of some Emperor Charles, and that its *étalon* was situated in the courtyard of the old Châtelet, on the outside of one of the pillars of the building. It still existed in 1714, but entirely falsified by the bending of the upper part of the pillar. In 1668 the ancient toise of the masons was reformed by shortening it five lines; but whether this reformation was an arbitrary change, or merely a change to remedy the effects of long use and restore the *étalon* to conformity with some more carefully-preserved standard, is not quite clear. These old *étalons* were iron bars having their two ends turned up at right angles so as to form *talons*, and the standardizing of end measures was effected by fitting them between the *talons*. Being placed on the outside of some public building, they were exposed to wear from constant use, to rust, and even to intentional injury by malicious persons. Under such conditions every *étalon* would, sooner or later, become too long and require shortening.

Respecting the ancient toise of the masons there are two contradictory stories. On December 1, 1714, La Hire showed to the French Academy what he characterized as "a very ancient instrument of mathematics, which has been made by one of our most accomplished workmen with very great care, where the foot is marked, and which has served to re-establish the toise of the Châtelet, as I have been informed by our old mathematicians." Forty-four years later, on July 29, 1758, La Condamine stated to the Academy that "We know only by tradition that to adjust the length of the new standard, the width of the arcade or interior gate of the grand pavilion, which served as an entrance to the old Louvre, on the side of the rue Fromenteau, was used. This opening, according to the plan, should have been 12 feet wide. Half of it was taken to fix the length of the new toise, which thus became five lines shorter than the old one." Of these two contradictory statements that of La Hire seems altogether most trustworthy, and the ordinary rules of evidence indicate that it should be accepted to the exclusion of the other.

In 1668 the *étalon* of the new toise, since known as the *toise-étalon du Châtelet*, was fixed against the wall at the foot of the staircase of the *grand Châtelet de Paris*—by whom or at what season of the year is not known. Strange as it now seems, this standard—very roughly made, exposed in a public place for use or abuse by everybody, liable to rust, and certain to be falsified by constant wear—was actually used for adjusting the toise of Picard, that of Cassini, the toise of Peru and of the North, that of La Caille, that of Mairan; in short, all the toises employed by the French in their geodetic operations during the seventeenth and eighteenth centuries. The lack of any other recognized standard made the use of this one imperative, but the French Academicians were well aware of its defects, and took precautions to guard against them.

The first toise copied from the *étalon* of the Châtelet for scientific purposes was that used by Picard in his measurement of a degree of the meridian between Paris and Amiens. It was made about the year 1668, and would doubtless have become the scientific standard of France had it not unfortunately disappeared before the degree measurements of the eighteenth century were begun. The second toise copied from the *étalon* of the Châtelet for scientific purposes was that used by Messrs. Godin, Bouguer, and La Condamine for measuring the base of their arc of the meridian in Peru. This toise, since known as the *toise du Pérou*, was made by the artist Langlois under the immediate direction of Godin in 1735, and is still preserved at the Paris Observatory. It is a rectangular bar of polished wrought iron, having a breadth of 1·58 English inches and a thickness of 0·30 of an inch. All the other toises used by the Academy in the eighteenth century were compared with it, and, ultimately, it was made the legal standard of France by an order of Louis XV., dated May 16, 1766. As the toise of Peru is the oldest authentic copy of the toise of the Châtelet, the effect of this order was simply to perpetuate the earliest known state of that ancient standard.

The metric system originated from a motion made by Talleyrand in the National Assembly of France, in 1790, referring the question of the formation of an improved system of weights and measures, based upon a natural constant, to the French Academy of Sciences; and the preliminary work was intrusted to five of the most eminent members of that Academy—namely, Lagrange, Laplace, Borda, Monge, and Condorcet. On March 19, 1791, these gentlemen, together with Lalande, presented to the Academy a Report containing the complete scheme of the metric system. In pursuance of the recommendations in that Report, the law of March 26, 1791, was enacted for the construction of the new system, and the Academy of Sciences was charged with the direction of the necessary operations. Those requisite for the construction of a standard of length were:—

(1) The determination of the difference of latitude between Dunkirk and Barcelona.

(2) The remeasurement of the ancient bases which had served for the measurement of a degree at the latitude of Paris, and for making the map of France.

(3) The verification by new observations of the series of triangles employed for measuring the meridian, and the prolongation of them as far as Barcelona.

This work was intrusted to Méchain and Delambre, who carried it on during the seven years from 1791 to 1798, notwithstanding many great difficulties and dangers. The unit of length adopted in their operations was the toise of Peru, and from the arc of 9° 40′ 45″ actually measured, they inferred the length of an arc of the meridian extending from the equator to the Pole to be 5,130,740 toises. As the metre was to be 1/10,000,000 of that distance, its length was made 0·5130740 of a toise, or, in the language of the Committee, 443·296 lines of the toise of Peru at a temperature of 13° Réaumur (16¼° C. or 61¼° F.).

Before attempting to estimate how accurately the standards we have been considering were intercompared, it will be well to describe briefly the methods by which the comparisons were effected. In 1742, Graham used the only instruments then known for the purpose—namely, very exact beam compasses of various kinds, one having parallel jaws for taking the lengths of the standard rods, another with rounded ends for taking the lengths of the hollow beds, and still another having fine points in the usual manner. The jaws, or points, of all these instruments were movable by micrometer screws having heads divided to show the eight-hundredth part of an inch directly, and the tenth of that quantity by estimation; but Mr. Graham did not consider that the measurements could be depended upon to a greater accuracy than 1/1600 of an inch.

Troughton is generally regarded as the author of the application of micrometer microscopes to the comparison of standards of length, but the earliest record of their use for that purpose is by Sir George Shuckburgh in his work for the improvement of the standards of weight and measure in 1796-98. Since then their use has been general; first, because they are more accurate than beam compasses, and, second, because they avoid the injury to standard scales which necessarily results from placing the points of beam compasses upon their graduations. As the objective of the microscope forms a magnified image of the standard, upon which the micrometer wires are set by the aid of the eye-piece, it is evident that in order to reduce the effect of imperfections in the micrometer, the objective should have the largest practicable magnifying power. To show the progress in that direction, the optical constants of the microscopes, by means of which some of the most important standards have been compared, are given in the accompanying table.

Date.	Observer.	Power of microscope.	Magnifying power of objective.	Equivalent focus of eye-piece.	Value of one revolution of micrometer screw.

NOTE.—The magnifying power of Sir Geo. Shuckburgh's microscope seems to be referred to a distance of 12 inches for distinct vision. The powers inclosed in parentheses are estimated upon the assumption that the respective micrometer screws had 100 threads per inch.

In the Memoirs of the French Academy nothing is said respecting the method adopted by the Academicians for comparing their various toises; but in his "Astronomy," Lalande states that the comparisons were effected partly by beam compasses, and partly by superposing the toises upon each other and examining their ends, both by touch and with magnifying glasses, they being all end standards. For the definitive adjustment of the length of their metres, which were also end standards, the French Metric Commission used a lever comparator by Lenoir.

In 1742, Graham used beam compasses, which he considered trustworthy to 0·00062 of an inch, in comparing standards of length; but at that time the French Academicians made their comparisons of toises only to one-twentieth or one-thirtieth of a line, say 0·00300 of an inch, and it was not until 1758 that La Condamine declared they should be compared to 0·01 of a line, or 0·00089 of an English inch, "if our senses, aided by the most perfect instruments, can attain to that." Half a century later, ten times that accuracy was attained by the lever comparator of Lenoir, which was regarded as trustworthy to 0·000077 of an inch ("Base du Système Métrique," t. iii. pp. 447–62).

The heads of micrometer microscopes are usually divided into 100 equal parts, and if we regard one of these parts as the least reading of a microscope, then in 1797 Sir George Shuckburgh's microscopes read to 1/10,000 of an inch; and the least reading of microscopes made since that date has varied from 1/20,000 to 1/35,000 of an inch. A few investigators, among whom may be mentioned Prof. W. A. Rogers, of Colby University, have made the least reading of their microscopes as small as 1/90,000 of an inch, but it is doubtful if there is any advantage in so doing. At the present day the errors committed in comparing standards arise, not from lack of power in the microscopes, but from the difficulty of determining sufficiently exactly the temperature of the standard bars, and the effect of flexure upon the position of their graduations. In order to ascertain the length of a 3-foot standard with an error not exceeding 0·000020 of an inch, its temperature must be known to 0°·06 F. if it is of brass, or to 0°·09 F. if it is of iron. To get thermometers that will indicate their own temperature to that degree of accuracy is by no means easy, but to determine the temperature of a bar from their readings is far more difficult. Again, we imagine the length of our standards to follow their temperature rigorously, but what proof is there that such is the case? If we determine the freezing point of an old thermometer, then raise it to the temperature of boiling water, and immediately thereafter again determine its freezing-point, we invariably find that the freezing-point has fallen a little; and we explain this by saying that the glass has taken a set, from which it requires time to recover. Is it not probable that an effect similar in kind, although less in degree, occurs in all solids when their temperature is varying? When we look at the highly polished terminals of an end-standard, we are apt to regard them as mathematical surfaces, separated by an interval which is perfectly definite, and which could be measured with infinite precision if we only had the necessary instrumental appliances; but is that a correct view? The atomic theory answers emphatically, No. According to it, all matter consists of atoms, or molecules, of a perfectly definite size, and with definite intervals between them; but even if that is denied, the evidence is now overwhelming that matter is not homogeneous, but possesses a grain of some kind, regularly repeated at intervals which cannot be greater than 1/2,000,000 nor less than 1/400,000,000 of an inch. Accordingly we must picture our standard bar as a conglomeration of grains of some kind or other, having magnitudes of the order specified, and all in ceaseless motion, the amplitude of which depends upon the temperature of the bar. To our mental vision the polished terminals are therefore like the surface of a pot of boiling water, and we recognize that there must be a limit to the accuracy with which the interval between them can be measured. As a basis for estimating how near this limit we have approached, it will suffice to say that for fifty years past it has been customary to state comparisons of standards of length to 1/100,000, of an inch. Nevertheless, most authorities agree that, although 1/100,000 of an inch can be distinguished in the comparators, 1/25,000 of an inch is about the limit of accuracy attainable in comparing standards. Possibly such a limit may be reached under the most favourable circumstances, but in the case of the yard and the metre, which are standard at different temperatures, the following values of the metre by observers of the highest repute render it doubtful if anything like that accuracy has yet been attained:—

1818	Capt. Henry Kater	39·37079 inches.
1866	General A. R. Clarke ...	39·37043 ,,
1883	Prof. Wm. A. Rogers ...	39·37027 ,,
1885	General C. B. Comstock ...	39·36985 ,,

The earliest standard of English weight of which we have any very definite knowledge is the Mint pound of the Tower of London. It weighed 5400 troy grains, and the coinage was regulated by it up to the year 1527, when it was abolished in favour of the troy pound of 5760 grains. Contemporaneously with the Tower pound there was also the merchant's pound, whose exact weight is now involved in so much doubt that it is impossible to decide whether it consisted of 6750 or of 7200 grains. The Tower pound and the troy pound were used for weighing only gold, silver, and drugs, while all other commodities were weighed by the merchant's pound until the thirteenth or fourteenth century, and after that by the avoirdupois pound. It is not certainly known when the troy and avoirdupois pounds were introduced into England, and there is no evidence of any relation between them when they first became standards. The present avoirdupois pound can be clearly proved to be of similar weight to the standard avoirdupois pound of Edward III. (A.D. 1327–77), and there is good reason for believing that no substantial change has occurred either in its weight or in that of the troy pound since their respective establishment as standards in England.

The oldest standard weights now existing in the English archives date from the reign of Queen Elizabeth, and consist of a set of bell-shaped avoirdupois weights of 56, 28, and 14 pounds, made in 1582, and 7, 4, 2, and 1 pounds made in 1588; a set of flat circular avoirdupois weights of 8, 4, 2, and 1 pounds, and 8, 4, 2, 1, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, and $\frac{1}{16}$ ounces, made in 1588; and a set of cup-shaped troy weights, fitting one within the other, of 256, 128, 64, 32, 16, 8, 4, 2, 1, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$ (hollow) and $\frac{1}{8}$ (solid) ounces, also made in 1588. All these standards were constructed by order of Queen Elizabeth, under the direction of a jury composed of eighteen merchants and eleven goldsmiths of London, the avoirdupois weights being adjusted according to an ancient standard of 56 pounds, remaining in the Exchequer from the time of Edward III.; and the troy weight being adjusted according to the ancient standard in Goldsmiths' Hall.

In view of the fact that the weight mentioned in all the old Acts of Parliament from the time of Edward I. (A.D. 1274–1307) is universally admitted to be troy weight, the Parliamentary Committee of 1758, appointed to inquire into the original standards of weights and measures in England, recommended that the troy pound should be made the unit or standard by which the avoirdupois and other weights should be regulated; and by their order three several troy pounds of soft gun-metal were very carefully adjusted under the direction of Mr. Joseph Harris, who was then Assay Master of the Mint. To ascertain the proper mass for these pounds, the Committee caused Messrs. Harris and Gregory, of the Mint, to perform the following operations in their presence:—

(1) In the before-mentioned set of troy weights, made in 1588, which were then the Exchequer standard, each weight, from that of 4 ounces up to that of 256 ounces was compared successively with the sum of all the smaller weights; and by a process for which no valid reason can be assigned, it was concluded from these weighings that the troy pound composed of the 8 and 4 ounce weights was $1\frac{1}{2}$ grains too light.

(2) The aforesaid 8 and 4 ounce weights of the Exchequer were compared with five other authoritative troy pounds, four of which belonged to the Mint and one to Mr. Freeman, who, like his father before him, was scale-maker to the Mint, and from the mean of these weighings it appeared that the sum of the Exchequer 8 and 4 ounce weights was 1 grain too light.

The Committee adopted the mean between the latter result and that which they had deduced from the Exchequer weights alone, and accordingly Mr. Harris made each of his three troy pounds $1\frac{1}{4}$ grains heavier than the sum of the Exchequer 8 and 4 ounce weights; but sixty-six years were destined to elapse before Parliament took action respecting them.

The Commissioners appointed in 1818 to establish a more uniform system of weights and measures repeated the recommendations of the Committee of 1758, and as the avoirdupois pound which had long been used, although not legalized by any Act of the Legislature, was very nearly 7000 troy grains, they recommended that 7000 such troy grains be declared to constitute a pound avoirdupois. These recommendations were embodied in the Act of Parliament of June 17, 1824, and thus one of the troy pounds made in 1758 became the Imperial standard. That standard, like Bird's standard yard, was deposited in the Houses of Parliament, and was burned up with them in October 1834.

The present English standard pound was made in 1844–46 by Prof. W. H. Miller, who was one of the members of the Commission appointed in 1843 to superintend the construction of the new Parliamentary standards of length and weight destined to replace those destroyed in 1834. A number of weights had been very accurately compared with the lost standard; namely, in 1824 or 1825, by Capt. Kater, 5 troy pounds of gun-metal, destined respectively for the use of the Exchequer, the Royal Mint, and the cities of London, Edinburgh, and Dublin; and in 1829, by Capt. von Nehus, two troy pounds of brass and one of platinum, all in the custody of Prof. Schumacher, and a platinum troy pound belonging to the Royal Society. The first step for recovering the mass of the lost standard was manifestly to compare these weights among themselves, and upon so doing it was found that for the brass and gun-metal weights the discrepancies between the weighings made in 1824 and 1844 amounted to 0·0226 of a grain, while for the two platinum weights the discrepancies between the weighings made in 1829 and 1845 was only 0·00019 of a grain. With a single exception, all the *new* brass or gun-metal weights had become heavier since their first comparison with the lost standard, the change being probably due to oxidation of their surfaces, and on that account the new standard was made to depend solely upon the two platinum weights. For convenience of reference these weights were designated respectively S*p* (Schumacher's platinum, and RS (Royal Society). A provisional platinum troy pound, T, intermediate in mass between S*p* and RS was next prepared, and from 286 comparisons made in January, February, July, and August, 1845, it was found that in a vacuum

$$T = Sp + 0·00105 \text{ grain},$$

while from 122 comparisons made in January, July, and August, 1845,

$$T = RS - 0{\cdot}00429 \text{ grain.}$$

By combining these values with the results of the weighings made in 1824–29—namely,

$$Sp = U - 0{\cdot}52956 \text{ grain,}$$
$$RS = U - 0{\cdot}52441 \text{ grain,}$$

where U designates the lost standard—the comparisons with S*p* gave

$$T = U - 0{\cdot}52851 \text{ grain,}$$

while those with RS gave

$$T = U - 0{\cdot}52870 \text{ grain.}$$

To the first of these expressions double weight was assigned, because the comparisons of T and U with S*p* were about twice as numerous as those with RS. The resulting mean was therefore

$$T = U - 0{\cdot}52857 \text{ grain} = 5759{\cdot}47143 \text{ grains,}$$

and from that value of T the new standard avoirdupois pound of 7000 grains was constructed.

From some time in the fifteenth century until the adoption of the metric system in August 1793, the system of weights employed in France was the *poids de marc*, having for its ultimate standard the *pile de Charlemagne*, which was then kept in the Mint, and is now deposited in the Conservatoire des Arts et Métiers. The table of this weight was

72 grains	= 1 gros	=	72	grains.
8 gros	= 1 once	=	576	,,
8 onces	= 1 marc	=	4608	,,
2 marcs	= 1 livre	=	9216	,,

The origin of the *pile de Charlemagne* is not certainly known, but it is thought to have been made by direction of King John (A.D. 1350–64). It consists of a set of brass cup-weights, fitting one within the other, and the whole weighing 50 marcs. The nominal and actual weights of the several pieces are as follows:—

	Marcs.		Grains.
Boîte de 20 marcs ...	20	+	1·4
Pièce de 14 ,, ...	14	+	4·5
,, de 8 ,, ...	8	–	0·4
,, de 4 ,, ...	4	–	2·1
,, de 2 ,, ...	2	–	1·0
,, de 1 ,, ...	1	–	0·7
Marc divisé	1	–	1·7
	50	±	0·0

In determining the relation of the *poids de marc* to the metric weights, the Committee for the Construction of the Kilogramme regarded the entire *pile de Charlemagne* as a standard of 50 marcs, and considered the individual pieces as subject to the corrections stated. On that basis they found

1 kilogramme = 18,827·15 French grains;[1]

and as a kilogramme is equal to 15,432·34874 English troy grains, we have

1 livre, poids de marc = 7554·22 troy grains.
= 489·505 grammes.

The metric standard of weight, called a kilogramme, was constructed under the direction of the French Academy of Sciences simultaneously with the metre, the work being done principally by Lefèvre-Gineau and Borda. It was intended that the kilogramme should have the same mass as a cubic decimetre of pure water at maximum density, and the experimental determination of that mass was made by finding the difference of weight in air and in water of a hollow brass cylinder whose exterior dimensions at a temperature of 17°·6 C. were: height = 2·437672 decimetres, diameter = 2·428368 decimetres, volume = 11·2900054 cubic decimetres. The difference of weight in question was first measured in terms of certain brass weights, by the aid of which the platinum kilogramme of the Archives was subsequently constructed, special care being taken to apply the corrections necessary to reduce all the weighings to what they would have been if made in a vacuum ("Base du Système Métrique," t. iii. pp. 574–75).

[1] "Base du Système Métrique," t. iii p. 638.

The best results hitherto obtained for the weight of a cubic decimetre of water, expressed in terms of the kilogramme of the Archives, are as follows[1]:—

Date.	Country.	Observer.	Weight of a cubic decimetre of water at 4° C.
			Grammes.
1795	France ...	Lefèvre-Gineau	1000·000
1797 } 1821 }	England ...	Shuckburgh and Kater	1000·480
1825	Sweden ...	Berzelius, Svanberg, and Akermann	1000·296
1830	Austria ...	Stampfer	999·653
1841	Russia ...	Kupffer	999·989
		Mean	1000·084

These results show the extreme difficulty of determining the exact mass of a given volume of water. The discordance between the different observers amounts to more than one part in a thousand, while good weighings are exact to one part in eight or ten millions. Without doubt two weights can be compared at least a thousand times more accurately than either of them can be reproduced by weighing a specified volume of water, and for that reason the kilogramme, like the English pound, can now be regarded only as an arbitrary standard of which copies must be taken by direct comparison. As already stated, the kilogramme is equivalent to 15,432·34874 English troy grains, or about 2 pounds 3 ounces avoirdupois.

In consequence of the circumstance that the mass of a body is not affected either by temperature or flexure, weighing is an easier process than measuring; but in order to obtain precise results many precautions are necessary. Imagine a balance with a block of wood tied to its right-hand pan and accurately counterpoised by lead weights in its left-hand pan. If, with things so arranged, the balance were immersed in water, the equilibrium would be instantly destroyed, and to restore it all the weights would have to be removed from the left-hand pan, and some of them would have to be placed in the right-hand pan to overcome the buoyancy of the wood. The atmosphere behaves precisely as the water does, and although its effect is minute enough to be neglected in ordinary business affairs, it must be taken into account when scientific accuracy is desired. To that end the weighing must either be made in a vacuum, or the difference of the buoyant effect of the air upon the substances in the two pans must be computed and allowed for. As very few vacuum balances exist, the latter method is usually employed. The data necessary for the computation are the latitude of the place where the weighing is made and its altitude above the sea-level; the weights, specific gravities, and coefficients of expansion of each of the substances in the two pans; the temperature of the air, its barometric pressure, and the pressure both of the aqueous vapour and of the carbonic anhydride contained in it.

Judging from the adjustment of the *pile de Charlemagne*, and the Exchequer troy weights of Queen Elizabeth, the accuracy attained in weighing gold and silver at the mints during the fourteenth, fifteenth, and sixteenth centuries must have been about 1 part in 10,000. The balance which Mr. Harris, of the London Mint, used in 1743 indicated one-eighth of a grain on a troy pound, or about one part in 50,000; while, according to Sir George Shuckburgh, the balance used by Messrs. Harris and Bird in making their observations upon the Exchequer weights, apparently in 1758 or 1759, turned with 1/230,000 part of its load. In 1798, Sir George Shuckburgh had a balance sensitive enough to indicate 0·01 of a grain when loaded with 16,000 grains, or about one part in 1,600,000. The balance used by Fortin in 1799, in adjusting the kilogramme of the Archives, was not quite so delicate, its sensitiveness being only the 1,000,000th part of its load; but in 1844, for the adjustment of the present English standard pound, Prof. Miller employed a balance whose index moved about 0·01 of an inch for a change of 0·002 of a grain in a load of 7000 grains. He read the index with a microscope, and found the probable error of a single comparison of two avoirdupois pounds to be 1/12,000,000 of either, or about 0·00058 of a grain. At the present time it is claimed that two

[1] This table has been deduced from the data given by Prof. Miller in Phil. Trans., 1856, p. 760.

avoirdupois pounds can be compared with an error not exceeding 0·0002 of a grain, and two kilogrammes with an error not exceeding 0·02 of a milligramme.

The mean solar day is the natural unit of time for the human race, and it is universally adopted among all civilized nations. Our ultimate standard of time is therefore the rotation of the earth upon its axis, and from that rotation we determine the errors of our clocks and watches by astronomical observations. For many purposes it suffices to make these observations upon the sun, but when the utmost precision is desired it is better to make them on the stars. Until the close of the seventeenth century, quadrants were employed for that purpose, and so late as 1680, Flamsteed, the first English Astronomer-Royal, thought himself fortunate when he succeeded in constructing one which enabled him to be sure of his observed times within three seconds.[1] About 1690, Roemer invented the transit instrument, which soon superseded the quadrant, and still remains the best appliance for determining time. Most of his observations were destroyed by a fire in 1728, but the few which have come down to us show that as early as 1706 he determined time with an accuracy which has not yet been very greatly surpassed. Probably the corrections found in the least square adjustment of extensive systems of longitude determinations afford the best criterion for estimating the accuracy of first-class modern time observations, and from them it appears that the error of such observations may rise as high as ± 0·05 of a second.

During the intervals between successive observations of the heavenly bodies we necessarily depend upon clocks and chronometers for our knowledge of the time, and very erroneous ideas are frequently entertained respecting the accuracy of their running. The subject is one upon which it is difficult to obtain exact information, but there are few time-pieces which will run for a week without varying more than three-quarters of a second from their predicted error. As the number of seconds in a week is 604,800, this amounts to saying that the best time-pieces can be trusted to measure a week within one part in 756,000. Nevertheless, clocks and chronometers are but adjuncts to our chief time-piece, which is the earth itself, and upon the constancy of its rotation depends the preservation of our present unit of time. Early in this century Laplace and Poisson were believed to have proved that the length of the sidereal day had not changed by so much as the 100th part of a second during the last 2500 years, but later investigations show that they were mistaken, and, so far as we can now see, the friction produced by the tides in the ocean must be steadily reducing the velocity with which the earth rotates about its axis. The change is too slow to become sensible within the lifetime of a human being, but its ultimate consequences will be most momentous.

Ages ago it was remarked that all things run in cycles, and there is enough truth in the saying to make it as applicable now as on the day it was uttered. The Babylonian or Chaldean system of weights and measures seems to be the original from which the Egyptian system was derived, and is probably the most ancient of which we have any knowledge. Its unit of length was the cubit, of which there were two varieties—the natural and the royal. The foot was two-thirds of the natural cubit. Respecting the earliest Chaldean and Egyptian system of weights, no very satisfactory information exists, but the best authorities agree that the weight of water contained in the measure of a cubic foot constituted the talent, or larger unit of weight, and that the sixtieth or fiftieth parts of the talent constituted, respectively, the Chaldean and Egyptian values of the mina, or lesser unit of commercial weight. Doubtless these weights varied considerably at different times and places, just as the modern pound has varied, but the relations stated are believed to have been the original ones. The ancient Chaldeans used not only the decimal system of notation, which is evidently the primitive one, but also a duodecimal system (as shown by the division of the year into twelve months, the equinoctial day and night each into twelve hours, the zodiac into twelve signs, &c.), and a sexagesimal system (by which the hour was divided into sixty minutes, the signs of the zodiac into thirty parts or degrees, and the circle into 360 degrees, with further sexagesimal subdivisions). The duodecimal and sexagesimal systems seem to have originated with the Chaldean astronomers, who, for some reason which is not now evident, preferred them to the decimal system, and by the weight of their scientific authority impressed them upon their system of weights and measures. Now observe how closely the scientific thought of to-day repeats the scientific thought of four thousand years ago. These old Chaldeans took from the human body what they regarded as a suitable unit of length, and for their unit of mass they adopted a cube of water bearing simple relations to their unit of length. Four thousand years later, when these simple relations had been forgotten and impaired, some of the most eminent men of science of the last century again undertook the task of constructing a system of weights and measures. With them the duodecimal and sexagesimal systems were out of favour, while the decimal system was highly fashionable, and for that reason they subdivided their units decimally, instead of duodecimally, sexagesimally, or by powers of two; but they reverted to the old Chaldean device for obtaining simple relations between their units of length and mass, and to that fact alone the French metric system owes its survival. Everyone now knows that the metre is not the 10,000,000th part of a quadrant of the earth's meridian; and in mathematical physics, where the numbers are all so complicated that they can only be dealt with by the aid of logarithms, and the constant π, an utterly irrational quantity, crops up in almost every integral, mere decimal subdivision of the units counts for very little. But in some departments of science, as, for example, chemistry, a simple relation between the unit of length (which determines volume), the unit of mass, and the unit of specific gravity, is of prime importance; and wherever that is the case the metric system will be used. To engineers such relations are of small moment, and consequently among English-speaking engineers the metric system is making no progress, while, on the other hand, the chemists have eagerly adopted it. As the English yard and pound are the direct descendants of the Chaldean-Babylonian natural cubit and mina, it is not surprising that the yard should be only 0·48 of an inch shorter than the double cubit, and the avoirdupois pound only 665 grains lighter than the Babylonian commercial mina; but, considering the origin of the metric system, it is rather curious that the metre is only 1·97 inches shorter than the Chaldean double royal cubit, and the kilogramme only 102 grains heavier than the Babylonian royal mina. Thus, without much exaggeration, we may regard the present English and French fundamental units of length and mass as representing respectively the commercial and royal units of length and mass of the Chaldeans of 4000 years ago.

Science tells us that the energy of the solar system is being slowly dissipated in the form of radiant heat; that ultimately the sun will grow dim; life will die out on the planets; one by one they will tumble into the expiring sun; and at last darkness and the bitter cold of the absolute zero will reign over all. In that far-distant future imagine some wandering human spirit to have penetrated to a part of space immeasurably beyond the range of our most powerful telescopes, and there, upon an orb where the mechanical arts flourish as they do here, let him be asked to reproduce the standards of length, mass, and time, with which we are now familiar. In the presence of such a demand the science of the seventeenth and eighteenth centuries would be powerless. The spin of the earth which measures our days and nights would be irretrievably gone; our yards, our metres, our pounds, our kilogrammes would have tumbled with the earth into the ruins of the sun, and become part of the *débris* of the solar system. Could they be recovered from the dead past and live again? The science of all previous ages mournfully answers, No; but with the science of the nineteenth century it is otherwise. The spectroscope has taught us that throughout the visible universe the constitution of matter is the same. Everywhere the rhythmic motions of the atoms are absolutely identical, and to them, and the light which they emit, our wandering spirit would turn for the recovery of the long-lost standards. By means of a diffraction grating and an accurate goniometer he could recover the yard from the wave-length of sodium light with an error not exceeding one or two thousandths of an inch. Water is everywhere, and with his newly recovered yard he could measure a cubic foot of it, and thus recover the standard of mass which we call a pound. The recovery of our standard of time would be more difficult; but even that could be accomplished with an error not exceeding half a minute in a day. One way would be to perform Michelson's modification of Foucault's experiment for determining the velocity of light. Another way would be to make a Siemens's mercury unit of electrical resistance, and then, either by the British Association method, or by Lord Rayleigh's modification of Lorenz's method, find the velocity which measures its resistance in absolute units. Still another way would be to find the ratio of the electro-static and electro-magnetic units of electricity. Thus all the units now

[1] Account of the Rev. John Flamsteed. By Francis Baily. Pp. 45-9 (London, 1835, 4to.)

used in transacting the world's business could be made to reappear, if not with scientific, at least with commercial accuracy, on the other side of an abyss of time and space before which the human mind shrinks back in dismay. The science of the eighteenth century sought to render itself immortal by basing its standard units upon the solid earth; but the science of the nineteenth century soars far beyond the solar system, and connects its units with the ultimate atoms which constitute the universe itself.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for July contains an article by Prof. H. A. Hazen on storms and a central-ascending current. The author discusses a few of the arguments for and against the theories of storm formation, viz. the theory of an ascensional current in the centre of a storm, and that of the increase of energy, through the liberation of latent heat and consequent production of a partial vacuum. Some of the conclusions arrived at are that the theories are exceedingly unsubstantial, and that, above all things, positive information of the processes going on in upper air strata is necessary; that the dependence of the generation of storms on temperature distribution in a vertical direction appears open to doubt; and that, reasoning from the behaviour of thunderstorms, it seems possible that some electrical action, not thoroughly understood, supplies the force which keeps up their energy.—Mr. A. L. Rotch contributes an article on the organization of the Meteorological Service in Holland. The Institute at Utrecht existed as a private establishment as early as 1849, and its Director, Dr. Buys Ballot, first stated publicly in 1857 the relation between wind and atmospheric pressure in the law which bears his name. Dr. Buys Ballot has for many years endeavoured to combine trustworthy observations all over the world with each other, and has published, in his "Year-book," detailed observations for various distant parts. Branch offices are established at Amsterdam and Rotterdam, and the collection of observations made at sea is actively carried on. At present the work bears upon the South Atlantic in connection with the Deutsche Seewarte, and, independently, upon the Indian Ocean.—Prof. C. F. Marvin continues the discussion between himself and Prof. Hazen as to the cause of differences obtained in anemometer experiments. Prof. Hazen attributes them to the influence of the natural wind blowing at the time, while Prof. Marvin thinks this of little importance and calculates its effect by a formula. He thinks that the momentum theory of the cups explains the discrepancies in a satisfactory manner.—Lieut. J. P. Finley contributes tornado statistics for the State of Iowa for fifty-two years ending 1888.

SOCIETIES AND ACADEMIES.

London.

Entomological Society, August 7.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Prof. C. V. Riley, of Washington, was elected an Honorary Fellow in place of the late Dr. Signoret, of Paris.—Mr. Walter F. Blandford exhibited a specimen of *Cardiophorus cinereus*, taken at Tenby, and remarked that the species had rarely, if ever previously, been found in the United Kingdom. Mr. C. O. Waterhouse said he believed that there was a specimen in the collection of his late father, and also another specimen in the collection of the British Museum.—Mr. Waterhouse stated that the British Museum had just received from the Rev. A. Elwin, of Hangchow, China, a luminous larva about 1½ inch long, and 3½ lines broad, which he believed to be one of the *Lampyridæ*.—Lord Walsingham exhibited specimens of *Conchylis degreyana*, McLach., bred from seed-heads of *Plantago lanceolata* at Merton, Norfolk; also a specimen of *Tineidæ* allied to the genus *Solenobia*, probably belonging to *Dissoctena*, Staud., but differing somewhat in the structure of the antennæ. He said that the specimen was taken by himself at Merton on July 31 last, and that the species was apparently undescribed.—Herr Meyer Darcis exhibited a collection of Coleoptera, comprising specimens of a species of *Locthrus* from Turkestan; *Julodis globithorax*, Stev., from the Caucasus; a new species of *Julodis* from Kurdistan; *Cardiaspis Mouhotii*, Saunders, from Sikkim; *Carabus smaragdinus*, Fisch., from Siberia; *Julodis ampliata*, Mars., from Aintab, Asia Minor; and *Julodis luteogramma*, Mars., from Syria, and a variety of the same from Kurdistan.—Mr. H. Goss read extracts from letters from Mr. R. W. Fereday, of New Zealand, and Sir John Hall, K.C.M.G., relating to a number of Lepidoptera recently collected at sea, about half-way between the River Plate and Rio, at a distance of over 250 miles from land, in about 30° S. lat. and 46° W. longitude. It was stated that the ship was surrounded by swarms of moths. Mr. J. J. Walker, R.N., observed that he had seen large numbers of insects at sea about 150 miles off the coast of Brazil, and he referred to other records of the capture of insects at sea in Darwin's "Voyage of the *Beagle*," and Dr. Carpenter's "Cruise of the *Alert*." The discussion was continued by Dr. Sharp, Lord Walsingham, Mr. White, and Mr. Kirby.—Mr. E. Meyrick read a paper entitled "On some Lepidoptera from New Guinea," and exhibited the species described in the paper. He stated that the specimens were derived from two sources, viz. (1) a portion of the collection received by the Society from Baron Ferdinand von Müller, F.R.S., and collected by Mr. Sayer when accompanying the Australian Geographical Society's Exploring Expedition; and (2) a number of specimens collected by Mr. Kowald near Port Moresby.—Mr. Blandford read a letter from Mr. Wroughton, of Poona, asking for assistance in working out certain Indian Hymenoptera and Diptera in the collections of the Bombay Natural History Society. Lord Walsingham, Colonel Swinhoe, and Mr. Moore made some remarks on the subject.

Paris.

Academy of Sciences, July 29.—M. Des Cloizeaux, President, in the chair.—On a means of studying the natural history of the river-eel after its migration from fresh to salt water, by M. Émile Blanchard. It was shown by the author many years ago that, during its sojourn in fresh-water lakes and rivers, the eel remains in an immature state, incapable of reproduction. With a view to completing its life-history, he now suggests that large numbers should be taken on their way seawards, labelled with a little metallic plate, and then returned to the water, in the hope that a few so marked may afterwards be captured at intervals in the sea, and thus enable zoologists to follow their complete evolution. To give effect to this project, he seeks the co-operation both of Government and naturalists.—On the variations of latitude in the solar spots, by M. R. Wolf. Attention is directed to pp. 84–91 of No. 73 of the *Astronomische Mittheilungen*, where the author infers, from his studies of solar physics, that the abrupt change of latitude noticed at the epoch of the minimum does not depend exclusively on the period of $11\frac{1}{9}$ years, but also on the longer period of $66\frac{2}{3}$ to $88\frac{1}{3}$ years. This longer period determines the altitude of the maxima, so that the extent of the change in latitude and the altitude of the ensuing maximum increase or diminish simultaneously. Hence the change of latitude recorded by Spoerer for the second half of the seventeenth century would not appear to have been anomalous, but merely the result of the low maxima reached at that time. — On the transmission of power by alternate currents, by M. Maurice Leblanc. But for the difficulties caused by the phenomena of self-induction, alternate currents might be advantageously employed for transmitting power, as they may easily receive the highest tensions, while they do not alter the insulators, as is the case with continuous currents. The author here describes an apparatus by means of which he hopes that these difficulties may be obviated.—On the conductibility of electrolytes at very high temperatures, by M. Lucien Poincaré. The methods employed by MM. Bouty and Poincaré in their experiments on the electric conductivity of salts in solution cannot be directly applied beyond the melting-point of glass. But, by various dispositions here detailed, M. Poincaré has been enabled to obtain measurements to within about one-fiftieth of absolute accuracy.—On a new method of volumetric analysis for silver, mercury, and thallium, by M. Adolphe Carnot. Chemists possess excellent processes for the volumetric analysis of silver, but very defective ones for that of mercury. M. Carnot here describes a new method, based on the use of potassium iodide, which is about equally applicable to both of these metals, as well as to thallium.—Researches on the sulphites, by M. P. J. Hartog. Despite the difficulty of its preparation, the author has succeeded in obtaining an anhydrous and crystallized sulphite of potassa in large quantities. By the same process, which is described in detail, he has also prepared the sulphite of soda in the same form, but not in a pure state, and the double normal sulphite of potassium and soda. The preparation of other sulphites will be described in a future communication.—Synthesis of some selenium compounds in the aromatic series, by M. C. Chabrié. The syntheses here undertaken are those in which the metalloid is united directly with the carbon of the cyclic nucleus. By making selenium tetrachloride act on benzine, M. Chabrié has obtained compounds corresponding to the sulphides and thiophenols prepared by Friedel and Crafts from sulphur and the chloride of sulphur.—On the oxidizing action of nitroso-camphor under the influence of light, by M. P. Cazeneuve. This substance, recently obtained by the author (*Comptes rendus*, cviii. p. 857), yields Liebermann's blue reaction with phenol and sulphuric acid, and also presents the curious phenomenon of becoming decomposed under the influence of light. The conditions seem somewhat analogous to those attending the formation of chlorophyll and of the colouring-matter in flowers.—On the isocamphols, by M. A. Haller. The paper deals more particularly with the influence of solvents on the rotatory power of the isocamphols.—Respiratory combustion by the nervous system in its relation to the size of the animal, by M. Charles Richet. A large number of experiments on dogs confirm, for animals of the same species, the law established by Regnault and Reiset for animals of different species—namely, that the respiratory combustions, by kilogramme of living weight, increase in inverse ratio to the size of the animal.—On the products of microbes favourable to the development of infections, by M. G. H. Roger. Amongst the substances secreted by Bacteria, some are known to produce intoxicating phenomena, while others possess vaccinating properties. M. Roger's researches lead to the inference that there are others that tend to stimulate the development of certain pathogenic agencies, at least in the case of symptomatic charbon.—On a new Mediterranean species of the genus Phoronis, by M. Louis Roule. This specimen was found in the Zoological Station at Cette, and has been named *Ph. sabatieri*, from the founder of that station. The characteristics of the species are here described by contrast with *Ph. hippocrepis*, Str. W.—On the growth of the oceanic sardine, by M. Georges Pouchet. Observers have failed to determine the region where the sardine is hatched and passes the first phases of its development. Those reaching the fishing-grounds are already several months old, and the observations made at several points present so many discrepancies that no general law can be laid down regarding their growth during the fishing season. The difficulty of determining this point is increased by the fact that the shoals themselves appear to be continually renewed by fresh arrivals throughout the whole season.

August 5.—M. Des Cloizeaux, President, in the chair.—Heat of combination of fluor with hydrogen, by MM. Berthelot and Moissan. After many failures, the authors have at last succeeded in measuring the heat of combination of these bodies. Reserving for a future communication the details of their experiments, they here give the broad results expressed in the formulas :—

$$H + F \text{ gas} = HF \text{ gas} \quad \ldots \quad + 37{\cdot}6 \text{ calories}$$
$$H + F = HF \text{ dissolved} \quad \ldots \quad + 49{\cdot}4 \quad ,,$$

—On the relations of atmospheric nitrogen with vegetable soil, by M. Th. Schlœsing. Continuing his researches on this subject with fresh samples of earth taken from various districts and under varying conditions, the author has still failed to discover any soil which being destitute of vegetable germs fixes gaseous nitrogen. Hence he concludes that if any exist they must be regarded as quite exceptional, and not to be depended on by agriculturists.—Observations of Davidson's comet (July 23) made at the Observatory of Algiers, by MM. Trépied, Sy, and Renaux. The observations cover the period from July 26 to July 30, when the nucleus of the comet was comparable to a star of the eighth magnitude.—A study of the electric phenomena produced by solar radiations, by M. Albert Nodon. Numerous observations made at the laboratories of the Sorbonne and the Collège de France show that on meeting an insulated metallic or carbon conductor the solar rays communicate to it a positive electric charge ; that the amplitude of this charge increases with the intensity of the rays, and decreases with the hygrometric state of the air, the phenomenon attaining its maximum value in Paris about 1 p.m. in summer, when the atmosphere is pure and dry ; lastly, that the effects cease during the transit of clouds across the face of the sun. If these results can be extended to non-metallic bodies, then solar radiation may be regarded as one of the causes of the electrization of the clouds.—Researches on the sulphites (continued), by M. P. J. Hartog. Here are studied the double normal sulphites of potassium and ammonium, and the bisulphite sulphite of sodium and potassium.—On the heat of combustion of some organic compounds, by M. J. Ossipoff. The bisubstituted succinic acids, presenting certain analogies with the fumaric and malic acids, are here studied thermochemically with a view to determining their heat of combustion.—A chemical and thermic study of the phenolsulphuric acids (continued), by M. S. Allain Le Canu. In the present paper the author confines his researches to orthophenolsulphuric acid, the preparation and properties of which are fully described.—On the distribution of Nemertes on some points of the French seaboard, by M. L. Joubin. A systematic exploration of the Roscoff and Banyuls districts has resulted in the discovery of nearly sixty species of Nemertes in those two localities alone. About ten of these have not yet been described, and will form the subject of a future memoir.—On the mechanism of the photodermatic and photogenic functions in the siphon of *Pholas dactylus*, by M. Raphael Dubois. Although these mollusks possess no eyes, they display extreme sensibility to light, the least change of its intensity sufficing to excite a more or less sudden contraction of the siphon. M. Dubois's already described graphic process has enabled him to verify the existence of two distinct functions, one receptive, the other emissive, thus showing that the mechanism of sight belongs to the category of tactile phenomena in the higher animals gradually differentiated and localized in a special organ. It also appears that the photodermatic (receptive) function is stimulated by luminous vibrations from without, while the photogenic (emissive) has for its final outcome the emission of luminous rays through the circumambient medium.—On some habits of the sea trout, by M. A. Giard. The author's observations in the Wimereux estuary and neighbouring waters, tend to show that many smelts and grilses, and even a number of adults (bull-trout ?), pass a much longer time in the sea than is generally supposed by ichthyologists.—On the colouring matter of the spermoderm in the Angiosperms, by M. Louis Claudel. The results are here given of a series of studies on the pigments of grains made in the botanical laboratory, Marseilles. It appears generally that the solid pigments of grains are scarcely ever presented under the form of leucite, and that they derive directly from the protoplasm. In this respect they differ from the pigments of flowers and pericarps which, according to Flahault and others, derive from pre-existing leucites.—On the recent eruption of the island of Vulcano (Lipari Group), by M. O. Silvestri. The volcanic phenomena presented by the eruption, which began on August 2, 1888, are characteristic of a special phase, which has already been observed by M. Silvestri at Etna, and to which he proposes to give the name of *Vulcanian phase*.

THURSDAY, AUGUST 22, 1889.

AFRICAN FARM PESTS.

Notes and Descriptions of a Few Injurious Farm and Fruit Insects of South Africa. Compiled by Eleanor A. Ormerod, F.R.Met.Soc., &c. (London: Simpkin, Marshall, and Co., 1889.)

MISS ORMEROD is indeed energetic. Not content with waging bitter war against the destructive pests of British crops, she extends her campaigns to far distant lands. Although applications of farmers for information as to the attacks of many injurious insects arrive incessantly from all parts of the United Kingdom, Miss Ormerod finds time to deal with the complaints of cultivators in all other parts of the world, and surveys insects from China to Peru. In 1887 an elaborate treatise upon a scale-insect (*Icerya purchasi*) which seriously injures vines, fig, orange, peach, and other trees and shrubs in Australia, was published by Miss Ormerod, giving full scientific details as to the life-history of this coccid, and as to methods of prevention and remedies likely to be beneficial. Just recently another work has appeared, entitled "Observations on some Injurious Insects of South Africa," written in Miss Ormerod's usual clear and interesting style, and admirably illustrated. From this we propose to take some extracts to show the cosmopolitan entomological knowledge of the authoress, as well as to give some idea of the enemies of cultivated plants in "Afric's golden sands."

The first reflection that arises from the perusal of this book, and of others descriptive of the usual plagues which follow in the wake of civilized cultivation, is that no clime nor culture under the sun is exempt from them. No sooner had orange groves been formed in the suitable lands of Florida than various scale-insects swarmed upon the trees. The purple scale, the white scale, the red scale, and the "chaff" scale, among others, threatened to ruin the crops and to kill the trees, until remedies were discovered by the skilful economic entomologists of the United States.

In the newly made tea plantations of Assam a red spider (*Tetranychus bioculatus*) has suddenly shown itself, and threatens serious mischief to the plants, unless some wash can be invented which will kill the spiders, and leave no taste in the tea-leaves.

So in Africa, scale-insects, especially the *Icerya purchasi*, have within the last few years, as shown by Miss Ormerod, extensively spread in Cape Colony, upon oranges, lemons, vines, and other kinds of fruit-trees. This scale-insect has also now become one of the most dangerous pests infesting fruit-trees in California. It is the opinion of Prof. Riley, the United States Entomologist, that the *Icerya purchasi* originated in Australia. There was some doubt at first as to this. It was thought that it came from Mauritius; but it was discovered that it was the species known as *Icerya sacchari* which was imported from thence upon sugar-canes to California.

Frequent and rapid communication between countries, and the general interchange of commodities of all kinds, have undoubtedly disseminated insects throughout the world. Thus the Hessian fly was brought from the United States with straw in packing-cases, and the flour moth (*Ephestia kuhniella*), has been recently imported into England from some European country, as the authorities conclude.

At the same time it is considered that the conditions of cultivation adopted in these days, being somewhat of a forcing and unnatural nature, favour the increase of insects, and, in a degree, predispose plants to their attacks, which become more varied and intensified year by year not only in this country but in all others. It is of the greatest importance, therefore, that cultivators should be advised by competent persons as to the life-histories of these crop destroyers, and as to measures to be taken to prevent their spread, and remedies to be used against them.

Miss Ormerod has arisen, a very *Dea ex machinâ*, and for several years has given timely instruction and advice to agriculturists of many nations, just as Professors Riley, Lintner, and Comstock have helped the tillers of land in the United States to detect and combat the onslaughts of many crop-destroyers. Prof. Lindeman is doing the same good work in Russia, Dr. de Man in the Netherlands, Dr. Taschenberg in Germany.

And in this her latest work, "Notes and Descriptions of Injurious Farm and Fruit Insects of South Africa," Miss Ormerod conveys much practical information which can be readily understood and easily utilized. At the same time it is scientific enough for entomologists, and interesting to those who are not cultivators or men of science.

Miss Ormerod explains her reasons as follows for publishing this account of African farm pests, though no explanation appears necessary for such a valuable service:—

"About four years ago, Mr. J. D. Bristow, President of the East Province Natural History Society of Cape Colony, wrote to inquire whether, if I were furnished with notes regarding pests of the crops in East Province, Cape Colony, I would publish them. At that time there was not the opportunity which there now is of procuring sound and clear directions for treatment of insect as well as other attacks of crops and stock, by reference to the *Agricultural Journal*, published by the Department of Agriculture of Cape Colony, therefore I willingly agreed to do my best, in case trustworthy agricultural observations could be procured, and specimens of the insects referred to also sent for identification. Specimens of about fifty kinds of insects were sent over, of which a few proved to be of undescribed species; and I have given in the following pages, as far as I can, figures and observations of habits and means of prevention of some of the pests, and means by which they might be identified."

The first insect described is one of the well-known dangerous family *Melolonthidæ*, to which the familiar British cockchafer belongs. The scientific name is *Eriesthis stigmatica*, but it is commonly termed the "mealie," or maize, chafer, as it is the worst pest in the country for crops of maize, and destroys it from near Fort Beaufort right down to the Fish River mouth. This is very much smaller than the cockchafer, and smaller, too, than the rose chafer (*Cetonia aurata*), which is, however, of a different family.

Another chafer, *Hypopholis sommeri*, injures vines considerably, probably by devouring the leaves, in the perfect state, and feeding on the roots, in the larval state. It is

S

much larger than the "mealie," of a red-brown colour, and, "judging from the number of specimens usually contained in collections received from South Africa, this would appear to be a very common species in that country."

It is desirable to destroy the insects belonging to this family both in their beetle and larval conditions. In the former case they may be shaken down from the trees and shrubs upon which they rest in a sluggish state during the day. The larvæ can be reduced in numbers by digging round the roots of the infested plants. "In Ceylon," Miss Ormerod remarks, "where the grubs of various kinds of chafers do much harm to coffee-plant roots, it is noted that on one estate a gang of coolies was employed to dig them out of the ground (for they are always near the surface at the end of the feeding rootlets), which they did at the rate of about a quarter of a bushel per man per day. Lime, salt, and carbolic acid were tried without effect, I believe."

Some species of Melolonthidæ, especially the common cockchafer (*Melolontha vulgaris*), are so destructive to trees, vines, and other plants in France, that the French Minister of Agriculture has recently issued orders to the various prefects to take steps to reduce their numbers.

A beetle of the family *Dynastidæ*, styled *Heteronychus arator*, and the "keever" by the farmers, is the most widespread and destructive of the African pests, according to a correspondent, being a subterraneous worker, attacking wheat by eating away the roots. In length of body it is from 12 to 15 millimetres, and resembles the British beetle *Aphodius fossor*, belonging, however, to a quite distinct family, of which no member occurs in Britain.

They are rarely seen above ground, biting off the wheat plants about an inch under ground. It will be plain to all practical persons that this insect must be a very difficult foe to deal with, as it comes out of the ground and flies about trees during the night, and retires to the wheat roots during the day. Miss Ormerod states that it is also found in St. Helena, and it is more particularly to be met with along the sides of roads near hay-fields and grass-lands, where it may often be seen dead in considerable numbers, "which points to this 'keever' beetle being a grass as well as a corn pest, and may give some clue as to where to look for their grubs, as in common course of things beetles die just after having laid their eggs." It is recommended to dress wheat plants thus attacked with paraffin and sand, or ashes, or dry earth, to prevent the attack of this beetle.

Two other beetles, the *Pentodon nireus* and *Pentodon contractus*, injure the wheat crops. They are larger than the *Heteronychus arator*, but are similar in their method of attack. Neither of these appears to have any common or local name.

Yet another beetle, belonging to the family of *Cetoniidæ*, in which the British rose chafer is grouped, and defined as *Rhabdotis semipunctata*, a pretty insect with a bright green upper surface marked with white lines and spots, causes much injury to the blossoms of apple and plum trees, and later on to ripening peaches and figs. In some parts it is so plentiful that the only peaches and figs saved were those tied up in muslin bags. Miss Ormerod suggests that the only measures against this insect are to catch the beetles in nets when flying in the sunshine, as is done in England, and destroying their grubs at the roots of trees and plants.

Among other Coleoptera figured are the *Mylabris oculata*, a large, handsome black beetle, with red or yellow bands, of the family *Cantharidæ*, possessing the same vesicating properties, and sadly troublesome to peas and beans and fruit blossoms. Also a *Bruchus*, an unknown species, but which Miss Ormerod conjectures may be *subarmatus*, Gyllenhal. "Of the British *Bruchi* this species is most nearly allied to *Bruchus loti*." From Miss Ormerod's careful account of its larva, it does not much differ from that of *Bruchus pisi*.

This species of *Bruchus* infests peas and beans just in the same manner as the British *Bruchus rufimanus*.

> "Its attack is seriously hurtful. In two of the beans figured above, I found four holes showing where the beetles had escaped; in another seven beetles had been present, and in another I found five beetles, or coloured chrysalids, still within. Mr. Bairstow reported that this pest when in larval condition reduces the interior of the seed to a fine powder, and passes into a pupa, sometimes in its powdery bed, which disappears almost immediately on the emergence of the perfect insect."

Miss Ormerod gives an elaborate account of the modes of attack of this *Bruchus*, which do not much differ from those of its British congener. Also, it is recommended that infested beans should be steeped in a solution of Calvert's carbolic acid, so diluted as not to damage the seed.

Among the destructive Lepidoptera, butterflies and moths, in South Africa, the large handsome *Papilio demoleus*, or orange butterfly, figures prominently. The larvæ of this insect eat the leaves of orange trees, appearing "generally at the end of November, or beginning of December, and in greater numbers on trees whose lower branches are allowed to trail on the ground. It is advisable to cut all branches one foot above the ground, to turn as often as possible the soil within a circle of one foot from the trunk, keeping it moist, and to watch for the grubs, which are large, and of a yellowish-green colour, during the summer season."

The caterpillars of a moth, *Trilocha ficicola*, belonging to the *Bombycidæ*, cause much damage to fig trees by eating their leaves and nascent buds. For this attack, hand-picking is advised, and turning over the soil beneath the trees where the cocoons may be.

The "diamond-back" moth (*Plutella cruciferarum*), so well known in Britain, is a source of much trouble to Cape cabbage-growers, for which Miss Ormerod prescribes nitrate of soda applications to push on the growth of the plants, and sweeping the infested plants with boughs fixed to a scuffler.

To fruit-growers, the orange fly "Trypeta" (*Ceratitis citriperda*) is a bitter enemy. "In some districts last year," Mr. Hellier writes, "Albany amongst the rest, four-fifths of our peaches, apricots, figs, and plums were uneatable." The fly deposits some half-a-dozen eggs in a fruit when it is getting ripe. From these maggots come, and soon render the fruit useless. Concerning its life-history, Miss Ormerod quotes Prof. Westwood's remarks, from which extracts will be received with much interest by all economic entomologists.

"The perfect insect is one of the most beautiful of the order to which it belongs; the male is singularly distinguished by having two slender filaments arising between the eyes, knobbed at the tips, a peculiarity which we believe is possessed by no other dipterous insect, and which is wanting in the female. The larva is a white, fleshy grub destitute of legs, very similar to the celery fly, and like it possesses two small black hooks at the front of its body, which it alternately protrudes and retracts, thereby tearing the delicate membrane in which the drops of juice are contained. There are generally several of these larvæ in each orange, and when removed and placed upon a flat surface, they have the power of springing to a considerable distance, in the same manner as the well-known cheese-mite. When full-grown they eat their way out of the orange, and undergo the change to the pupa state on the outside."

Prof. Westwood adds that the presence of infestation might be inferred sometimes by a puncture not larger than that made by a pin, but generally surrounded with a withered and discoloured spot varying in size from sixpence to half-a-crown.

Miss Ormerod characteristically observes:—

"One main point of information wanted to check attack is, Where does the maggot in natural circumstances undergo its changes to the chrysalis state? It might be found out very easily whether the maggots drop to the ground, by laying cloths smeared with any sticky material, which would prevent their straying away, beneath a few of the infested trees. Any fruit that is infested should not be allowed to remain on the ground to continue the attack, and if on investigation it should prove that the later maggots go into the chrysalis state in the ground, or even that a large proportion of them do so—or if it could be found where the flies generally hibernate—these points would help greatly in lessening attack."

Ostrich-farming, extensively adopted in South Africa, is much hindered by "a terrible pest," in the shape of the ostrich flies, of which sometimes there are "thousands on the ostriches, and that they irritated the birds so that half of their time was taken up in pecking at the flies, and that, judging from the increase in the last two years, if something was not done to destroy them, the feathers would not be worth sending to market, and the writer believed that in time they would destroy the birds."

The fly in question is akin to the "forest fly" (*Hippobosca equinæ*), which is found upon horses and ponies in the New Forest, in Hants. These get accustomed to the flies, and make no special demonstrations concerning them; but a horse which is strange to their attacks goes half mad when one of these insects gets upon it.

In the case of ostriches, Miss Ormerod considers tobacco decoctions, soapsuds, and other washes applied to the birds would be found to succeed. McDougall's dip has been used, and Miss Ormerod thinks that sulphur would be useful.

Cattle ticks (*Amblyomma hebræum*), of the family *Ixodidæ*, some of them three-quarters of an inch long by three-eighths wide, described as the "disastrous hide perforators of these regions," sadly vex the South African cattle, so that it would indeed be a boon to the country if any means could be discovered to destroy, or, what would be better, "prevent the presence of a little creature which moves a market downwards at a high percentage."

The most interesting part, perhaps, of this work is that which deals with some of the *Coccidæ*. First among these is the "Australian bug" (*Icerya purchasi*), which was noticed in the Botanic Garden at Cape Town in the latter half of 1873, and has now spread over 680 miles in the eastern provinces of Cape Colony. Where it came from, Miss Ormerod says, it does not appear, "but there is not room for doubt that the attack was set on foot by imported specimens, and that it rapidly became naturalized. It attacks" orange trees, vines, fig trees, deciduous fruit-trees, ornamental shrubs, and garden plants, even strawberry plants.

The life-history of this insect is remarkable. When the female, a salmon-coloured, tortoise-shaped insect, with six legs and long antennæ, is one-sixth of an inch long, it secretes snow-white cotton-like matter, which is formed under the mother for the covering and protection of its eggs. For some time the female moves about, but after a while all movement is arrested, and the insect seems glued to one spot. In time the eggs are hatched, and larvæ, as many as 200 often from one female, go forth to find congenial food upon the plant, and in turn lay eggs in the same manner. The eggs are not hatched at once, but the process continues for several weeks. In the meantime the mother shrivels up, and becomes a mere dead husk, covering the eggs and hatching young. The whole process extends over many weeks, and gives ample opportunity for immense damage to be caused.

The male is rarely seen. It has wings more than a fourth of an inch in expanse; its body is about the eighth of an inch long, orange-red in colour, with long ten-jointed antennæ. Prof. Riley gives the best account of the male insect, stating that it is "fond of shelter, and will get under any projecting piece of bark or under bandage placed round the tree, often creeping under clods of earth. It is rather sluggish during the day, remaining motionless in crevices of the bark or wedged in between females on the tree. There seems, in fact, a well-marked attempt at concealment. At the approach of night they dart rapidly about on the wing, swarming round infected trees."

Miss Ormerod prescribes various washes as remedies against this and other coccids, and gives a list of insect enemies, which are happily numerous and formidable. The larva of the "golden eye" (*Chrysopa perla*) is most useful, destroying the young "Australian bug" just at hatching-time within the sac of the female. The Chrysopa also devours quantities of Aphides which infest hop plants in England. Species of ladybirds (*Coccinellæ*) are by far the best friends to African cultivators. They are invaluable in destroying the perfected young in the nidus of the female "bug," just as they, both as larvæ (niggers) and perfect insects, eat myriads of hop Aphides in the English plantations.

There are other insects which do good service in keeping down this *Icerya*, described by Miss Ormerod, of which, however, there is not space to give any account. Other destructive and useful insects have not been alluded to for the same reason, but those who take an interest in economic entomology will do well to peruse this instructive little book, and extract for themselves its valuable contents.

THE FOREST FLORA OF NEW ZEALAND.

The Forest Flora of New Zealand. By T. Kirk, F.G.S., late Chief Conservator of State Forests to the Government of New Zealand, &c. Folio, 345 pages and 160 plates. (Wellington: By authority; George Didsbury, Government Printer, 1889.)

MR. EDWARD BARTLEY states[1] that only four kinds of New Zealand timber are used in Auckland for building purposes, and that these are: kauri (*Dammara australis*), rimu (*Dacrydium cupressinum*), totara (*Podocarpus totara*), and kahikatea (*Podocarpus dacrydioides*); but Mr. Kirk's "Forest Flora" goes far beyond the timber-yielding element of the New Zealand forests. It illustrates and describes nearly the whole of the shrubby and arboreous plants of New Zealand, and gives very full particulars of their dimensions, qualities, uses, distribution, and propagation. It is by no means a mere compilation; and, although the author acknowledges various sources of information, a slight examination of the work is sufficient to convince us that it is very largely based upon personal observation, and that the details are elaborated with great care.

Altogether the flora of New Zealand contains rather less than a thousand species of flowering plants, and of these 115 are illustrated in the present work; some of the more important and specially interesting species by several plates. The tree ferns, which form so conspicuous a feature in the vegetation of the country, are not included, and some shrubby plants are omitted whose claims to notice are at least equally as strong as some of those admitted; but this is explained by the author's desire to do the work thoroughly as far as he went. For this reason, several of the small shrubby Coniferæ are figured, and a considerable number of plates are devoted to the illustration of the heterophyllous members of various natural orders.

Heterophylly is not a peculiar feature of insular floras, though it is perhaps nowhere more conspicuously developed than it is in New Zealand and Rodriguez.[2] Many of the New Zealand Coniferæ, the most valuable of the timber-trees, exhibit this peculiarity in a high degree, insomuch that different parts of the same tree have been referred to different species and even to different genera. Thus different parts of *Dacrydium Colensoi* might represent a juniper and a cypress, while in *D. Kirkii* there is a still more remarkable dimorphism. In explanation of Plate 97, Mr. Kirk writes:—

"As in the preceding species (*D. Colensoi*), the foliage is of two kinds, but the difference is of a still more striking character. The lower branches are spreading, the upper ascending or erect, the ultimate branchlets forming fan-shaped masses. The lower branches, sometimes to the height of 40 feet, are clothed with long narrow flat leaves; the upper branches are clothed with small scale-like, closely appressed leaves; so that the lower part of the tree resembles a silver-fir, while the upper part puts on the appearance of a cypress."

Figures are given of the dimorphic foliage of these conifers, and the confusion in nomenclature which has arisen in consequence of one kind only having often been taken by collectors is unravelled. It should be added that it is only the cypress-like branches that bear flowers and fruit.

In these New Zealand Coniferæ the foliage is dimorphic, but in several plants belonging to other natural orders it is polymorphic. Noteworthy among these are several members of the Araliaceæ, also *Rubus australis* and *Hoheria populnea*, of the order Malvaceæ. Mr. Kirk has very fully illustrated some of these remarkable plants, devoting five plates to the last-named, and as many to *Pseudopanax crassifolium* (Araliaceæ), a plant not unknown in cultivation in this country. The earliest leaves following the cotyledons of this *Panax* are small, narrow, and sharp-pointed, with entire margins; "but the leaves next produced are very different: they are distinctly stalked, 1 to 2 inches in length, rhomboid or elongate rhomboid in shape, and sharply toothed or deeply lobed, bearing some resemblance to those of the common hawthorn. Succeeding leaves are longer and of uniform width, until they sometimes attain the length of 3 feet 6 inches, while they scarcely exceed half an inch in width and are invariably deflexed. In this stage the leaves are thick and leathery in texture and acute at the apex, with distant sharp marginal teeth." This is the form in cultivation in this country, sometimes called the fish-bone tree, which Sir Joseph Hooker named *Panax longissimum*, as it had retained its peculiar character unchanged for fifteen years; though subsequent investigation proved that it was no other than *P. crassifolium*. In this stage of development the stem is invariably unbranched, and rises to a height of 20 feet; and, as it often retains its leaves almost to the base, it presents a very remarkable appearance. Following these long, narrow, undivided leaves, come others composed of three to five separate leaflets, and borne on petioles from 1 to 5 inches in length. The leaflets are less stiff than the long leaves, narrower, and having sharply-toothed margins. These are succeeded by similar leaves on longer petioles, having broader leaflets, thicker in texture, with coarser, more distant teeth. Flowers are sometimes produced at this stage, but not unless the stem has given off lateral branches. In the usual flowering stage the leaves have again become simple, and they gradually become thicker, the toothing almost wholly disappears, and they are from 4 to 6 inches in length, and borne on short stout petioles. To add to the perplexities of the plant, the male and female flowers are borne on different individuals. It is not surprising, therefore, that botanists working with herbarium specimens only have failed to limit or define the species correctly. As already stated, many other New Zealand plants are remarkable for the great variability of their leaves at different stages of development, and the kind of variation is as diverse as the extent of it.

There are so many other interesting subjects in Mr. Kirk's book that one is at a loss which to select for notice. Specially noteworthy is the presence in New Zealand of three species of *Fuchsia*, a genus otherwise restricted to America; and remarkable among these is *F. excorticata*, which sometimes attains a height of 45 feet, with a gnarled trunk up to 3 feet in diameter. The Central American *F. arborescens* is the only species that equals or approaches it in dimensions. *F. excorticata* has

[1] "The Building Timbers of New Zealand," Transactions and Proceedings of the New Zealand Institute, xviii. p. 37.

[2] For particulars of the latter, see Dr. Bayley Balfour's account of the botany of the island in the Philosophical Transactions of the Royal Society of London, vol. clxviii., 1879.

medium-size flowers, at first of a greenish colour streaked or blotched with purple, and finally of a dull red, with very small, almost black petals. The tube of the calyx is very much constricted immediately above the ovary, and there is a second constriction a little higher up. Moreover, the flowers are trimorphic in the relative lengths of the style and stamens. That this *Fuchsia* yields "one of the strongest and most durable timbers in the colony" will be news to most people. But, as the trunk is often crooked or gnarled, it is difficult to procure logs exceeding 8 or 9 feet in length, and its commercial value is therefore greatly diminished. Mr. Kirk says the wood is hard, dense, compact, and even, and deep brown in colour, relieved by streaks of a paler shade, and short narrow waved black markings. When much waved, it is of a highly ornamental character. Further, it is almost indestructible even by fire, except in a closed furnace.

Many more interesting facts might be extracted from this admirable book, the botany of which appears to be equally as good as the practical part. A few new species are described, and the female flower of *Podocarpus totara* and the male catkin of *Dacrydium cupressinum* are figured and described for the first time.

One more point deserves mentioning. Mr. Kirk is very much concerned about the many inappropriate popular colonial names, which he proposes to reform; but we think he has undertaken a task in which he must inevitably fail. From the time of the earliest settlements, the various species of native beech (*Fagus*) have been called red birch, white birch, &c., though not uniformly throughout the colony; and the Maori language has only one common name for all the species. Now, Mr. Kirk proposes calling them "entire-leaved beech," "tooth-leaved beech," and so on. Supposing it were possible to effect a reform in this direction, the substitution of such uncouth names as those proposed is less to be desired than the retention of their present botanically inaccurate appellations.

W. Botting Hemsley.

AN ELEMENTARY TEXT-BOOK OF CHEMISTRY.

An Elementary Text-book of Chemistry. By William G. Mixter. Second and Revised Edition. (London: Macmillan and Co., 1889.)

THIS volume belongs to the well-known series of "Manuals for Students," and will pleasantly surprise those who imagine that the multitude of elementary text-books of chemistry has made originality impossible. Of those smaller matters that readers and students generally accept with no more thought than their daily mercies, the index deserves especial mention as being exceptionally inclusive, and bearing evident signs of having been compiled by someone who had a sufficient knowledge of the subject to go beyond the mere verbiage, and enough patience to carry the task through.

Looking at the book simply as a treatise on chemistry, the adoption of the periodic system as a method of classification is very desirable, but the difficulty as to which of its elements a compound shall be associated with is not easily settled. The tendency is doubtless to keep the compounds of any one metal together, and this is what the author has done as far as possible, but as, for example, nine metals are treated of before oxygen and sulphur, and thirty-eight metals before carbon, the compounds of those metals that are considered in the earlier pages are spread through the book in a manner that is doubly confusing, the interpolated sections seriously interfering with the general arrangement. The sulphates of sodium, for instance, cannot be considered with sodium itself before sulphur has been mentioned, nor can they be added to sulphuric acid, as that would disturb the natural sequence of sulphur, selenium, and tellurium compounds, and the best place remaining for them is in the middle of one of the groups of elements. As a natural result of this apparently unavoidable irregularity, such a common salt as manganese sulphate finds no place at all, and it cannot be supposed that it is intentionally omitted when manganese tetrafluoride, hydrogen auryl sulphate, gold sulphate, and other equally rare compounds have considerable space allotted to them.

There is another marked innovation that certainly deserves success—namely, the introduction of gravimetrical quantitative experiments. The very first experiment in the division of the book headed "Chemistry" is the preparation of hydrogen by the action of sodium upon water, and the student is directed, after weighing the sodium and measuring the gas, to calculate the relative weights of the two, making all due corrections. In the next experiment the proportion between the weights of equivalent amounts of zinc and hydrogen is determined.

If the volume before us were simply an experiment in text-books, we might leave off here by congratulating the author on the measure of success that he has realized; but his first words in the preface are, "This work is designed for use in schools and colleges." The tendency at the present time is not merely to introduce the study of chemistry, but to extend the general scope of education in many other ways, so that the time devoted to chemistry has been very much reduced in some cases to allow of the addition of other subjects to the student's carriculum. It would be difficult to find a student who would have time to work through 238 experiments in elementary chemistry, especially when many of them are in reality a combination of three or four; and besides the specific experiments enumerated there are suggestions in the text that the student should prepare certain compounds and verify their properties. We do not hesitate to say that the intelligent performance of a fifth of the number of experiments set down to be done, accompanied with suitable study, would give the student as serviceable a knowledge of the subject as if he went through the mass of practical work prescribed.

The author also says in his preface that "Graphic and constitutional formulas are much used," and the body of the book fully bears out the statement. Graphic formulæ have been perseveringly tried in this country as an aid to the elementary student of inorganic chemistry, and have been deliberately discarded as uselessly cumbrous, and as making what is difficult to the beginner more difficult still. Such formulæ, however, are occasionally useful; but we would ask what good end is served by setting down the graphic formula of $Na_4W_3O_{11}$, which is given at p. 190? The best formula is that which most simply expresses the properties of a compound, but it would be difficult to say what properties are indicated by such formulæ as that referred to.

There are a few statements on important subjects that at the present time concern no one but the historian. For example, the classification of salts as normal, acid, or basic, according to the proportion between "the bonds of the acid radical" and "the bonds of the basic radical," was never generally accepted, and is now universally allowed to be an altogether faulty method. The extraordinary prominence given to hydrogen dioxide or "free hydroxyl," which has four pages devoted to it, while sulphuric acid has little more than two, is scarcely justifiable, we think, at the present time. But on the whole, the book is a useful compendium of the principal properties of not only the more important substances but also of many of the compounds of the rarer elements.

OUR BOOK SHELF.

A Treatise on Geometrical Conics. By A. Cockshott and Rev. F. B. Walters. (London: Macmillan and Co., 1889.)

THIS work is not intended to supersede such works as Besant and Taylor, which, being drawn up for University students, naturally cover a good extent of ground, but to meet what is a pressing need in school teaching. The need of some recognized sequence of propositions, as our authors state, has long been admitted. It was with a view to meet this need, as we have previously stated in this journal, that the Association for the Improvement of Geometrical Teaching published its syllabus of the subject, which had been accepted by the Association at its annual meeting in January 1884. The work before us has been drawn up in accordance with the syllabus, the authors' aim being to invest the skeleton of the syllabus with suitable raiment. A main feature of the outline was the prominence given to Adams's property (which boys will call Adam's property), the S U K I (now changed rightly, as O is used for the external point, to the S U O I) proposition. In the parabola, we are told we may employ the property in proving tangential propositions; in the case of the ellipse and hyperbola, the authors use Adams's, and also give two other constructions. But this is a matter of detail. The proofs are neat and well suited to beginners. A capital feature is the appending quite elementary riders to the respective propositions, these not being too difficult; and in most cases, being true riders on the propositions they follow, they will encourage the young student to prosecute a study which becomes very fascinating when once the student gets a grasp of it. A short chapter on orthogonal projection follows that on the parabola, and is likely to be of use as showing the intimate connection which exists between the circle and the ellipse. A large collection of Cambridge problems, duly labelled, closes the work.

We have waited long for this quasi-authorized edition of the Association's syllabus, "thereby hangs a tale," and now it has reached us we are not disappointed. There are very numerous figures, many of which are excellent, but others are like Pharaoh's lean kine, "very ill-favoured."

Phormium tenax as a Fibrous Plant. Edited by Sir James Hector, K.C.M.G., M.D., F.R.S., &c. With Plates. Second Edition. (Wellington, New Zealand: By authority, George Didsbury, Government Printer, 1889.)

THE original edition of this little hand-book appeared in 1872, since which period a great deal of consideration has been given in this country to the further development of vegetable fibres generally, amongst which New Zealand flax or hemp has had its share. The book has such a varied amount of authentic information on the subject with which it treats that the appearance of a new edition is a distinct gain to those—and they are many—who are occupied at present in the investigation of vegetable fibres.

The description of the *Phormium tenax*, its habit and rate of growth, cultivation, transplanting, and propagation, with an account of the native and European methods of preparing the fibre, are all brought together here in a compact form. The reports, prepared in New Zealand by Messrs. Skey, Nottidge, and Hutton, together with those of Profs. W. R. MacNab and A. H. Church, prepared in this country, are also very valuable. These latter appear in full in the new edition, and the former are in some particulars more detailed. The book is, however, almost a reprint of that which appeared in 1872, in some cases even to the reproduction of errors; thus on p. 2 of both the old and new editions the Raupo, *Typha angustifolia*, is printed *Typhus*.

The most interesting part, at the present time, of Sir James Hector's new issue is, in consequence of its being the newest matter, the preface, from which we learn that during the last two years the demand for *Phormium* fibre has been steadily on the increase, and that one important application is for the production of twine for use in the harvesting machine, it having been found that as a substitute for wire in reapers and binders no fibre is equal to it.

Revision of the British Actiniæ. By Prof. A. C. Haddon. Part I. (London: Williams and Norgate, 1889.)

THIS revision of the British sea anemones by Prof. Haddon, will be welcomed by all students of this interesting group. We know a good deal already of our native species, thanks to the writings of Sir J. Dalzell, Dr. George Johnston, and P. H. Gosse; and the last-mentioned author, in his well-known "History of the British Sea Anemones and Corals" (1858), succeeded, by the aid of chromo-lithography, in giving very fair representations in colours of the living forms. But the "Report on the Actiniaria of the *Challenger*," by Richard Hertwig, in which he sought by anatomical investigations to establish a scientific classification of the group, opened up a new standpoint for the study of these forms, of which Prof. Haddon has most wisely and energetically availed himself; and in this first part of his revision we have a most excellent monograph of the *Chondractininæ*, and studies of several genera, which may be regarded as more or less representing the various stages in the evolution of the typical hexamerous Actiniæ. These latter belong to the families *Edwardsidæ* and *Halcampidæ*. There is also a description of the remarkable *Gonactinia prolifera*, Sars, some notes on *Zoantheæ* and on the development of Actiniæ.

Chitonactis marioni, *Paraphellia expansa*, *Edwardsia tecta*, and *Halcampa arenarea*, are described and figured as new species.

Seven plates accompany this memoir, of which the first two, representing *Chitonactis marioni*, n. sp., *Gephyra dohrnii* (von Koch), *Actinange richardi* (Marion), *Paraphellia expansa* (g. et sp. nn.), *Halcampa arenarea* (n. sp.), *Chondractinia digitata* (Müller), and an undescribed species of *Sagartia*, are very beautifully printed in colours, being perhaps the most life-like illustrations of Actiniaria as yet published in the Transactions of any of our learned Societies.

This memoir forms Part V. of the fourth volume of the Royal Dublin Society's Transactions.

Practical Iron-Founding. By the Author of "Pattern-Making," &c. (London: Whittaker and Co., 1889.)

THIS little volume is an attempt to give, in a condensed form, an account of the principles and practice of iron-founding. To begin with, iron-founding is an art most difficult for the non-professional man to understand, even when going through a foundry, where the various branches of the work are going on before his eyes. How much more difficult it must be for a student to get much real knowledge of the art from a book it is easy to imagine.

As an elementary hand-book this volume will, no doubt, serve its purpose. At the same time, it ought to be clearly understood that the iron-foundry is the only place where iron-founding can be learned thoroughly. A little idea of the art may be obtained by other means, but moulding, of all the engineer's arts, is the one which requires the practical work in an engineer's foundry for its development. The machine tool is largely to blame for the deterioration of our skilled workmen generally, but this has been least felt in the foundry. The moulder must still have his trade between his fingers to be efficient, and no amount of machinery as at present designed will help him to mould, say, a pair of locomotive cylinders in one casting. The book is carefully written, and represents good all-round practice as far as it goes. The illustrations of tools, &c., are clear and accurate.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Ice Blocks on a Moraine.

BLOCKS of ice, so far as I know and so far as I remember to have read, are not usual constituents of a moraine. So it may be well to call attention to an instance which I saw lately when walking over the Gorner Glacier with my friend Mr. J. Eccles, who is even more familiar than I am with glaciers, and to whom the sight was novel. At the base of Monte Rosa, where it begins to rise from the Gorner Glacier, are two buttresses of ice-worn rock; the northern called *Ob dem See*, the southern *Auf der Platte.* Between these a glacier, evidently of no great thickness, descends towards the west, and adjacent to each, rather on the in-side, as it may be called, is a little lake. In the northern of these (called the Gorner See, and the only one some five-and-twenty years ago, if I remember rightly) several blocks of ice are now floating; not far from it are the blocks on the moraine.

To explain how they attained their present position, in some cases more than a hundred yards from the water, and probably quite twenty above it, a little more topographical description is needed. The moraine of which they form a part is not a ridge composed of, or at least masked by stones, but a very gentle swell of ice, over which, especially on the eastern side, blocks are scattered in open order. It extends from one lakelet to the other, and is produced as follows. As said above, the glacier which passes between these rock-buttresses is by no means a thick one, but the southern flank of Auf der Platte is swept by a huge ice-stream which descends from the snow-fields of the Lys-joch, and is prevented from much lateral expansion by the pressure of a second large glacier which drains the northern face of the Zwillinge. This enormous mass of ice tends to pond back the smaller glacier; thus the moraine, mentioned above, is mainly formed by the left lateral moraine of the latter, by a few blocks which come down its mid stream, and possibly by the right lateral moraine of the Lys Glacier. The obstructed ice, however, is forced up so as to form a sort of flattened wave, so that if one were coming right down the face of Monte Rosa one would mount 50 or 60 feet from the margin of the Gorner See, or perhaps half as much from the middle part of the Monte Rosa glacier, and then, after a slight descent, would again ascend a gentle slope in order to arrive on the broad united ice-stream which bears the name of the Gorner Glacier.

The blocks of ice are numerous. A few of the largest must contain about 8000 cubic feet—many vary from 2000 to 5000 cubic feet—indeed, in the northern part of the moraine I think the ice exceeds the rock in actual volume. These ice-blocks, in some cases, are mounted on ice-pedestals, just as is rock in a glacier-table; the support rising perhaps a couple of feet above the level of the glacier. Of course they were "perspiring" freely under a July sun, and do not make a long journey; probably few succeeding in getting a furlong away from their source.

That these blocks of ice began as bergs in the Gorner See is indubitable. They have been elevated to their present position by the strugggle between the confluent ice-streams; the smaller of these impinging upon the larger almost at right angles, and being thus forced upwards by the obstacle. The number of the blocks suggests the possibility that the glacier itself may form part of the bed of the Gorner See; for they would be more readily removed from the water, if the actual bed of the lakelet, instead of being at rest, were slowly travelling forward and upward.

The above description illustrates the way in which (as I have seen suggested) blocks of rock in past geological ages may sometimes have been carried up-hill by glaciers. At the same time I may observe that I should myself be reluctant to found upon it any very sweeping generalization.

T. G. BONNEY.

The Inheritance of Injuries.

IN the notice of Dr. Weismann's "Ueber die Hypothese einer Vererbung von Verletzungen" (NATURE, July 25, p. 303) there occurs the following commentary:—It is not so certain that all will admit Weismann's contention that the demolition of the inheritance of injuries furnishes strong presumptive evidence that acquired characters are not inherited. *It might well be urged that there is a great distinction between characters which are obviously not useful (such as injuries) and useful characters.*"

I have italicized the last sentence, desiring to call the attention of those interested in the subject to some points of difference between useful and not useful or disabling variations, as these may be supposed to lend themselves to transmission by inheritance. The appreciation of these points of difference is calculated, I believe, to greatly assist in settling the important question as to the inheritance of acquired characters.

In my work on "Dissolution and Evolution and the Science of Medicine" (Longmans and Co.) an attempt is made to show from various considerations that non-congenital diseases, including injuries, are not inheritable. The chief contention is that diseases and injuries are simply disorganizations of pre-existent functions and structures. They are not, as useful and normal characters are, integrated and organized arrangements of the organism's energies, but bodily disintegrations inseparable from the actions of the environment. Diseases as dissimilar as a common burn and general paralysis of the insane, are shown, in the work I speak of, to be alike in so far that they are disintegrations of the body and causally related to the environment. It is this intrinsic nature of disease and injuries and their dependence on external conditions which goes far, as I believe, to make them uninheritable. Since my work is probably accessible to few of the readers of NATURE, I may perhaps be permitted to quote the following extracts as further argument and illustration.

"True diseases, as we have just seen, cannot be separated from their causes; and causes, being of the environment, are not handed down. But there are additional reasons for the feeble hold which heredity has upon pathological states. When we discriminate between the variations of function and structure that are passed on by parent to offspring and those that are not, we are forced to see that natural selection, working always in confederation with heredity, seizes upon *favourable* variations. Natural selection appropriates organismal acquisitions. But analysis discloses the fact that diseases are losses, not gains; are unfavourable variations, and offer no 'purchase' for the co-operative influence of these two modes of action. . . . But more important than influences of this sort is that influence which springs from the differences of nature and conditions between normal and abnormal traits. Normal structures were evolved in long periods of time, and have been transmitted through generations unnumbered; therefore, the tendency to their perpetuation by inheritance must be immensely predominant over any tendency to the perpetuation by inheritance of the transitory changes of disease. I believe that the 'vestiges' of once useful structures owe their astonishing persistence to the fact that they have become deeply pressed into the organic arrangement by the selection and transmission of such structures for secular periods. This makes intelligible the rarity with which deprivation of a limb or other part leaves any impress upon offspring. Though circumcision has been practised among the Jews for ages, it has not produced congenital preputial imperfection in the race.

Nor do we ever find that amputation of a limb, or loss of the cortex of the kidney from Bright's disease, is followed by corresponding anatomical deficiencies in children. In the African transported to northern latitudes, the dark skin persists through indeterminable generations—provided there is no cross-breeding—but the endemic diseases of his race are not transported with him.

"Hitherto all reasoning upon the heritableness of diseases has proceeded on the tacit assumption that morbid changes are subject to the same laws of vital action as healthy changes. It has been discovered, however, that the two are dissimilar both in nature and in the circumstances of their genesis. The traits we every day recognize as inherited are the results of an infinity of co-ordinate actions. There may be instanced the bony framework of the face, the colour of the iris, the gait, special mental aptitudes. All these, and attributes of the same order, represent a vast integration of forces, groups of organized energies. It is this organization which gives them individuality and makes their hereditary transmission possible. They are, in other words, self-existent, having been independent of the original conditions out of which they grew."

The conclusion, deduced from evolutionary principles, that non-congenital diseases and injuries are not inheritable, might, I think, be supported inductively from the facts of medical observation, and it is most interesting that the results of Dr. Weismann's investigations are confirmatory. But from what has been said it clearly appears, in harmony with the annotation I commenced by quoting, that the non-inheritance of injuries is no evidence of the non-inheritance of acquired useful variations. C. Pitfield Mitchell.

24 De Vere Gardens, W.

Classified Cataloguing.

Whenever a collection has been catalogued anew, and all the numbers are in the museum order of the specimens, the placing of additions at the end, without any sequence but that of acquisition, always seems a melancholy collapse of the order just established. So strongly is this felt that some curators even enter additions with the same numbers as similar specimens, distinguished by letters, as 3247*a*; but, as formerly in the British Museum, this system breaks down when such additions far outnumber the original series, and we reach figures like 3247*fy*. At the same time this is an approach to an entirely different and logical system of cataloguing, which ought to be considered. Another stage of arrangement has been by appropriating so many thousand numbers to each branch, so that the articles of one class may have contiguous numbers.

The complete system of cataloguing which has been thus felt after, and sought for, is what may be called "fractional cataloguing," treating all numbers as decimal fractions and arranging them accordingly. Thus 21·765, 21·77, 21·8, and 22 might appear as successive numbers in a catalogue: the numbers being arranged solely by their successive order of the left-hand figures, regardless of the length of the number. By this system, therefore, any quantity of additions can be brought into their right order without disturbance; fifty new specimens like No. 371, for instance, being numbered 371·01 to 371·50.

The first two or three places of the number will therefore indicate the nature of the specimen in any given catalogue: and this leads at once to the desirability of all collections having a similar numerical basis for their catalogues, so that if all the parrots, for instance, begin with 56 in one collection they should do so in all other museums.

The first step therefore in classified cataloguing would be to agree on a set of 100 or 1000 numbers, to subdivide each branch of science, the distribution of the numbers being partly settled by the average number of specimens, partly by natural divisions. Thus in mineralogy, elements might be 001 to 099; binary compounds 100 to 299; silicates 300 to 799; non-metallic acid salts 800 to 899; metallic acid salts 900 to 999. In all museums, then, silicates, say of lime, magnesia, and alumina, would begin with 61, the different species being marked 610 to 619, and varieties and individual specimens numbered with additional decimals following these bases, *e.g.* 615·47. The set of numbers in each science would be best fixed by a committee at some International Congress, so as to insure general acceptance, like the scheme of geological colouring.

The disadvantages of this system would be—(1) that the catalogue would have to be kept like that of a library, subject to additions at any point, and therefore on slips which could be transferred; and (2) that the total number of specimens would not be known except by counting. These are not serious difficulties, and the following advantages seem to entirely out-weigh them.

(1) The numbers would indicate to all students the nature of the specimens quoted in any collection. (2) The catalogue would be classified in natural order throughout, so that all similar specimens would be described together. (3) The numbers in the museums would be in order from end to end. (4) Any specimens moved could be rearranged by unskilled assistance, solely by the numbers. (5) Any object in the catalogue or hand-books could be at once found in the museum by its number. (6) A great help would be given to the arrangement of minor museums by having a uniform scheme of cataloguing fixed. (7) The numbers being in constant use would soon form technical symbols for species, a short-hand briefer than chemical symbols even, and applied to all sciences; and also a valuable key to the memory.

Bromley, Kent. W. M. Flinders Petrie.

Head Measurements of Students at the University of Cambridge.

I was rather too precipitate when I stated that the figures relied on by Mr. Galton were totally inadequate to support his conclusions; for, as regards the second of them, viz. that the "high honour" man has a head perceptibly larger than the "poll" man, the evidence is fairly strong; but with regard to the other three conclusions, referring to the growth of heads, I must repeat what I have said. In the light of the discussion given below of a large number of observations, I cannot even admit that the tables and curves given in Mr. Galton's paper (see Nature, vol. xxxviii. p. 15) give even "an approximately true idea of what we should find, if we had the opportunity of discussing a much larger number of observations."

Having heard that all the measurements taken have been indexed for reference, I went to the laboratory, and, by the kind permission of the custodian, copied out the head measurements of fifteen individuals, each of whom had been measured at least five times. In one case, measurements had been taken at seventeen times. The average number was 7·1.

Since the first case quoted in my last letter forms one of these, I had better point out that Mr. Galton's objection to it is unsound. He notes a grouping of the observations, which makes him suspect that "some peculiarity in the shape of the head caused doubt as to the exact line of maximum height." But the observations of height are 5·2, 5·3, 5·4, 5·5, 5·5, and 5·6; and show no grouping. Mr. Galton must have meant that the calculated products were grouped. This is the case, but could not be due to the cause he suspects, for that would cause grouping in the simple heights.

The fifteen series of measurements fully bear out the conclusions which I drew before from two only. The measurements of width vary 0·1, 0·2, or 0·3 inch, those of length vary to the same extent, and in one instance up to 0·4 inch, while the height in most cases varies 0·4 or 0·5 inch. In only two cases does it vary so little as 0·2 inch, while in one case it varies 0·7 inch. The last case (where the figures are 5·4, 5·6, 5·1, 5·8, 5·5) is partly accounted for by the fact that the first three observations were taken by one observer, the other two by a second. (The statement in Mr. Galton's original paper that all the measurements were taken by one observer, must have been due to misinformation.) I have calculated the probable error of each observation of the height of head for each series of observations, using the approximate formula

$$r = \frac{0·845\Sigma v}{\sqrt{n(n - 1)}},$$

and I find it on the average 0·095 inch. Since the average height is less than 5·5 inches, this error amounts to 1·7 per cent. If the error in length and width were each half of this, the probable error of the product would be about 2 per cent.

To test whether any of the variation found is due to actual growth, and not to accidental error, I have used the following method. Arrange all the measurements of any one individual in the order of the dates on which they were taken, and separate them into two equal groups. Take the mean measurements of the first set, and put opposite them the mean of the dates; then do the same with the second set. On subtracting these we can see at once whether the head has grown in any direction.

As an example, G. F. R., who was measured sixteen times, gave the following mean values:—

Date.	Width.	Length.	Height.
September 1886	5·91 ...	7·82 ...	5·74
October 1888	5·94 ..	7·81 ...	5·60
	+0·03 ...	−0·01 ...	−0·14

The differences show the alterations occurring in twenty-five months.

I have calculated the other fourteen cases in the same way, and find that if the growth in width of the whole fifteen be added together, and the same be done with the length and height, the totals are only

+0·24 inch in width,
−0·56 inch in length,
−0·82 inch in height.

The average period during which these changes took place was thirteen months.

These 107 measurements which I have discussed therefore show a small *diminution* in the head capacity as the individual grows one year older, but this is so small compared with the probable error, that the observations are quite consistent with the hypothesis that the head remains quite stationary.

Ten measurements of the height of one individual, taken at successive years from twenty to thirty, would give us a better idea of the normal growth during that period, than many times that number if each were taken on separate individuals, for the range of individual variation at any age far surpasses the amount of growth in any one of them. For the same reason I think that the above 107 measurements made on fifteen individuals furnish a surer answer to the question, "Does the head of a University student grow after the age of nineteen?" than ten times the number made indiscriminately, and simply grouped by age. F. M. T.

Trinity College, Cambridge, August 3.

The Supposed Connection between Distant Earthquake Shocks.

It is very commonly assumed, whenever seismic disturbances at different localities occur synchronously, that, however remotely they may be situated, there is necessarily a connection of some kind between the shocks, originating in a common cause. A forcible illustration of this fallacy, as I think, having recently appeared in your columns, I beg to take this opportunity of questioning the position so generally adopted, and of testing the validity of the involved theory of earthquake causation by the light of the evidence furnished in the concrete case which has been presented in support of it.

On April 18 a somewhat remarkable earthquake took place in Japan, at about the same time that some rather considerable shocks were registered at two seismic stations in Germany. These occurrences were ably treated from the point of view in question in NATURE of July 25 (p. 294), by Dr. E. von Rebeur-Paschwitz, of Potsdam, and argued to a final issue.

It is taken for granted, primarily, under this hypothesis, that every minor earthquake-shock at any given point is the effect, direct or indirect, of some more violent disturbance elsewhere, near or distant; and it is further supposed that the latter is, in its turn, a more direct result of a volcanic outburst at some special centre of activity, known or unknown. From this premise it must be inferred that no micro-seismic shock can ever take place otherwise than as a throw-off from some violent disturbance more or less remotely located. When we examine this conclusion, however, and consider more broadly the concomitant relations of earthquake phenomena, we shall, I think, find that it possesses no foundation whatever in facts, and that the hypothesis does not bear the strain of such evidence as may be adduced from recent observation. We know, for instance, (1) that seismic activity is an experience of almost daily frequency in some localities, as in Japan, obviously without relation to the volcanic eruptions which occasionally take place in near proximity; (2) that, on the other hand, volcanic explosions sometimes occur unaccompanied by any widespread upheaval or distant undulations; and (3) that the earth's crust is, moreover, subject to an apparently constant state of slight vibrations or micro-seismic palpitation, in parts of the globe where perceptible shocks are less commonly experienced.

In the light of these facts the theory under discussion might be readily disposed of as a foregone conclusion, but it will be more satisfactory to prove its fallacy by means of the evidence afforded by the earthquakes recorded in these pages as having taken place at Tokio and in Germany on April 18, especially as the data have been so completely recorded by Dr. von Rebeur-Paschwitz. After considering the details registered by the seismometers stationed at Potsdam and at Wilhelmshaven (distant about 220 English miles), he has applied himself to the problem of making these facts fit in with the record of a shock which was experienced at Tokio at nearly the same time. It is to be remarked that the only source of information respecting the latter shock is the note which appeared in NATURE of June 13 (p. 162), in which the information that a violent volcanic eruption was taking place at Vries Island, "possibly 60 miles off," is repeated from a note on the previous page where the island is spoken of under its local name, Oshima. Dr. von Rebeur-Paschwitz too hastily accepts the connection suggested, and upon this slender basis rests his whole argument.

Now it would certainly happen that any earthquake transmitting its effects to a locality on the opposite side of the earth would affect also, in varying degrees, all the countries along the line travelled by the seismic wave; and that a constant diminution in its force would be a characteristic feature of such a phenomenon. But what is the actual evidence in the case in point? We are told that at Tokio the maximum oscillation registered was no more than about 17 mm., while at Potsdam the greatest amplitude of oscillation is stated to have been 154 mm. The seismometers in use may possibly be different in type, but there is surely not such great difference in construction as to cause the complete reversal of the readings, as would be required also by the accepted theory; it may rather be accepted, no doubts being entertained, that the resultant figures may be fitly compared. But the conclusion arrived at is at once seen to be absurd, for the lesser shock at Tokio could not possibly produce the ninefold greater one in Germany; while no mention whatever is made of any intermediate effects being produced along the path of the wave. It is, moreover, especially stated (p. 163) that this particular shock at Tokio was by no means a strong one; its "peculiarity lies, not in its violence, but in the extreme slowness of its oscillations." Yet it is calculated by Dr. von Rebeur-Paschwitz that the mean velocity of transmission of the wave (occupying 1h. 4·3m.) was "2142 metres of propagation," which is really 167 metres above the mean of the different rates computed by the two authorities cited.

Again, the volcanic eruption of Oshima or Vries Island, at about 60 miles distance from the main island, which is said to have destroyed upwards of 300 houses, and killed 170 persons, took place, *not* on the 18th, but on the 13th and 14th of April (cf. pp. 162 and 179, where fuller details are given). Besides this difference in the dates, no exceptional earthquake shocks are reported to have occurred at Tokio during the eruption, and I fail to see the possibility of any connection between the two particular phenomena considered.

If there were any direct seismic connection between Japan and Germany, the latter country would surely be subject to regular transmissions of the shocks which prevail at Tokio. The ample data furnished suffice to prove that it is not the case. We are informed, in a postscript to the letter under consideration (p. 295), that several other shocks were recorded at both Potsdam and Wilhelmshaven about this period, viz. on April 5, 8, 15, 28, and May 31; at Potsdam *alone* on April 25, May 21, 25, and 26; and at Wilhelmshaven two shocks were felt on May 30, "probably connected with the English earthquake of this day." These various shocks were not experienced equally by the instruments at the two stations, and they do not even seem to have been necessarily connected throughout, for we are told that on May 30 there was "perfect steadiness at Potsdam," while four of the shocks mentioned were not felt at Wilhelmshaven.

It is curious to note that no connection is supposed in respect of other earthquakes, and of volcanic activity in nearer proximity in Europe, although several such occurrences have happened during the same period. Thus, on April 26, several shocks were experienced at Schaffhausen, &c. (NATURE, vol. xl. p. 84); on April 27, a "severe" one, lasting 4 seconds, was felt at Agram (*ibid.* p. 45), a district much subject to seismic disturbance; on April 30, there was one along the coast of Norway (p. 133); and on May 8, a "severe" one, lasting 3 seconds, took place at Plevje, in Bosnia (p. 84). From Dr. Johnston-Lavis we further learn that Vesuvius was in a state of active eruption during the end of April and the beginning of May (p. 34), but no relation is suggested even in this case, and it is quite evident that the facts do not serve to prove the connection assumed.

I do not wish to assert that in no case are synchronous earthquakes related, for we have undoubted evidence that certain shocks have been very *widespread* from a single centre (as the great Lisbon earthquake in 1755); but it is my belief that nearly every earthquake, whether large or small, is due to strictly local stratigraphical causes, quite irrespective of volcanic agency. Having made many fruitless attempts myself to co-ordinate different well-authenticated shocks, I have been compelled to disbelieve the theory of their general connection, and have now adduced sufficient evidence to show that the verdict pronounced by Dr. von Rebeur-Paschwitz, that "we may therefore safely conclude that the disturbances noticed in Germany were really due to the volcanic action which caused the earthquakes of Tokio," is not proven, and fallacious.

4 Mecklenburgh Square, W.C. WILLIAM WHITE.

The Sources of Nitrogen in Vegetation.

THE discrepancy between the results obtained in the experiments on plants grown in free air instead of closed vessels appears to be general, as stated in NATURE (p. 333). Some years ago I ventured to suggest an explanation of this, based on an observation made in the course of some investigations of atmospheric dust particles.

Sheets of paper, smeared with adhesive coatings, and shallow vessels of water, were laid on the ground in a garden near Willesden. The resulting catch included far more organic than inorganic matter, the organic matter consisting chiefly of small insects. The amount of these was surprisingly great towards the end of summer or beginning of autumn, quite sufficient, I think, to account for the varying results obtained by Sir J. B. Lawes and Prof. J. H. Gilbert, especially for the "eccentric" behaviour of the Leguminosæ—"sometimes the plants died of nitrogen hunger; sometimes, after a time of such hunger, they recovered and produced abundant growth." The explanation may be confirmed or refuted by exposing an unplanted layer of sterilized sand, or other soil, of the same area as that on which the experimental plants are growing, and comparing the gain of combined nitrogen in both cases. W. MATTIEU WILLIAMS.

The Grange, Neasden, August 16.

Do Cats Count?

AFTER reading all the accounts of the interesting experiments lately performed on the famous "Sally," I am persuaded the following incident may not be without a certain interest to some readers of NATURE.

About two weeks ago, the cat of a dairyman in this neighbourhood gave birth to three kittens. Next day, one of them was removed, during the mother's absence, and drowned. On returning from a foraging expedition, and discovering her loss, puss immediately set out in search, presumably, of the missing one. All her efforts in this direction, of course, proved fruitless; but, evidently determined to at least make up the right number, she did so, curiously enough, by carrying off, from its nest close by, a young hare, not more than a week old. This she is at present suckling side by side with her own kittens. In view of these facts the above question very naturally suggests itself.

Winchburgh, N.B., August 15. J. T. WALKER.

Anapophyses.

MY attention has been called to a statement by Prof. Cope (NATURE, July 25, p. 298), that anapophyses are "wanting from the vertebræ of anthropoid apes and man." He probably means that they are very feebly developed, which is true. I have found them, however, to exist distinctly in *Troglodytes* and *Simia* from the eleventh dorsal to the second lumbar vertebra, and in *Hylobates* from the tenth to the fifteenth trunk vertebra, and sometimes beginning as high up as the third dorsal vertebra.

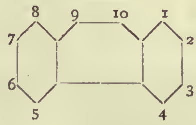
ST. GEORGE MIVART.

Hurstcote, Chilworth, August 12.

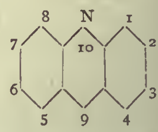
The International Chemical Congress—A Correction.

A MISPRINT has occurred in the notation adopted by the Chemical Congress for phenanthrene. The Secretary of the Nomenclature Section has also informed me that a slight modification has been made on the minutes, with regard to acridine, to make the notation adopted correspond more closely to that of the other "multi-ring" compounds. The two formulæ should be—

Phenanthrene.



Acridine.



YOUR CORRESPONDENT.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE eighteenth meeting of the French Association for the Advancement of Science opened under the happiest auspices. The magnificent Exhibition on the Champ de Mars and the Esplanade des Invalides, which has attracted to Paris an exceptionally large number of foreign men of science, is in itself the most conclusive proof of French energy and the progress of French science during the last decade. It is, perhaps, as M. de Lacaze Duthiers remarked, a more effective declaration of a sincere desire for peace than the utterances of certain diplomatists. But there is no place for politics in the principles of the French Association. Foreigners of all nations have been welcomed to Paris not only with warm-hearted hospitality, but with an artistic splendour of which they may well be envious for their own countries, and to which we shall allude later.

We may mention the presence of Messrs. J. H. Gladstone, F.R.S., R. McLachlan, F.R.S., Catalan, Candèze, Istrati, Berlinerblau, Orloff, Stephanos, Van Beneden, General Wauwermans, MM. Szabo, Valdemar Schmidt, Alexeieff, Bierens de Haan, Coleman, Colley, Franchimont, William Watson, Egoroff, Joukovsky, R. de Luna, A. Macfarlane, Ragona, Thomas Wilson, Benedikt, Hugo Gyldèn, Packard, Retzius, de Selys-Longchamps, Angström, Brusina, Flavitzky, Graebe, Dufour, Timiriazeff, von Goldschmidt.

The first meeting took place on Thursday, August 8, in the large hall of the Palais des Sociétés Savantes, which has just been erected by private enterprise in the quaint little rue Serpente which now affords a home to so many of the learned Societies of Paris.

The President of the Association for the year is the well-known Professor of Zoology at the Sorbonne, M. de Lacaze Duthiers, who chose as the subject of his inaugural address, "The Development of Zoological Method."

M. de Lacaze Duthiers began his address by thanking the Municipality of Paris for their invitation and for their generous subvention of £1200 recently voted towards the year's expenses. He then made a touching allusion to the foundation of the Association.

"It was one day in July 1871, that Wurtz, whose geniality and whose kindly vivacity you have not forgotten, took me, in his friendly way, by the arm, and said to me as we left the Academy of Sciences, 'Come to my house to-morrow night; I want to speak to some of our colleagues of a plan which I much wish to succeed.' On the Tuesday we met at M. Wurtz's house, just a few friends, MM. Delaunay, Claude Bernard, Decaisne, and myself. One may say that this was the first meeting of the French Association.

"As the only survivor of those who were our masters and our friends, I could not forbear from speaking to you of the intimate conversation in which our Association originated. I still seem to see and hear Wurtz with his kindling enthusiasm, with an activity at times feverish, but always good-hearted, striding across his drawing-room and giving us a picture of what our Society should, according to his idea, be—of what it has since become."[1]

M. de Lacaze Duthiers then proceeded to describe the state of zoology a hundred years ago.

"When 1789 came, Linnæus and Buffon had just died, and their fame was at its greatest splendour. They were the absolute masters of zoology, and the whole science was summed up in their work. Yet how different were the two in their nature and their work.

"Linnæus, precise, methodical, a classifier above all, introduced clearness and order into the most minute details of natural history, and as he proposed a nomenclature at once simple and precise his influence acquired such a preponderance that von Haller complained of his tyranny. If the reform of scientific language proposed by Linnæus took such immediate and powerful hold on the scientific world, it was because it exactly corresponded to the need of the moment.

"Before Linnæus, the objects of natural history were designated by the help of names or phrases formed by the addition of adjectives describing their characteristics, which overburdened the memory. All this he reduced to two words, just as in our families we distinguish the various members by a family name and a Christian name. The simplicity, the ease of application, and above all the opportune appearance of his nomenclature were the causes of its great success; but we must add that its intrinsic value is such that even to-day we hardly depart from the rules on which it is founded.

"The opposite of Linnæus, Buffon delighted in broad delineations, and his general reflections were animated by a potent inspiration. We are carried away and enthralled by the profundity of his thought, the elevated standpoint from which he views science. By reasoning and the consequences of observations which he interprets, he seeks as much to discover what will take place, and what must have taken place, as to determine the exact nature of what he observes. And thus he was often in advance of his epoch, and his lofty views could be understood only by the few.

"Linnæus, on the contrary, established *facts* with simplicity and clearness.

"With qualities such as these, these two men of genius, who died towards the end of the last century, must often have been at variance; and though the name had not yet been pronounced, we may already at this epoch distinguish between the school of facts and the school of theories (*l'école des faits et l'école du raisonnement*).

"But there was wanting to the works of Linnæus and Buffon a foundation whose necessity made itself imperatively and universally felt. For it was beginning to be perceived that the study of the habits, of the geographical origin, and of the external characters of animals was not sufficient.

"Then came Cuvier. It was the great merit of Cuvier to see clearly that if zoologists would arrive at a truer knowledge of animals, they must not content themselves with a description of their external forms, but must investigate their internal construction. It was thus that he introduced the notion of *anatomy* into natural history."

M. de Lacaze Duthiers proceeded to defend Cuvier's memory from unjust attacks which it had suffered owing to his opposition to Lamarck.

"Let us not judge great men by their weaknesses. By wishing to depreciate them, we often arrive at a contrary result, and lessen ourselves by a display of systematic and unjustifiable hostility. Let us see in them only what is good and great. And then we shall not fail to recognize the fact that Cuvier is entitled to our fullest meed of admiration."

The lecturer continued by pointing out that Geoffroy St. Hilaire and Lamarck occupied the same position with regard to Cuvier that Buffon had held with regard to Linnæus. Their speculations were too advanced, they came before their time.

"Zoology remained stationary for many years after Cuvier, and it was not before the beginning of the century that new ideas sprang up directing research along fresh paths, and profoundly modifying certain branches of biological science.

"It is strange to see how books and observations of considerable value often remain obscure for years, and are then finally brought to light by some unexpected discovery.

"I remember that about the year 1855 Prof. Huxley, the illustrious English *savant*, wrote to me (I was then Professor at Lille): 'In England we are all much excited about the discoveries of M. Boucher de Perthes.' You all remember the interest aroused by the discovery of the chipped silexes of St. Acheul, and the famous jaw of Moulin Quignon.

"English geologists came to Amiens. The most lively discussions took place, and an International Committee was formed to direct an official excavation.

"But perhaps the real discovery made, and this was due chiefly to the journey of the English *savants*, was that of the books, the researches, and the new ideas of Boucher de Perthes, which had hitherto passed almost unnoticed.

"We may say that from this moment dates the study of prehistoric times, which has undergone so immense a development. The excitement produced by the discoveries of M. Boucher de Perthes had begun to calm down, and researches were being pursued in every direction, when the first of Darwin's essays appeared in 1858 and 1859. These dates will remain for ever memorable in the history of natural science, for henceforward zoology (the only science of which I am at present speaking) takes an entirely new direction.

"We must acknowledge that whatever the measure of confidence we have in the theory of transformism, if we admit it to its full extent, with all its consequences, or if we reject it, it can be a matter of doubt to no one that this theory has led to a truly extraordinary scientific activity. Partisans and detractors both—in seeking for proofs of their opinions, either in the mysteries of embryology or in the investigation of the animal remains in geological strata—all, whatever their method, their ideas, their opinions, or their hostility, have caused zoology to take great strides.

"How far removed we are from the time of Linnæus, when external characteristics were everything—from the time of Cuvier, when anatomical notions and the study of exterior forms alone guided the classifier!

"To-day, what we seek for first of all is the enchainment of animals, either by going back to the forms of the past from those of the present, or the converse. We seek to explain the varied forms we see by the laws so happily formulated by Darwin—laws, indeed, which are as true as they are seductive.

"Who can deny the struggle for existence? Is it not to be found everywhere? And who will not admire the effects of selection? But why exaggerate its true bearings?

"Evolution is to be met with everywhere, in the civilized world as in the world of Nature, development is the great and eternal problem, resolved by the destruction of some, by the advancement of others; everywhere the struggle for life shows itself, inflexible and fatal.

"One may be a partisan or not of the theory of evolution—and I have not here to declare my own opinions, but rather to determine the exact influence of certain dis-

[1] It need hardly be said that Wurtz founded the French Association on the model of our British Association. From the war of 1870 dates a remarkable renaissance in French scientific activity, which had been in abeyance during the Empire, or at least till M. Duruy came into power in 1869 as Minister of Public Instruction, and founded that unique institution for the encouragement of research, the École des Hautes Études.

coveries and certain men on the progress of science—but one is forced to bow to facts, and to acknowledge the magnitude of the prodigious impulse given to science by the great English naturalist. But, as Claparède would say, there are *enfants terribles* of evolution—men more anxious to be spoken of than to discover the truth.

"We must carefully distinguish them from the conscientious men of science who investigate precise facts patiently, scrupulously, and laboriously, to deduce from them consequences in support of their theory. Men such as these make science advance surely, whereas the others sometimes compromise the cause.

"The only thing to oppose to exaggeration, the influence of excessive enthusiasm, is recourse to *experiment*. To-day, that is the great reform which we feel to be as necessary as those other reforms of whose history I have spoken."

Before developing this idea, the lecturer spoke of Lamarck, and of the reason why his ideas were not adopted during his lifetime.

"Of late years people have thought they had re-discovered Lamarck, and have severely blamed the generation of zoologists who neglected for half a century the author of the 'Philosophie Zoologique.'

"It is true that in the works of Lamarck there are whole pages which contain the theory of transformism completely developed, to which Darwin has added nothing, and which we may say he has but confirmed.

"But if Lamarck had not the satisfaction during his life-time of seeing his ideas admitted, it was that the minds of zoologists were not sufficiently prepared for them; it was that he had not the rare good fortune of finding a precise and lucid formula, whose truth is evident, and which is necessarily accepted by all.

"Some of Lamarck's conceptions of Nature are even difficult to understand, and especially to make clear to others; and I do not see that even his most ardent admirers have insisted on this portion of his work, and yet it is by no means inconsiderable.

"We should have been glad to see it more clearly explained than it is in the original, and brought within the comprehension of all, and one wonders why it should never be referred to.

"For a reformer to succeed, his idea must be striking in brilliancy and precision; it must master us by its intrinsic seduction.

"Take Darwin, showing us the struggle for existence taking place everywhere and at every instant, and leading to the selection and survival of the victor.

"Take Cuvier, who, it was said, reconstructed an extinct animal from a fragment of bone. A statement like this appealed to the imagination of the masses, and he excited the admiration of a whole generation when he compared an organism to an equation of which we may determine the unknown by the known quantities it contains.

"If Lamarck did not have the success he deserved, it was because of the abstract form he gave to his opinions, and the often *naïve* proofs which he adduced in confirmation of his theories at a moment when enthusiasm and popular attention were diverted to another aspect of science.

"Lamarck was, moreover, regarded as a visionary because he believed in the possibility of forecasting the weather from observations of the atmosphere and of the forms of clouds, and yet who would now blame him for his hopes?

"Lamarck was a man of genius who foresaw the advances of science on many sides, but who did not possess the faculty of being able to present his ideas in a felicitous form intelligible to his contemporaries."

The lecturer then returned to his theme, that experimental research in zoology is the need of the hour, and proceeded to give some striking examples of the results to which it has led.

Firstly, he described the alternation of generations in the gall-producing insect, whose two forms were originally known as Biorhiza and Teras. The Biorhiza, a wingless and asexual form, is born from eggs laid in the roots of the oak; it crawls up to the branches, and there causes the gall excrescence as it lays its unfertilized eggs. From these eggs issue the sexual winged form Teras, which conjugate; and the female then lays her eggs in the roots of the oak, and from these spring the Biorhizæ.

He then spoke of the strange metamorphoses of a certain insect *Sitaris*, semi-parasitic on a species of bee, *Anthophora*, which have been investigated by M. J. H. Fabre, and of those of the lobster. In all these cases, forms supposed to have been different have proved to belong to the life-history of one and the same animal.

"It is because zoology is at this moment at a critical period, and because of the positive nature of the affirmations made by the partisans of transformism, that the methods of the science must be modified, and that besides simply registering the existence of species, we must have constant recourse to the test of experiment. Such is the conclusion at which we logically arrive, and which to-day, I repeat, has become imperative.

"I have sought to point out to you the considerable part which our country has played in the progress of the natural history of man and of animals during the century which is drawing to a close.

"I should have wished to speak also of the origin and development of other branches of biology, of comparative and general anatomy, of experimental physiology, anthropology, and palæontology. But I think I have said enough to show that I am justified in spurning the reproaches and inimical accusations so often made against us, that France is a country in which scientific work is on the decline, and whose decadence is at hand.

"We open our meeting full of joy in the present, of hope for the future, in presence of the imposing spectacle whose success has but increased since it began in May, and which demonstrates the inanity of these accusations. Let your labours, varied as they are important, prove once more, during a year so fertile in pacific manifestations, that we work only for the restoration of our country, and that the peace of which others speak much, and perhaps believe in but little, is the sole preoccupation of all men of sense, of all who are in earnest in this country of France—France whose desire is to remain free and independent, ever animated by the most generous and patriotic sentiments."

At the conclusion of M. Lacaze Duthiers' speech, which was most enthusiastically cheered, the Treasurer announced that the receipts for the year had been £3760, the expenses £3480, and that the total capital of the Association amounted to £33,060. An important legacy of about £7000 had been bequeathed to the Association by M. Girard, for the promotion of researches on prehistoric man.

The proceedings concluded with a report on last year's meeting at Oran, and the members then adjourned to the École des Ponts et Chaussées, where the Sectional sittings took place.

The French Association is subdivided into seventeen Sections and sub-Sections: (1 and 2) Mathematics and Astronomy; (3 and 4) Civil and Military Engineering and Navigation; (5) Physics; (6) Chemistry; (7) Meteorology; (8) Geology and Mineralogy; (9) Botany; (10) Zoology, Anatomy, and Physiology; (11) Anthropology; (12) Medical Science; (13) Agriculture; (14) Geography; (15) Political Economy; (16) Pedagogy; (17) Hygiene.

An immense number of papers were contributed to the

Sections. We may mention:—(Sections 1 and 2), M. Joukowski, on an apparatus for determining moments of inertia. (3 and 4) M. Pichou, on a universal paddle-wheel; by altering the direction of the paddles, a steamer may be reversed without reversing the engines. (5) MM. Baille and Féret, on a method for reading the oscillations of the balance with great precision; the authors employ a very simple optical arrangement, which allows them to estimate the 1/2000th part of a milligram by the displacement of a series of Newton's rings. (6) MM. Alexeieff and Werner, on the heat of neutralization of certain aromatic compounds; the authors show that the general results already acquired enable one to determine in certain cases the position of disubstituted compounds. Messrs. Gladstone and Perkin, on the relation between constants of refraction, dispersion, and magnetic rotation in organic compounds. M. Cazeneuve, on camphor derivatives. M. Franchimont, on the action of nitric acid on organic bodies according to their function. M. C. Chabrié, on the synthesis of selenium organic compounds. M. Raoult, on a new form of the apparatus for cryoscopic observations; the author produces cold by the evaporation of carbon disulphide. M. Meunier, on insoluble crystalline compounds of mannite and sorbite, with the aldehydes, serving to isolate these bodies from organic mixtures (the juice of fruit, &c.). M. Berlinerblau, on a sweet body, $NH_2 . CO . NH . C_6H_4 . OC_2H_5$. M. Istrati, on new general methods for the synthesis of aromatic compounds. (7) M. Crova, on the standardization of actinometers. M. D'Abbadie, on the qobar. M. Angot, on the representation of the variation of temperature by a harmonic formula. (8) M. Szabo, on the opal mines of Hungary. M. Malaise, on the Belgian Olethamias. M. Bleicher, on the glacial formation of the Vosges. (9) M. Timiriazeff, on the *rôle* of light-intensity in the assimilation of carbon by plants. M. Mer, on variations of structure in the wood of pines. M. Clos, on certain cases of hybridity in plants, and on the vegetation of *Marchantia polymorpha*. (10) M. de Lacaze Duthiers, on the fusion of nerves and ganglia in Mollusca, and on the interpretation of the membrane which separates them. M. Beauregard, on the Cetacean ear. M. Packard, on the distribution of the organs of taste in insects. M. Sirodot, on the dentition of elephants. M. Jourdain, on the necessity of conjugation for the continued propagation of Protozoa. M. de Varigny, on the action of certain convulsive poisons on *Carcinus mœnas*. (11) M. A. Bertillon, on the anthropometric characteristics of the French nation classed by the departments. M. V. Schmidt, on the Stone Age and the prehistoric Iron Age in Denmark. M. de Mortillet, on right- and left-handed individuals in prehistoric times. M. Manouvrier, on anthropometric researches on natives of Algeria. Dr. Maurel, on the relation of the section of the thorax to the height and the length of the foot. (12) M. Massé, an instrument for determining the position of the fissure of Orlando. M. Steinhaus, on the causes of suppuration. M. Jolly, on the use of iodine in tuberculosis. M. Luys, on the pathological anatomy of madness, and on the action of rotating mirrors on the nervous system. M. Michel, on the influence of drinking-water on public health. (13) M. Kunckel, on the destruction of locusts in Algeria. M. Ladureau, on a rapid method of colorimetrical analysis for nitrates. M. Dehérain, on the loss and gain of nitrogen in arable lands and on the graphic representation of crops. (14) M. Castonet des Fossés, on the future of the Negro race. M. Gauthiot, on a route for mining exploration from Bangkok to Korat. The Prince of Monaco, on dragging in deep water. M. de Guerne, on an exploration of the Forno de Graciosa (Azores). (15) M. Arthur Raffalovich, on economic legislation in England in 1888. M. Martineau, on the true motives for the introduction of free trade into England. M. Ch. Grad, on insurance against old age and infirmity in Germany. (16) M. Frederic Passy, on a system of writing which permits blind people to communicate with the non-blind; M. Paul Passy, on spelling reform; M. Herzen (of Lausanne), on the organization of certain secondary schools to enable them to continue the teaching of the primary schools. M. Morel, on the organization of the *enseignement spécial* in the secondary schools of Paris. (17) M. Delthil, on diphtheria and its treatment. M. Teissier, on diphtheria at Lyons. MM. Dubief and Brutel, new experiments on the value of sulphurous acid as a disinfectant.

The work of the Sections was most usefully supplemented by visits to different institutions and to the Exhibition. Sections 1 and 2 inspected the collection of calculating machines at the Conservatoire des Arts et Métiers, under the guidance of M. Ed. Lucas. Sections 3 and 4 examined the new steerable balloons with the inventor, Commandant Renard, while various other parts of the exhibition of the Minister of War were explained by officers of the special departments. Section 6 inspected the fine collection of chemical products at the Champ de Mars (Class 45), general explanations being given by MM. de Clermont, Riche, Suilliot, Billault, Istrati, and others. M. Tanret showed his interesting exhibit, including specimens of pelletierine, the alkaloid of the pomegranate bark now so extensively used as a tænifuge, and ergotine, the active principle of ergot of rye, by whose discovery M. Tanret has rendered such signal service to therapeutics; and last, but not least, M. Grimaux, Professor at the École Polytechnique, gave an account of the fine exhibition of Lavoisier's papers and instruments, which he had selected from the collection of M. de Chazelles, to whom they belong,[1] and pointed out the portrait of M. and Mme. Lavoisier, by David, in the Palais des Beaux Arts. Section 7 met at the Exhibition to see the instruments which record the direction and the vertical and horizontal components of the wind on the top of the Eiffel Tower, the results being transmitted electrically to the Palais des Arts Libéraux, and inscribed on MM. Richard's revolving drums. The Section also met at the Central Meteorological Office to see experiments on cyclones by M. Weyher. Sections 8, 9, and 10 inspected the fine galleries at the Museum, which have just been opened.

Other scientific visits were paid to the Institut Pasteur, the sewers of Paris, and to various glass-works, gas-works, &c. On Thursday, August 8, the Municipality of Paris threw open their magnificent suite of rooms at the Hôtel de Ville to the members of the French Association; while extraordinary animation was lent to the scene by the presence of the students of Paris and their foreign comrades, 8000 guests in all having been invited. On the following evening, the Association was received by M. Yves Guyot, the Minister of Public Works, and Mme. Guyot at the Ministry in the Boulevard St. Germain. A concert was given during the evening by members of the Opéra Comique; while the gardens lighted up by Chinese lanterns afforded a pleasant change from the crowded *salons*.

On Sunday, August 11, an excursion was made to St. Germain-en-Laye, and to Meudon, dinner being served in the orangery which belongs to the beautiful grounds of the Astronomical Observatory, directed by M. Janssen. M. Janssen offered a warm welcome to the members, and said that he should be very willing to let his Observatory be used for the scientific purposes of the Association. On Monday, August 12, a lecture was delivered by General Tcheng-Ki-Tong, on the social economy of China. On Wednesday, August 14, the Association offered a banquet to its foreign members at the Restaurant d'Alsace-Lorraine on the first story of the Tour Eiffel.

M. de Lacaze Duthiers made a short speech, in which he declared that he would not say good-bye to the foreign guests, but *au revoir*, as he hoped to see them all again

[1] M. Grimaux has published this year a remarkable monograph on Lavoisier (Félix Alcan).

at the meeting of the Association next year at Limoges. That they did not forget past events was proved by the name of the restaurant in which they met, but he firmly believed that "*Le temps prime la force*," and he drank "to the peace of the whole world."

MM. van Beneden, Dekterev, Istrati, Hartog, Ramon de Luna, Llaurado, Stephanos, Timiriazeff, and Watson, spoke in the name of their respective countries, and drank to the cause of peace and to the prosperity of France.

On Friday, August 16, a general excursion took place to the paper works at Essonne, and to the works of M. Decauville (the constructors of the narrow-gauge railway in the Exhibition), who offered a lunch to their guests.

Thus concluded this brilliant and successful session of the French Association.

All foreigners must have carried away with them a pleasant memory of their welcome. Special thanks are due to Prof. Gariel, the Secretary of the Association, and to the Vice-Secretary, Dr. Cartaz, for the remarkable kindness and courtesy they showed to the foreign guests.

EXPERIMENTS ON ELECTRO-MAGNETIC RADIATION, INCLUDING SOME ON THE PHASE OF SECONDARY WAVES.

IN continuation of some experiments which were described in NATURE, vol. xxxix. p. 391 ("Repetition of Hertz's Experiments and Determination of the Direction of the Vibration of Light") attempts were made to obtain periodic reflection of electric radiation from plates of different thicknesses, analogous to Newton's rings, with the view of further identifying these radiations with "light."

It was there described how a sheet of window-glass refused to reflect the Hertzian waves, but how a masonry wall reflected them readily. The non-reflection from the thin sheet is due to the interference of the reflected waves from each side which takes place owing to a change of phase of half a period on reflection at the second surface, as in the black spot of Newton's rings.

By making the reflecting plate such a thickness that the reflection from the back has to travel half a wave-length further than that from the front, the two reflections ought to be in accordance, for they differ by a whole period, half arising from difference in path, and half from change of phase on reflection; but if the difference in paths were made a whole wave-length by doubling the thickness of the plate, there ought again to be interference, and so on.

The first plan tried with this end in view, was to fill a large wooden tank to different depths with water or other liquids. On gradually filling the tank reflection should be obtained, and at a certain depth equal to $1/4\,(\lambda \sec r)/\mu$, reach a maximum; further addition of the liquid then should diminish the reflection, and at double the above depth the reflection should reach a minimum, the two waves interfering.

The mirrors for concentrating the radiation had for this purpose to be suspended over the tank as shown in the figure. The tank was first tried empty, but unfortunately the wooden bottom was found to reflect, thus it was useless for the purpose intended. I then tried what ought to have been tried before constructing the tank—namely, whether ordinary boards, such as flooring, reflected. The floor was found to reflect readily. This was attributed to moisture in the wood causing it to conduct, specially as wood was found not to polarize by reflection. Experiments were then undertaken to determine if water reflected, even though in thin sheets. A large glass window was placed beneath the mirrors and flooded with water; this was found to reflect well, both when the mirrors were in the position shown and when rotated to the position "at right angles." Thus water also acts like a metal, reflecting the radiation however polarized. The glass had to be hardly more than damp in order to get some reflection.

The wooden tank being unsuitable, a glass tank was thought of, but was given up for solid paraffin, which, being in slabs, could be easily built up into a vertical wall of any desired thickness. Through the kindness of Mr. Rathborne a large quantity of this was lent for the purpose.

A thin sheet of paraffin about 2 centimetres thick was found not to reflect, as was expected. Next a wall 13 centimetres thick (180 centimetres long, 120 centimetres high) was tried, and found to reflect, this being the thickness required in order to add another half period to the retardation of the wave reflected from the back at an incident angle of 55°, the wave-length being taken as 66 centimetres, and the index of refraction being taken as 1·51, the square root of 2·29, the value taken as the specific inductive capacity of paraffin.

Then a wall twice the thickness was tried, but it also reflected, contrary to expectation. While in doubt as to the cause of this, it was decided to make a determination by direct experiment of the index of refraction of paraffin for these waves, by a method suggested in NATURE (vol. xxxix. p. 393), which consists in interposing a sheet or wall of paraffin between the resonator and the metallic reflection in the Hertzian experiment of loops and nodes which are formed by the interference of the reflected wave with the direct radiation; the ratio of the velocity in the wall to that in the air being easily found from the observed shifting of the loops and nodes towards the screen.

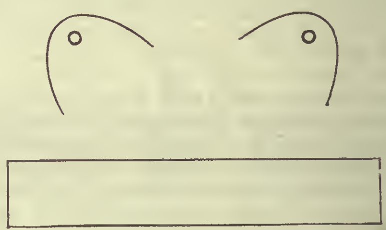


FIG. 1.

In this way the index of refraction for the radiation of the period employed was found to be about 1·8, so that the paraffin walls which had been used were too thick; The proper thickness being about 10 and 20 centimetres—exactly so for an incident angle of 51°. On making this alteration I fancied I could detect a slight difference between the reflections from the thick and thinner walls; still the difference was not sufficient to be at all satisfactory. The nature of the observing apparatus makes it almost impossible to say if the reflection on one occasion is more intense or less so than on another so long as sparks can be obtained. This is due to the sparking-point in the receiving apparatus continually requiring readjustment when working with small sparks, as the distance between them changes either from shaking or from the points getting burnt up. Dust and moisture from the observer's breath are also troublesome.[1] Thus it might be quite possible that the points had always to be much closer with the 20 centimetre wall than with the 10 centimetre wall in order to get sparks, and yet the difference escape detection; the thing observed being whether sparks can be obtained or not, the eye being incapable of comparing with any degree of accuracy the intensity of light on one occasion with that on another.

However, if it had been possible to suddenly change the wall, while viewing the sparking, from being 10 to 20 centimetres, it would have been easy to detect any

[1] With *very small* sparks the thermal expansion must be counteracted by unscrewing.

difference which might have existed, but unfortunately it took some little time to alter the wall.

In order to obviate this difficulty the following device was resorted to with the object of showing that there was a difference in the behaviour of the wall when 10 centimetres thick to its behaviour when 20 centimetres thick. (For at the time I did not see that the experiment was inconclusive, the effects observed being the same whether the back reflected at all or not). A *small* sheet of zinc was placed at the back of the wall, and the effect on the sparking observed while an attendant suddenly removed or again replaced the zinc. It was supposed that when the wall was 20 centimetres thick and there was sparking, that on suddenly placing the zinc on the back the sparking would increase, owing to the phase of the reflection from the back being half a period different from that of the reflection from the zinc; but when the wall was 10 centimetres thick that the presence of the zinc would diminish the sparking.

It was with no little surprise that the reverse was observed. That is to say, placing a sheet of zinc about 30 centimetres square on the back of the wall actually aided the reflection from the back so as to diminish the sparking with the 20 centimetre wall, but increasing it with the 10 centimetre wall. This observation made it look as if it must be on the first reflection from the paraffin—that is to say, on passing from a rare to a dense medium—that the "change of phase" occurs, and not at the back,—at a reflection from a dense to a rare medium, as is ordinarily supposed. For Hertz's experiment of loops and nodes showed that there was no change of phase on metallic reflection—that is, of the *magnetic* displacement. There is a change of phase of the *electric* displacement. It is important to bear in mind that the electric loop and the magnetic node occurred at the same place, and of course so too the electric node and the magnetic loop.

In order to investigate this, attempts were made to obtain Hertz's loops and nodes off a paraffin wall as reflector, but no reflection could be discovered, the intensity of the vertically reflected rays being insufficient. However, by inclining the incident radiation to an angle of 57°, the intensity of the reflection was found to be amply sufficient. With a circular resonator, which is for these

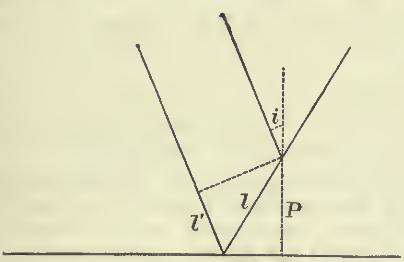

Fig. 2.

waves about 10 centimetres in diameter, sparks were obtained close to the reflector, the circle being held at right angles to the wall so as to be equally inclined to both direct and reflected radiation, and this was confirmed by a straight resonator giving none there. At 30 centimetres from the wall [1] there was interference with the circle, and vigorous sparking with the straight resonator. This being about the right distance for the loop to be from the reflector at an incident angle of 57°,

$$\frac{\lambda}{2} = l + l' = p \sec i(1 + \cos 2i) = 2p \cos i.$$

Thus there is no doubt that it is on the second reflection that the change of phase occurs.

Here, then, was a difficulty—the small sheet of zinc at the back of the paraffin undoubtedly reflected with a change of phase, while, according to the Hertzian experiment, metallic reflection is unaccompanied by change of phase. On mentioning this to Prof. Fitzgerald, he pointed out to me its complete agreement with wave theory. For by considering the secondary waves produced by dividing up a primary wave with reference to any point into half-period zones, it can be seen that the effect of the primary is equivalent to half of that arising from the central circle, and in consequence is half a period behind the phase which would be at the point if an infinitesimal portion of the centre alone acted. For the effect of each ring can be considered as destroyed by half the effect of its two

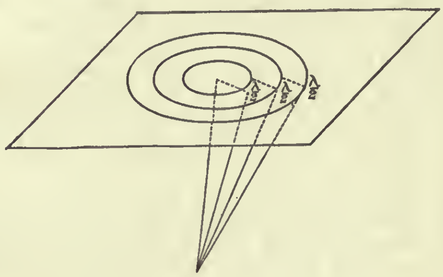

Fig. 3.

neighbours, and thus half the effect of the central circle is left uncompensated. But the distance of the edge of this circle is half a wave-length further from the point than its centre is, so that the resultant phase at the point will be behind that due to the centre, but in front of that due to the edge, which effect would be half a period behind that arising from the centre. Taking the mean between them, the resultant phase then at the point is a *quarter* [1] of a period behind what it would be if the centre alone acted. Thus it was that the reflection from the *small* sheet of zinc differed from what I had expected it to be.

Experiment showing Phase of Secondary Waves.—To experimentally test this, the small sheet of zinc was used as reflector in the Hertzian experiment of loops and nodes. Employing the circular resonator, the position of interference was found to have shifted out from 17 to over 24 centimetres, which nearly corresponds to an acceleration of phase of a quarter of a period, the wave going in all nearly a quarter of a wave-length further, and nevertheless being still only half a period behind the phase on starting. The furthest out the loop could be is 25·5 centimetres: to obtain this would require an indefinitely small reflector. Of course, when the resonator was close in to the sheet, no change of phase was found to occur, the sheet being then practically infinite.

Another interesting observation was made. A *long* sheet of zinc 30 centimetres wide was found to act similarly to the sheet 30 centimetres square, provided it was placed with its breadth parallel to the electric displacement. When thus placed at 24 centimetres from the circular "resonator," there was interference, but on rotating the reflector so as its length was parallel to the electric displacement, sparking occurred, and now the "resonator" had to be brought back to 17 centimetres in order to again obtain interference. This experiment is interesting in connection with the electro-magnetic way of looking at the acceleration of phase as being due to the accumulations of electricity on the edges of the reflector, which is the same as the reason why it is necessary to use *long* cylindrical mirrors, as was pointed out by Prof. Hertz in a letter last February to Prof. Fitzgerald. This experiment is really the same as Stokes's *experimentum crucis*, as Prof. Fitzgerald points out.

If, instead of using the whole primary wave in the

[1] It would occur at about 17 centimetres on vertical reflection. This experiment was also tried with a metallic reflector.

[1] That it aided the back rather than the front was probably due to their phase not being an exact period or half period different from each other.

former experiment, it be passed through a screen with a hole in it (either square or a long slit at right angles to the electric displacement), the position of interference, as might be anticipated, was not shifted out as much as before. In the rough experiment made, it was found to occur at about 19 centimetres from the screen.

It was now thought well to repeat the determination of the index of refraction with a larger wall and metallic reflector than had been used before, as this change of phase might have affected the former results. But it was found that it had not done so to a sensible extent. However, the result of these new experiments was finally to give for paraffin, $\mu = 1·75$, and at the same time it was found that the wave-length given by the "vibrator" was 68 and not 66 centimetres, as had been assumed.

Two new knobs for the "vibrator" had been made, and the fact had been overlooked that they were slightly larger than the old ones, which gave a wave-length of 66 centimetres. These new knobs were electro-plated with gold, and were a great saving of trouble, as they could be cleaned by merely rubbing with paper; apparently, the gold which was carried across by the sparking in the form of a black powder coming off, but some may have reburnished on. It was a curious thing that, if the knobs were left uncleaned over-night, the next morning it was very hard to get the black off, some molecular change probably occurring.

If the value of μ thus found be not in some way due to the paraffin being in separate blocks, it would show a remarkable anomalous dispersion for paraffin near these curiously slow vibrations, and, as suggested by Prof. Fitzgerald, may be connected with the vibration periods of atoms in the molecule, as it can hardly be connected with the vibrations in the atoms themselves. It might be interesting to investigate whether these slow vibrations could cause dissociation, and thus lead to a photographic method of observing them. It may also be allied with ordinary electrolysis by very long period currents, as is also suggested by Prof. Fitzgerald.

Assuming $\mu=1·75$,[1] and $\lambda=68$ centimetres, the thicknesses of the walls in the "Newton's ring" experiment, as above described, were wrong. However, it was found more convenient to alter the angle of incidence to suit the walls than to change the thickness of the walls. Thus, the mirrors were put at 25°, which is the proper angle with the above data for 10 centimetre and 20 centimetre walls. On now repeating the experiment, better results were obtained than I should have anticipated. When the wall was 10 centimetres thick, continuous sparking was easily obtained, but, when 20 centimetres thick, it was only after much adjustment and patience that perhaps one slight spark could be obtained. This was quite sufficient, considering the nature of the wall, for it was only built up of plates, which afforded internal reflections, weakening the transmitted rays, and also since it requires the sum of the effects arising from the multiple reflections back and forward inside the wall to completely interfere with the front, and some of these are lost at the edge of the beam.

FRED. T. TROUTON.

ICE GROWTH.[2]

SEVERAL of the Arctic Expeditions have instituted observations on the rate of growth of the ice during the winter, and in the "Contributions to Arctic Meteorology," vol. i., 1885, records of this nature are given for the following stations: Gulf of Boothia, Assistance Bay, Port Bowen, Walker Bay, Cambridge Bay, Camden Bay, Princess Royal Islands, and Mercy Bay. The second German Arctic Expedition has also undertaken such investigations and published results in its report (Leipzig, 1874).

In the present paper these observations are compared with the results of the theory of ice-formation, the basis of which has been explained by the author in a paper on some points in the theory of the conduction of heat.

The theory gives for the thickness (λ) of ice formed in the time (t) the following formula, which is approximately correct—

$$\lambda^2\left(1 + \frac{cb}{3\lambda}\right) = \frac{2kT}{\lambda\sigma}.$$

In this formula (c) is the specific and (λ) the latent heat of ice; (k) is the coefficient of conduction, (σ) is specific gravity, (f) is the temperature at the surface of the ice at the time (t), (k) the sum of cold for the same time; the last is the sum of the temperatures counted downwards from 0° C., from the commencement of ice formation up to the time (t).

The squares of the measured ice-thicknesses were taken and multiplied by the factor contained in the above formula, and the differences between the successive values were divided by the sums of cold for the corresponding intervals of time. The quotients for the different observations of each station differ in some degree from each other. Those which are most regular are the Gulf of Boothia, Assistance Bay, Port Bowen, and the German Expedition. The mean values for these four stations are, respectively, 0·877, 0·851, 0·869, and 0·878. Of the stations which show considerable differences, Walker Bay gives 0·919, Cambridge Bay 0·780, Camden Bay 0·791. The smallest quotients are, 0·755 for Princess Royal Islands, and 0·700 for Mercy Bay in the first winter, whilst it is 0·810 for the second winter.

We may take 0·87 as the normal value of the quotient. If any station gives considerably less than this, it may be concluded that some disturbance of the process of ice formation has occurred, such as, *e.g.*, if the station was affected by a warm current which brought up warmer water, and so delayed the formation of the ice.

The units for the figure 0·87 are the Fahrenheit degree, the English inch, and the day. For Celsius, centimetres, and the day, the figure would be 10·092. From it the coefficient of conduction of Polar ice, k, is 362·4. If the second be taken as the unit of time, the value of k would be 0·0042.

DR. C. FORSYTH MAJOR'S DISCOVERIES IN THE ISLE OF SAMOS.

WE are glad to learn that Dr. H. Woodward, who has just returned from Florence, has secured for the Palæontological Department of the British Museum (Natural History) the valuable collection of Vertebrate remains of Lower Pliocene age obtained by Dr. C. Forsyth Major during the year 1887 in the island of Samos, in the Turkish Archipelago. Dr. Forsyth Major lately contributed to the *Comptes rendus* (vol. cvii. pp. 1178–81) a preliminary notice of this collection. Among the remains are a large number of forms specifically identical with the mammals from the equivalent deposits of Pikermi in Attica, Baltavar in Hungary, and Maragha in Persia; but there are also some new types, which are of interest either from a distributional or a purely zoological point of view. Among these new forms is a species of ant-bear (*Orycteropus*), which is the only representative of that genus yet known beyond the Ethiopian region. A large pangolin, which is estimated to have been nearly three times the size of the West African *Manis gigantea*, is made the type of the new genus *Palæomanis*; and is of interest as showing how the African pangolins may have been connected with those of India. Perhaps the most striking new

[1] This value agrees with polarization experiments. No reflection was obtained at its corresponding angle, while at $\tan^{-1} 1·51$ some sparks were occasionally seen.

[2] Abstract of Dr. Stefan's paper, "Ueber die Theorie der Eisbildung, insbesondere über die Eisbildung im Pola-Meere," from the *Sitzungsberichte* of the Vienna Academy.

type is a large ruminant, referred by the author to the *Giraffidæ*, and stated to connect *Helladotherium* and the giraffe with some of the aberrant antelopes of Pikermi. Finally, a large ostrich is especially noteworthy from a distributional point of view, since we now have remains of this genus from Samos, the Thracian Chersonese, and Northern India.

NOTES.

WE regret to have to record the death of the eminent American physicist, Prof. Elias Loomis. He was born at Wellington, Connecticut, in 1811, and was educated at Yale College, where he acted for some time as tutor. He was successively Professor of Mathematics and Natural Philosophy in Western Reserve College, Ohio; Professor of Natural Philosophy in the University of the City of New York; and Professor of Natural Philosophy and Astronomy in Yale College. The latter appointment he received in 1860, and he held it until his death. Prof. Loomis was the author of more than 100 scientific treatises. Among his works was a series of text-books on mathematics, natural philosophy, astronomy, and meteorology. Of this series more than 500,000 copies were sold. During the last twenty-five years of his life he devoted himself chiefly to original research, and gave much time and energy to the preparation of a full account of the principles of meteorology. He was a member of various American and European scientific Societies.

ON August 19 the fiftieth anniversary of the foundation of the Observatory at Pulkowa was celebrated. Among those present on the occasion were the President of the St. Petersburg Academy of Science, the Grand Duke Constantine Constantinovitch, the Russian Ministers and Court dignitaries, the German and French Ambassadors at the Russian Court, and deputations from the Universities and Academies of Russia, and from foreign observatories, including Greenwich and the chief German observatories. Numerous congratulatory telegrams were received. The Czar expressed in a telegram high appreciation of the scientific merits of the Observatory.

THIS week the meeting of the Photographic Convention of the United Kingdom is being held in London. It was opened on Monday in St. James's Hall, where an interesting collection of photographic appliances and specimens of the best photographic work had been brought together. In his inaugural address, Mr. Andrew Pringle, the President, reminded his hearers that the present year was the fiftieth of practical photography, and traced the history of the art from its birth to its jubilee.

AT the meeting of the Linnean Society of New South Wales on June 26, Dr. Oscar Katz read a paper giving an account of experimental researches with the microbes of chicken-cholera. In this paper the author describes the investigations undertaken by him since last year with regard to the microbes of chicken-cholera. The larger portion of the experiments were made on wild rabbits; in addition, the action of the microbes on domestic poultry, as well as on indigenous birds, on hares, guinea-pigs, and ferrets was studied. A number of other points in the life-history of the chicken-cholera bacteria are dealt with in the paper: for instance, their behaviour when transmitted through the bodies of rabbits in successive generations; towards desiccation, putrefaction, &c. Rabbits were repeatedly protected against a virulent infection, in consequence of having previously partaken, at intervals, of cultures of the microbes in which the latter had been killed by moderate heat.

ON August 17, at 1 o'clock a.m., a severe earthquake shock of an undulatory character, lasting six seconds, was felt at Jablanica, Bosnia. The direction of the seismic wave was from south-east to north-west. According to a telegram from Mostar, a shock, lasting ten seconds, was felt there also on August 17. Some damage was caused to the railway line between Mostar and Ostrojac, while at Konjica a wall collapsed. The duration of the shock at the latter town was only five seconds.

THE Pilot Chart of the North Atlantic Ocean for the month of August shows that fine weather prevailed generally over the greater part of the North Atlantic during July. The only storms worthy of notice were two which prevailed in the western part of that ocean; the first was situated in latitude 40° N., longitude 58° W., on the 10th, and moved across Newfoundland on the 16th; the next day it was joined by the second storm, which passed out to sea from the coast of New Jersey on the 15th. The storm then travelled about north-north-east, and disappeared off the south coast of Greenland. Much fog has been experienced along the Transatlantic routes, and icebergs have been numerous, within the usual limits.

THE Report of the Meteorological Commission of the Cape of Good Hope for the year 1888 contains monthly summaries and results for 38 stations and rainfall statistics at 292 stations, including returns from Basutoland, Orange Free State, &c. In addition to the tables, there are some extremely interesting diagrams showing the actual rainfall in 1888 at a number of stations throughout the colony, as compared with the average rainfall. They show that in nearly all months the fall in 1888 was much above the average. Storm warnings are not yet issued, but weather telegrams are received from a number of stations, and after correction and collation, reports are sent to coast stations and entered on charts, for the information of seamen and others.

VOLS. IX. AND X. of *Aus dem Archiv der Deutschen Seewarte* contain reports of the activity of that institution during the years 1886 and 1887. The collection of observations at sea, and at distant stations, has been carried on with vigour, while weather telegraphy and the verification of chronometers and nautical instruments also receive great attention. Dr. Neumayer regrets that the ever-increasing routine work curtails the time for scientific investigation, yet the volumes contain many valuable researches by members of the staff, to some of which we can only very briefly refer, although all are worthy of careful study. In vol. ix. Dr. van Bebber, dealing with typical weather-conditions, investigates the passage of barometric depressions over Europe during the years 1881–85, in continuation of a former paper referring to 1876–80. The object of the discussion is to trace the influence of the depressions upon the weather, with a view to the discovery of the laws of the changes of direction of their tracks, and of their rates of progression. The author shows that the depressions move along certain tracks with greater velocity than the motion of minima generally. The text is illustrated by twenty plates. The other articles are: on the determination of the refraction constants; and remarks from ships' logs relating to weather, &c., in Eastern Asiatic waters. In vol. x. Dr. Köppen contributes a useful paper on the determination of air-temperature. The author investigates the influence of radiation on different thermometers and screens, and gives a *résumé* of the experiments with regard to the latter in various countries, and of the observations on local differences of temperature (including the influence of radiation). These experiments seem to show that screens through which the air can freely pass are better than large shelters, and that the effect of radiation is lessened by the free circulation of the air, and by the smallness of the thermometer-bulbs. M. Möller contributes an article on the circulation of the atmosphere between the equator and the Poles. The results arrived at differ from those of Prof. Ferrel, especially with regard to the force of westerly winds in latitude 38°, in the lower and upper strata. The volume concludes with an article on Combe's apparatus for testing chronometers.

FROM the statistics of the Education Department in India during the past year, it appears that the percentage of those of school-going age who actually attended was 11·8 as compared with 10·7 the preceding year. The total attendance increased about 120,000 on the preceding year, but the numbers at the training-schools fell from 5716 to 4761. Year by year the Mahometan pupils have increased, and during the past year their numbers were 804, 485 as against 752,441 in 1886–87. The total expenditure on education has increased from 2,52,41,414 rupees in 1886–87 to 2,61,91,280 rupees in 1887–88; but the indirect expenses—that is, the cost of inspection, buildings, scholarships, &c.—fell from 54,11,098 rupees in 1886–87 to 52,81,471 in 1887–88. The fees increased from 65,29,958 rupees to 72,94,023 rupees. Except in the circumstance that the numbers attending the training-schools have declined very much, the Government thinks that everywhere marks of great progress are shown. The expenditure by local bodies on education has also increased from 37,14,579 rupees in 1886–87 to 46,41,551 rupees in 1887–88.

A SWEDISH paper gives an account of some experiments made by Captain R. von Mühlenfels in Carlskrona in storing live fish, his object being to discover the maximum degree of confinement they could bear without deteriorating in quality. With this aim he placed 1300 kilogrammes of live cod in a cask, covered within and without with asphalt tar, and of about 52 cubic metres in content. The cask was firmly fixed in a stream of fresh running water. During the first few weeks of their confinement the fish grew thinner, and had deteriorated in quality. At the end of six weeks, however, it was found that those which remained had much improved by their captivity.

THE French *Journal Officiel* recently contained a report which Prof. Edmond Perrier had sent in to the French Government on the subject of the best means of protecting fishermen against porpoises. Although the depredations of these creatures have been exaggerated, it is certain that they do considerable damage, especially on the Mediterranean coasts of France, by tearing the nets. For at least a quarter of a century past, efforts have been made to lessen the numbers of the porpoises by offering a reward per head, and by other remedies. In 1865 the Government invited the fishermen themselves to organize a seine-net fishery for porpoises, and they were offered special nets, and sums of from 5 to 25 francs for each animal. It was, however, found in practice that as soon as the porpoises felt themselves to be surrounded, they simply jumped over the seine-nets and were at large again. Some years later the fishermen of Cannes, Saint Tropey, and La Ciotat petitioned Government to lend them a gun-boat, filled with torpedoes, for the purpose of firing at the porpoises. This was done, and the cannon and the torpedoes scared away the porpoises for about eight days, but they scared away the fish as well, so that there was no fishing for at least a week. The porpoises, moreover, are too numerous and too agile to be shot, one by one, in an effective manner. The report sums up that the employment of artillery against porpoises is perfectly useless, that a reward for killing them singly is equally unavailing, and that the only thing to do is to encourage the fishermen to unite in chasing the porpoises, and in forming a mutual insurance guarantee against their depredations. In the meantime the Department of the Marine might continue to indemnify, to a certain extent, the proprietors of any nets that have been very seriously injured.

A FRUITFUL study may be made of the sociology of small sections of a community. M. Dumont finds in the rural communes of France much individuality as regards density, wealth, mobility, birth, marriage, and death rates, &c. We will give a few facts from his interesting paper (*Rev. Scient.*). Unlike what usually occurs near large towns, the eleven rural communes in the outskirts of Caen are with one exception (Mondeville) being depopulated. Great mobility in the rural populations is generally associated with a low birth rate, great fixity with a high one. Examples of a low birth rate occur in the communes near Caen (13 to 17); on the other hand, the natality is high in some of the poor and miserable communes of the Côtes-du-Nord (40 to 41). Side by side in the same department, and even the same canton, are very different birth rates. For the nine communes of Paimpol (Côtes-du-Nord), some 20,000 inhabitants, the rate varies from 20 to over 30. In Bretagne, with a generally high birth rate, there are isolated communes with a very low one; and two communes are cited, which are apparently much alike, and where subsistence is drawn from the sea, but the birth rate of one is 35·1, that of the other 21·7. In the canton of Isigny (Calvados) the birth rate was in general steadily low throughout the century till ten or twenty years ago, when there was a remarkable rise. The marriage rate in Ile-de-Ré is considerably above the average for France, while the fecundity of marriage has of late been going down. But one commune, the small town of Saint Martin, shows a recent decline of its marriage rate (25 per cent. in three decades) while the constancy of its low birth rate points to an increased fecundity of marriage. The death rate in many communes (those of Douvres, *e.g.*) is now much greater than early in the century. The increase of illegitimacy and high mortality of infants are often obviously the cause of a rising death rate.

CONSIDERING the progress of biology, Dr. Düsing remarks (in a recent number of *Humboldt*) that for 25 years the effort of zoology has been mainly to determine the descent of animals by means of their morphological features. The flourishing of morphology has been favoured by the discovery of a large number of lower forms of animal life. But the time is not far off when it will become more and more difficult to discover new animals, and those known will have been efficiently described. Investigation will therefore be directed more to the mode of life, which, in the case of most animals, is but little known. This demands long observation and a special talent of observation, which is quite different from that required by morphology. Several investigators have entered this sphere, studying especially the higher animals; but most continue in the direction impressed on zoology by Darwin. The prevailing tendency is exemplified in the founding of a Professorship of Phylogeny at Jena. And it is a remarkable fact that the present occupant, Prof. A. Lang, is one of those who are leaving the older paths for biology, as shown by his recent work, which is entitled "On the influence of a fixed mode of life on animals, and on the origin of non-sexual propagation through fission and budding."

THE *Kew Bulletin* for August consists of a full account of the fluted scale-insect (*Icerya purchasi*, Maskell), which is described as one of the most destructive pests injurious to plants. Of late years it has made its appearance in South Africa, New Zealand, and California. The best account of the insect has been published by Prof. Riley, and the results of his inquiries are made easily accessible in the *Bulletin* to a wide circle of readers.

MR. WRAY, Curator of the Museum of Perak, in the Malay Peninsula, communicates to the *Perak Government Gazette* a note on the mango weevil, a pest which has lately excited some alarm in various parts of the East. Mr. Wray describes it as a small beetle infesting the mangoes in Perak, particularly the introduced varieties, which has been examined and found to be identical with the mango weevil of India, known to science as *Cryptorhynchus mangnifera* of Fabricius. It is a small dark rusty-grey insect about a quarter of an inch long, and, though it and its ravages have long been known, little or nothing has up to the present time been discovered of its habits. It is believed that it lays its eggs in the flower or very young fruit, for in the ripe fruit there is no external mark to show where it gained an entrance, and it is not until the perfect insect eats its way out of the mango that it is possible to tell whether any particular fruit is sound or diseased. Some varieties of the mango enjoy complete immunity from the attacks of this insect, and it has been noticed that even particular trees of varieties which are not so favoûred always escape. This fact seems to hold out the hope that, by careful selection, good varieties of the fruit could be raised which would not be subject to the attacks of this destructive pest. The character which renders the fruit unsuitable as food for the weevil is, and probably always will remain, unknown, as our senses may not be keen enough to detect the particular taste or smell which prevents the female from laying her eggs in the fruit of the naturally protected trees.

Dr. Henry C. McCook is about to issue an elaborate work on "American Spiders and their Spinning-work." It embraces studies extended over more than fifteen years, and will be printed in three volumes. Volumes I. and II. will contain the author's personal observations, studies, and illustrations of the habits and industry of spiders. The studies are particularly directed to the spinning habits of the great group of spiders known as orb-weavers; but these are expressed in their relations to all the other tribes in both hemispheres. Volume III. will contain the systematic part of the work, and embrace descriptions of the orb-weavers of the United States, illustrated by a number of lithographic plates, painted by hand in the colours of Nature. The volumes will be illustrated, wholly from Nature, the number of engravings in the first volume alone exceeding two hundred.

Messrs. J. and A. Churchill hope to publish in September a work on "Fuel and its Applications," by Mr. E. J. Mills, F.R.S., and Mr. F. J. Rowan. It will be the first volume of a large work on chemical technology, of which Mr. C. E. Groves, F.R.S., will be the general editor, and which will be founded on one written by Richardson and Ronalds, familiarly known as "Knapp's Technology." Messrs. Mills and Rowan's work on fuel is in reality a new work, dealing with the applications of fuel to arts and manufactures as introduced by the most modern discoveries. The volume is profusely illustrated.

Messrs. George Philip and Son have published a new edition of Mr. T. Rhodes's useful "Steamship Guide and Holidays Afloat." The work has been thoroughly revised, and much new information is embodied in the present edition.

A work on "The Microscope in the Brewery and Malt-house," by C. G. Matthews and F. C. Lott, will be published early next month by Messrs. Bemrose and Sons.

A Calcutta firm has published a book entitled "The Game, Shore, and Water Birds of India," by Colonel A. Le Messurier, which is an attempt to describe the miscellaneous water-fowl of India. The author treats of the birds under three heads—namely, "Scratchers," "Waders," and "Swimmers,"—and, besides classifying them under these heads, he gives the native names of the birds in the various languages. There are in all 121 illustrations. The book might well be enlarged, particularly by the addition of a list of places where the various species may be found.

The additions to the Zoological Society's Gardens during the past week include a Great-billed Touracou (*Corythaix macrorhyncha*) from West Africa, presented by Lady Charlotte Blandford Griffith; a Water Chevrotain (*Hyomoschus aquaticus*) from West Africa, a Blue and Yellow Macaw (*Ara ararauna*) from Brazil, deposited.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *AUGUST* 25–31.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 25

Sun rises, 5h. 4m.; souths, 12h. 1m. 50·6s.; daily decrease of southing, 16·4s.; sets, 19h. 0m.: right asc. on meridian, 10h. 17·6m.; decl. 10° 37′ N. Sidereal Time at Sunset, 17h. 17m.

Moon (New on August 26, 14h.) rises, 3h. 21m.; souths, 11h. 16m.; sets, 18h. 59m.: right asc. on meridian, 9h. 32·0m.; decl. 18° 0′ N.

GEOLOGY IN RUSSIA.[1]

The Geological Committee of St. Petersburg has made an important contribution to Russian geology by bringing out a new sheet of the Geological Map of Russia, covering the Southern Urals.[2] A volume of explanatory text accompanies the map. It appears from the recent explorations of the members of the Committee that, contrary to the current opinion as to the Southern Urals consisting of a number of chains radiating from Mount Yurma, the great chain consists in its southern parts of a number of chains parallel to one another, and all running from the south-west to the north-east. The main water-parting is built up of granites, syenites, and gneisses, considerably worn down by denuding forces; it has a steep slope towards the east, where its base disappears beneath the Tertiary deposits, while towards the west it is over-

[1] *Memoirs* (vols. ii. and iii.) and *Izvestia* (vols. iv. and v.) of the Russian Geological Committee.

[2] "Carte géologique générale de la Russie," Feuille 139; "Description orographique," by A. Karpinsky and Th. Tchernysheff; "Hauteurs absolues de l'Oural méridional," by A. Tillo; and "Explication de la Carte," by A. Karpinsky and Th. Tchernysheff, in *Memoirs*, vol iii. No. 2. (In Russian, with summaries in French.)

lain by thick beds of Devonian, Permian, and Carboniferous deposits, and these strata are so folded as to make several parallel chains rising more than 3300 feet above the sea, and containing the highest summits of the region. Further west the country assumes the character of a plateau which is built up of nearly horizontal strata of the formation—so characteristic of the Urals—which has a fauna intermediate between the Permian and Carboniferous of Western Europe. Above this there are Triassic deposits.

Several other contributions will be devoted to the same region. One, already published, contains a most elaborate work "On the Lower Devonian Fauna of the Western Slopes of the Urals," by Th. Tchernysheff. Until 1880, the bituminous, gray, and dolomitic limestones of the Urals—very poor in fossils as a rule—were thought to be Silurian, but M. Tchernysheff describes 107 species recently found in these limestones, and shows that their fauna is of Lower Devonian age. This conclusion is of great importance, as it throws light on the age of the very same series of limestones, quartzites, and slates in Siberia and Turkestan (also arrayed in ridges running south-west to north-east).

Another sheet of the geological map covers the most interesting region on the right bank of the Lower Volga.[1] Upper Carboniferous strata appear in that region in the deeper ravines only; the Cretaceous formation is represented by beds belonging to the *étage Aptien* and Neocomian groups of the Lower Cretaceous, as also by the Cenomanian, Turonian, and Senonian groups of the Upper Cretaceous. Nearly the whole of the region is covered, however, by Eocene clays and sands; boulders, partly of local origin, and partly carried from North-Western Russia, are strewn over the surface, and the manner of their distribution is such as to exclude the possibility of transport by floating ice. Prof. Sintsoff concludes, therefore, that the ice-sheet of Russia extended as far south-east as the Volga under the 50th degree of latitude.

Finally, an important contribution to the palæontology of Russia—"The Ammonites of the *Aspidoceras acanthicum* Beds of East Russia"—is published in the same *Memoirs* (ii., 3) by Prof. Pavlow. These beds, which are met with in Simbirsk and the Southern Urals, have a mixed fauna, the characters of which may be best explained by the statement that during the Jurassic period Central Asia was under the sea, and that this basin was in connection with the Jurassic basins of both Tibet and Central Europe.

Besides the above larger works, the Geological Committee has brought out two volumes of *Izvestia* (*Bulletins*), which contain a mass of valuable information. Prof. Mushketoff's notes upon the Kalmuck Steppes are, as usual, rich in most suggestive remarks about the activity of wind and water in the desert. He shows also that during the Quaternary period the Caspian Sea did not extend further west than the Ergheni Hills, communicating with the Black Sea through the Manytch Valley only. In a paper on the limits of glaciation in Central Russia and the Urals (vol. iv.), M. Nikitin shows that the ice-sheet extended in Russia as far south as 48° 30′ N. latitude on the Dnieper, and 50° on the Volga.[2] In a subsequent paper (vol. v.), devoted to the post-glacial deposits of Germany, the same author distinguishes two different kinds of loess, one of which may be due to the agency of wind. Many papers are devoted to the Urals—their crystalline rocks, the traces of glaciation (M. Krotoff, in vol. iv. fasc. 9), and the intermediate Permian-Carboniferous beds, the fauna of which, according to Prof. Stuckenberg, contains forty-one Carboniferous species, thirty-four Permian, seven species belonging to both, and twenty-three characteristic of the Permian-Carboniferous groups. Four papers are devoted by M. Mikhalsky to Poland, and it appears that the beds of Poland, which were formerly thought to be Jurassic, must be regarded as Neocomian—that is, Cretaceous. M. Lagusen describes a new sub-genus, *Lycophoria*, of the *Strophomenidæ* family; Prof. Schmidt deals with the glacial and post-glacial deposits of the Baltic provinces; M. Pavlow describes the *Exogira virgula* beds, as also some Cretaceous and Tertiary deposits of South-East Russia; and M. Nikitin gives a sketch of the Carboniferous deposits and the loess of Samara.

Another work, issued by the Russian Geological Survey, deserves especial mention on account of its general interest and value. This is the annual bibliography of works on geology, mineralogy, palæontology, &c., published in Russia, or works published elsewhere which refer to Russia ("Bibliothèque géologique de la Russie"). Brief abstracts, in Russian with a French translation, are given of the more important papers. The titles are given in the original language; if the original is Russian, then a French version is given; if the original is not Russian, a translation into this language is added.

The publications for the year 1885 number 256; for 1886, 356; for 1887, 405; and for 1888, 390. But the later series include omissions in earlier numbers. The editor of this useful annual is M. S. Nikitin; his chief assistant in the work is Mdlle. Marie Tzwetaev.

[1] "Carte géologique générale de la Russie," Feuille 93; "Kamyschin," by I. Sintsoff, in *Mémoires du Comité Géologique*, vol. ii. No. 2.

[2] An abridged translation of this paper has been published in *Petermann's Mitteilungen*.

SCIENTIFIC SERIALS.

American Journal of Science, August.—On the observation of sudden phenomena, by S. P. Langley. The paper deals with the apparently inherent defects of human observation, especially in recording unexpected natural phenomena, its object being to reduce this personal error to a minimum. The author believes that a means may be found by which any person, skilled or ignorant, may make not only meridian observations, but an observation of any sudden visible event, of whatsoever nature, so accurately that no correction need be applied. An instrument constructed for the purpose, and here illustrated, has been tried by various observers in various ways, the probable error for any single observation being rather less than one-twentieth of a second.—A spectro-photometric comparison of sources of artificial illumination, by Edward L. Nichols and William S. Franklin. These experiments, made in Cornell University during the summer of 1888, consist in the spectro-photometric comparison of various artificial sources of light and of daylight with that emitted by a sixteen candle-power incandescent lamp. The sources of light subjected to measurement were a standard candle, various petroleum and illuminating gas flames, a lime-light, two electric arc lights, clear daylight, an incandescent lamp of high resistance at various temperatures, and an incandescent lamp of low resistance at normal candle power. The general result is that candle-power as determined by means of the Bunsen photometer affords no correct measure either of light-giving energy or of the luminosity of the source of light, the direction of the error always being such as to favour sources of a low degree of incandescence when compared with those of higher temperature.—On the possibility of hemihedrism in the monoclinic crystal system, with especial reference to the hemihedrism of pyroxene, by George H. Williams. A fresh study of the remarkable crystals of pyroxene from Orange County, New York, recently described by the author as hemimorphic, seems to show that they should rather be regarded as hemihedral, and that they are by no means an isolated instance of this peculiar development in pyroxene.—On the earlier Cretaceous rocks of the north-western portion of the Dominion of Canada, by George M. Dawson. The purpose of this paper is to call attention to certain facts recently brought to light respecting the equivalency of the Queen Charlotte Islands and Kootanie formations, and to the importance of the earlier Cretaceous rocks, of which they are representatives, over great areas of the western and extreme north-western portion of the continent. These facts are just now specially interesting from their analogy to those lately developed by Mr. R. T. Hill respecting a similar earlier Cretaceous formation in the south-western region of the United States.—A new occurrence of gyrolite, by F. W. Clarke. This specimen, from the New Almaden quicksilver mine, California, is shown on analysis, and by comparison with How's figures for a Nova Scotia gyrolite, to be a somewhat impure gyrolite associated with apophyllite, and agreeing approximately with the formula $Ca_2Si_3O_8 . 3H_2O$—On action of light on allotropic silver, by M. Carey Lea. The author's further studies of this subject show that light can convert yellow or red-yellow allotropic silver to white, and cause the blue-green modification to pass to the gold-yellow.—Papers were contributed by J. F. Kemp, on certain porphyrite bosses in North-Western New Jersey; by W. B. Dwight, on recent explorations in the Wappinger Valley limestones and other formations of Dutchess County, New York; by George F. Becker, on silicic acids; and by O. C. Marsh, on gigantic horned Dinosauria from the Cretaceous. Mr. Marsh also continues his memoir on the discovery of Cretaceous Mammalia, illustrating the subject with two plates of the teeth of American Cretaceous mammals.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 2.—"On the Spectrum, Visible and Photographic, of the Great Nebula in Orion." By William Huggins, D.C.L., LL.D., F.R.S., and Mrs. Huggins.

I have added the name of Mrs. Huggins to the title of the paper, because she has not only assisted generally in the work, but has repeated independently the delicate observations made by eye.

In the year 1882 I had the honour to lay before the Royal Society a note on the photographic spectrum of this nebula, in which I described a new bright line in the ultra-violet, to which I gave a wave-length of about 3730. In addition to this new line, the lines of hydrogen, $H\beta$ and $H\gamma$, which I had discovered by eye in my early observations on the visible spectrum, were to be seen upon the plate.

On account of the faintness of the object the slit had been placed rather wide, and for this reason the character of the line and its position, as I stated in the paper, could not be ascertained with the accuracy which I desired.

On February 5, 1888, a photograph of the spectrum of this nebula was obtained with a narrow slit; the same apparatus, so far as the essential parts, which were described in my paper, on the "Photographic Spectra of the Stars" (Phil. Trans., 1880, p. 672) being employed.

In this photograph, in addition to the strong line about λ 3730, a pair of less conspicuous lines is seen on the less refrangible side of the strong line.

The continuous spectra due to the two of the four bright stars of the Trapezium which fell upon the slit are present.

Across these continuous spectra at least four groups of bright lines can be seen, of which the greater number can be traced into the nebula for some little distance from the stellar spectra.

It is scarcely necessary to state the importance of this observation as showing that these stars of the Trapezium are not merely optically connected with the nebula, but are physically bound up with it, and are very probably condensed out of the gaseous matter of the nebula. This observation would seem also to show that the nebula, as a whole, may not be at a distance from us greater than that which we should attribute to such stars, if they occurred alone in the heavens.

The first group, of six lines, occurs between λ 4116 and 4167. The lines of this group do not extend far from the continuous star spectra, with the exception of two lines. These can be seen faintly in another photograph taken in 1889. Beyond there is a fainter group, probably of four lines a little beyond *h*. I am pretty sure that these lines extend into the nebula. The third group from λ 3896 to 3825, of which I have endeavoured to measure ten lines, is faint, but here there is no doubt that the same lines are present in the adjoining nebular matter. There are two lines a little more refrangible than the strong line seen in 1882, at about λ 3709 and λ 3699. I have a suspicion of a faint group about this place, and also of another group on the less refrangible side of G.

I shall discuss further on, the probable chemical significance of these lines.

During the time that Orion was favourably situated for observation in the season of 1888 and in that of the present year, the unusual continuance of bad weather made it impossible for me to give so complete an account of the spectrum of the nebula in the photographic region as a few really fine nights would have enabled me to do. However, on February 28 of the present year I obtained another photograph, the slit being very narrow, which gives some more new information of the nature of its spectrum. I was astonished on looking at the photograph not to see the strong line about λ 3730, which was by far the most conspicuous feature of the photograph taken in 1888. The pair of lines near it on the less refrangible side, which I found for the first time in 1888, are present; and on a further scrutiny of the plate I discovered two other pairs of lines, most probably rhythmically connected with them, in the still more refrangible region, the last pair, accompanied by a third line, being near the ultra-violet limit of ex-terrestrial light.

I was also able to see faintly two of the bright lines which I have described as present across the continuous spectra of the brighter stars of the Trapezium in my photograph of 1888. It is not quite certain whether these very faint and short lines are really due to the matter of the nebula proper, or have come upon the plate in consequence of the stars of the Trapezium having fallen accidentally upon the slit for a time too short to impress the continuous part of their spectra. No trace of a continuous spectrum can be seen upon the plate, but these lines in the plate of 1888 do extend beyond the continuous spectra of the stars of the Trapezium.

I regret extremely that bad weather has made it impossible for me to work out the circumstances on which depended the disappearance of the strong line about λ 3730. Both the photographs which show this line include two stars of the Trapezium, and it may possibly be that this strong line is associated with the groups near it in the spectra of the stars, and may therefore come out in those parts of the nebula only which are more condensed. A few photographs with the slit differently placed upon the nebula would doubtless have thrown light upon this point. The suggestion presents itself strongly that the mottled and broken-up character of the nebular matter, shown in Lord Rosse's drawing from eye observations, and much more strikingly brought out in the recent photographs of Mr. Common and Mr. Roberts, may be connected with differences of spectrum in the photographic region, though in the visible region there is no known alteration of the spectrum of the four bright lines, except, it may be, some small differences of relative brilliancy of the lines.

Until next winter we cannot go beyond the new information which these photographs give to us. On the plate of the photograph of 1889 two pairs of spectra for comparison were taken: two spectra, one above and one below the nebular spectrum, of burning magnesium; and two spectra, similarly placed, of the light of the sky.

From the photographs of 1888 taken with a narrow slit, the position which I gave in 1882 to this line is shown to be, as I expected from the wide slit then used, approximate only. I find from the later photograph that the wide slit had caused the strong line to unite with a line near it, and that in 1882 I measured the middle of the broad band produced by the union of the wide images of two lines. Its position is about six tenth-metres more refrangible. It does not therefore agree, as I then suggested, with the hydrogen line ζ in my spectra of white stars. A statement of the position of this line relatively to the magnesium-flame triplet will be given further on, when I come to discuss the comparison of this spectrum with that of the nebula.

The position of the pair of lines a little less refrangible than this strong line, seen with it in the photograph of 1888, and present without the strong line in the photograph of 1889; and the positions of the two other more refrangible pairs, presumably connected with the first pair, are given in the following table:—

1st pair about	λ 3752·0 3741·0
2nd pair about	3285·0 3275·0
Line at about	3060·0
3rd pair about	3053·0 3047·0

In both photographs I suspect the indications of other lines, which are too faint to permit any certain conclusion to be formed about them, whether they are true lines, or imperfections only of the film.

[The continuous spectra of the stars of the Trapezium can be seen on the plate from about F to about λ 3570, but they are very faint beyond λ 3660.—*May* 18.]

The Visible Spectrum.

a. Brightest line.—In 1872 ("On the Spectrum of the Great Nebula in Orion, &c.," Roy. Soc. Proc., vol. xx. (1872) p. 383), I stated, as the result of numerous direct comparisons of this line with the brightest line in the spectrum of nitrogen, that the nebular line was "sensibly coincident with the middle of the less refrangible line of the double line of nitrogen." To avoid repetition I will call this line N_1. Except where it is otherwise stated, I use this line of nitrogen simply as a fiducial point in the spectrum, without any reference to its chemical significance.

In a still more critical examination of the position of the nebular line for the purpose of determining whether there was any indication of relative motions of the gaseous nebulæ in the line of sight, I found some experimental difficulty from the circumstance that the nebular line is narrow and defined, while N_1 is nebulous. I was fortunate to find a more suitable fiducial line of comparison in a narrow line of lead, which falls almost upon the middle of N_1 ("On the Motions of some of the Nebulæ towards or from the Earth," Roy. Soc. Proc., vol. xxii. (1874) p. 252). In December 1872, I compared this line directly with N_1, and found it sufficiently near in position to serve as a fiducial line of comparison.

Six other gaseous nebulæ were also examined, each on several nights, with the result that "in no instance was any change of relative position of the nebular line and the lead line detected" (*ibid.*, p. 253).

In the simultaneous observation of the nebular line and the lead line, it was found if the lead line was made rather less bright than the line of the nebula, the small excess of apparent breadth of this latter line appeared to overlap the lead line to a very small amount on its less refrangible side, so that the more refrangible sides of the two lines appeared to be in a straight line across the spectrum. The clearness of position of the two lines was shown by the observation that when the line of the nebula passed across the field of the spectroscope, and the lead line was thrown in, the lead line was not seen, but only an increase in brightness of the nebular line. By comparing the end of the nebular line near the Trapezium where it is refined to a point, I estimated that the difference of position of the middle of the lead line and that of the nebular line might be possibly from λ 0000·2 to λ 0000·3 (*ibid.*, p. 252). Some recent measures of the position of the lead line with the middle of N_1 show that the lead line is about λ 0000·12 more refrangible.

These direct comparisons of the nebular line with the lead line confirmed, therefore, my former conclusion, that the brightest line in the gaseous nebulæ is very near N_1, when seen under a dispersion equal to nearly eight prisms of 60, namely 36° 25′ from A to H.

This result is based on direct comparisons, on twenty-four different nights, with N_1 or with the line of lead.

The wave-length of N_1 has been determined by Kirchhoff, Thalén, and by myself. Watts's reduction of my measure to wave-lengths is clearly not accordant with my measures of air lines immediately preceding and following this line. I have therefore reduced my original measure to wave-lengths, and find for N_1 the value λ 5004·5.

Kirchhoff	5004·6
Thalén...	5005·1

Thalén's value is clearly too high, as Thalén gives for the lead line, coincident nearly with N_1, λ 5004·6, and N_1 is seen on the more refrangible side of the solar iron line given by Ångström as λ 5004·9. In Ångström's map N_1 is laid down on the more refrangible side of the iron line 5004·9, at about 5004·5. The same position is given to N_1 in Kirchhoff's map.

I have made a new determination of the position of N_1, using the second spectrum of a grating 17,300 to the inch, relatively to the solar iron line at 5004·9 according to Ångström.

The value came out λ 5004·6, which agrees with Kirchhoff's value, and with Thalén's measure of the lead line which falls upon it, and also with the maps of Ångström and of Kirchhoff.

The wave-length of the brightest nebular line may therefore be taken at from

λ 5004·6 to λ 5004·8 . . . . (1)

The micrometric measures of this line, given by D'Arrest, Vogel, and Copeland, agree closely with this value.

D'Arrest's[1] mean value	5004
Vogel's ,, ...	5004
Copeland's[2] ,, ...	5004

b. Second line.—In 1872 (Roy. Soc. Proc., vol. xx., 1872, p. 385), I stated that I had found this line, by comparison with a line of barium, and subsequently with an iron line, to have

A wave-length of	λ 4957·0 . . (2)
D'Arrest's mean value from micrometric measures	λ 4956·6
Copeland's mean value from micrometric measures	4958·0

c. Third line.—In my original paper (Phil. Trans., 1864, p. 437), "On the Spectra of some of the Nebulæ," in 1864, I showed, by direct comparison with hydrogen, that this line is undoubtedly the line of that gas at F of the solar spectrum. This observation was afterwards repeated (Phil. Trans., 1868, p. 545), and has been confirmed by the photographs of 1882 and 1888.

[1] "Undersögelser over de nebulose Stjerner" (Copenhagen, 1872, p. 23).
[2] *Monthly Notices R.A.S.*, vol. xlviii. p. 361.

The wave-length of this line is therefore	λ 4860·7 . . (3)
D'Arrest's value from measures	4860·6
Copeland's ,, ,, ...	4861·0

d. Fourth line.—In 1872 (Roy. Soc. Proc., vol. xx., 1872, p. 385) I stated that I had satisfied myself of the coincidence of this line with Hγ, but, on account of its faintness, it is very satisfactory to find this observation of coincidence confirmed by the photographs taken in 1888 and 1889. There can be no doubt that this is a line of hydrogen, and that

The wave-length therefore is	4340·1 . . (4)
Copeland's mean value	4342·0

Dr. Copeland gives the measures of two still fainter lines which he has seen in this nebula—namely, one at λ 5874, possibly coincident with D_3, and a line at λ 4476 (see also Mr. Taylor, *Monthly Notices R.A.S.*, vol. xlix. p. 125). I defer the consideration of these and other faint lines which I have often suspected in the faint continuous spectrum of the nebula, as in consequence of the great strain upon the eyes from my recent direct comparison of the spectrum of the nebula with the spectrum of burning magnesium, I was not able, during the very few fine nights when Orion was favourably situated, to undertake an examination for these very faint lines.

Comparisons with the Magnesium-flame Spectrum.

In 1882, Dr. Copeland, in his paper on Schmidt's Nova Cygni (*Copernicus*, vol. i. p. 109), remarked in a foot-note, "that it is worthy of note that this line (λ 5006·5 of burning magnesium) almost absolutely coincides with the brightest line in the planetary nebulæ."

This line—namely, the bright edge of the first band in the magnesium-flame spectrum—is very near in position to the brightest nebular line. We have seen that the wave-length of this line in the nebulæ (1) is 5004·6 to 5004·8; now the wave-length of the end of the magnesium-flame band is 5006·5, consequently it does not coincide with the nebular line, but falls on the less refrangible side at a distance of λ 0002 nearly from that line.

The wave-length of the termination of the magnesium-flame band is, as determined by—

Lecoq de Boisbaudran	5006·0
Watts	5006·5
Liveing and Dewar[1]	5006·4

I have recently determined the position of the end of the band, by direct comparison with the solar iron line given by Ångström at λ 5006·58.

My result places the magnesium-flame band line at λ 5006·5 . . . . (5)

In a paper read before the Royal Society in 1887,[2] Mr. Lockyer says:—"Only seven lines in all have been recorded up to the present in the spectra of nebulæ, three of which coincide with lines in the spectrum of hydrogen, and three correspond to lines in magnesium. The magnesium lines represented are the ultra-violet low temperature line at 373, the line at 470, and the remnant of the magnesium fluting at 500. the brightest part of the spectrum at the temperature of the bunsen burner." At p. 137 (*loc. cit.*) Mr. Lockyer says:—"In the nebulæ we deal chiefly with lines seen in the spectrum of magnesium at the lowest temperature."

In a later paper in 1888 ("Suggestions on the Classification of the various Species of Heavenly Bodies," Roy. Soc. Proc., vol. xliv. p. 21) Mr. Lockyer states:—"In a paper communicated to the Royal Society on November 15, 1887, I showed that the nebulæ are composed of sparse meteorites, the collisions of which bring about a rise of temperature sufficient to render luminous one of their chief constituents—magnesium. This conclusion was arrived at from the facts that the chief nebular lines are coincident in position with the fluting and lines visible in the bunsen burner when magnesium is introduced, and that the fluting is far brighter at that temperature than almost any other spectral line or fluting of any element whatever."

Although the number of direct comparisons which I had made of the brightest line in the nebulæ with N_1 and with the lead line, not to speak of the accordant results of the micrometric measures of other observers, left little doubt in my mind that this line could not be coincident with "the remnant of the mag-

nesium fluting at 500," really at 5006·5, yet I thought it desirable to undertake the laborious task of comparing, with the necessary care and precautions, the nebular line directly, in the spectroscope attached to the telescope, with the spectrum of burning magnesium.

Arrangements were made by which the light from burning magnesium was thrown into the telescope from the side and then reflected down, under conditions similar with the light from the nebula, upon the slit of the spectroscope. By this arrangement any flexure in the tube connecting the spectroscope with the telescope would affect both spectra alike. The coincidence in position of the spectrum from burning magnesium with that of a heavenly body to which the telescope was so directed that its light fell upon the slit of the spectroscope, was tested with great care on several occasions by comparing the three bright lines of magnesium with the corresponding lines, b_1, b_2, b_4, in the spectrum of the moon. Indeed, to prevent any possible error in the observation of apparent want of coincidence of the nebular line, if the light from the burning magnesium should by an accident so come upon the slit as to bring its spectrum in a very minute degree on the less refrangible side of its true position relatively to the nebular line to be observed with it, the arrangement was purposely made that the lines of magnesium were seen to fall upon the corresponding dark lines at *b* in the moon, a very little on the more refrangible side of the middle of those lines. This state of things would diminish a little the interval which should be seen between the nebular line and the edge of the magnesium-flame band, and so make the determination more difficult; but if under such circumstances the nebular line was seen on the more refrangible side of that of magnesium, the observation would be much more trustworthy, for in the case of coincidence with magnesium the line would have appeared towards the opposite and less refrangible side of the magnesium line, broadening the magnesium line on this side. I considered that the comparison could be made most satisfactorily by the complete superposition of the two spectra, that from burning magnesium being gradually reduced in brightness by the interposition of coloured glass screens, until the ground of the spectrum between the successive bright lines of the band of the magnesium-flame spectrum was sufficiently subdued to allow of the nebular line being seen upon it.

Under these circumstances, if the nebular line had the position which my direct comparisons and the micrometric observations of other observers assign to it, it would be seen as a bright line at a very small interval within the line ending the band, and to the observer the band would appear to commence with a double line.

This direct comparison was first successfully made on March 6, 1889. The observations were made with the 15″ refractor belonging to the Royal Society. The spectroscope used has two compound Grubb prisms, each with 5 square inches of base, and giving nearly twice the dispersion of a single prism of 60°, namely, 9° 20′ from A to H; and collimator and telescope of 1·25-inch aperture. An eye-piece magnifying eighteen times was employed. The nebular line was brought upon the cross-wires, and when carefully focussed and clearly seen, the light from burning magnesium was thrown in. This observation is one of great difficulty, especially as the interval to be observed had been purposely reduced by causing the magnesium to fall, for the sake of the greater trustworthiness of the observations, on the more refrangible side of its true position. Although I consider the results to be satisfactory, I prefer to say that I, and Mrs. Huggins independently, believed fully at the time that we saw the appearance which all former observations of this line led me to expect—namely, the nebular line to fall within the termination of the magnesium band, and to form with the band-boundary a double line. The relative positions of the two spectra are represented in diagram across the page. The line at the end of the magnesium band was then brought upon the cross-wires, without any attention being given to the nebular line; when the burning magnesium went out, the nebular line was seen to be at a measurable distance to the left of the intersection of the wires—namely, on the more refrangible side.

When the object glass of the telescope was covered, the magnesium band presented its usual appearance—namely, terminating in a single line. These comparisons were repeated and confirmed generally on March 9, March 11, and March 16. On March 9 a single successful comparison was made with a more powerful spectroscope, giving a dispersion equal to nearly eight prisms of 60°. [Comparisons have been made since with the planetary nebula in Hydra. The short line of the nebula was found to fall within the termination of the magnesium band at about the small distance which corresponds to the known position of the two lines.—*April* 26.] On all these nights the comparisons were repeated independently and fully confirmed by Mrs. Huggins.

These comparisons can be successfully imitated in the laboratory by directing a spectroscope of sufficient power to the line of lead which the nebular line is sufficiently near, the slit being narrow, and the electrodes of lead near each other; and then causing, with the necessary precautions, the light of burning magnesium to fall also upon the slit. The lead line will be seen to fall within the end of the band, and to form with it a double line.

It may be mentioned in this place that this line of lead, and the iron line at 4957 at the position of the second nebular line, can be conveniently used in the laboratory in any chemical research on the nature of the nebulæ. No terrestrial line which does not fall almost exactly at these positions in the spectrum can have any claim to further consideration.

(*To be continued.*)

PARIS.

Academy of Sciences, August 12.—M. Des Cloizeaux, President, in the chair.—Remarks in connection with the "Introduction à l'étude des Races humains," Part II., presented to the Academy by M. A. de Quatrefages. In this second part the author passes from the general questions touching the evolution of man to those touching the evolution of the human races, of which he reckons at least one hundred and seventy-two, exclusive of minor varieties, all however reducible to the three fundamental black, yellow, and white stems. Adhering to the natural method of classification, as understood by Jussieu and Cuvier, he divides these stems into *branches* corresponding to primary and secondary divisions, under which come the *families* and *groups*. Much stress is laid on the early migrations of man, resulting in crossings of all sorts, and the general displacement of pure by half-caste races. The position of fossil man in the general scheme of classification is also studied, the five or six known varieties discovered in Europe being divided into two distinct branches allied to the white stock. Two distinct Quaternary types are also recognized in America, that of the Pampas affiliated to the Siberian, and that of the Lagoa Santa to the Eskimo branch of the yellow stock. Some bold speculations are indulged in regarding the primæval homes of the three fundamental groups and their subsequent dispersion from common centres over the face of the globe. In this scheme the north of Asia is considered the cradle of mankind, whose three primary divisions grouped themselves round the great central tableland, whence they gradually spread over the continents during Tertiary and Quaternary times. In the Oceanic world the Eastern Polynesians are affiliated to the white, the Melanesians (Papuans) to the black, and the Malays to the yellow stock, each division migrating from the mainland in the order already indicated by Prof. Keane ("Indo-Chinese and Inter-Oceanic Races and Languages"). The work is illustrated with 441 figures inserted in the text, four plates, and seven maps.—On a general law of induction in circuits devoid of resistance, by M. G. Lippmann. In this study the author proceeds exactly as in rational mechanics, where the fundamental laws are established, apart from the disturbing element of friction, which is afterwards considered as a particular force. He seeks the most general law of induction by assuming resistance to be null, and justifies this procedure *a posteriori* by the simplicity of the results, by their easy application and agreement with recent experiments.—On the vascular apparatus in animals and plants, studied comparatively by the surgical and thermochemical methods, by M. Sappey. In previous communications the author showed that in the vertebrates the thermochemical method is not only useful but preferable to the older process for the study of certain organs, especially the harder parts. In the present paper he directs attention to the structure of the vascular apparatus in plants and animals studied both by the surgical and thermochemical methods. The latter process is shown to yield as complete, accurate, and satisfactory results as could be desired; it is unquestionably superior to the former in the analysis of the veins and arteries of animals, and of the woody and other vessels of plants.—The virus of diphtheria, by M. C. H. H. Spronck. The author communicates the results of the researches on human diphtheria made by him, jointly with MM. Wingtens, Van den Brink, and Van Herwerden, in Utrecht. The disorder is studied chiefly in connection with its action on the region of the kidneys.

These researches seem to leave no doubt that the bacillus of Klebs is the real active principle in diphtheria.—On the rotatory polarization of quartz, by M. H. Le Chatelier. Having already shown (*Comptes rendus*, May 20, 1889) that towards 570° C. the dimensions of quartz undergo a rapid increase, if not an absolutely sudden change such as that noticed in dimorphic transformations, the author here endeavours to place beyond doubt this sudden change by resuming the study of the rotatory polarization of quartz already begun by M. Joubert. From his investigations it seems evident that at the specified temperature this body really undergoes a sudden allotropic transformation while retaining under both states its rotatory power as well as its crystalline symmetry.—On the production of crystallized cobaltous and ferrous hydrates, by M. A. de Schulten. The author has obtained these hydrates in the crystallized state by using the same method that has enabled him to prepare artificial brucite and pyrochroite, as explained in the *Comptes rendus*, ci. p. 72, and cv. p. 1265.—Papers were contributed by M. C. Patein, on a source of error in the search for, and quantitative analysis of, albuminoid substances in the animal organism; by M. Maupas, on the agamous multiplication of some rotifers and other lower Infusoria; and by M. Th. Moureaux, on the cause of certain disturbances in the curves of the magnetographs.

Berlin.

Physiological Society, July 26.—Prof. Munk, President, in the chair.—Prof. Zuntz spoke on heat-regulation in man, basing his remarks on experiments made by Dr. Loewy. The store of heat in the human body at any one time is very large, equal in fact to nearly all the heat produced by the body during twenty hours, hence the heat given off to a calorimeter during a given period cannot be taken as a measure of the heat-production; this determination must be based rather upon the amount of oxygen consumed, and of carbonic acid gas given off. The purpose of the experiments was to ascertain what alteration the gaseous interchange of the body undergoes by the application of cold, inasmuch as existing data on this point are largely contradictory. The observations were made on a number of men whose respiratory gases were compared, during complete rest, when they were at one time clothed, at another time naked, at temperatures from 12° to 15° C., and in warm and cold baths. Each experiment lasted from half an hour to an hour, during which period the gases were repeatedly analyzed. As the result of fifty-five experiments, twenty showed no alteration of oxygen consumption as the result of cooling, nine gave a lessened consumption, while the remaining twenty-six showed an increased using up of oxygen. This diversity of result is explicable on the basis of observations made by Prof. Zuntz, who was himself experimented upon, as to his subjective heat-sensations during the experiments. He found that after the first impression due to the application of cold is overcome, it was quite easy to maintain himself in a perfectly passive condition; subsequently it required a distinct effort of the will to refrain from shivering and throwing the muscles into activity, and finally even this became no longer possible, and involuntary shivering and muscular contraction supervened, as soon as the body-temperature (*in ano*) had fallen $\frac{1}{2}$° to 1° C. During the first stage of cooling, Zuntz's oxygen consumption showed a uniform diminution; during the period also in which shivering was repressed by an effort of the will, cooling led to no increased consumption of oxygen, but as soon as shivering became involuntary there was at once an increased using up of oxygen and excretion of carbonic acid. This explains the differences in the results of Dr. Loewy's experiments, and may be taken to show that in man, and presumably in all *large* animals, heat-regulation as directly dependent upon alteration (fall) in temperature of the surrounding medium does not exist; the increased heat-production is rather the outcome of the movements resulting from the application of cold to the body. In *small* animals, on the other hand, there undoubtedly exists a heat-regulation dependent upon an increased activity of chemical changes in the tissues set up by the application of cold to the surface of the body, and in this case the thermotaxic centres in the brain most probably play some part.—Dr. Herter gave an account of experiments made by Dr. Popoff on the artificial digestion of various and variously cooked meats. Lean beef and the flesh of eels and flounders were digested in artificial gastric juice; the amount of raw flesh thus peptonized was in all cases greater than that of cooked meat similarly treated. The flesh was shredded and heated by steam to 100° C. The result was the same for beef as for fish. When compared with each other, beef was on the whole the most digestible, but the amount of fish-flesh which was peptonized was sufficiently great to do away with the evil repute which fish still has in Germany as a proteid food. Smoked meat differed in no essential extent from raw meat as regards its digestibility.—Dr. Cowl described his experiments on the mechanical latent period of a muscle. The muscle was hung up by one end, and its movements were recorded by a lever passing through the middle of the muscle, and writing on a spring-myograph. When both electrodes (using a "breaking" induction shock) were applied to the half of the muscle above the lever, the curve obtained showed a short latent period, after which it rose above the base-line. When the electrodes were applied below the lever, the same latent period was observed, after which the curve first fell slightly below, and then rose above the base-line. When one electrode was applied above and the other below the lever, then the elongation of the muscle was now present, now absent; in the latter case the length of the latent period was equal to the latency plus the duration of the visible elongation. From this it follows that the elongation of the muscle accounts for part of the latent period.

CONTENTS.

THURSDAY, AUGUST 29, 1889.

THE SCIENTIFIC WORKS OF SIR WILLIAM SIEMENS.

The Scientific Works of Sir William Siemens, LL.D., D.C.L., F.R.S. 3 Vols. (London: John Murray, 1889.)

THE "Life of Sir William Siemens," which was noticed in the pages of NATURE some months ago, has been followed by three most interesting volumes containing a reprint of his scientific papers. The task of editing the collection was committed by the executors to Mr. E. F. Bamber, for many years private secretary to Sir William Siemens, and it has been admirably discharged. The labour has been no light one; for the volumes contain, besides the greater and more highly finished contributions to the learned Societies, a very large number of extracts from the published proceedings of the various Societies and from the scientific journals—reports of the speeches delivered by Sir William Siemens during the discussions at scientific meetings.

Many of these papers are of high scientific importance, particularly to various classes of engineers, electricians, and chemists; and the whole collection forms a monument of unusual interest, exhibiting the many-sided nature of Siemens' labours and inventions. Both the papers and the unwritten speeches are very remarkable for clearness of thought and of style. Siemens was pre-eminently a man who made up his mind with complete decision, after careful thought, on whatever came before him. This decisiveness gave him the power of taking hold of a matter by the right end in the exposition of it: and the consequence is a clearness of thought and of diction which are alike unusual and satisfactory. The reader seldom requires, even in the case of descriptions of complicated apparatus, to reperuse a sentence; nor is it ever difficult to follow the reasoning on which an opinion is based.

Of the three volumes before us, the first contains the contributions of Siemens to the subjects of heat and metallurgy. The second is mainly taken up with electricity and miscellaneous subjects; while the many lectures and addresses, which from time to time he was called upon to deliver, are collected in the third volume.

It is impossible, in a brief article like the present, to review in detail these substantial volumes, or offer any lengthened criticism of their contents. We must content ourselves with such brief notice of them as will indicate to our readers some of the chief features in the life-work of this remarkable man.

In the second volume, under the heading "Miscellaneous Subjects," will be found two papers of no great length, but of special interest. These papers contain an account of Siemens' improved water-meter. Of what vast importance this invention proved to the inventor is probably not generally known. To use a common expression in the widest sense, "it made his fortune." It was his first thoroughly successful invention; and it gave to the young engineer the pecuniary assistance (greatly needed at the time) which enabled him to push forward into higher and yet higher regions of invention and success.

The meter was invented in 1850–51, and patented in 1852. It satisfied the tests of a committee of inquiry of the Manchester Corporation Waterworks; and very soon a large number of the meters were at work, and were giving complete satisfaction. The general principle is that of using "various arrangements of screws or helices, which are caused to revolve by the passage of water or other fluid through them, and of fixed guides and channels in connection with such screws or helices to regulate and direct the current of the fluid, together with various contrivances for registering the number of revolutions of the screws." For the larger meters a many-bladed screw is used, the blades and guides being properly shaped that the blades may "partake fully of the onward motion of the water without sensibly impeding or agitating the same." For the smaller meters a kind of Barker's mill is used, with conditions as to the inlet and outlet arranged to fulfi the object in view.

"From a practical point of view," says Mr. Pole, in his "Life of Siemens," "the Siemens water-meter has been one of the most useful and valuable machines ever brought into hydraulic engineering. . . . . Down to the end of 1885 nearly 130,000 meters had been sold by Messrs. Guest and Chrimes (the first makers) alone, and in many cases it has been established as the standard apparatus for the sale of water." The two papers contained in the present volume were contributed in 1854 and 1856 to the Institution of Mechanical Engineers, and they contain a full discussion of the conditions necessary to be fulfilled by a water-meter, and descriptions, with illustrative drawings, of the inventions in this direction of the author.

In the first volume are contained the papers of Siemens on heat and metallurgy. These are well known to all workers in these departments of science and industry, and a brief notice must suffice here, in spite of their vast intrinsic importance. Very early in his life we find Siemens devoting his attention to the "regenerative principle" in heat. The words "regenerator" and "regenerative" are most unfortunate—utterly misleading to those who attempt to imagine the nature of the "principle" from the name by which it is called. The names, however, were not due to Siemens, but to Dr. Stirling, inventor of the hot-air engine; and it is worthy of being mentioned here that Siemens objected to the name, and wrote to Mr. Manby, a friend of Dr. Stirling, that "perceiving him (Stirling) to repudiate the name of 'respirator,' I really think he would confer a benefit on posterity if he would give his child a proper name, that of 'regenerator' being certainly incorrect, and likely to produce misconception."

The name "respirator" readily suggests the nature of the principle here spoken of. The metallic plate of a respirator, used by delicate people to protect the lungs or throat, takes up the heat of the outgoing breath and parts with it again to the air which is inspired; and this is precisely the principle of the heat-saving arrangements with which the name of Siemens is so closely connected. It may be, however, that a better name than either of these could easily be found.

In this first volume of the papers we find the titles of many communications describing arrangements for heat-saving and for obtaining increased temperatures by causing what would otherwise be waste heat to warm the air or gaseous fuel used in the process of combustion. Thus we have a "regenerative condenser for high-pressure and low-pressure steam-engines"; a "regenerative steam-engine"; the regenerative furnace applied to glass houses and to various metallurgical processes—to the manufacture of steel, the puddling of iron, &c.

Towards the close of his life, Siemens took up warmly the question of abatement of smoke in large towns, and economy in domestic heating and lighting. Accordingly we find interesting and important papers on the use of coal-gas as a fuel, and on gas supply both for heating and illuminating purposes. These papers contain a description of a regenerative domestic fire and a regenerative gas-lamp. It is very surprising that the views of Siemens on these important subjects have been so little appreciated by the gas companies on the one hand, and by the general public on the other. The smoke nuisance becomes year by year more and more terrible in our large towns; while the gas companies are undoubtedly neglecting to take advantage of sources of enormously increased profits to themselves.

Space fails us to enter into any detailed account of the important papers on metallurgy contained in the second part of the volume just now before us. In these are elaborated the descriptions of his improvements in iron processes. The two main features of the inventions are, first, the production of "mild steel," as it is called, of a quality surpassing that obtained by older processes; and, second, the production of first-class steel by the "direct process"—that is, directly from the ore instead of from the pig-iron of the blast-furnace, or from puddled iron. It is probable that even now, when there are over a million tons of steel being produced annually in Great Britain alone by the processes of Siemens, we are far from seeing in full the results of these improvements. It must be remarked, however, with regard to the direct process that the very existence of the enormous establishment of blast-furnaces in this and other countries constitutes a formidable adversary to its introduction.

The volume containing the papers of Siemens on electrical subjects is naturally divided into two parts: one containing papers on cable-laying, &c., and the other on the production of electricity by the dynamo-electric machine, and its application when so produced. The life of Siemens was intimately associated with the electrical developments which have made the last forty years startling in the rapidity of growth and improvement. By the electric telegraph, the commercial and social relations not only of individuals, but of the nations, have been revolutionized; while with regard to the dynamo-electric machine, much as its invention has accomplished, there can be no doubt but that its past and present are but infinitesimal compared with its future importance. The papers of Siemens must always have exceptional interest in connection with the early history of these two industries.

We cannot do more here than mention a few of them. First we have three papers largely taken up with land-line telegraphs, and giving an account of the progress which Dr. Werner Siemens was making in Germany, both in the construction of telegraph lines and in the improvement of telegraph instruments. Next we meet with a paper describing a machine for covering telegraph wires with india-rubber. Then we have contributions to the tests of deep-sea cables; and again, a paper on the outer covering of deep-sea cables. A most interesting paper gives an account of the steamship *Faraday* and her appliances for cable-laying. The *Faraday* was built with the object of laying the Direct United States cable, and was fitted with every appliance which the experience of former great submarine cables had suggested as important. A number of minor papers give descriptions of accessory instruments and appliances connected with the work of laying down deep-sea cables. Thus we have a deep-sea thermometer, the bathometer, &c., described in short interesting memoirs.

The papers connected with the production of electricity by the dynamo-electric machine, and of the uses of the great currents so produced, deal with a department of science and industry in which Sir William Siemens and his brothers were pioneers. The Siemens family, and the manufacturing firms of Siemens in this country and in Germany, designed and produced machines which undoubtedly were the best of those early days, and which served Siemens in setting on foot the first electric railways, the first electric furnaces, and first and only experiments on horticulture by electric light.

Only a few lines remain to us in which to refer to the third of these volumes. A man of Siemens's power and standing, and one who was able to speak with authority on so many subjects of high scientific and commercial interest, was naturally called on to give many more or less popular expositions of these subjects. Many lectures and addresses were therefore obtained on various occasions from this gifted and public-spirited man. These are collected in the third volume of the papers. Here we find addresses on deep-sea telegraphs, testing electric cables; on fuel, a popular lecture to the working classes under the auspices of the British Association at Bradford; on air-engines and steam-engines, in which the regenerative principle is explained; on utilization of heat, a lecture under the Glasgow Science Lectures Association; on waste, delivered to the Coventry Science Classes; several addresses and speeches on subjects connected with the production and uses of steel. We have also addresses which he delivered as President of various learned Societies—as President of the Mechanical Section of the British Association; two addresses to the Society of Telegraph Engineers, two to the Iron and Steel Institute, his address as President of the British Association in 1882, and many other minor addresses and speeches.

Among other subjects on which Siemens had thought deeply, is the highly important one of technical education, which is exercising the minds of so many at the present time. He had more than common opportunities for forming a correct judgment on the requirements of those who are to advance the various arts and industries of the world; and his knowledge of Germany and England, and of German workmen and English workmen in very varied departments, gave him special title to speak with authority on this subject. The consequence is that in many of his shorter addresses and speeches very valuable remarks and criticisms are to be found on this question so vital to our national prosperity.

In taking leave of these important volumes, we cannot but feel that scant justice has been done to them in this brief article. It is only a very small proportion of the subjects on which Siemens thought and wrote to which we have been able even to allude. Very many subjects occupied his active mind, and it is most remarkable how thoroughly and completely each one of them was worked out and brought down to a definite conclusion. Much he attempted; and pre-eminently he acted on the principle that "whatever is worth doing is worth doing well."

THE ADVANCEMENT OF MEDICINE.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by J. Batty Tuke, M.D., and G. Sims Woodhead, M.D. Vol. I. (Edinburgh and London: Young J. Pentland, 1889.)

IT is a healthy and most welcome sign of the increased interest taken in pathological research that, at the conclusion of what is but the first year of its existence, the laboratory instituted by the Royal College of Physicians of Edinburgh has been able to issue a volume of Reports of such importance as the one lying before us. When, further, it is noted that this is, if we mistake not, the first volume of its kind published in the United Kingdom—the first collection of papers emanating from a single laboratory, and treating of pathology alone—then the energy that is being displayed north of the Tweed in the advancement of medicine by research should gain the cordial appreciation it well deserves.

Willing as our own Royal Colleges of Medicine have of late shown themselves to encourage investigation, they have, from a variety of causes, been unable to bring forward their schemes to a practical issue with the rapidity and thoroughness displayed by their Edinburgh *confrère*, and although the idea of instituting a research laboratory has for long engaged the attention of the authorities in Lincoln's Inn Fields, we are still very far from seeing that laboratory in complete working order.

It must be admitted that, to devise the details of a new departure such as this is far from being an easy task. Many and opposing interests have to be taken into account, and, as may be gathered from Dr. Sims Woodhead's introductory article, at Edinburgh, despite the ardour of Dr. Batty Tuke and his Committee, nearly two years elapsed before plans could be developed to the stage at which they were at the same time feasible and acceptable to the College of Physicians. But, this stage once passed, no time was lost. A commodious house was taken and adapted to the required purposes, a scientific superintendent appointed in the person of Dr. Woodhead, and in the course of a very few weeks the laboratory was ready.

The regulations laid down by the College are conceived upon a broad and generous basis. The laboratory is open without fee to Fellows and Members of the College, and, with the sanction of the Committee and Curator (Dr. Batty Tuke), to any Licentiate, and "to any medical man or investigator who shall obtain the sanction of the Council of the College, as well as of the Curator and Committee, to use the laboratory for the purposes of scientific research." The scientific superintendent, while himself undertaking the prosecution of original research, shall be prepared to assist, if required so to do, in the work of the investigators, and it would appear that leave having once been given to work in the laboratory, little or no restriction is placed upon the investigators with regard to the nature of their work beyond the broad control exercised by the superintendent. All these points are worthy of attention at the present time when a similar institution is in the process of development in London. This volume, coupled with the fact that during the first year two-and-twenty investigators in one or other department of medicine have made use of the laboratory, yields full evidence of the success of the scheme.

We note with some curiosity what is apparently an effort to reconcile opposing views as to the functions of the new laboratory, in the regulation requiring the superintendent to furnish the Fellows of the College "with reports. . . upon the histology of morbid specimens and of the chemical and microscopic characters of urines." Certainly, by undertaking work of this kind the laboratory becomes of very definite service to the Fellows, and could our English Colleges, for example, see their way to the institution of departments to which members might send any morbid material as to whose nature they desired advice, they would, by adding largely to the possibilities of a correct diagnosis, confer no little benefit upon the public, apart from the benefit they would bestow upon their members. It is, however, questionable whether this form of work falls within the province of medical corporations; it is still more questionable whether such work can wisely be required of one whose time and energies, as director of a research laboratory, are liable to be wholly utilized in a very different direction.

Coming now to the consideration of the papers which form the volume before us, we may say that they well exemplify the tendencies and traditions of the Edinburgh medical school. Bacteriology is represented by the details of an investigation into the air of coal-mines; by Dr. Woodhead's very able "Notes upon the Use of Mercuric Salts in Solution as Antiseptic Lotions"; by the report of an inquiry undertaken in Japan as to the causation of cholera, the work of Dr. N. Macleod and Mr. W. J. Miller (tending to confirm Koch's views); and also by the condensed report of Dr. Woodhead's lectures before the Grocers' Company upon tabes mesenterica and pulmonary tuberculosis. This last, and Dr. Bruce's article upon a case of absence of the corpus callosum in the human brain, are both of very general scientific interest, and represent the accurate and thoughtful work done at Edinburgh in the domain of pathological histology; while the large proportion of four papers out of the eleven of which the volume is composed, reflects the prominent position long held by Edinburgh in the department of gynæcology.

With scarce an exception, the reports bear upon practical matters, and have more than an academic value. But at the same time they exhibit the one especial weakness of the school. Pathology, embracing as it does the whole of medicine save the treatment of disease, is capable of being advanced by two equally valuable methods, the synthetic and the analytic, as they may be termed: on the one hand by studying the part played by individual factors in producing diseased conditions, and, on the other, by determination of those factors through examination of diseased organs; that is to say, by the methods of experimental pathology and pathological anatomy respectively. The first of these is almost unrepresented in the volume, save by the record of work done away from Edinburgh. We venture to express a hope that, the laboratory offering as it does every facility, this neglect of constructive pathology is apparent and not real, and that it is due not to the absence of experimental inquiry, but to the fact that investigations along these lines have not become completed in the course of a short twelve months.

The facts and suggestions contained in the article upon tuberculosis, by Dr. Woodhead, above referred to, are deserving of a far wider circulation throughout the country than is rendered possible by the conditions under which they now appear. On the Continent, and, especially at this moment, in France, the infectiousness of tuberculosis, and the appalling extent of its distribution, is at length exciting that serious and general attention which precedes active measures. No disease contributes so largely to the lists of mortality. As Dr. Woodhead points out, the maximum affection by mesenteric tubercle—by tuberculosis of the lymphatic glands of the intestines—is attained between the ages of one and five years, and a large mass of evidence would seem certainly to indicate that the cause is to be sought for in the milk derived from tubercular cows.

"Many Commissions on the subject have sat, and have delivered themselves of what must, to all who know anything about the matter, seem most sound judgments, but nothing is done. Where is our inspection of milk—not a mere chemical analysis—but a thorough chemical and biological examination? Where are our clauses for the compulsory notification of disease, either in the farm or the farm-house? Where are our regulations for the examination at regular intervals, and by competent veterinary authorities, of the cattle from which the milk is derived? . . . We must strike at the root of the whole matter as regards the connection between bovine and human tuberculosis. We then not only remove one set of centres of infection, but in so doing we, in turn, diminish the number of human centres from which the disease may spread."

Finally, a word is deserving to be said concerning the appearance of the volume. No expense has been spared in making the reports worthy of their origin. The type is large and clear, the individual contributions are well and profusely illustrated; the appearance of the volume, as a whole, is excellently calculated to make critics fulfil the motto of the College displayed ingenuously upon the back—"*Non sinit esse feros.*" J. G. A.

TREATISE ON HYDRODYNAMICS.

Treatise on Hydrodynamics. Vol. II. By A. B. Basset, M.A. (London: George Bell and Sons, 1888.)

THIS second volume of Mr. Basset's "Treatise on Hydrodynamics," the publication of which followed at no long interval that of his first volume, is in all respects a fitting complement to that work, and fulfils the expectations of value and completeness aroused by its appearance.

The prevailing impression on studying this volume and contrasting it with the first is, that many more avenues for research and discovery lie open in the subjects here treated, than can possibly be found in the more fully explored parts of hydrodynamics that constitute the subject-matter of the first volume.

This impression is borne out by the fact that many results here collected together are the results of recent years, placed in this volume in a more accessible form than when engulfed in the original papers. When we find that this book enters fully into such diverse branches of the subject as vortex motion, tides, and viscous fluids —not that these exhaust its contents—we can realize the width and variety of reading necessary to make the matter of the book as valuable and accurate as it unquestionably is, and also the probability that the author must expect to see these chapters rendered incomplete by the advance of knowledge in these directions.

The chapters on vortex motion owe their results and form largely to the writings of Prof. J. J. Thomson; in the discussion of the stability of the vortex it seems impossible to evade long and arduous algebraical processes, even though the kinematical surface condition used may be of the simplest. The author himself has given in addition an investigation of the fluted vibrations of a circular vortex ring, making use of toroidal functions, and obtaining the same equation for the periods as in the case of similar vibrations of a columnar vortex.

We have read with considerable interest a method given in the first chapter on vortex motion, in which the principle of inversion is applied for the first time to a hydrodynamical problem. It is true that its success is restricted to cases of motion in two dimensions; but a new field might be opened up if, by use of co-ordinates in an inverse system, the ordinary equations of motion would admit of yielding at once two solutions to each problem, in a way similar to the electrical method of inversion. Apparently, the co-ordinates cannot so be changed, nor is any simplification obtainable in the case of viscous fluids, where certain product terms are always disregarded.

Another most interesting chapter is that on the motion of a liquid ellipsoid under its own attraction; here the various shapes possible to rotating fluid are passed in review, and, placed as they are in order, beginning with the familiar instance of Maclaurin's spheroid, the necessary criteria that separate one possible surface from another are easily distinguished.

The question of the stability of some of these shapes is considered, and reference made to the papers of Poincaré in the *Acta Mathematica*, though certain *ex cathedrâ* statements in Thomson and Tait's "Natural Philosophy" have to go unexplained.

To enter on the discussion of waves and tides seems, by contrast with vortices, to begin a fresh subject, so totally distinct are the equations and methods; yet these two chapters are not the least valuable in the book. The chapter on waves contains all the known solutions of waves in canals or on the sea, and also includes Sir G. Stokes' masterly investigation of the form of the wave-front in the deep sea. In the chapter on tides, after a brief account of the equilibrium theory, Prof. Darwin's version of Laplace's dynamical solution is laid under contribution.

The last four chapters of the book are devoted to viscous fluids, and include, besides the theorems usually given, the oscillatory motion of a sphere and cylinder, published first by Stokes in 1850, and also a solution, due to the author, of the motion of a sphere under any forces. In this latter, certain integrals suggested by the theory of conduction of heat are used to obtain the equation of motion of the sphere, the solution of which can be obtained by approximation.

Certain miscellaneous theorems find a place in the last chapter, including an article on the effects of viscosity on a vortex sheet, which plainly has an important bearing on the practical determination of the stability of such a sheet.

The very full array of references to original papers adds considerably to the usefulness of this work, which is in all respects one of the most valuable on mathematical subjects that has appeared for some time. The results are accurate, the discussion of each branch is thorough and complete, and the analytical methods are powerful and in touch with the most recent developments.

THE LAND OF MANFRED.

The Land of Manfred, Prince of Tarentum, and King of Sicily: Rambles in Remote Parts of Southern Italy, with Special Reference to their Historical Associations. By Janet Ross. Illustrated by Carlo Orsi. (London: John Murray, 1889.)

THAT part of Italy lying to the south-east, forming the "heel," was once a land full of stirring events, but it has long lapsed into a state of semi-oblivion; to tell of its past glories and its present prospects is the object of this charming little volume by Mrs. Ross.

Italy seems possessed of powers of rejuvenescence, and the time appears approaching for the revival of some of the past glories of this "Land of Manfred." The traveller from Naples can now journey by rail from Naples to Taranto and Brindisi, and thence by the East Coast line north to Bari and Manfredonia; but, to get some idea of the beauty of this fair portion of Italy, one must leave the iron road and wander over flowery meads, climb up the gently sloping hills crowned with many an ancient castle and overlooking the grey olive gardens and out to the blue encircling sea; then in some measure can the land's loveliness be comprehended. This district of Apulia is not only out of the range of the ordinary tourist, but is even to this moment so little known to the inhabitants of Northern Italy that it is regarded by them as not safe to travel in; the newly-made lines of railway, the building of a great harbour for the Italian fleet at Taranto, will no doubt speedily dissipate such notions. These pages of Mrs. Ross's will undoubtedly tempt many of her compatriots to visit this fair unknown land, to its and the travellers' benefit; and they will also show that the perils of Apulia consist solely in bad inns —a peril getting less and less each season.

Many of the towns along the coast were visited by Mrs. Ross, and the leading events connected with their history are very graphically described; such as Manfredonia, Trani, Barletta, Bari, Brindisi, Otranto, and Taranto. Of the more remarkable inland places visited may be mentioned Castel del Monte, Foggia, Lucera, and Benevento.

As the chief events associated with each city or town are recorded, it is difficult to make a selection. At Bari the immense fortress-like priory attracted deserved attention; the crypt is described as formed of pillars, apparently innumerable, with their capitals richly carved in every conceivable design. Under the silver altar were the bones of St. Nicholas. The Cathedral of St. Sabinus was even more ancient than the Priory of St. Nicholas, its crypt being said to have existed in 733.

To tell of all the churches and cathedrals mentioned, and castles and fortresses described, would be but to reprint the volume, so we must content ourselves with transcribing the charming description given of Sir James Lacaita's residence at Leucaspide. The *loggia*, or arcade, running all along the south-west front of Leucaspide, overhangs a garden full of orange trees, wallflowers, stocks, Parma violets, carnations, and roses; beyond, an expanse of brilliant green corn grown under the colossal olive trees, said to be 2000 years old; then a belt of cultivated land, across which now and then the white smoke of a rushing train reminds us that we really are in the nineteenth century; and last a long line of dark pines, which fringe the Gulf of Taranto. On the opposite side of the Bay rise the Basilicata Mountains, tipped with snow, and further to the left, dimly perceptible on a clear day, are the wild and rugged hills of Calabria. The whole country is redolent of rosemary, and in the Gravina or deep ravine of Leucaspide, the myrtle, white and pink gum-cistus, the lentick and wild pears, were in a blaze of bloom. Troops of small black sheep, with eyes like topazes, graze upon thyme and other fragrant herbs among the rocks, while their shepherd dressed in a waistcoat and trousers of goat-skin, all made in one, leans against a tree or a wall, and plays wild and melancholy music on a little pipe made out of a cane.

The clever sketches by Carlo Orsi assist in illustrating a country about which Mrs. Ross tells us much, but about which it seems evident there is much more to be told, and about which we may hope to have from the same pen some still further details.

OUR BOOK SHELF.

The Zoology of the Afghan Delimitation Commission. (Trans. Linn. Soc., Zoology, Vol. V., Part III.) By J. E. T. Aitchison, M.D., C.I.E., F.R.S., &c.

ALTHOUGH this is very far from being a complete account of the fauna of North-Western Afghanistan, there is good reason to congratulate the author on his success in collecting a fairly representative series of the animals inhabiting the frontiers between Afghan and Russian territory. As Dr. Aitchison explains, his special calling is that of a botanist, and he undertook the office of collecting the fauna under considerable difficulties. The specimens obtained, representing 16 mammals, 123 birds, 35 reptiles, 2 batrachians, 7 fishes, about 100 insects, and a few *Arachnida*, *Myriopoda*, and *Crustacea*, were determined, and the new forms described, by the officers of the British

Museum, notes on distribution, &c., being added by Dr. Aitchison.

The publication by the Linnean Society of the whole series of descriptions in one fasciculus is a manifest advantage. If it has no other effect, it may perhaps convert from error some of those who, like the contributor of the part "Aves" to the last four numbers of the *Zoological Record*, still retain the mistaken idea that the Afghan fauna belongs to the Oriental or Indian region Not only does the prevalence of genera like *Arvicola*, *Ellobius*, *Cricetus*, and *Alactaga*, among mammals; *Pica*, *Accentor*, and *Phasianus*, amongst birds; *Teratoscincus*, *Phrynocephalus*, *Scapteira*, *Taphrometopon*, and *Vipera*, amongst reptiles; and *Schizothorax*, amongst fishes, show plainly the Palæarctic character of the fauna, but there is a remarkable absence of Indian types, with the exception of wide-ranging forms like the tiger, which is found here and there in suitable localities throughout Central Asia, from the Caucasus to the banks of the Amoor (and which, as its absence from Ceylon shows, is doubtless a comparatively recent immigrant into the Indian peninsula). A few species, like the wild ass and *Ovis cycloceros*, extend into the extreme north-west of India, but cannot possibly be said to form a part of the typical Indian fauna. Even amongst non-migratory birds, only two or three kinds, like *Pratincola caprata* and *Lanius vittatus*, are characteristic Indian species, and the forms named have a considerable range beyond the limits of the Oriental region.

It is interesting to find that some of the naturalists who have described the *Invertebrata* notice affinities between the forms collected and those inhabiting the Mediterranean basin. The *Vertebrata*, on the other hand, are characteristically Central Asiatic, as is shown by the genera already noticed.

The illustrations are excellent, and the representation by figures of all species of insects and *Arachnida* described as new is much to be commended. W. T. B.

A Text-book of Paper-making. By C. F. Cross and E. J. Bevan. (London: E. and F. Spon, 1889.)

An increase in the number of technical schools and institutes will no doubt call for a number of trustworthy text-books on various chemico-mechanical industries, arranged not only for the student proper but for the manufacturer as well; indeed, it is perhaps the latter who needs and can use a good text-book to greatest advantage.

It would be well for us if we had other text-books as commendable in their particular connection, and as clear, concise, and thorough, as this on paper-making chemistry, for that is what it amounts to.

The authors state in their preface their belief in the importance of a scientific training for paper-makers. This of course would apply to many trades besides paper-making with equal force. As the earlier and most important operations in paper-making are of a purely chemical nature, or at any rate more chemical than mechanical, the authors have very rightly treated this portion more fully than the mechanical operations proper, which would involve descriptions of complex machines and details not exactly fitted for a text-book of an instructive nature as this.

The introductory note and chapter i. treat of the chemical properties and composition of cellulose and its varieties as far as is known at present. It is a somewhat concentrated chapter on the natural history of this class of substance, and to appreciate it fully the reader should already have a fair acquaintance with the more common chemical processes and elementary principles. It is a useful and valuable chapter, and nobody is better able to discuss it than the authors. The same applies to chapter v., in which processes for isolating cellulose from plant substances are considered.

The chapter on the special treatment of fibres is a very exhaustive one. The remainder of the book—with the exception of short sections on "chemical analysis" for paper-makers, and "paper-testing," and the "Willesden paper"—is taken up with the more mechanical part of paper-making. They are very fully illustrated with large diagrams.

Many besides paper-makers will find interesting matter and much information in this book. W. R. H.

Boilers: their Construction and Strength. By Thomas W. Traill, F.E.R.N., M.Inst.C.E., Engineer-Surveyor-in-chief to the Board of Trade. (London: Charles Griffin and Co., 1888.)

As a hand-book of rules, formulæ, tables, &c., relative to material, scantlings, and pressures for boilers, this volume will prove most useful. The name of the author is a sufficient guarantee for its accuracy. It will save engineers, inspectors, and draughtsmen a vast amount of calculation, and the fact that the information is calculated from formulæ embodying the Board of Trade practice will add greatly to the confidence of those using it in any particular design. The tables contain over 60,000 results, and include in their scope most of the information required in any ordinary case. Engineer inspectors will also find valuable information pertaining to the qualities of iron and steel generally in use, and many good hints as to what ought to be allowed or prohibited in the ordinary working of the material. Among the many duties of the Board of Trade inspectors is that of determining a safe working steam-pressure for old boilers. In the tables relating to this subject thin plate scantlings are given. The decision as to a suitable pressure must, of course, to a large extent depend on the actual condition of the old boilers under inspection, whether the plates are corroded or pitted, and on the condition of the stays and rivet heads. One hears an occasional "growl" about the severity of the Board of Trade inspection, but there is no branch of engineering more carefully and conscientially done than that under Mr. Traill's control, and the present volume should be of great service to his inspectors. The work is the result of much thought and labour, and the author deserves the cordial thanks of all who have to design and superintend the construction of boilers. N. J. L.

Lord Howe Island: its Zoology, Geology, and Physical Characters. Printed by order of the Trustees of the Australian Museum, Sydney. (Sydney: Charles Potter, 1889.)

In 1887, by the order of the trustees of the Australian Museum, Sydney, a collecting party was despatched from Sydney to Lord Howe Island. Most of the results of the expedition are described in the present volume. An excellent epitome of the general zoology of the island, by Mr. R. Etheridge, Jun., is first given. Then come detailed descriptions of the specimens obtained by the members of the party. Mr. A. J. North deals with oology, Mr. J. Douglas Ogilby with reptiles and fishes, Mr. A. Sidney Cliff with insects, Mr. R. Etheridge, Jun., with geology and physical structure, and Mr. T. W. Edgeworth David with rock specimens. The memoir also includes descriptions of various collections made in Lord Howe Island, by Mr. Alexander Morton, in 1882; of collections, chiefly entomological, made by Mr. George Masters, in 1869; and of some gatherings made by Mr. E. H. Saunders after the return of the Museum party. The contributors to the volume have evidently striven to write accurately, concisely, and clearly, and everyone who may have occasion to consult their work will admit that it is well done. The various papers are carefully illustrated. We may note that the descriptive account of the Mollusca is not yet ready, but that the plates are here issued in advance.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sunset Glows at Honolulu.

THERE has just been at Honolulu a reappearance of the phenomenon of sunset glows like those so familiar in 1883–84. It was first noticed after sundown of July 13. It seemed somewhat brighter on the 14th and 15th. After this it declined in intensity, but could be distinguished until the 20th.

A space of 15° radius around the sun was occupied by a whitish glow like that in "Bishop's ring." The outer coloured ring seemed to be entirely wanting.

We have no cable, and no foreign mail has arrived since the 6th. By a mail due to-morrow, we hope to hear of a probable cause to which this remarkable appearance may be due.

I note the following differences between these sunset glows and those of 1883–84. These are very much less bright than those; possibly equal to what those became after one year's continuance. Perhaps the most notable difference is the appearance of a tertiary glow after the primary and secondary. This consisted of a delicate rosy flush occupying a large tract of sky above the western horizon, from the altitude of 10° to that of 45°, and about 60° horizontally. This shaded off into purple at the edges against our clear blue Hawaiian sky. I think this the most exquisite and lovely tint I have ever seen in the sky, comparable only to that of some perfect jewel.

The larger stars were visible at the time of this tertiary glow. It continued for only a very few minutes each evening. A faint purple tint extended along the horizon quite to the south. This third glow failed to gather down upon the horizon like those preceding it.

Another marked peculiarity is the much earlier time at which the primary and secondary take place. The primary glow gathers soon after the sun is down, and makes its display while the sky is still bright. So it fails to be very effective as a show, although casting upon the western sky broad streaming radiations of glowing surface.

The secondary glow promptly follows and makes the chief display. It differs from the secondary Krakatão glow in the earlier time when it takes place, being nearly finished before any stars are visible. The Krakatão secondary lingered until after full darkness, settling down into a low blood-red stratum simulating the reflection of a remote conflagration. That peculiar simulation was entirely absent from the late appearances. Both at its close and throughout its course this secondary glow substantially resembles the primary glows as seen in 1884. It especially resembles the latter in presenting a well-defined and serrated upper edge bordered by dark sky. That, however, had small and numerous serrations, apparently due to cumuli upon a very remote horizon. The serrations of this, on the contrary, are large and broad, the interspaces being apparently the inverted shadows of cloud-masses upon a somewhat near horizon.

It seems evident that the reflecting stratum of haze in the late appearances was very low down as compared with the Krakatão haze. Hence the rapid succession of the glows. The reflected rays of the sun, traversing a much smaller extent of the lower atmosphere, show less red, having less of the other colours intercepted. For the same reason, they retain force enough for a third reflection, in which a very pure though faint red appears.

Honolulu, July 25. SERENA E. BISHOP.

Globular Lightning.

THE following account of a display of globular lightning will, I think, be of interest to your readers, as it was well observed by several independent observers, and differs in some respects from those previously recorded. It is greatly to be wished that this phenomenon could have its place assigned to it in electrical theory.

On Monday, the 5th instant, at midday, this district was visited by a violent storm of rain, which lasted half an hour, and was accompanied by thunder and lightning. When the storm had passed over and the sky was getting bright, a rod-like object was seen to descend from the sky. It is described as being of a pale yellow colour, like hot iron, and apparently about 15 inches long by 5 inches across. These dimensions are given by an observer who estimated its distance (about correctly, as it subsequently appeared) at 100 yards, and are not therefore affected by the uncertainty attaching to estimates of the sizes of objects whose distance is quite unknown. This object descended "moderately slowly," "not too fast to be followed by the eye" and quite vertically.

On reaching a point about 40 feet from the ground, and in close proximity with a chimney-stack belonging to a house in Twickenham Park, the object seemed to "flash out horizontally as if it burst," showing an intensely white light in the centre and a rosy red towards the outer parts. At the same instant a violent explosion was heard, and soon afterwards a strong smell was perceived, which is described by the observers as "resembling that of burning sulphur," for which the smell of ozone and nitric oxide might easily be mistaken.

Ordinary lightning is frequently most capricious in its action. In this respect this globular flash was in nowise behind.

I examined the outside of the chimney stack carefully, but no external effect whatever was visible. Inside, however, remarkable effects were produced, and I quote the following:—

"The back rooms consist of (1) basement kitchen; (2) ground floor dining-room; (3) first and second floor bed-rooms, and at the top a half attic. A stack of chimneys runs up the whole, and projects about 6 feet above the roof. There are no chimney-pots. No one was in any of the rooms except the kitchen, in which the servants were, and in which a fire was burning.

"The explosion filled the kitchen with smoke and soot. The dining-room also was filled with smoke and soot, though no fire was burning in it.

"The master of the house was just coming into the dining-room from the conservatory when he heard the detonation and simultaneously saw a bright flash of light. He staggered back a moment, and then ran through the smoke and soot to the hall, and called out to know if anyone was hurt. Finding all safe he returned into the dining-room. A Japanese umbrella set open as an ornament in the empty grate, but not fixed in any way, was undisturbed, though the hub of it was hot to the touch. Piles of soot spread out in a semicircle to the centres of the side walls of the room, and an arm-chair, which had been standing close to the fire-place, was 6 feet from its previous position, and had evidently been turned round and thrust against the wall. In the bed-room, on the first floor, soot was on the floor and in the fire-place. The slab of marble forming the architrave under the mantel-shelf, and extending the whole width of the fire-place, had been thrust out from its setting, and was, with a number of bricks, lying 6 feet away on the floor. The mantel-shelf and pier-glass were undisturbed. In the second-floor bed-room, soot and mortar were in the fire-place and on the floor; one end of the grate was broken and a piece of the detached cast iron (some 3 inches square) was lying against the wall 6 feet to the right. In the attic bed-room, mortar reduced to the condition of fine silver sand was lying in the fire-place and on the floor; the wash-stand, which stood against the fire-place, was pushed some 2 or 3 feet towards the centre of the room, but not overturned; and the carpet was rumpled up. There is in this room a bell on the wall opposite the fire-place, and a helical check-spring passes from this bell to an attachment in the wall. At this point of attachment a piece of plaster of the size of one's hand had been detached from the wall, and was found near the fire-place, 18 feet off at the other end of the room."

At this time, when electrical theory is receiving so much attention, the views of a theorist such as Dr. Lodge would, I think, be of great interest on the subject of these rare discharges. To all appearance a detached portion of something—is it atmospheric, or ethereal?—is carried along bodily through the air, bearing with it a very considerable potential energy, and at the same time radiating light. At an instant determined, perhaps, by its proximity to the chimney-stack, its constraint is suddenly relieved, and a discharge like ordinary lightning seems to occur between it and the earth, *viâ* (as it seems) the heated air of the chimney. Has anyone an explanation for this?

A. T. HARE.

Neston Lodge, East Twickenham, August 24.

On some Effects of Lightning.

I CAN fully corroborate Mr. A. F. Griffith's account of the remarkable way in which two trees in a wood near St. Albans have been broken in two, and rent to splinters, by lightning. The first tree which he mentions, however, suggests very forcibly that the "explosion" must have occurred at the core of the tree, for long wedge-like splinters of the wood have been forced outwards, and are now projecting from the stem. The fact, also, that the whole of the bark was in each case torn off, and projected in every direction round about the trees, can be accounted for only by an impulse proceeding from the middle of the stem southwards. One feature of the case which Mr. Griffith did not mention is the twisting which seems to have occurred with the second tree: the portion which is nearly broken off appeared to have been twisted through about 90°, and the portion of the stem which is left standing is also considerably twisted in the same direction; as to the stem, however, it is difficult to estimate how much of the twisting may be due to the growth of the tree.

That any part of the effects are due to wind, is, I think, quite out of the question. It is indeed a curious sight to see two sound oak-trees, some 6 or 8 feet in circumference at their base, broken off, twisted, and torn to splinters, as if they had been so much matchwood; but one of the most remarkable features of the case appears to me to be, that there are *two* trees which have been treated in almost exactly the same manner. If it were the effect of one shock, that shock must have divided itself into nearly equal portions, and must have struck two trees which are some 30 yards apart, which do not stand in any isolated position, and which are separated from each other by several other trees, all of which remained untouched. On the other hand, it is quite inconceivable that two shocks of such an exceptional character should have occurred within a few yards of the same spot, and should have produced identical effects of such an extraordinary character.

The case is one which certainly deserves investigation.

Harpenden, August 18. SPENCER PICKERING.

Some Lake Ontario Temperatures.

THERE are, among the great lakes of the St. Lawrence, exceptional opportunities for observing the effect of heat and cold upon large bodies of fresh water. The vast area and depth of the lakes, the different latitudes in which they lie, and the extremes of heat and cold of the Canadian seasons, all combine to render observations of interest.

It thus far appears that, in their main expanse, Lake Superior and the Georgian Bay (the eastern basin of Lake Huron) constitute, in midsummer, great bodies of colder water—the former registering at the surface as low as 39½° F. (Hind), and the latter at 10 fathoms indicating 45° F., and, at the bottom, even lower than 39½° F. (Boulton). On the other hand, the lower lakes, including Ontario, are shallower than Superior, lie in warmer latitudes, have some affluent streams from even farther south, and may be said to have perceptible, though light, currents through them. The temperatures of their waters are thus very different from those of Lake Superior and the Georgian Bay. Thus, on May 6 of this year, at 4.15 p.m., Commander Boulton, R.N., found the surface of the water off Griffiths Island, in the Georgian Bay, 35° F., and the bottom, at 60 fathoms, 35½° F.; whilst on May 23, at 11 a.m., near the outlet of Lake Ontario—my first soundings there—I found the air (the day being calm and cloudy) 55° F., the surface-water 52¼° F., and the bottom at 13 fathoms 50¼° F., and this was after a cool and exceptionally windy spring.

Some general results, which seem warranted by very numerous thermometer-readings near Kingston, may be of interest. The north-east end of Lake Ontario here does not usually exceed 20 fathoms in depth, but through it flow into the St. Lawrence all the waters of the great lakes.

Areas of Water of Different Temperatures.—At the surface the water is not uniform in temperature, even at points relatively near each other, and which appear to have the same conditions —the variations being generally from 1° to 3°. At different depths down to the bottom there are equally marked variations. In the tributary streams similar results appear. In a shallow creek fully exposed for an eighth of a mile to the sun's rays, and slowly flowing over a succession of limestone ledges, the mercury, in 1½ inch of water on a warm June afternoon, could be seen rising and falling between 81° and 83° F. Here there were exceptional causes, but in the line of outflow from the lake to the St. Lawrence the fluctuations are to be ascribed rather to the great evaporation at the surface, and the cooler waters beneath ascending to supply the place of the evaporated water. As the evaporation would be irregular, varying with the passing clouds, and the gusts of wind, the ascending currents would also be irregular. These ascending waters would give rise to an inflow at the bottom from the deeper and cooler parts of the lake to take their place, and both these currents would be affected by the general light onward flow of the lake waters towards the entrance of the St. Lawrence.

Gradual Absorption of Heat.—The general rise in the temperature of the Lake Ontario waters as the summer advances is at first slow compared with the general rise in the temperature of the air, but as midsummer is reached, the rise is more rapid both at the surface and at the bottom. A comparison with temperatures from Lake Erie will, eventually, better explain this. The circumstance, however, has its bearing on the well-known modifying effect of great bodies of water on the climate of the immediately surrounding land. In illustration of it, on June 14, at noon, when the air indicated 79¾° F., the surface water in the main channel—2 miles from Kingston—was still as low as 57½° F., or only 5° higher than on May 23. On July 5, the readings in the same place had increased to 69½° F., with the air at 79° F., and on July 10 to 74¾° F., with the air at 92¾° F., the thermometer always being in the sun. The most marked change was between June 25 and July 5, when the advance registered was 9°. The bottom temperatures indicate somewhat similar results. On May 23 at 13 fathoms the deep sea thermometer registered 50¼° F.; on June 14 at 12 fathoms, 52° F.; on July 10 at 17 fathoms, 53° F.; and on July 25 at 12 fathoms, 67° F.

The absorption and retention of the sun's heat is, however, most noticeable in the small streams and quiet pools. There we find well illustrated the general proposition that in high temperatures the surface of comparatively still water, where unaffected by deep under currents, absorbs and retains the heat of the sun to a much greater degree than the immediately overlying air. A marked example of this was observed in the shallow lightly flowing stream already referred to, where on June 14 at 3.15 p.m. the air at 3 feet above the water indicated a slight breeze 73° F., and at the surface 76°, whilst the water at 1½ inch registered 83° F., at 4 inches varied between 79½° and 82½°, and at 7 inches on the bottom fell to 72½° F. The records of other creeks did not indicate such extremes, but showed that each stream in its current, bottom, and surroundings, may have circumstances which vary the temperature. In very shallow, still pools, exposed freely to the sun and breeze, the difference between the air and water surface temperatures is even more marked, the water on sunny afternoons in June and July showing about 11° higher range. In such shallow, still pools, however, the water, though indicating some variation, is tolerably uniform in temperature, even to the bottom.

Effect of Channel Currents.—Near Rockport, among the Thousand Islands, there is a broad and deep channel where the current down the river runs at about 2 miles an hour. Here at 37 fathoms, in different localities, the deep sea thermometer gave the same readings as the surface thermometer, showing that the water was completely churned up.

Another illustration was in the Gananoqui River immediately below the falls. The temperature at the bottom here on June 10 was 62¾° F.; a quarter of a mile down stream at the outlet to the St. Lawrence, it was 61½° F.; in the St. Lawrence, 150 yards off the outlet, 57° F.: and 200 yards further up the St. Lawrence, 54¼° F.; the surface water at each of these points varying only between 62¼° and 63° F. These records show how the deeper and colder waters of the St. Lawrence gradually asserted themselves on coming into contact with the Gananoqui River waters. A. T. DRUMMOND.

The Yahgan.

THE tribe in Tierra del Fuego described by the Rev. C. Aspinall are called the Yahgan (Jahgan being a German form and not the English). The missionaries have translated the Gospels into Yahgan with some interpolations of special English terms. There are two or three other distinct languages for the scanty population. It can be seen that the Yahgan is a language of Old World roots, and words can be recognized that philologists determine to be typical Aryan roots. The variety of languages is a fact noticeable among small exogamous communities, and it is a matter of interest to find such variety at the extremity of the New World. H. C.

Electrolysis of Potassium Iodide.

THE following form of this experiment differs from that producing blue iodide of starch usually given in text books, and as I am not aware of it being known it may be of interest to those engaged in teaching the subject to which it belongs.

Into a U-tube pour a solution of the salt coloured with red (slightly acid) litmus solution, then, on introducing the electrodes (carbon for the anode) and passing a current, the solution in the anode limb is turned brown, due to the solution of I in KI, while at the kathode the liquid turns blue from the liberation of potassium.

This form of the experiment is very pretty, and is suitable for large classes.

For small classes the poles of a battery may be drawn over red litmus paper moistened with KI solution.

It is well to exhibit the action of iodine and potassium (potash) upon separate portions of the red solution before conducting the experiment. E. F. MONDY.

Dacca College, Bengal, July 24.

Spherical Eggs.

WILL you allow me to thank Profs. Greenhill and Liveing for their notes in reply to mine on the question of the packing of spherical eggs. The chief drawback of life in New Zealand is the inaccessibility of works of reference, such as those mentioned by Prof. Greenhill. W. STEADMAN ALDIS.

Auckland, New Zealand, July 11.

ANOTHER PHOTOGRAPHIC SURVEY OF THE HEAVENS.

WE gather from two circulars received from Prof. Pickering that another photographic map of the heavens is to be made, in addition to that arranged for at the Paris Conferences. The first circular runs as follows:—

It is proposed to establish an Astronomical Observatory on one of the mountains of Southern California, under climatic conditions probably superior to those at any similar institution now existing, with possibly one or two exceptions. It is therefore extremely important to increase these natural advantages by a plan of work and form of instrument which shall give results such as cannot be obtained elsewhere. Moreover, in California the interest in astronomy is wide-spread. There are many persons of large means who might be willing to make an important contribution to science if they could be sure that the promised results would be attained. The plan detailed below provides for a telescope with which stars could be studied that would be beyond the reach of any other instrument. The amount of material accumulated would be far greater than that obtained by telescopes of the usual form. A satisfactory test of the work could be made before a large part of the money had been expended. No great delay would probably arise, so that the donor could soon see the results arising from his gift. When money is given to erect a building without sufficiently endowing it, the value of the gift is greatly diminished if the name of the donor is attached to the building. This objection does not hold in the present case, since a large part of the expenditure is for current work. On the other hand, the donor's name would always be honourably associated, not only with the instrument, but with the work done with it. As in the case of the Henry Draper Memorial, it is believed that by such a living reminder a patron of science will be more widely known and appreciated than by a much larger expenditure for a building or fund.

Photography is rapidly changing the older methods of astronomical study. It gives an accurate representation of many objects at the same time; and, since copies may easily be made, it permits the results to be studied at leisure at any place and time. In a recent paper before the National Academy of Sciences, the writer recommended the construction of a large photographic telescope of the form described below. The lens should be like that used by photographers rather than like that of an astronomical telescope, and should consist of two achromatic lenses. Its aperture should be 24 inches, and its focal length 11 feet, thus giving images of objects on a scale of 1 millimetre to a minute of arc. Its great advantages would be the large region covered by a single photograph, since 5° square could be represented by it upon a plate 12 inches square. This is six or eight times the area covered by a telescopic objective. The time required to photograph a given portion of the sky would be reduced in this proportion. Such a lens, if mounted in a favourable location and kept constantly at work, would add more to our knowledge of the stars than could be obtained by a large number of telescopes of the usual kind. A telescope of this form, but of one-third its size, is now in use at Cambridge, and illustrates the advantages and amount of work which can be obtained by such an instrument. 3186 photographs have been taken with it, and from them a catalogue of 28,000 spectra of 11,000 stars has been prepared; also a catalogue of 1200 stars near the equator as standards of brightness, and a catalogue of 1000 stars within 1° of the Pole, where the most extensive existing catalogues only contain about forty stars. A search for new nebulæ was made on a small number of these plates covering about 1/250 of the entire sky. Eighteen nebulæ were already known to exist in this region. Twelve new ones were found upon the plates. These results are derived from a small portion of the entire series of plates, and much additional material will be extracted from them. The large telescope should first be used in making a map of the entire sky. All the stars north of − 30° can be advantageously photographed in the latitude of Southern California. This region, covering three-quarters of the sky, has an area of 30,000 square degrees. If each plate covered 25 square degrees, 1200 plates would be required. There are about 3600 hours of darkness in a year. Allowing one-half for clouds and moonlight, and one-third of the remainder for imperfect plates, the whole work could be done in one year, allowing an exposure of an hour to each plate. Perhaps longer exposures would be found advisable, and two years should be assigned to this work. An equal time should be spent in repeating the work, since it is essential that every part of the sky should appear on at least two plates, to verify all supposed discoveries. By using a prism to cover the lens the spectra of all the stars may be taken in the same way and in the same time. When this work is completed, it should be repeated, since we ought to have a complete map of the sky at intervals of about five or ten years in order to detect changes. Moreover, the improvement in photographic processes would perhaps be so great that a second series of plates would be desirable. The recent applications of erythrosin and other coal-tar products to photographic plates render them much more sensitive to red and yellow light. The difficulty of photographing satellites, asteroids, comets, nebulæ, and red variable stars may therefore be diminished.

The telescope should be mounted in a place having the best possible climatic conditions, preferably on a mountain where the air is as clear and steady as possible. No work need be done there except taking the photographs and developing them. Accordingly, the work might be done by a single observer; but, to avoid interruptions due to illness or accident, at least two would be required. Since their duties would be a routine requiring only ordinary skill, such services would not be expensive.

The results would take the form of a series of glass photographs about a foot square, each of which would depict all the stars visible in a part of the sky 5° square. Glass positives could be made from these by direct printing, and copies could be furnished for about a dollar apiece to any astronomer desiring to discuss them. Or an edition of paper photo-engravings could be issued. A complete set of about 1200 plates could probably be furnished for about $200. This would be a very small sum compared with the cost of a telescope which would show far less. The cost of the lens should not exceed $20,000; of the prism, $5000; of the mounting, $5000; of the building, $5000; total, $35,000. A large additional sum might be spent upon a building, but the experience of modern astronomers has shown that the best results are obtained by mounting each instrument in a small detached building which will readily assume the temperature of the air. It is more difficult to estimate the current expenses. The photographic plates alone would cost $1500 annually. The total annual expenses would not be less than $5000, not including superintendence, reductions and discussion of the observations, and publications. An outlay of $50,000 would probably complete the instrument, and secure photographs of the entire northern sky. If the anticipated results are attained, this should be followed by an endowment of $100,000, which would keep the instrument permanently at work.

The faintest stars photographed with the 8-inch telescope in Cambridge are invisible with the 15-inch telescope. The inner satellites of Uranus have been photographed at Cambridge with a 13-inch lens, although they are among the most difficult test objects known. We may therefore expect that stars too faint to be detected with any other instrument might be photographed with a 24-inch lens. We thus see that any person could obtain at a comparatively small cost a map of a portion of the sky showing stars too faint for him to observe in any other way. Many investigations might be carried on by means of these plates; for instance, a search for double stars, for nebulæ, for asteroids, for variable stars by comparison of plates of the same region taken on different nights, for stars having large proper motion when we have plates repeated after a considerable interval of time. In all these cases the plate furnishes an accurate measure of the object discovered, which is often wanting in the first observation of an object by the eye. Studies of the distribution of the stars can now scarcely be undertaken in any way except by photography. The stellar spectra might lead to the discovery of planetary nebulæ, variable stars, bright-line spectra, and other interesting objects. The number of stars shown on the charts would be so vast that it would probably be impossible to catalogue them all. In some cases it is estimated that twenty or thirty thousand stars have been photographed upon a single plate. A systematic examination of all the plates for the detection of objects of interest would itself be a laborious undertaking. Such work could, however, be done at any place and time, and therefore under the most favourable conditions as regards expense. One great advantage of the work would be, not only that we could discover certain objects of a given kind, as a particular class of double stars, but that we could make our catalogue complete, and be sure that no other objects of this kind existed, which in visual work is an extremely difficult matter.

There is always danger of failure in the construction of a new instrument. This danger is diminished in the present case, since an instrument of one-third the size is already in successful operation. Moreover, the front portion of the proposed double lens should form a good photographic objective, and might be made of the reversible form, which may be used either for visual or photographic purposes. The 13-inch lens referred to above is of this form, and proves that such an instrument is entirely practicable. We should thus be able to use the telescope in three ways: for visual purposes, as a telescope having an aperture of 24 inches, and a focal length of 17 feet; as a single photographic lens of the same dimensions; and as a photographic doublet covering a large field, and having a focal length of 11 feet. The prism could be used with each of these, making really six instruments in one. The short focal length would greatly diminish the cost of the mounting, and of the dome required to contain the instrument. The difficulties from exposure to violent winds and storms would also be much less than in an instrument of the usual form.

Should the proposed plan be carried out successfully, a contribution to astronomy would be made of continually increasing value, since each year would increase the facility with which slow changes in the stars might be detected by the comparison of later photographs with those first made.

In connection with the second circular we may remind our readers that we lately referred to the fact that the Astronomical Observatory of Harvard College has received from Miss C. W. Bruce, of New York, a gift of fifty thousand dollars to be applied "to the construction of a photographic telescope having an objective of about 24 inches aperture, with a focal length of about 11 feet, and of the character described by the Director of the Observatory in his circular of November last; also to secure its use under favourable climatic conditions in such a way as in his judgment will best advance astronomical science." This, then, is a very concrete reply to the first circular.

The second circular contains full details of the instrument, which will differ from other large telescopes in the construction of its object-glass, which will be a compound lens of the form used by photographers, and known as the portrait lens. The focal length of such a lens is very small compared with its diameter, and much fainter stars can be photographed in consequence. The advantage is even greater in photographing nebulæ or other faint surfaces. Moreover, this form of lens will enable each photographic plate to cover an area several times as great as that which is covered by an instrument of the usual form. The time required to photograph the entire sky is reduced in the same proportion. A telescope of the proposed form, having an aperture of 8 inches, has been in constant use in Cambridge for the last four years, and is now in Peru, photographing the southern stars. It has proved useful for a great variety of researches. Stars have been photographed with it, too faint to be visible in the 15-inch refractor of the Observatory. Its short focal length enables it to photograph as faint stars as any which can be taken with an excellent photographic telescope having an aperture of 13 inches. The 8-inch telescope will photograph stars about two magnitudes fainter than can be taken with a similar instrument having an aperture of 4 inches. A corresponding advantage is anticipated from the increase of the aperture to 24 inches. Each photograph will be 13 inches on a side, and will cover a portion of the sky 5° square, on a scale of 1′ to a millimetre. The dimensions will be the same as those of the standard charts of Chacornac and Peters. The entire sky would be depicted upon about two thousand such charts.

In an article in the *Observatory* for August the action taken by Prof. Pickering in making the appeal for a money grant to carry out the new map is distinctly challenged on the grounds—(1) that in the appeal there was no statement made that very nearly similar work was about to be commenced by all the civilized nations of the world after most careful consideration of the whole question by the strongest gathering of astronomers that has ever been seen; (2) that Prof. Pickering suggested to the Conference the use of a telescope similar to the one he has induced Miss Bruce to supply; and (3) that there are conditions of construction and execution of such difficulty that Prof. Pickering's plan may fail altogether.

THE JOURNAL OF MORPHOLOGY—A RECORD OF PROGRESS.

WE have before us the third and concluding part of the second volume of this excellent publication. It contains five papers (260 pages) with seventeen plates (with one exception folding ones) and fifty-four woodcuts. The illustrations are most admirable, and the plates, which bear the magic names of Werner and Winter, possess an exceptional charm. While all familiar with this Journal must admit that it has, from the first, taken high rank among its contemporaries, few will have been prepared for the magnificent display of the part now under review. With respect to its get up, the editors may well-nigh defy competition, so liberally have the publishers responded to their demands. Much that is proffered is truly American, in its revolutionary and highly sensational character; but, contrary to that which so often prevails, the startling deduction is based upon a solid foundation of fact, whereby the thing becomes tolerable, and the reader's attention is arrested. A refreshing thoroughness permeates the whole, and the work teems with originality.

The senior editor and Dr. W. Patten each contribute a short paper embodying "facts and conclusions . . . . stated in advance," of papers to be published in full in forthcoming numbers of the Journal. It is in connection with these that the revolutionary element to which we have alluded is most marked; and the reader is worked into a tremor of enthusiasm by the following among other declarations:—

"The eyes (of certain leeches) are segmental in origin, and strictly homologous with the segmental sense-organs. . . . The only evidence of an eye is a single large visual cell, on either side of the head, without a trace of pigment investment. In view of these facts . . . . we can no longer regard pigment as an essential element of the leech eye. It will not do to fall back on the hypothesis of degeneration; . . . . the visual cells are here as perfectly developed as in the pigmented eyes, and the same is true of the optic nerves."

Again—

"The segmental sense-organs of the leech are identical with the lateral line organs of vertebrates," and "when we find strong grounds for thinking that the lateral line organs have served as the point of departure for the formation of gustatory, olfactory, and auditory organs, our suspicion in regard to the eyes no longer appears incredible.[1]

The paper in which the above cited statements occur is entitled "Some New Facts about the Hirudinea," and the author defines these animals as "a group, characterized by the possession of *segmental* sense-organs on the first ring of every somite." Writing of the leeches in especial relation to the progressive development of sense-organs, he tells us that "nowhere is the transition from lower to higher sense-organs so perfectly illustrated as in the leech," and he then gives us the following remarkable passage:—

"*Branchelliopsis*, *Clepsine*, and *Hirudo* reveal all the intermediate steps, beginning with the purely tactile organ; then advancing to the compound organ, in which a few of the cells have been modified to serve the purpose of vision, while the rest have retained their primitive character; and finally, culminating after a long series of progressive encroachments—the visual elements increasing gradually at the expense of the tactile—in an organ in which the original function has been entirely suppressed and a new one substituted for it."

Again, we read—

"As the metameric arrangement of these sense-organs characterizes marine as well as fresh-water and land leeches, and as they everywhere agree in certain remarkable details of number, topography, and structure, I am led to believe that the diffuse or non-metameric arrangement, exemplified in *Nephelis* and some other forms, has been secondarily acquired."

[1] Somewhat similar views have already been postulated, for the eye by Hill (*Brain*, 1888, p. 422), and for the taste organs by Beard (*Anat. Anz.* 1888, p. 879.)

Dr. Patten's "*vorläufige*" is entitled "Segmental Sense-organs of Arthropods." His concluding remarks read as follows:—

"The ventral cord and brain of Arthropods is at first composed entirely of minute sense-organs, which in Scorpions have the same structure as the segmental ones at the base of the legs. On the lateral edge of each ganglion of the ventral cord of scorpions are two of these sense-organs, conspicuous on account of their size and dark colour. In each segment of the brain are similar but still larger ones. All these sense-organs are converted into the ganglion-cells of the brain and ventral cord."

The deductions above cited involve absorbing topics of contemporary research. We eagerly await the full papers and the discussions which they will raise, in the earnest hope (on a knowledge of that which has gone before) of an amicable settlement.

Prof. A. E. Dolbear contributes a paper on "The Organization of Atoms and Molecules," in reply to the senior editor's remarks upon "The Seat of Formative and Regenerative Energy," previously noticed in these pages. The author deals only incidentally with the biological aspects of the question; he claims that

"in late years chemists have adopted the term *Chemism* in place of chemical affinity, and have given to it a greater range of proclivities, finding no difference but one of degree between it and cohesion;"

that

"chemists have not attempted to give a physical explanation of the cohesion of atoms into molecules, but have stopped with chemism, as if it were an ultimate fact or property;"

while he attempts, as his chief object, to give

"a physical explanation of chemism or atomic cohesion, and to extend it to the building up of geometrical crystalline forms."

To this paper the editor adds some trite remarks, for which, in his modesty, he asks the reader's forbearance. The editor claims that the article in question "cannot be said to come strictly within the scope" of his journal. With that we cannot agree. The physicist's view of the nature of organic phenomena is very welcome, and we are of opinion that much good would result could we replace many a purely discursive biological article with one such as this, if only with a view to a more definite agreement with the physicist than at present exists, upon a sound basis for future work.

The papers which will attract most attention are those of Minot and Allis, upon the mammalian placenta, and the lateral line system in Amia, respectively. Each is a masterly monograph: the chief interest of the first-named centres in its revolutionary character; that of the last-named in its solidity and thoroughness. Prof. Minot deals in full only with man and the rabbit, and he proceeds at the outset to supplement previous work in matters of detail. He seeks to show that "the changes in the uterus during gestation" are "a prolonged and modified menstrual cycle," and that "the ovum has no power of initiating the development of a *decidua*, but only of modifying the menstrual process; hence pregnancy *can* begin only at a menstrual period." In discussing the views of others he is dogmatical but never disrespectful, and the following may well be cited in example:—

"We know positively scarcely more than that the maternal and fœtal circulations are brought very close together in the placenta. We infer that there must be a transfer of nutritive material from one blood to the other. As to *what* material is transferred and *how*, we have only theories, but of them an abundance. Under these circumstances, the best beginning is undoubtedly a frank acknowledgment of our ignorance."

The author contends that "we are brought squarely to the conclusion that the fœtal placenta is chorionic," and that "from this premise phylogenetic speculation must start." He tells us that, "so far as our present knowledge enables us to judge, the discoidal is probably the primitive placental type." With this we heartily agree, and it has always appeared to the writer of the present article that the same conclusion is, on the Balfourian hypothesis (from which Prof. Minot dissents) that both the yolk-sac and allantois were primitively concerned in rendering the chorion vascular, by far the most natural one warranted by the facts. The belief in the primitive nature of the diffuse placenta is, beyond doubt, largely attributable to its non-deciduous character. With Dr. Minot, we are opposed to Ryder's theory of the "origin of the discoidal placenta by constriction of the villous area of the zonary placenta." We would rather reverse the order, and regard the zonary type as transitional between the more primitive discoidal one and the more recent and modified diffuse cotyledonary and metadiscoidal varieties, regarding the replacement of the discoidal in the zonary type as primarily due to extension consequent upon the complete withdrawal of the yolk-sac from the chorion. Under this hypothesis the simple nature of the villi of the diffuse placenta might well be considered secondary.

Dr. Minot's paper furnishes a moral which cannot be too often borne in mind, viz. that it is not necessary to look beyond the most familiar organisms for material for legitimate work: neither a "new body" nor "a hitherto undescribed organism" are indispensable to the building up of a reputation.

Mr. Allis's paper is one for which we have eagerly watched, it being (as our readers will be aware) the first of a promised series. The author maps and classifies the sense-organs of the head with minute accuracy, at the leading stages of growth. When he tells us that "as many as thirty-seven hundred" pores "were counted on the head of a single large specimen," some idea of the laboriousness of his task may be formed; and on finding that he has worked out the detailed relationships of the parts to the individual bones, that he has, in addition to working out their development, determined the limits of individual variation and taken count of abnormalities, it is clear that his labour is a labour of love. The thoroughness of his work and the beauty of his illustrations must be seen to be appreciated; and should he complete his task, maintaining the standard of excellence with which he has started, he will have merited the regard of biologists for all time. He has brought to light the surprising fact that many of the first formed openings of the cutaneous canal system fuse to form pores, and that the dendritic systems and groups of pores which, in the adult, replace these, arise to a large extent from their repeated dichotomous division.

The author deals neither with polemics nor generalities,[1] nor does he even allude to striking facts which his figures show, foreign to his immediate inquiry. Consideration of these is doubtless deferred. He deals incidentally with the neuro-epithelium of the spiracular cleft discovered by Wright; this he regards as a sense-organ, which was "regularly developed in the epidermal covering of the head along with the other organs of the infra-orbital line, but, lying near the edge of the spiracular cleft, it wandered into this cleft as it was closed." Indeed, it is upon this observation that the author's co-editor confessedly bases his belief in the migratory origin of the gustatory organs; and Mr. Allis's allied discovery that "the nasal pits are inclosed in the same way that the lateral canals are" will be welcomed with especial interest by embryologists of the hour.

We have often wondered that our American brethren should have been so tardy in working out the structure and development of their native *rarissima*. Their Opossum and their Urodeles are now receiving attention, a beginning has been made with Lepidosteus, the Gymnophiona remain. Zoologists of the Old World could desire nothing better at the hands of their New World *confrères* than a series of exhaustive monographs upon the structure and development of the animals named, uniformly with the one now under review. A better model of conscientious work it would be difficult to produce.

G. B. H.

[1] He appears to have overlooked an important paper by Fritsch, in *Stzb. Berlin Akad.*, 1888, viii., p. 273.

THE AUGUST PERSEIDS OF 1889.

THE moon being full on the morning of August 11, it was hardly to be expected that the Perseid meteors would exhibit a notable display this year. Apart, however, from the ill effect the moonlight must certainly have exercised upon the visible character of the shower, there is no doubt that the phenomenon has proved one of minor importance. I have never observed, during the previous twenty-two years, so scanty a fall of the August meteors.

I made observations on July 26, 27, 29, 30, 31, and August 3, for the express purpose of determining the radiants of early Perseids, but failed to secure an adequate number of paths to carry out that intention. In watches extending over eleven hours I counted 89 meteors, but not more than 6 of these could have been Perseids. It was evident that this system was very feebly represented. Yet in 1887 it formed a very distinct and fairly active display as early as July 19 and 22, and I have sometimes remarked decided traces of it in the second week of July. In 1878 and several other years I observed that the Perseids made a prominent shower towards the close of that month, and it was easy to find the position of its radiant on every clear night. But this has been quite impracticable in 1889, owing to the exceptional scarcity of mteors.

On August 7, 1889, I looked towards the eastern region of the firmament during the $2\frac{1}{2}$ hours from $11\frac{1}{2}$h. to 14h., and recorded 28 meteors only. Amongst these were 10 Perseids with a radiant point very sharply defined at $41° + 58°$. They were rather small and traversed short paths; nearly all of them appeared near the centre from which they radiated. The shower was, however, of greatly inferior character to what was expected on a date so near the maximum. The ensuing nights were pretty clear, but in the brilliant moonlight meteoric apparitions were very infrequent. On August 10 only 8 Perseids were noticed in one hour before midnight.

My recent observations would seem to indicate that we have passed through a minimum of the August meteors.

The Aquarids which are generally very abundant at the end of July were also weakly displayed this year. I registered 6 of them between July 27 and August 3, from a radiant at $336° - 13°$. Of the other streams which distinguish this epoch I saw several, the principal of them being a shower of Cepheids from $329° + 62°$ and of Cassiopeids from $8° + 52°$.

W. F. DENNING.

NOTES.

WE print to-day the Report of the Committee appointed by the Treasury on the Scientific Collections at South Kensington under the control of the Science and Art Department. It is some seventeen years since the Duke of Devonshire's Commission recommended their formation, and it would seem now that something may really be done after so long a delay. The Committee, it will be seen, discuss both the question of a new building and that of the proper organization of such collections. The eminence of the members of the Committee adds great weight to their recommendations, and the Report has been very favourably received by the Press.

THE meeting of the Iron and Steel Institute in Paris on the 24th and following days of September promises to be of great interest. A large attendance of members is expected. They will be received and entertained by an influential committee under the presidency of M. Eiffel; and the French Society of Civil Engineers will entertain them at breakfast on the Eiffel Tower. Among the papers will be one by Sir Lowthian Bell on the subject of water gas, and Prof. Jordan will deal with the mining and metallurgical exhibits at Paris. Excursions will be made to the iron-works of the Loire and St. Etienne, and of the Nord, and to other centres of the iron and steel industry. Luxembourg and the works of M. Schneider at Creusot will also be visited.

PROF. LÖWIG has resigned his appointment as Director of the Chemical Laboratory at the University of Breslau. He has seen nearly sixty years of academical service.

A SEVERE shock of earthquake was felt in Greece on August 26. According to a Reuter's telegram from Athens, the direction of the earthquake was from north-west to south-east. Its effects were most severe in the district of Acarnania. Most of the houses in the towns of Amerinion and Aetolikon have become uninhabitable, and chasms were formed emitting sand and water. The centre of the shock is believed to have been in the Gulf of Corinth, where the telegraph cable was broken.

THE National Home-Reading Union has now opened its office at Surrey House, Victoria Embankment, W.C. Miss Mondy has been appointed Secretary to the young people's section, and Mr. George Howell, M.P., Secretary to the artisans' section. All communications concerning either of these sections should be addressed to them respectively. Miss Mondy has also been appointed Office Secretary, and communications concerning the general work of the Union, as well as concerning the general readers' section, should be addressed to the Hon. Secretary. Letters of inquiry should be accompanied by a stamped and addressed envelope.

THE *Victorian Naturalist* for May and June contains a most interesting paper, by Prof. Baldwin Spencer and Mr. C. French, describing a trip through the district of Croajingolong. Speaking generally, they describe West Croajingolong as composed of Lower and Upper Silurian strata—slates, shales, sandstones, more rarely conglomerates, and at times metamorphosed by contact with irruptive rocks. The latter are in the form of (1) continuous bands of granite, or (2) a series of knobs of granite, both running along lines lying roughly north and south. In the former case they are traversed along their length by river-valleys. In districts where there are isolated knobs of granite, the rock masses stand out, forming prominent peaks and ridges. The weathering of the granite on Mount Ellery is described as most striking. On the surface it has been formed into huge boulders from 20 feet to 75 feet in height, which lie piled up on one another in indescribable confusion. One huge mass, the egg shape of which gave to the mountain the native name of "Goonegerah," stands out high above the dense forest, which, save in this instance alone, clothes to their summits the long ridges and many peaks of this wild district. So far as the insect life of the district is concerned, the most striking phenomenon seems to be the vast number of ant-hills in every part. Over large areas the mounds of "jumper" ants were so thick as to remind the travellers of "mole-hills" at home. In their study of the flora of Croajingolong they were most impressed by the numerous specimens of the cabbage-tree palm (*Livistona australis*) and the waratah (*Telopea oreades*). The existence of the latter species, peculiar to Victoria, was first discovered by Baron von Mueller during his journeying through the Genoa district in East Croajingolong. This tree, which sometimes reaches the height of 50 feet, grows with equal profusion and strength in the deepest valleys and on the tops of the loftiest hills.

THE Board of Regents of the Smithsonian Institution have issued Part 1 of the Annual Report, showing the operations, experiments, and condition of the Institution, for the year ending June 30, 1886. A general appendix contains papers relating to anthropology, by various writers; a paper on certain parasites, commensals, and domiciliares in the pearl oysters, by R. E. C. Stearns; a paper on time-reckoning for the twentieth century, by S. Fleming; a report on astronomical observatories, by G H. Boehmer; and a catalogue of publications of the Smithsonian Institution, by W. J. Rhees.

MR. J. H. HART, Superintendent of the Botanic Gardens, Trinidad, refers, in his Report for 1888, to the comparatively large number of American and European tourists by whom these gardens are now visited. Mr. Hart has been more impressed by the energy and enthusiasm displayed by visitors from the north than by "anything seen from the European side of the world." "In fact," he says, "Europeans must look to their laurels in these matters. Speaking as one myself, it cannot be said that any prejudice dictates this expression of opinion, but I record it as a fact worthy of the attention of my countrymen." Tourists of all classes at Trinidad, it seems, agree in one respect—in their love of photographing forms of plant life which are new or strange to them. Mr. Hart is so unkind as to describe this as a "prevailing epidemic." The expenditure of dry plates in the Trinidad Gardens is "so large as to afford a rich harvest to the manufacturers."

THE Committee of the Chester Society of Natural Science and Literature has issued its Report, with statement of accounts, for 1888–89. This Society was founded by Charles Kingsley in 1871, and has made steady progress in every department of its work. It has now 617 members. Originally, it included only three sections; now there are seven, "with the prospect of an eighth in the coming year." During the past year the debt on the present building was entirely wiped out through the liberality of some of the members, and the Society looks forward with satisfaction to an increase of accommodation.

A PAPER on the soft palate in the domestic cat, by Dr. T. B. Stowell, has been reprinted from the tenth volume of the Proceedings of the American Society of Microscopists. It is offered as a preliminary contribution to a more general inquiry "as to the phylogenesis and the function of the uvula of the palate, or the conditions which favoured or led to the uvula of the palate, or the conditions which favoured or led to the development of the uvula of the soft palate." On March 2, 1888, the same writer read before the American Philosophical Society, a paper on the glosso-pharyngeal, the accessory, and the hypoglossal nerves in the domestic cat. This paper has also been issued separately.

La Nature of August 17 contains an interesting account, by M. Angot, of the laboratories and instrumental arrangements of the Central Meteorological Office in Paris, which now occupies a large building and grounds formerly connected with the Emperor's stables, with an entrance in the Rue de l'Université. The building is lighted, when required, by electricity, and contains, in addition to the usual offices, several rooms for the verification of instruments, of which a great number are tested annually, darkened chambers for the photographic registration of earth currents and magnetic elements by instruments designed by M. Mascart. These instruments are influenced by surrounding buildings, and are principally intended for the instruction of visitors; the more accurate records are made at the Observatory of the Parc St. Maur. Another large room is devoted to the apparatus invented by M. Weyher for reproducing atmospheric whirls artificially. In the grounds are evaporation tanks, and a platform for anemometers of various descriptions; the records of one of Richard's sensitive instruments are compared with a similar instrument on the Eiffel Tower, and it is said that the comparison has already led to some interesting results; the platform also contains an actinometer on M. Violle's principle, with two spheres, one blackened and the other gilded. It is intended to erect in the garden a whirling machine for anemometer experiments, having a circumference of 40 mètres, with a maximum motion, by electricity, of one revolution per second, which is equivalent to about 90 miles per hour.

Das Wetter for August contains the first part of a lecture by Dr. W. Köppen, entitled "Biological Considerations upon Cyclones and Anticyclones." He points out that the word cyclone was first proposed by Piddington, in his "Sailor's Horn-Book," in 1848, to describe the violent hurricanes of the tropics, in which the wind rotates, in the northern hemisphere, in a direction opposite to the hands of the watch. The term anticyclone was first used by Mr. F. Galton, in his "Meteorographica," in 1863, to represent the opposite class of atmospheric disturbance, in which the wind circulates in the same direction as the hands of a watch. The use of synoptic charts, with isobaric lines, drawn for large areas, shows that the same cyclonic motion occurs in our latitudes, in all degrees of force, down to a gentle breeze. This constitutes one of the most important discoveries of modern meteorology, which dates from about the year 1860. The author points out that the circuitous motions of the atmosphere, whether cyclonic or anticyclonic, consist of three component parts, which can be proved by the laws of mechanics, viz. one rotating motion, one in the direction of the radius, and one perpendicularly to both of these, parallel to the axis of the whirl. The behaviour of the atmospheric motions in the higher regions is more difficult to describe, but so much seems certain from observations of clouds, &c., that the rotation is similar to that below, but the component falling in the direction of the radius is the opposite to that below, viz. an indraught below corresponds to an outflow above. He explains the more frequent gyration of the wind-vane to the right than to the left by the fact that stations in our parts are generally to the right of the storm-areas. He also shows how the ascending current of cyclones produces cloud and rain, by cooling and condensation of vapour, and how the descending current in anticyclones produces dry and bright weather. The remaining article is a discussion by Dr. Kremser, of the extraordinarily high temperatures in North Germany during May and June last. He has compared the daily temperatures of the last forty-two years with those for 1889, and shows the result in a diagram; from which it is seen that for the whole period (April 19–June 20) the temperature was on an average 9° above the normal value. The author states that the Berlin observations, which date back to 1719, show that no May has been so warm, and that the temperature of June has only once been slightly higher, viz. in the year 1756.

Mr. Edward Stanford has published a little volume containing useful "Algerian Hints for Tourists," by Mr. Charles E. Flower. The writer intends that it shall be used as an appendix to the guide-books. He tells his readers what there is in Algeria to see, and "how to get to see it." For further information they are directed to the guide-books properly so called.

We have received Parts 11 and 12 of the Transactions of the Leicester Literary and Philosophical Society. Part 12 includes the Report of the Council, and the Annual Reports of the Sections, presented to the general meeting on June 24.

Messrs. George Philip and Son have issued, in two sheets, an excellent topographical map of the Riviera. It has been published by A. Donath, in Genoa.

The Calendar of University College, Dundee, for the seventh session, 1889–90, has been issued. University College, Bristol, has also published its Calendar for the session 1889–90. In a prefatory note attention is called to the fact that the Bristol College particularly affords appropriate instruction in those branches of applied science which are more nearly connected with the arts and manufactures.

"Flowerland," an introduction to botany, by Robert Fisher, is about to be issued by Messrs. Bemrose and Sons. The work includes 150 illustrations.

At a recent meeting of the Vaudois Society of Natural Sciences, Prof. Blanc gave some interesting information about lake trout reared at the agricultural station of Champ de l'Air. The peculiarity of the experiment was keeping the ova in complete darkness throughout the time of incubation. The water used had a temperature of 4°·8 C. Prof. Blanc compares the experiment with one at Moudon. There, with a temperature of 2°·3, the hatching occurred after 145 days. At Champ de l'Air (temperature 4°·8), it occurred after 160 days, a difference of 15 days, due to the darkness. There are sundry advantages in prolonging the incubation: (1) the young fry put into the streams in April or May more readily find food than in February or March; (2) they are found to be more vigorous; (3) there are few or no monstrosities.

Some curious facts bearing on the *morale* of the lower animals are given by a correspondent of the *Revue Scientifique*. One source of animal sociability is a permanent sexual friendliness, making individuals mutually agreeable. Thus in stables without stalls, it is desirable to put animals of opposite sex next each other, to avoid injuries. A mare may be safely put into a field containing a horse unknown to it, but if two unacquainted horses be thus put together they will fight. A stallion, indeed, will sometimes get injury from an unknown mare put into a field with it. Again, the authority of the oldest and strongest in a group of males often favours sociability. In the Spanish *ganaderias*, a horseman will lead about a numerous troop of bulls, by means of five or six bulls who obey him and maintain order. In the Madrid circus the writer saw three of these animals bring to its stall a vicious bull which had ripped up five or six horses and mortally wounded its *Espada*. They made a slight movement of the horns, and the creature, after a little hesitation, turned and followed them. Once more, when flocks of wild ducks and geese have to go long distances, they form a triangle to cleave the air more easily, and the most courageous bird takes position at the forward angle. As this is a very fatiguing post, another bird, ere long, takes the place of the exhausted leader. Thus they place their available strength at the service of the society.

The attention of the French Government has recently been drawn to the destruction of small fish, especially flat-fish, round the coasts, by shrimp trawls, and the question was referred to the French Fisheries Committee to be inquired into. The Committee have now published their report, in the *Journal Officiel*, in which they recommend the entire prohibition of fishing for shrimps with trawls, and advocate in its place the adoption of two other methods which were brought to their notice at Croisic and at Saint Gilles, where they are already in practical use. At Croisic the engine consists of a trap, somewhat on the principle of an ordinary lobster-pot; it is a wooden frame, in shape like a barrel, and about 2 feet 6 inches long, covered with a small meshed net drawn in at the ends, thus forming two funnels. Each funnel terminates in a small opening through which the shrimps are attracted by bait suspended inside the trap. The machine, which is weighted with stones made fast to the frame, is further provided with a mooring line, and cork float. These traps, of which each fisherman may own from twenty-five to thirty, are kept permanently on the fishing-grounds during the shrimping season, and are visited daily, when the catches are taken out through a hinged opening at the side, and fresh bait put in. The second method recommended consists of a conical pocket of small meshed net about 18 inches deep, fixed to an iron ring with a diameter of 2 feet 6 inches to 3 feet. Four short lines are attached to the ring, and are made fast to a rope and cork float. The bait, which consists of bits of fish, is either placed at the bottom of the pocket or on two lines stretched across the iron ring. These nets require to be raised every 15 or 30 minutes; they should be sunk so that the ring just rests on the bottom, the supporting lines being kept clear of the bait by means of a float fastened at the junction of the lines with the mooring rope. This method is said to be most successful when carried on at low water in the early morning.

A RECENT number of the *China Review* (vol. xvii. No. 3) contains a paper by Dr. Macgowan on the alleged avenging habits of the cobra in Indian and Chinese folk-lore. The belief in India is that a wounded cobra which escapes will sooner or later revenge itself on the man who has caused the injury, wherever he may go or whatever he may do. Dr. Macgowan says that this belief is prevalent in Indo-China and China as well as in India. But in China there is also a strong prejudice against killing the cobra, lest its spirit should haunt the slayer ever after. Cobras, therefore, are shunned rather than pursued and attacked. Popular stories of the dire consequences of slaying them keep up the superstition: a high official who had killed one died soon afterwards of some mysterious disease, and the death is attributed to the slain snake; again, the spirit of the snake enters into possession of its slayer, and employs the vocal organs of the latter in uttering imprecations on himself until death mercifully removes him. Dr. Macgowan gives a large number of stories of this character. A number of others refer to the retribution on snake-killers after their own deaths. Gratitude, as well as vindictiveness, is ascribed to snakes, of which some characteristic stories are given. In conclusion, Dr. Macgowan observes that the recently established vernacular press in China furnishes inexhaustible stores of folk-lore. "Paragraphs describing popular superstitions, impossible occurrences, monstrosities, and so forth, constitute a great portion of their matter." In regard to snakes, the marvel is that any are killed at all in China, so many dreadful punishments are supposed to overtake their destroyers; and, indeed, it is considered a work meriting favour here and hereafter to purchase captured snakes and liberate them. Nevertheless, poisonous snakes are not numerous in China, probably because their presence is inconvenient to Chinese farmers, and they are therefore destroyed, folk-lore notwithstanding.

IN connection with the recent discussion, in Parliament and elsewhere, respecting emigration to South America, it may be interesting to reproduce certain observations of Dr. Alfredo da Luy, at a late meeting of the Academy of Medicine at Rio, on the effect of climate on race. They are quoted in a report from the British Legation in Brazil, which has recently been published. "I have long noticed," he says, "that Brazilians in general are more pallid, and are less vigorous and energetic, than persons coming from temperate and cold climates. Here in Rio de Janeiro the degeneration of the Portuguese race may also be noted. In fact such inhabitants of Rio de Janeiro as are not coloured persons are generally pallid, weak, of short stature, and of but little muscular strength. I have found that an anæmic condition is very common among us, and, in most cases in our country, malarious infection is the cause of the impoverishment of blood, whenever this impoverishment exceeds physiological limits. I believe, however, that such malarious impoverishment of blood seldom kills by itself, but this it is which makes children in Rio de Janeiro show so little resistance to other maladies, and it is one of the causes which concur to produce the great infant mortality in the city of Rio de Janeiro. The average annual mortality of children in Rio de Janeiro, up to seven years of age, was 2900 in the five years from 1882 to 1886, excluding those born dead. It is chiefly among the children of Europeans resident in Brazil that I have met with the most accentuated impoverishment of blood and debility, and I believe the explanation to be marshy malaria (*impaludismo*). I have noticed in my practice that the children of Portuguese and Italians do not fare so very badly in the Brazilian climate, but that the children of foreigners coming from the north of Europe show a noted physical degeneracy, and a frail vital resistance, so that the greater part of them succumb at a tender age, and even if they reach adult life they never show any grade of robustness and energy comparable to that of their progenitors. Although I am fully persuaded of the good moral qualities of the European colonist, I think it my duty to state that Germans, French, Belgians, and other persons from climates very different from ours, will never be able to give a prosperous colonization to our warmer provinces, except in the case of crossing with races better adapted to hot climates."

IN Consul-General Playfair's Report to the Foreign Office on the agriculture of Algeria, it is said that viticulture in that country is beset with many dangers. In spring, hailstorms frequently destroy the young shoots; the flowers are often ruined by fogs; and the ripe fruit by the sirocco. The most serious enemy is, of course, the *Phylloxera*, but the officials have been fairly successful in dealing with this pest. Another is the *altise*, a small beetle that causes great destruction, particularly when in its larval condition. The mode of killing the *altise* commonly adopted is to place bundles of grass and vine-cuttings around the vineyard when winter is approaching; in these the insects conceal themselves in large compact masses, and the whole is then set on fire. Other diseases are the *oïdium*, *anthrachnosis*, *peronospera*, and *chlorosis*. It is calculated that the want of intelligent treatment of these diseases causes the owners of the vineyards to lose annually nearly a third of the crop. The olive seems to grow everywhere in Algeria except in marshy ground, and attains dimensions quite unknown on the northern coast of the Mediterranean. At present, however, from careless cultivation, the plant has not proved as remunerative, nor have its products been as good, as in Europe.

THE British Consul at Bogota, in his last Report to the Foreign Office on the agricultural condition of Colombia says that for tobacco cultivation in that country no manure is used, and the same land is used over and over again for an indefinite number of years. In some districts, where disease has completely exterminated the tobacco plantations, it has been found that when plants are brought from other districts they are not attacked for a few years, but ultimately they are also destroyed. This, perhaps, might be avoided by constantly importing fresh seed; but the experiment was tried on some of the best tobacco land in Colombia, with the result that as the seed brought from inferior districts began gradually to improve by transportation to the better soils, it became more liable to disease, while the plants grown from seeds brought from the better districts were attacked at once. Another instance of the ignorance of scientific agriculture in Colombia appears in the case of cocoa. It is most carelessly cultivated, though it is a crop which requires constant care and labour to weed and clean the ground, and free the trees of the numerous insects, especially the caterpillars, which infest them. A most destructive disease has lately attacked the trees in the south of the Tolima, which is one of the very richest districts in Colombia. This disease does not seem to have been investigated, and no remedy has been suggested, but the extent of its ravages will be understood from the fact that one of the plantations attacked produced only 175 pounds instead of 18,000 pounds of cocoa.

THE additions to the Zoological Society's Gardens during the past week include a Formosan Deer (*Cervus taëvanus* ♂), a Japanese Deer (*Cervus sika* ♀) from Japan, two Three-striped Paradoxures (*Paradoxurus trivigatus*), a Great Eagle Owl (*Bubo maximus*) from China, presented by Capt. C. Taylor s.s. *Aberdeen;* a Common Fox (*Canis vulpes* ♀), British, presented by Mr. Edward Hall; a Bewick's Swan (*Cygnus bewicki*) from China, presented by Mr. Jansen; a Peregrine Falcon (*Falco peregrinus*) from Cyprus, presented by Dr. W. Hoad; a Mantchurian Crane (*Grus viridirostris*) from North China, eighteen Spanish Blue Magpies (*Cyanopolius cooki*) from Spain, an Indian Python (*Python molurus*) from India, two Water Rattlesnakes (*Crotalus adamanteus*) a Mocassin Snake (*Tropidonotus fasciatus*) from North America, deposited; five African Lepidosirens (*Protopterus annectans*) from the River Gambia, West Africa, purchased; a Royal Python (*Python regius*) from West Africa, received in exchange; an Indian Muntjac (*Cervulus muntjac* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1889 *d* (BROOKS, JULY 6.)—The following elements and ephemeris for this object are by Herr Otto Knopf (*Astr. Nach.*, No. 2916):—

T = 1889 July 12·2616 Berlin M.T.

$$\left.\begin{aligned} \pi &= 330^\circ\ 7'\ 5'' \\ \Omega &= 29\ \ 4\ 56 \\ \iota &= 5\ 44\ \ 7 \end{aligned}\right\} \text{Mean Eq. } 1889{\cdot}0.$$

$$\log q = 0{\cdot}35280$$

Error of middle place (O − C).
$d\lambda \cos\beta = +20''$; $d\beta = -2''$.

The observations on which these elements are based were obtained at Lick, July 8; Vienna, July 21; and Dresden, July 30.

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Aug. 31	0 7 30	5 53·2 S.	0·3665	0·1326	1·37
Sept. 4	0 6 29	5 48·4	0·3686	0·1324	1·36
8	0 5 14	5 43·8 S.	0·3709	0·1333	1 34

The brightness on July 8 is taken as unity.

On August 1, Mr. Barnard observing at the Lick Observatory, found the comet to be composed of three distinct adjacent comets, perhaps more; and Prof. Weiss, under date August 6, reported it as fourfold.

COMET 1889 *e* (DAVIDSON).—Dr. Becker gives the following elements and ephemeris for this comet, derived from observations made at Rome on July 26, Vienna on August 4, and Dun Echt on August 15.

T = 1889 July 19·29538 G.M.T.

$$\left.\begin{aligned} \pi - \Omega &= 345^\circ\ 53'\ 6''{\cdot}9 \\ \Omega &= 286\ \ 8\ 16{\cdot}2 \\ \iota &= 65\ 59\ 59{\cdot}7 \end{aligned}\right\} \text{Mean Eq } 1889{\cdot}0.$$

$$\log q = 0{\cdot}016949$$

$\Delta\lambda \cos\beta = +6''{\cdot}6$; $\Delta\beta = -0''{\cdot}3$; (O − C).

Ephemeris for Greenwich Midnight.

The brightness on July 22 has been taken as unity.

NEW MINOR PLANETS.—Two new minor planets were discovered on August 3; the one, No. 285, by Herr Palisa at Vienna, the other, No. 286, by M. Charlois at Nice.

NEW DOUBLE STARS.—Mr. Burnham reports that η Ophiuchi is a close double, the two components being of nearly equal magnitude. The present position of the fainter is angle = 274°·7, and distance = 0″·35. It will probably be found to be a binary of somewhat short period.

θ Cygni has a small companion at position-angle 43°·9, and distance 3″·62, recently discovered by Mr. Burnham. The companion is about the fourteenth magnitude.

STARS WITH REMARKABLE SPECTRA.—The examination of the photographs of stellar spectra taken at Harvard College in connection with the Henry Draper Memorial has shown DM + 43° No. 3571 to have a spectrum crossed by bright lines, and similar to those of the three stars discovered by Wolf and Rayet in 1867. Two other stars, DM + 66° No. 878, and DM + 84° No. 516, especially the latter, have the most strongly marked spectra of Secchi's third type which have yet been recognized, except in the case of some variables of long period.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 SEPTEMBER 1–7.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 1

Sun rises, 5h. 15m.; souths, 11h. 59m. 46·7s.; daily decrease of southing, 18·9s.; sets, 18h. 45m.: right asc. on meridian, 10h. 43·1m.; decl. 8° 8′ N. Sidereal Time at Sunset, 17h. 30m.

Moon (at First Quarter September 2, 20h.) rises, 11h. 59m.; souths, 16h. 50m.; sets, 21h. 31m.: right asc. on meridian, 15h. 33·9m.; decl. 15° 29′ S.

THE SCIENCE COLLECTIONS AT SOUTH KENSINGTON.

THE following is the Report of the Committee appointed by the Treasury to inquire into the Science Collections at South Kensington :—

1. Our original instructions are contained in the Treasury Minute of the 19th February 1889, which will be found in the Appendix (No. 1). Upon consideration, we found that some amplification of these instructions were necessary, and we accordingly communicated to Government the resolution which is printed in the Appendix (No. 2). In reply to this resolution we received a letter from the Treasury under date of the 23rd March, Appendix (No. 3).

2. After some preliminary deliberation, and an inspection of the collections which form the subject matter of our inquiries, we proceeded to take evidence from representatives of the Science and Art Department and others who had been practically concerned in the formation and arrangement of these collections ; and, during our inquiries, we have again inspected the several branches of the Museum in company with professors of the Normal School of Science and others specially conversant with the contents of each ; we have also been furnished with detailed catalogues of the collections. By these means we trust that we have secured an acquaintance with the contents of the science collections sufficiently exact for the purpose of our present inquiry.

3. It may be convenient that we should recapitulate the different collections with which we have had to deal, noticing at the same time the manner in which they are at present housed. In these respects, the changes since Sir Frederick Bramwell's Committee reported have been not inconsiderable.

The collections have been classified by the Department (January 1888) under two main divisions :—

I. Instruction and Research.

II. Industrial Applications.

Division I.—The collection of Scientific Instruments and Appliances for science teaching occupies 6325 square feet on the ground floor and 15,840 square feet on the upper floor (in all 22,165 square feet) of the Western Galleries.[1]

It is grouped by the Department under the following heads, corresponding in the main with the arrangement of the Science Directory.

A.—Mechanics and Mathematics.

B.—Physics.

C.—Chemistry, Metallurgy, and Principles of Agriculture.

D.—Biology.

E.—Geology, Mineralogy, and Mining.

F.—Navigation, Nautical Astronomy, and Physiography.

The collections illustrative of Mining are, however, housed in the Geological Museum in Jermyn Street, in connection with the Royal School of Mines. These we have not examined or considered.

Division II.—Industrial Applications.

(*a*) The collection of Machinery and Inventions (including the selected specimens from the old Patent Museum, and also some few illustrations of metallurgical operations) occupies 18,476 square feet on the ground floor of the "Southern Galleries."[2]

(*b*) The collection illustrative of Naval Architecture and Machinery occupies 15,374 square feet in all on the upper and ground floors of the "Southern Galleries," the machinery being on the ground floor.

(*c*) The Fish Culture collections and some miscellaneous objects occupy 5630 square feet in a wing at the west end of the "Southern Galleries."

4. In addition to these branches of our subject we should, in order to complete the list of scientific collections, mention the two following, which lie beyond the terms of our reference :—

(i.) The Educational Library of Science. This is now placed in the Museum, to the east of Exhibition Road, in connection with the Art and General Library.

(ii.) The collections of Food and Animal Products, formerly at South Kensington. These are now housed in the Bethnal Green Branch Museum.

It may be convenient to add that about 16,000 square feet on the two floors of the eastern end of the Southern Galleries (formerly the National Portrait Gallery) are now occupied by a collection of modern industrial products, furniture, and ornaments, removed thither from Bethnal Green, which belongs to the Art division of the Museum, and has no connection with the Science collections upon which it is our duty to report. Further, about 9200 square feet on the ground floor of the Western Galleries are used only for examination rooms.

[1] The Western Galleries are those adjoining Queen's Gate and north of the new Imperial Institute Road.

[2] The Southern Galleries are those extending from Exhibition Road to Queen's Gate to the south of the new Imperial Institute Road.

5. It will be observed that in our enumeration of the branches of the Science Collections as at present existing, we have made no reference to two branches mentioned in the Report of Sir F. Bramwell's Committee :—

(*a*) The Educational Collection.

(*b*) The Structural Collection.

For these sections spaces of 7000 square feet and of 15,000 rising to 25,000 square feet respectively, were demanded by the Committees whose recommendations were adopted in that Report.

These sections have been suppressed for reasons given by General Donnelly, the articles of which they were composed having been returned to the lenders or otherwise disposed of. It was probably the aspect of these collections which, upon a superficial view of them, led to the severe strictures sometimes passed on the contents of the Southern Galleries.

As regards these two sections, we may here say that in our opinion the necessity for the exhibition of school furniture and fittings, such as are required for schools receiving grants under the Elementary Education Acts, no longer exists ; but (under proper limitation) a series of diagrams and models of the best forms of construction and a collection of specimens of material, specially designed for scientific and technical education, might with advantage be exhibited in connection with the subject of mechanics as taught in the Norman School, and with that subject and with building construction as taught in science classes, and with the general collection of applied science. Such a collection should be strictly technical in character ; otherwise there would be a risk of indefinite extension in this department.

6. The order in which we have described the collections in our third paragraph follows the arrangement adopted by the Science and Art Department in January 1888, and agrees with that suggested in paragraph 26 of Sir F. Bramwell's Report, where the "instruction given in the Normal School of Science" coupled with "the teaching of science generally throughout the United Kingdom," precedes "the acquisition of other objects in the interest of science or of the arts."

It is indeed evident that the collections in the Western Galleries, containing instruments and appliances indispensable for the teaching of science, are more closely connected with the work of the Normal School and the science classes in connection with the Department than the machinery, to which, however, some of the professors refer by way of illustration in their lectures ; and the machinery is more closely connected with the Normal School and science classes than are the ship models, which at present are not used at all for the school ; whilst the fish collection serves no direct educational purpose at all. We learn from the Treasury Letter of March 23 that the view as to the object of these collections expressed in paragraph 26 of Sir F. Bramwell's Report has in substance been adopted by Government, with the qualification that "the teaching of science generally" must be subject to "reasonable regulations."

Prof. Huxley, who, in one capacity or another, has had a very large share in the formation of these collections, maintains that the connection of the collections with the Normal School of Science is "accessory and accidental," the essential object of them being, firstly, "to facilitate practical instruction in science, particularly in the teaching in the science classes connected with the Department, by enabling teachers to acquaint themselves with the various apparatus, models, and specimens which are indispensable to proper scientific instruction, or which have been found especially useful in such instruction, and in original investigation," and, secondly, "the preservation of apparatus and models which possess historical interest as marking stages either in the progress of discovery or in that of the application of scientific principles to art and industry."

Without attempting to determine the relative value of such collections as regarded from different points of view, we would state that in our opinion their direct educational bearing does not afford an adequate test of their value and importance.

7. We proceed to consider *seriatim* the several sections of the collection, beginning with the "Appliances for Instruction and

Research" now in the Western Galleries. For this section, which now occupies a little over 22,000 square feet, the committee of professors, whose report was adopted by Sir F. Bramwell and his colleagues, estimated that 37,000 square feet were required, with an addition of 3,000 square feet in the next ten years, *i.e.* nearly double the area at present available. The space now provided is well filled but hardly overcrowded; the objects exhibited are, speaking generally, either of historical interest as illustrative of the development of scientific discovery, or representing the latest and most improved forms of scientific instruments and appliances. The collection is clearly of great use to the students in the Normal School, the professors of which draw upon it largely for illustrations of their lectures, or bring their classes into the galleries when that course is more convenient; and these remarks apply to the historical side of the collection almost as much as to its more immediately practical portions. It is of no less use to such of the teachers and students in science schools throughout the country (which receive grants from the Science and Art Department) as have opportunities of visiting it, whether singly or in organized classes. A special feature in the collection is the series of appliances for the teaching of science which it contains, sometimes systematically arranged ready for class use, sometimes shown as a group of similar objects made by different makers, with prices attached. We think that these samples (as they may be called) require very careful administrative watching in order to keep the selection exhibited up to the latest date and the best quality. For such specimens the Department has, especially in the early stages of the collections, been largely indebted to the assistance of private firms; for whom proper consideration must therefore be shown. These samples are doubtless of service to teachers, especially in the present comparatively undeveloped condition of elementary scientific teaching in this country; and the space occupied by them (mostly in wall cases) need not be large.

The collections now under consideration appear to have been on the whole carefully watched by a committee of professors in the Normal School, who, under the exigencies of a limited space, have eliminated from them almost all objects of an obsolete character. Little further weeding is possible in them as they now stand, except perhaps in the case of some of the samples described above. Turning to the other side of the question, the complaints of want of space do not appear to be very serious; and the future development of such collections can, we think, be met in part, but not altogether, by the elimination of objects which, appropriate and necessary to-day, will become obsolete in the inevitable progress of scientific knowledge and procedure. We say, "not altogether," because there ought to be retained a limited number of objects illustrating the historical development of the more important implements of scientific research; moreover, some natural increase must be contemplated arising from the introduction of new methods of scientific investigation. Wall space is all that is required for the exhibition of *diagrams*, which can often be usefully employed in lieu or in aid of actual objects or instruments.

The need for the exhibition of the appliances for elementary science classes may be expected to diminish as the organization of scientific education improves, in the same way as the universal extension of primary schools has removed the necessity for such an exhibition of school desks and fittings as formerly existed in this Museum.

Included in the 40,000 square feet provided for by Sir F. Bramwell's committee are 4000 square feet for "agriculture." At present only a very small collection exists in connection with this subject. Lectures are from time to time delivered at the Normal School, on the *principles* of agriculture, and the Department holds examinations in the same subject. But it is obvious that for the portions of this subject in which instruction can usefully be given in lecture-rooms, the illustrative collections required need occupy only a very moderate amount of space. Any complete collection of objects illustrative of the study of all branches of agriculture would require a space at South Kensington far larger than could be allotted to a mere branch of a Science Museum. The principal agricultural implements should be represented by models in the department of Machinery and Inventions; and provision seems to have been made for this purpose in the scheme for that department, to which we will subsequently refer.

The Western Galleries at present in use are fairly satisfactory as regards construction and lighting, and allow their nominal area and wall space to be utilized to the full extent of their capacity. They are, however, inconveniently situated as regards both the Normal School and the rest of the Museum, and we have little doubt that a building giving an equal accommodation could be provided at a cost less than the capitalized value of the rent (£2000 per annum) at present paid for them.

On the whole, we are of opinion that, having regard to the financial exigencies which must always be present to those intrusted with the expenditure of public funds, a moderate increase on the present space should, subject to one important proviso, suffice, for some time to come, for the needs of the Normal School and other requirements of this section.

The proviso to which we refer is, that there should be a well-organized system of management of the collection. We will revert hereafter to this point, which, in our judgment, affords the key to the whole question now before us.

8. Passing to the section devoted to Machinery and Inventions, we have to observe that this is of the nature of a technological museum rather than of a collection for the special benefit of the Normal School, or of the Science Classes connected with the Department. It is, however, to be observed that the Professor of Mechanics attaches great value to this collection for the purposes of his teaching; and that the objects used as illustrations by the Professor of Metallurgy (so far as he does not use diagrams) are practically included in this division of the Museum. Regarded from a broad point of view, the value and importance of this section must be admitted; and we approve of the policy which has been adopted by the Department in recent years, of developing it at the expense of less important collections. In pursuance of this policy the area of this section has increased from 11,000 to over 18,000 square feet, now occupied to nearly its full capacity. This is still very far short of the space of 45,000 increasing to 60,000 square feet adopted by Sir F. Bramwell's committee, and even of the more moderate demand of 40,000 square feet put forward by Mr. E. A. Cowper in his evidence before us, and based on carefully-detailed calculations. That gentleman has devoted a great amount of time and trouble to this collection, which bears the mark of his patriotic labours in the evident endeavour to utilize the available space to the best advantage. There are a few objects, but only a few, in this collection which could properly be eliminated; but we consider that care should be taken not to acquire or receive full-sized machines where models can be made to serve the same purposes, and also to avoid unnecessary multiplication of parts in either model or machine. For example, two or three rows of bobbins, &c., on a spinning frame show as completely the principles on which a machine is constructed as would a complete series, such as is to be found in actual use. Inferior or obsolete examples must be eliminated as better or more recent specimens are obtained, subject only to the retention of a few typical illustrations of historical development. Moreover, the development of the collection must inevitably be gradual, if properly carried out, as the right objects cannot be obtained off-hand, and the temptation to obtain or accept inferior examples should be avoided in every possible way. Even with these restrictions, we agree with Mr. Cowper that ultimate, if not immediate, provision of a maximum space of 40,000 square feet should be made for this branch of the Museum; and we believe that, under well-organized and efficient management such as we have already pronounced essential, this space, if provided by means of suitable buildings, ought to suffice to contain a technological collection worthy of a great manufacturing country. As a temporary measure, space might be found for the expansion of this section by the removal of the decorative objects which occupy the eastern end of the ground floor of the Southern Galleries.

9. *Naval Collections.*—Under this head are included complete models of vessels of various kinds, actual or proposed, forming an historical series, and mostly on loan; models illustrative of naval construction; and models of marine machinery, many of historic interest. In regard to this section of the Museum, we have had to consider the very debatable question of the suitability of South Kensington as a site for a marine collection. Though classes are examined by the Department in naval construction, no provision is at present made for teaching the subject in this locality. It is right, however, to say that "summer classes" in this subject are contemplated; and a class is intended to be held next autumn. It will be remembered that the School of Naval Architecture (in connection with which this collection was originally formed) has been removed to Greenwich, and has assumed a more prominently military character. It is not easy at first sight to regard the west end of London as

the most convenient centre for those interested in ship construction, especially considering the small amount of ship-building operations now conducted on the Thames. But it has been shown that there is a very strong sentiment among those interested in shipping in favour of the retention of the ship models in their present home, and the following are some of the practical reasons given in support of this view, by the Institute of Naval Architects and others :—

(1) The shipping companies and other owners of the large ornamental models have, it is said, declined to lend their property for permanent exhibition elsewhere than at South Kensington.

(2) The naval collections are closely connected with the Machinery and Inventions Section of the Museum.

(3) Being at South Kensington, the departmental system of circulation can, it is said, be applied to them.

This latter remark only applies in practice to a small portion of the collection, viz. the models, &c., illustrative of the details of ship construction. The large models of ships do not belong to the Department, and in any case are too large and too valuable to be sent round, under the plea of some slight educational utility, to local schools of elementary science ; though, under special circumstances, some of them have been lent by their owners to Exhibitions in the provinces, or even at Paris.

On the whole, we have arrived at the conclusion that it would be practically impossible to reconcile public opinion to the removal of this collection elsewhere, and that space must therefore be provided for it at South Kensington.

For this collection 10,500 square feet were demanded at once by the committee referred to in Sir F. Bramwell's Report, with an increase of 10,000 square feet. The space at present occupied is 15,374 square feet, or three-fourths of the maximum desired by the special committee. We consider that the present space should suffice, under proper administration, for an adequate exposition of the methods and results of the very important national industry of shipbuilding. In connection with this conclusion we would observe that, in our opinion—

(1) A certain number of the objects now exhibited could be eliminated "without injury to the value or representative character of the collections" ; and the fact that so much of the space is occupied by large ornamental models of ships, many of them on loan, would facilitate such elimination, when required for the introduction of new examples.

(2) Having regard to the fine historical and practical collection of war-ships which exists at Greenwich, and is readily accessible to the general public, the portion of the South Kensington collection which relates to ships of war should be reduced to a minimum. It now occupies twenty pages of the catalogue, in which fifty-three numbers are described.

(3) The additions to the collection, other than in substitution for objects eliminated, should mainly consist of diagrams or small models of *parts* of ships or machinery, suited for practical instruction in the art of ship-building. Such objects would be of use for circulation, and would not occupy any considerable amount of space.

10. *Fish Culture Collection.*—No mention of this collection is made in the departmental scheme of classification dated January 1888 ; and indeed it seems to bear little relation to the instruction given in the Normal School, to the teaching in science classes connected with the Department, or to the other sections of the Science Museum. Nor is South Kensington a situation naturally well adapted for fish-breeding operations. We beg to refer to the weighty opinion of Prof. Huxley as to the want of connection between this collection and its present surroundings, and the small educational or scientific value which it possesses in its present condition.

The greater part of this collection was bequeathed to the Department in 1880 by the late Mr. Frank Buckland, and a series of British fishes has, since that date, been presented to it by Dr. Day. This state of things would, however, in our opinion, hardly prevent the Department from transferring the collection to some other public institution. The Buckland Professorship, if the funds for its support are still available, might well be attached to the Marine Biological Laboratory at Plymouth, under regulations agreed to by the Science and Art Department. With the consent of the donors (when obtainable), some objects now forming part of this collection might find a place in the Natural History Museum ; and the remainder might be transferred to the Marine Biological Association, and the Scotch Fishery Board, provided that those bodies are able and willing to receive them. In any circumstances we are of opinion that there is no necessity for the collection being retained at South Kensington, and certainly no provision should be made for it in any building scheme there.

The large State barge and Venetian gondola now housed in the same galleries as the fish collection should also be removed.

11. *Circulation.*—With regard to that portion of the reference to us which relates to the system of circulation of objects in the provinces, we should explain that two different systems are comprised under that name. Under one of these, objects forming an integral part of the collections are lent by the Department, for a limited period, to local museums. This in the case of the science collections is only done on a small scale ; the space so vacated is insignificant and cannot be utilized for other purposes, and it has therefore no practical bearing on the housing of the collections. The other kind of circulation is confined to science schools in connection with the Department. It consists in the loan of a typical set of objects and apparatus suitable for the teaching of one branch or another of science, such as chemistry, geology, &c., with a view to improve the practical portion of local teaching. These circulating sets are never regularly exhibited at South Kensington, and therefore can only require a small amount of warehouse space for storage and arrangement. If the system of circulation grows, some additional warehouse space may be required, but no increase in the exhibition space would be involved.

12. The frequent mention in this Report of areas of exhibition space suffices to indicate how inevitably the question of housing the collections has been forced on our attention, notwithstanding that it does not explicitly form part of the terms of reference to us. In suggesting certain areas as, in our opinion, sufficient to meet the requirements of the case, we have assumed that the exhibition buildings should be well arranged, well lighted, and of a durable character. These requisites, however, are not fulfilled in the case of the Southern Galleries, the upper floor of which is, we are informed and believe, incapable of supporting considerable weights, so that collections of machinery cannot be placed in that portion of the building. It may also be observed that these galleries appear not to be well secured against fire. The rent of £1500 per annum is paid for the central block of this building, for the capitalized value of which sum a larger and more convenient building could apparently be erected. The present state of dispersion of the Museum involves extra expense in connection with the entrances, attendants, and police, and also increases the difficulty of an efficient superintendence by the superior officers in charge of the collections. We feel bound to call attention to these facts, which have been forcibly impressed on us by our observations on the spot as well as by the evidence we have received.

13. We have already adverted to another matter which, though outside the literal terms of reference to us, is in our judgment of the very greatest importance in regard to the substance of the questions under consideration. We allude to the organization for the custody and management of the collections. At present this duty rests, under the Secretary, with the staff of the Director of the Museum, whose functions cover both the Art and the Science divisions, which differ widely from one another. Attached, however, to each section of the Museum is a separate consultative committee ; which, for the collections of scientific instruments and appliances, consists of the professors of the Normal School ; while in the case of the other sections, the committees consist of gentlemen external to the Department. These committees can only recommend, not decide ; and even when their recommendations are adopted, it does not follow that they can see that they are carried out. To committees of this kind the task of refusing unsuitable loans is also peculiarly difficult and irksome ; and there is also some danger of different committees causing overlapping between different portions of the collections, although we have no reason to think that this has as yet happened. On the other hand, there seems to be no system of regular meetings of the committees at prescribed intervals (oftener than once a year), and regard being had to the composition of the committees, it is not to be expected that many members of them should be able to devote much time to this work, certainly not to the detailed and continuous supervision which collections require. It must not be supposed that nothing has been gained from the existence of these committees ; on the contrary, Mr. Cowper's work on the machine collections is an instance of the excellent service which individual members have rendered. But we consider the system defective in principle,

apart from the personal qualities of those working under it; and having formed a very decided opinion to this effect, we feel it our duty to call attention to the subject, in the interests of economy as well as of efficiency. The responsibility for the formation and supervision of these collections should certainly be of a more definite kind.

14. Suggestions have been made that these collections might encroach on the field occupied by other scientific museums. With regard to this point we would call attention to the evidence of Prof. Judd as showing that a practical distinction can readily be drawn even at a point where two Museums closely approach one another in character.

15. In conclusion, we may summarize the results of our inquiries by expressing the opinion that little, if any, space can be gained by weeding the existing collections, and that, subject to the reservations we have made as to effective organization and administration, and as to the character of the buildings to be assigned to the collections, an exhibition space of about 90,000 square feet should be provided without delay, and would suffice for the requirements of a creditable Science Museum, with adequate space for all the departments for which it appears at present necessary to provide. This space includes provision for a scientific structural collection on the lines indicated in paragraph 5 of this Report, but does not include any provision for offices, warehouses, workshops, or other accessories to such a Museum.

AN ITALIAN'S VIEW OF ENGLISH AGRICULTURAL EDUCATION.[1]

IN this *brochure*, M. Italo Giglioli, Professor of Agricultural Chemistry at Portici, has collected together a large amount of information upon agricultural education and agricultural research as carried out in the United Kingdom. A similar work upon the teaching of agriculture throughout Europe, by the same author, appeared last year. It is, however, noticeable that the volume on English agricultural education is three times the bulk of the earlier effort. M. Giglioli, as a foreigner, has considered our methods worthy of a much more detailed Report than those of the Continent. This can only be regarded as a tribute to the excellence of English agriculture. We have heard a great deal of late upon the small amount of interest taken in agricultural education in England compared with Continental countries. An Italian Professor finds material for a portly volume on our systems of agricultural education and research, while he is able to compress his information upon the German, French, and Hungarian systems into a pamphlet of comparative thinness.

As a matter of fact, the Continental nations have been, at least in the past, ahead of us in these matters. The value of what is done in England rests rather upon the quality of our agriculture than upon our efforts to systematically teach it. Continental Professors of Agriculture find it as essential to visit England and to study English agriculture, as would an American Professor of History to visit Europe, or a Biblical student to visit Egypt and Palestine. The most noted breeds of cattle, sheep, and pigs, the best types of implements and machinery, the best artificial manures, the best systems of farming, have originated in England and Scotland, and hence the attention which is paid to agricultural research as prosecuted in Britain. So far, however, as the study of Agriculture is concerned, or painstaking and wide-spread investigation goes, the Continental nations are before us. It is not by any means certain that with these advantages they will excel us in the actual practice of agriculture. As a nation we are more adapted for doing than for study, and our progress is generally the result of pressure under competition, and the spontaneous adoption of the best practices, as they are published in the press. Our improvements are less likely to emanate from technical schools than from the promulgation of new ideas, new processes, new material, new appliances, adopted by leading agriculturists, exhibited and reported upon.

M. Giglioli, like all Continental visitors to England, wonders with great admiration at the spontaneous character of our efforts. Here, we succeed without Government help. There, both teaching and research often languish, although supported by huge grants, and are always discontentedly asking for more. "Il carattere più saliente che le distingue da tutte le altre scuole agrarie di Europa, è quello della loro completa autonomia, anche finanziaria. Esse non ricevono sussidio alcuno nè dal Governo, nè da provincie, nè da associazioni agrarie: vivono completamente sopro quello che quadagnano. Il contrasto tra le scuole inglesi e le continentali appare nel seguente quadro." The author then recounts, in tabular form, the cost to the student, and the incomparably greater cost to the State, of agricultural education in Germany, France, and Italy; and, after showing that each student costs his State from 700 to 2500 lire, in addition to his own costs, he triumphantly writes "*niente*" in the column showing the cost to the State opposite the chief English agricultural schools.

The author's introductory remarks having been concluded, the principal Societies engaged in agricultural education in these countries are next passed in review, and their methods, examinations, prizes, diplomas, are described. Such matter will no doubt be more interesting to Italian agriculturists than to ourselves. The number of these means of instruction is probably greater than many Englishmen are aware of, and, as a point of considerable interest at the present time, we take the following list from M. Giglioli's book:—

The Royal Agricultural Society of England (an examining body).
The Rothamsted Experimental Station (for research only).
The Royal Agricultural College, Cirencester (instructional and examining body).
The College of Agriculture, Downton (instructional and examining body).
The Colonial College, Hollesley Bay (instructional and examining).
The Department of Science and Art, South Kensington (instructional and examining).
The Darlington Chamber of Agriculture (Lecturer employed).
The Normal School of Science, South Kensington (Agricultural Professorship).
The University of Oxford (Sibthorpian Professorship).
King's College, London (Agricultural Lectureship).
City of London College (Agricultural Lectureship).
The Worleston Dairy School, Cheshire.
The Sudbury Dairy School.
The Weald of Kent College of Agriculture.
The School of Agriculture, Aspatria, Cumberland.
The Agricultural School at Alvecote, Tamworth.
The agricultural instruction given at various County Schools.
The facilities for agricultural instruction in rural Elementary Schools.
The Forestry Department at Cooper's Hill.
The Surveyors' Institution, 12 Great George Street, Westminster (examining body).
The Royal Veterinary College, Camden Town.
The Brown Institute.
The Highland and Agricultural Society (examining body).
The Agricultural Department of the University of Edinburgh.
The Agricultural Department of the College of Science and Technology, Edinburgh.
Course of Agriculture at Glasgow Technical College.
The Agricultural Department in Aberdeen University.
The Royal Veterinary College, Edinburgh.
The New Veterinary College, Edinburgh.
The Veterinary College, Glasgow.
The Agricultural School at Templemoyle, Ireland.
The Royal Albert Institution, Glasnevin, Dublin.
The Dairy School for Females, Glasnevin.
The Munster Dairy School, near Cork.
Canon Bagot's Creameries, Ireland.
The Governmental agricultural instruction in Elementary Schools, Ireland.

The above Societies, Colleges, and Schools engaged in the work of agricultural education are all carefully described. The list might have been made longer, as M. Giglioli does not seem

[1] "Educazione agraria Britannica," relazione di Italo Giglioli. (*Annali di Agricoltura*, 1888.)

to be aware of various dairy and other agricultural schools which have been recently founded, or are now being promoted. Among these may be especially mentioned the Travelling Dairy School of the Bath and West of England Society.

JOHN WRIGHTSON.

"INFERNITO."

SOME strange natural phenomena are described in a recent report from the United States Consul at Maracaibo in Venezuela. That part of the département of Colon situated between the Rivers Santa Ana and Zulia and the Sierra of the Colombian frontier is very rich in asphalt and petroleum. The information we have regarding this extensive and interesting region, which is an uninhabited forest, is derived chiefly from the reports of the searchers after balsam copaiba, which abounds; but the following data were taken from the personal observations of an American gentleman who made a special exploration. Near the Rio de Oro, at the foot of the Sierra, there is a very curious phenomenon consisting of a horizontal cave which constantly ejects thick bitumen in the form of large globules. These globules explode at the mouth of the cave with a noise loud enough to be heard at a considerable distance; and the bitumen, forming a slow current, falls finally into a large deposit of the same substance, near the river bank. The territory bounded by the Rivers Zulia and Catatumbo and the Cordillera is rich in deposits and flows of asphalt and petroleum, especially towards the south, where the latter is very abundant. At a distance of a little more than 7 kilometres from the confluence of the Tara and the Sardinete, there is a sand mound of from 25 to 30 feet in height, with an area of about 8000 square feet. On its surface are a multitude of cylindrical holes of different sizes, which eject with violence streams of petroleum and hot water, causing a noise equal to that produced by two or three steamers blowing off simultaneously. For a long distance from the site of this phenomenon the ground is covered or impregnated with petroleum. The few explorers for copaiba who have visited this place call it the "Infernito" (little hell). Among other things, it is stated that from one only of these streams of petroleum was filled in one minute a receptacle of the capacity of four gallons. This represents 240 gallons in an hour, or 5760 gallons in 24 hours; and even if this calculation be somewhat exaggerated, the fact remains that such a considerable number of petroleum jets in constant active operation must produce daily an enormous quantity. This petroleum is of excellent quality, with a density of 83°, which is a sufficient grade for foreign markets. Considering the immense amount of inflammable gases which must be given out by the flows and deposits of petroleum as described above, it may be easily believed that this has a direct bearing upon the phenomenon known since the conquest as the Faro of Maracaibo. This, consisting of constant lightning without explosion, may be observed towards the south from the bar at the entrance to the lake, and Coddazzi in his geography explains it as being caused by the vapours arising from the hot water swamp situated about one league to the east of the mouth of the Escalante, at the southern extremity of the lake. Near the mountains, and not far from the River Torondoy, there are various flows of a substance which seems to be distinct from either asphalt or petroleum. It is a liquid of a black colour, with little density, and strongly impregnated with carbonic acid, and is almost identical with a substance met with in the United States among the great anthracite fields.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 2.—"On the Spectrum, Visible and Photographic, of the Great Nebula in Orion." By William Huggins, D.C.L., LL.D., F.R.S., and Mrs. Huggins.[1]

It might be suggested that the want of coincidence observed between the nebular line and the magnesium band, amounting to λ 0001·9 nearly, might be due to a motion of translation of the nebula towards the earth. The motion required to produce this shift of position is about sixty-seven miles in a second. [The earth's motion at the time of comparison with magnesium band may be taken at nearly seventeen miles in a second of recession from the nebula. This motion would bring the nebular line nearer the red, and diminish the apparent interval between that line and the termination of the band. If the nebula has a motion of approach, the earth's motion would bring the line back again, to an extent corresponding to about seventeen miles in a second, towards its true plane.—*May* 18.]

I showed in my paper on this subject in 1874 (Roy. Soc. Proc., vol. xxii. p. 253), that, in the case of the Orion nebula and six other gaseous nebulæ—namely, 4234, 4373, 4390, 4447, 4510, 4964, of Sir J. Herschel's "General Catalogue of Nebulæ"—"in no instance was any change of relative position of the nebular line and the lead line detected." We should have to resort, therefore, to the overwhelmingly improbable supposition that all seven nebulæ were approaching the earth with velocities such that, having respect to the earth's motion at the different times of observation, they all gave a sensible shift corresponding to 67 ± 15 miles in a second.[1] There is little doubt in my mind, therefore, from these comparisons, which, considering the strong evidence we possessed before of the relative positions of the nebular line and of the magnesium line, are, strictly speaking, supplementary and confirmatory evidence only, that this line of the gaseous nebulæ is not produced by "the remnant of the magnesium fluting."

In the diagram on p. 134 (Roy. Soc. Proc., vol. xliii.), Mr. Lockyer represents this nebular line followed by fine lines, which give it the appearance of a fluting similar to that of the magnesium band placed above. I am unable to find in the paper any authority for this representation of the line. In another place (Programme Royal Society *Soirée*, May 9, 1888, p. 12) Mr. Lockyer says: "On one occasion, at Greenwich, it was recorded as a fluting in the spectrum of the nebula in Orion." Mr. Maunder's words are ("Greenwich Spectroscopic Results," 1884, p. 5): "None of the lines (with two-prism train) are very sharp. λ 5005 showed a faint fringe mainly on the side nearer the blue."

Mr. Maunder has recently sent a note to the Royal Astronomical Society, in which he explains that the observation was made with a second half-prism added to the half-prism spectroscope. He says:—"The three principal lines of the nebular spectrum were seen as very narrow bright lines, but none of them were perfectly sharp, each showed a slight raggedness at both edges; but in the case of the line near λ 5005 it was clear that this fringe, or raggedness, was more developed towards the blue than towards the red. In the case of the other two lines, they were not bright enough for it to be possible to ascertain whether the fringes were symmetrical or not. But λ 5005 was clearly a single line. There was no trace of any bright line, or series of bright lines, close to it on either side; no trace of a fluting, properly so called. The entire line, fringes and all, was only a fraction of a tenth-metre in total breadth" (*Monthly Notices R.A.S.*, vol. xlix., 1889, p. 308). [It should be noticed that, with the instrumental conditions under which Mr. Maunder observed, the second and third lines were not sharp, but also showed fringes.—*May* 18.]

My own observations of this line, since my discovery of it in 1864, with different spectroscopes up to a dispersion equal to eight prisms of 60°, show the line to become narrow as the slit is made narrow, and to be sharply and perfectly defined at both edges.

[1] Continued from p. 407.

[1] [The following observations of Orion for motion in the line of sight have been made at Greenwich:—

1884. February 15—About thirty-one miles approach. Note, *measures purely tentative.*
February 18—About fifty-one miles approach. Note, *the measures are not trustworthy.*
March 10.—*Direct comparison.* With neither one nor two prisms, after very careful direct comparison, could any displacement be detected; the coincidence of the two spectra was evidently very close.
March 12.—*Direct comparison.* . . . Direct comparison with one prism-train showed coincidence as complete as could be detected, considering the faintness of the two spectra. . . . No part of the nebula showed any marked displacement, but at a point a little preceding the Trapezium the pointer did not seem perfectly central on the line, but a little (perhaps one-tenth, certainly not more) towards the red.

1887. October 25.—Six measures, three of which show approach, and the other three recession. Note, lines in nebula faint, and bisections very rough.

In a letter dated May 17. Mr. Maunder permits me to state that the measures and estimations made in 1884 and 1887 are of no weight, but that he considers the *comparisons* in March 1884 to be as satisfactory as possible with so faint an object, and to show that the nebula has very little, if any, sensible motion in the line of sight.—*May* 18.]

As some importance attaches to the precise character of this line, I wrote to Prof. H. C. Vogel for permission to quote the result of his experience, which has been nearly as long as my own, of the character of this line. He says in his reply, dated March 20, 1889: "Beeile ich mich Ihnen mitzutheilen, dass meine langjährigen Beobachtungen über die Spectra der Gas-Nebel *vollkommen* mit den Ihrigen darin übereinstimmen, dass die Nebellinie λ 5004 schmal, scharf und nicht verwachsen ist. Auch D'Arrest hat in seiner Untersuchung über die Nebel-Spectra (Kopenhagen, 1872) nicht erwähnt dass die hellste Nebellinie unscharf sei."

Dr. Copeland permits me to quote the following sentences of a letter dated March 19, 1889:—"Respecting the appearance of the line λ 5004 in the spectrum of the Orion nebula, I may say that I have always drawn and seen it quite sharp and well defined on both edges. About nine years ago I made a special effort to divide it, if possible, with a large spectroscope in which the viewing telescope was 3 inches in aperture. The lines were then seen as sketched." (The diagram shows the nebular lines with sharply ruled lines for edges.) "They were drawn by holding the note-book 10 inches from the left eye, in such a position that the image seen in the instrument with the right eye was apparently projected on the paper. If I had noticed any peculiarity about λ 5004, it would certainly have been noted."[1]

In an early observation of the dumb-bell nebula Prof. Vogel, indeed ("Beobachtungen zu Bothkamp," p. 59, 1872), describes this line as less defined towards the violet side. In a letter (April 3, 1889) Prof. Vogel says this appearance of the line was probably due to a slit not sufficiently narrow. He says that he re-examined this line in his observations with the great Vienna refractor, and that it did not then appear otherwise than defined and narrow.

The other line in the spectrum of the nebulæ upon which Mr. Lockyer mainly relies for the presence of magnesium is the line shown in my photographic spectrum of 1882 (Roy. Soc. Proc., vol. xxxiii. p. 425), and to which I assigned the wave-length of about 3730. Mr. Lockyer says of this line (Roy. Soc. Proc., vol. xliii. 1887, p. 122): "In the bunsen as ordinarily employed the fluting at 500 far eclipses the other parts of the spectrum in brilliancy, and at this temperature, as already observed by Messrs. Liveing and Dewar, the ultra-violet line visible is that at 373." Passing by a minor point, which Liveing and Dewar have already pointed out (Roy. Soc. Proc., vol. xliv., 1888, p. 244), namely, that their observation was made at the higher temperature of burning magnesium, this statement is insufficiently complete, for what occurs at this part of the spectrum, and is characteristic of the magnesium-flame spectrum, is a triplet, of which the line given by Liveing and Dewar at about 3730 is the least refrangible member only.

I have given a representation of this triplet at the wave-lengths given by Liveing and Dewar, namely λ 3730, 3724, and 3720. In the photograph of 1888, in which the strong line can be seen distinct from the lines near it, the line is found to be very near the middle line of the triplet. I have therefore assigned to this line the position of about λ 3724. This line appears pretty strong, and therefore if it were really one of the lines of the triplet, the other two members of the triplet should have appeared on the plate. On one side of the star-spectra this line is a little broader than on the other side, but as a similar appearance is presented by G, and the stronger of the lines of the group, it may arise from some optical or photographic cause. The line at 3724 impresses me strongly as a single line, and there is certainly no trace of the first line of the triplet at 3730. The line appears to me stronger where it is upon the star-spectra.

As therefore there is little doubt that the "remnant of the fluting at 500, which far eclipses the other parts of the spectrum in brilliancy," is not coincident with the brightest nebular line, and the next most characteristic group of this spectrum, the triplet at 3722, 3724, and 3730, according to Liveing and Dewar, does not appear to be present in the photographs, we may conclude that the remarkable spectrum of the gaseous nebulæ has not been produced by burning magnesium.[1]

I should mention that Mr. Lockyer attributes one other line occasionally seen in the gaseous nebulæ to the flame spectrum of magnesium—namely, a very faint line at about λ 4700. Now, according to my experience, it is only in the spark and arc that a line of magnesium appears at this place, a condition of the spectrum when the lines at *b* are very conspicuous, and the band at λ 5006·5 is usually absent. When, however, the spark is taken in magnesium chloride, the band is present under some conditions, but the triplet at *b* is always bright. I therefore consulted Prof. Liveing, who says:—"I have never seen the line at λ 4703 in the spectrum of the magnesium flame. As it is a conspicuous line in the arc and spark, we looked for it in the flame, but did not find it."

With reference to the second nebular line at λ 4957, Mr. Lockyer says (Roy. Soc. Proc., vol. xliii. p. 133): "The lines at 500 and 495 have been seen in the glow of the Dhurmsala meteorite when heated, but the origin of 495 has not yet been determined." And further (at p. 135): "I should add that the line at 495 makes its appearance much more rarely than the one at 500 in meteorite glows." In the diagram on the same page this line is represented as coincident with the nebular line.

The circumstance of a line appearing at 495 can scarcely be regarded, considering the very great number of spectral lines, as amounting to a presumption that the material to which it is due in the meteorite is the same as that present in the nebulæ which gives the line at 4957. If it should be shown that the unknown substance in the meteorite gives rise to a line at the position of the nebular line—namely, λ 4957—in that case the observation would have sufficient importance to make it desirable to compare the spectrum of the meteorite directly with that of the nebula.

[1] Mr. Taylor, late of the South Kensington Laboratories, observing at Sir Henry Thompson's observatory in November 1888, says:—"The 5001 line is by far the brightest in the spectrum. It is never seen sharp, but with the narrowest slit always has a fluffy appearance, this being much more marked on the blue than on the red edge. This line was most carefully examined for evidence of structure, but was always found to be single, and no decided evidence of fluting structure could be made out. It may be that greater dispersion may show structure, but with the dispersion used here no structure could be seen."—*Monthly Notices R.A.S.*, vol. xlix. p. 125.

[1] On the narrower basis of the magnesium spectrum only, Profs. Liveing and Dewar point out that "the appearance of a line in the position of the first band without any trace of the second band, which is nearly as bright as the first, and without any trace of the *b* group, is quite sufficient to create a suspicion of mistaken identity when Mr. Lockyer ascribes the sharp green line in the spectrum of nebulæ to this band of magnesia. This suspicion will be strengthened when it is noticed that the line in question is usually in nebulæ associated with the F line of hydrogen, if it be borne in mind

Chemical Significance of the Lines.

Until I can obtain more photographs taken on different parts of the nebula, I wish to be understood to speak on this point with much hesitation, and provisionally only. We know certainly that two of the lines are produced by hydrogen. The fineness of these lines points to a high temperature and condition of great tenuity of the hydrogen from which the light was emitted. This condition of the hydrogen may give us a clue as to the probable interpretation of the other lines. These may come from substances of very low vapour-density, and under molecular conditions which are consistent with a high temperature. It is in accordance with this view that the recent measures of Dr. Copeland, since confirmed by Mr. Taylor (*loc. cit.*), show with great probability that the line known as D_3, which has been supposed to indicate some substance of low vapour-density, which shows itself only at the hottest region of the sun, is present in the nebular spectrum. The great simplicity of the three pairs of lines seen in the photograph of 1889 suggests a substance of a similar chemical nature.

If hydrogen can exist at half its usual vapour-density, with a molecule of one atom only, we might possibly expect to find it in some of these bodies, but at present we do not know what its spectrum would be in such a condition. It may be possibly that it is in molecular states of our elements other than those we are acquainted with that we may have to look for an interpretation of some of the lines of these bodies.

[With respect to the groups of lines which cross the star spectra, any statements must also be provisional only.

These lines are distinct and fairly strong in the star spectra, and do extend, some farther than others, into the adjoining nebular matter. Whether they are peculiar to these particular stars and the matter close about them, or whether they will be found everywhere in the nebula, or in certain parts of greater condensation only, can be known only from future photographs.

The first group shows some general agreements with a strong iron group, but there are also formidable discrepancies.

The position of the third group suggested the well-known cyanogen group, especially as this group, beginning at λ 3883, is the first to appear under the chemical conditions which might have been conceived to exist under circumstances of condensation (see Liveing and Dewar, Roy. Soc. Proc., vol. xxxiv., 1883, p. 128). Under these conditions this group appears alone in a photograph, without the less refrangible group, as was probably the case in the photograph I took of Comet II., 1881. I therefore took a photograph of an oxy-coal-gas flame, the coal-gas having passed through ammonia, and a magnesium-flame spectrum on the same plate for comparison.

On comparing this photograph with that of the nebula it was seen by eye, and afterwards confirmed by measurement, that the nebula group begins sooner by one strong line than the cyanogen group, and presents besides in the relative strength and grouping of the lines a distinctly different character. The evidence appears to me to be against attributing these lines to cyanogen.

I took great pains to ascertain if the group of lines which accompanies the triplet of the magnesium-flame spectrum could be made to agree with the much longer group of lines in the nebula at this part of the spectrum. Again, as in the case of the cyanogen group, the whole aspect of the grouping of lines is quite different. The groups begin and end differently, and the relative strength of different parts of the group is not the same. The great increase of strength which is seen in the middle of the magnesium group is not present at the corresponding part of the nebula group. I do not think therefore there should be much weight given to the near positions of several individual lines of the two groups, which in the case of so close a grouping might well be accidental, especially as the wave-lengths can be but approximate only. (The strongest lines of the magnesium-flame group are those forming the triplet which appears also in the spark and the arc. A nebular line is near the middle line of the triplet, but there are no lines corresponding to the other lines of the triplet. The other lines of the flame group are too faint to be expected to appear, unless the triplet at 3720—3730 were strong upon the plate.—*May* 18.)

The three pairs of lines in the photograph of 1889, which are doubtless rhythmically connected, appear to me to possess great interest, especially if it should come to be found from future photographs that these groups are characteristic of the most tenuous part of the nebula. At present, I am not able to make any suggestion as to their chemical origin, but the suggestion presents itself that we may have to do with some molecule of very low vapour density.

The pair of lines on the more refrangible side of the line at λ 3724, may possibly be connected with the state of the nebula as it exists in the neighbourhood of the stars.—*April* 26.]

that the spark of magnesium in hydrogen does not give the bands, and that the oxyhydrogen flame hardly produces them from magnesia when the hydrogen is in excess" (Roy. Soc. Proc., vol. xliv. p. 245). Mr. Taylor records a brightening of the continuous spectrum of the nebula at λ 5200, which he suggests may be magnesium. But this position is twenty-five units from that of the middle of the magnesium triplet at *b* (*Monthly Notices R.A.S.*, vol. xlix p 125).

General Conclusions.

It seems to me premature until we can learn more of the significance of the new groups of lines, and especially of their connection with the nebular matter generally, or with certain condensed parts only, to express more than provisional suggestions as to the nature of these nebulæ. It may be that they represent an early stage in the evolutionary changes of the heavenly bodies.

As some physical importance, in the relation of these nebulæ to each other, has been given to my inability, in consequence of insufficient optical means in my original observations in 1864, to see all three of the bright lines in some faint nebulæ, I may mention that in the case of one object, the Ring Nebula in Lyra, in which at that time the light appeared monochromatic, as only the brightest line could be certainly seen, as soon as larger means were placed at my disposal by the loan of the Royal Society telescope in 1870, I had no difficulty in seeing all three lines on any night of sufficient clearness. There is little doubt that the same cause prevented me from seeing more than the brightest line in Nebula 4572 of Herschel's "General Catalogue." Vogel saw two lines ("Beobachtungen zu Bothkamp," 1872, p. 59).

These bodies may stand at or near the beginning of the evolutionary cycle, so far as we can know it. They consist probably of gas at a high temperature and very tenuous, where chemical dissociation exists, and the constituents of the mass, doubtless, are arranged in the order of vapour-density. As to the conditions which may have been anterior to this state of things, the spectroscope is silent. We are free, so far as the spectroscope can inform us, to adopt the hypothesis which other considerations may make most probable. On Dr. Croll's form of the impact theory of stellar evolution, which begins by assuming the existence of stellar masses in motion, and considers all subsequent evolutional stages to be due to the energy of this motion converted into heat by the collision of two such bodies, these nebulæ would represent the second stage in which these existing solid bodies had been converted into a gas of a very high temperature. They would take the same place, if we assume with Sir William Thomson (Roy. Instit. Proc., vol. xii. p. 15) the coming together of two or more cool solid masses by the velocity due to their mutual gravitation alone.

I pointed out in 1864 (Phil. Trans., 1864) that the gaseous nature of these bodies would afford an explanation of the appearance of flat disks without condensation which many of them present. The light emitted by the portions of the gas further from us would be in part or wholly absorbed by the gas through which it would have to pass, in this way giving to us the appearance of a luminous surface only.

In some of these bodies there is also a very faint continuous spectrum, which if we had more light might be found to consist, in great part at least, of closely adjacent bright lines. Such is probably the nature, in part, of the apparently continuous spectrum of the nebula with which this paper deals chiefly, the Great Nebula in Orion.

In other gaseous nebulæ strong condensations are seen, and a stronger "continuous" spectrum. When we come to nebulæ of which the nebula in Andromeda may be taken as representative, the strong bright-line spectrum is absent, and we have what for convenience I called, in my original observations of these bodies, a "continuous" spectrum, though I was careful to point out that it was probably "crossed by bright or dark lines."

Out of about sixty nebulæ and close clusters observed by me up to 1866, I found a proportion of about one-third—namely, nineteen—to present the spectrum of bright lines (Phil. Trans., 1866, p. 383).

The stage of evolution which the nebula in Andromeda represents is no longer a matter of hypothesis. The splendid photograph recently taken by Mr. Roberts of this nebula shows a planetary system at a somewhat advanced stage of evolution; already several planets have been thrown off, and the central gaseous mass has condensed to a moderate size as compared with the dimensions it must have possessed before any planets had been formed.

SYDNEY.

Royal Society of New South Wales, July 3.—Prof. Liversidge, F.R.S., President in the chair.—The Chairman announced that Mr. C. S. Wilkinson, the Government Geologist, had kindly consented to deliver (gratuitously) a course of (three) lectures in connection with the Clarke Memorial, commencing in October or November next.—The following papers were read:—Notes on the high tide of June 15–17, 1889, by John Tebbutt; and on the marine and fresh-water Invertebrates of Port Jackson and the neighbourhood, by Thomas Whitelegge. At the conclusion of the latter paper the President presented the Society's bronze medal, which, together with a money prize of £25, had been awarded to Mr. Whitelegge for his paper.—Prof. Anderson Stuart showed a modification of the "kymoscope" which he exhibited at the Society's last monthly meeting. This form demonstrated the phenomena of interference in wave motion—one series of tubes had one wave, a parallel series had the other, and both opened into a common series in which the interference was made visible. The two waves came from pumps which could be so arranged as to vary the amplitude of the waves and to change the position of the straight lines produced when the waves met or "interfered."

PARIS.

Academy of Sciences, August 19.—M. des Cloizeaux, President, in the chair.—Remarks on the conditions under which the fixation of nitrogen is effected in argillaceous soils, by M. Berthelot. Here is described a fresh series of experiments on the fixation of nitrogen in the ground with the co-operation of living organisms, microbes, and more highly organized plants. Replying to a recent communication of M. Schlœsing on the negative results of his studies, M. Berthelot accepts these conclusions, and even claims priority for them, adding, however, that they were given by him as defining the negative conditions of the phenomenon—that is, the conditions under which the fixation of nitrogen does not take place. In a second paper M. Berthelot describes some further researches on the fixation of nitrogen by vegetable humus under the influence of electricity.—Note on the glacial epoch, by M. H. Faye. It is argued that glaciation does not depend on any direct cause, such as a passing obscuration of the sun at the beginning of the Quaternary epoch, but is due to a far more remote cause—that is to say, the appearance of the seasons and of the poles of low temperature at a time when the sun had acquired its definite form and dimensions. A repetition of the great changes that took place during Tertiary times has been prevented by the continually increasing thickness of the terrestrial crust and by the slower rate of progress of the cooling process.—Observations on the sardine frequenting the Mediterranean waters, by M. A. F. Marion. The results are here communicated of the researches made by the author during the fishing season 1888–1889, for the purpose of verifying and completing his previous observations on the migrations and life-history of the sardine periodically visiting the shores of the Mediterranean.—On the total eclipse of August 19, 1887, by M. N. Egoroff. This is a summary of the Russian report on the observations of the eclipse of 1887 made at the seven stations of the Russian Physico-Chemical Society in accordance with the programme prepared by the Special Commission.—Electric figures produced by lightning, by M. Ch. V. Zenger. The curious effects are described of an electric discharge which struck a silvered mirror during a terrific thunderstorm near Prague, on June 9, 1889. The mirror shows over ten points at which the electric fluid penetrated through its gilded frame, volatilizing and transferring the gold to the anterior face of the glass, while on the opposite side the volatilization of the silver coating produced the most beautiful electric figures. These figures show that there occurred repeated and successive discharges, as also indicated by recent photographs of flashes taken with the oscillating camera obscura.—Observation of the occultation of Jupiter and its satellites by the moon, taken at the Observatory of Nice, by M. Perrotin. The hours of the various phases of the occultation that took place on August 7, 1889, are tabulated at mean time at Nice. The satellites are shown to have disappeared, not instantaneously, but gradually during several tenths of a second.—Observations of the new planet discovered at the Observatory of Nice on August 3, 1889, by M. Charlois. The observations are for the period August 3–6, when the planet had the brightness of a star of magnitude 13·5 to 14.—On a new mode of teaching music, based on the periodicity of the octave, by M. Ricard. The author aims at a radical reform in the teaching of music, and expounds his system in a series of fundamental propositions, such as: musical effect is quite different from acoustic effect; there can be no physical gamut, a major and a minor, but one only, that of the white notes of the piano, called the major, and so on.—On contraction in solutions, by M. Charpy. The object of these researches is to determine how the contraction produced in the process of solution varies with its concentration.—On the phosphotungstic acids, by M. E. Péchard. The methods hitherto employed for the preparation of these acids have all been indirect. But the study of metatungstic acid has suggested to M. Péchard the possibility of realizing the direct union of this acid with phosphoric acid. The general method of preparation consists in evaporating, under suitable conditions, a mixture of both acids in determined proportions.—On the passivity of cobalt, by M. Ernest Saint-Edme. It is shown that certain treatises on chemistry are wrong in stating that cobalt in the presence of concentrated nitric acid becomes *passive* like iron and nickel.—On the heat of combustion of some organic compounds (continued), by M. S. Ossipoff. The author's series of determinations is here concluded with teraconic acid, malic anhydride, methyl fumarate, and maleate of methyl.

SIR WILLIAM THOMSON'S POPULAR LECTURES.

Popular Lectures and Addresses. By Sir William Thomson, LL.D., F.R.S., F.R.S.E., &c. In Three Volumes. Vol. I. Constitution of Matter. With Illustrations. ("Nature Series.") Pp. xi. + 460. (London: Macmillan and Co., 1889)

TO review a book by the leader of British physical science in the ordinary sense of reviewing would be absurd. To attempt an estimate of merit and demerit or to offer a superficial criticism might easily become an impertinence.

The object of a review in such a case as this is mainly to give persons who have not concentrated their attention on physics some idea of the nature of the book, so as to enable them to form a judgment how far it is suitable and accessible to them.

For, inasmuch as the greater part of what is published by the author of this book is stiff reading for trained physicists and mathematicians, and inasmuch also as the subjects of which he treats even in popular lectures are usually extremely abstruse, and such as require, if they are to be accurately stated at all, a very carefully-selected form of words and a rather involved construction of sentences, the idea may easily grow that anything by Sir William Thomson is mainly unintelligible. And unintelligible it probably is to the general public in their after-dinner arm-chairs. Unintelligible it quite possibly was to a large percentage of the audience in their after-dinner seats at the Royal Institution, though the personality of the man and the magnetism of his enthusiasm could hardly fail to enchain the attention of the most cynical or casual hearer.

In the printed book this personal charm is fainter; it is not absent—to those who have ever heard him the manner in which the illustrations are brought forward, the very tone of voice with which the sentences were delivered, are continually suggesting themselves—but it is fainter; and it becomes a question how far these lectures, which are undoubtedly scientific, are really popular, *i.e.* are really adapted to intelligent persons interested generally in the subject but who make no claim to be specialists in it. To answer this question I will run through the contents in such order as may be convenient.

About the middle of the book there is a quite popular and easy essay on the sense-organs of man, including that most important and fundamental sense—the sense of muscular exertion—without which it is doubtful if we should be conscious of an external world at all, insisting on a distinct sense of heat, and lumping together taste and smell; an essay in which certain much-needed clarifying statements are made to counteract some confusions introduced by more than one very popular book, as, for instance, the familiar difficulty about the relationship between light and radiant heat.

Next comes a lecture on the wave theory of light, delivered in America, giving to anyone who has attended a course of lectures or read some popular treatise on light a very good general notion of what is meant by the elastic-solid theory of the ether, and of the way in which the difficulties introduced by supposing light to consist of ordinary mechanical transverse vibrations of an elastic medium have to be met.

Then follows a perfectly beautiful series of discourses or articles on the age of the sun's heat, which, looked at from the point of view of the general reader, perhaps form the gem of the whole.

The cool collected way in which a possible and more or less probable way of forming our sun is gone into, with every detail clear-cut and closely reasoned out, forms a study than which nothing more instructive, more suggestive, and more wildly interesting is likely to be accessible with equal ease to the imaginative reader.

A sustained power of attention, a period free from interruption, and a power of forming vivid conceptions, are all that is needed for a comparatively uninstructed reader to receive some of the most splendid cosmical speculations of our time. He may not know exactly why when the two earth-like bodies start to rush together it is stated that they will meet in six months, or that the collision will last half an hour, and perhaps he may find some difficulty in picturing the equatorial zone or disk and the axial rod between which forms the mass will subsequently oscillate till it settles down into a globular and white-hot sun; but he may rest assured that none of these statements nor any such numerical statements met with in this book are random ones; they are all the result of exact mechanical knowledge and arithmetic, and whether they be precisely true or not, they are, at all events, righter than anything else he is likely to come across.

Irrespective of that on which stress is laid in the title, viz. the *age* of the sun's heat, we have in these essays a popular and very clear exposition of the solution of that long-standing puzzle—the means by which solar heat is maintained.

With lumps of matter of ordinary size (*i.e.* not incomparably greater or less than the human body) gravitation is a force altogether insignificant in comparison with chemical affinity, and accordingly while the combustion of a lump of coal transforms great quantities of energy, the force of gravitative attraction between two such lumps or between one lump and the oxygen it can combine with is so minute as to require a Cavendish and a Boys to demonstrate its existence to an audience. But with lumps of matter of sizes such as are found in the depths of space the case is quite otherwise. Between them gravitative attraction is furiously greater than any known kind of chemical affinity; and the work such masses can do in falling together, nay even the work one lump can do in slowly contracting upon itself, is sufficient to maintain radiation at the sun's prodigious rate.

Take a large enough mass of gas (*i.e.* of detached atoms), let its parts gravitate together continually, and you have a sun—a sun, moreover, obeying simple mechanical laws, and with a life-period, in its molten and therefore uncrusted and radiative state, of roughly calculable length.

It may be worth while parenthetically to remark that, whereas the chemical (or electrical) attraction between two atoms at any distance exceeds their gravitative attraction at the same distance more than a thousand million billion billion times, the atoms being regarded as spheres oppositely electrified each to about the potential of a volt, the gravitative attraction between two worlds the size and density of our earth exceeds their electrical attraction when likewise oppositely charged each to a volt in just about the same ratio. The ratio of the forces depends, in fact, on the fourth power of the linear dimensions of the bodies concerned—other things being fixed. For a couple of small bullets the two forces would be approximately equal.

Again, if every atom be regarded as separately charged, and able to combine with each other, we get the maximum possible energy of combustion, which may be put down as at the most 20,000 therms per gramme. The heat of formation of our moon by combustion is on this estimate very comparable to that developed by the falling together of its materials from infinity under gravitation. But whereas the energy of combustion is simply proportional to the masses concerned, the energy of gravitation is proportional to the product, *i.e.* to the second power of the masses; and so we find that when a body is as big as the sun the gravitative energy of its mere earthquake subsidence as it shrinks is enormously greater than that which could be afforded by the combustion of an equal mass. So also it is shown to be greater than could be caused by any reasonably permissible hail of meteorites from infinity: meaning by "reasonably permissible," such a hail as would not introduce planetary perturbations of a conspicuously non-existent amount.

Returning now to the beginning of the volume, we find an altogether admirable, but rather stiff discourse on capillarity. How it can help being stiff when it enters into problems usually treated by the higher mathematics, and hitherto reserved for specialists, I do not know. It is a serious mathematical essay done into ordinary language. The diagrams of the precise shape of liquid surfaces are beautiful, and such as are nowhere else to be found. To a reader who will concentrate his thought upon this discourse, it will gradually become luminously clear, but perhaps the conscientious person who always reads books from cover to cover, may run the risk of being choked off by the accident of its coming first.

Appended to it are three notes, one on the "tears of strong wine," as explained by Prof. James Thomson; one on the author's remarkable and beautiful discovery of the reasons why mist globules cannot form without a nucleus, why big rain-drops form at the expense of little ones, and why put-away clothes get damp; and lastly, a note on the sufficiency of Newtonian gravitation to explain cohesion. This latter is a highly ingenious piece of special pleading. It is so easy to prove that gravitation will *not* explain cohesion, on any of the commonly current mental ideas of what atoms are like; but here, by assuming a sufficiently violent concentration of substance in certain regions, and sufficient absence of all substance from other regions of an atom, it is shown that cohesion *may* be explained by gravitation. At least, it can be seen that different atoms can cling to each other, but it is not so clear how the various parts of the atoms themselves hang together. No-how, it seems to me, unless they are exaggeratedly fibrous structures, and unless the ends of the fibres of one atom cling on to the next, and thus build up a body like a cobweb. Nothing but cobweb can cohere by gravitation, so it seems to me (perhaps wrongly, of course); and although one has gradually learnt that no hypothesis concerning reality is *a priori* absurd or unlikely, yet this does not feel, nor indeed is it intended, as anything final or satisfactory.

Then comes a long lecture on electrical units of measurement, wherein the foundations of the conventional "absolute" systems of electrical measurement are explained and illustrated by showing how by means of electrical observations the fundamental standards of length, mass, and time might, if lost, be conceivably recovered. The subject is rather technical, and scarcely of sufficient general interest to repay the unelectrical reader, though there are here, as everywhere, numerous suggestive remarks. One might, perhaps, suggest that the distinction between the conventional and the essential is not always sufficiently borne in mind and enforced.

The lecture on the size of atoms is intensely interesting to everybody. Physicists know by how many different lines of argument a limit of smallness for the space occupied by an atom can be fixed, or an actual estimate of the number of molecules in a given lump of matter can be made. A number of these methods suggested by the author are here stated, and, with many illustrations, explained. But, besides this, there are instructive mechanical models or images illustrating Prof. Stokes's theory of phosphorescence, Cauchy's theory of dispersion, and the polarization of light by small particles.

The remaining subjects dealt with in this volume—elasticity regarded as a mode of motion, and a kinetic theory of matter—are closely related to each other, are wholly the author's own, and are among the most brilliant speculations of the century. But a small inkling of the great field thus opened up is given here—enough, however to afford to the reader some glimpse of the possibilities of development lying in this direction.

Such are the contents of the volume before us, and a more comprehensive collection of scientific addresses has seldom been published. They do not, of course, really represent Sir William Thomson at his best: neither they nor any other intelligible production of his is able to convey to the general reader an adequate notion of the magnitude of his solid work, or of the grounds for the veneration with which his contemporaries regard him.

Such as they are, however, every physicist will be glad to read these papers again in this handy form, and every intelligent and educated man who feels an interest in the strong thought of physical science during this eventful century will do well to make a serious effort to grasp at least the main outlines of the profound studies shadowed forth in this small volume. OLIVER J. LODGE.

THE MATHEMATICAL THEORY OF POLITICAL ECONOMY.

Éléments d'Économie Politique Pure. Par Léon Walras. (Lausanne: F. Rouge, 1889.)

THE appearance of a new and enlarged edition affords us a wished-for opportunity of calling attention to this original work. Its author is one of the favoured few to whom belongs the honour of having made a discovery in political economy. The title of Ricardo to the theory of rent is not better than the title of Prof. Walras to a theory more comprehensive than that of rent. It is a claim founded on originality rather than priority. Prof. Walras is the last of a small band of original thinkers who, in the latter half of this century, have independently excogitated the cardinal article in the doctrine of value. They have contemplated in different aspects the same fundamental conception: that value in exchange is neither simply identical with, nor wholly different from, value in use, but corresponds to the utility of the last, the least useful, portion of the commodities exchanged. "Nutzlichkeit des letzten Mengentheilchens," "Degree of Final Utility," "Grenznutzen," and "Rareté"—in different tongues and various terminology they proclaim the one essential truth which will be for ever associated with the names of Gossen, Jevons, Menger, and Walras.

This chronological, and, as it happens, alphabetical, arrangement is not identical with the order of merit. In that order we should place nearest together the names which are first and last in the series above written. Gossen appears to have been a mere specialist with few valuable ideas beyond the one which has made him immortal. Prof. Walras's light is more diffused. Yet it is true that we find in him rather *multum* than *multa;* that his principal achievement is the copious exposition of the one fundamental theorem to which we have referred. His next most important contribution to the stock of economic ideas relates to the function of the *entrepreneur*. Prof. Walras is one of the first who correctly conceived the *entrepreneur* as buying agencies of production (use of land, labour, and capital), and selling finished products in four markets, which thus become interdependent. His criticisms of the English school on this head are often valuable. Of the *entrepreneur's* funds, not pre-determined in the sense which some have imagined to any particular form of outlay, he well says:—

"Il serait aussi impossible de distinguer ce fonds de roulement du travail du fonds de roulement de la rente foncière, ou du fonds de roulement du profit, que de distinguer dans un bassin à trois robinets l'eau destinée à s'écouler par un robinet de celle destinée a s'écouler par les deux autres."

But surely he goes too far in the way of abstraction when he insists that the ideal *entrepreneur* should be regarded as "making neither gain nor loss":—

"Pour ce qui est de la part du profit constituant le bénéfice de l'entrepreneur l'école anglaise ne sort pas qu'elle est alcatoire, qu'elle dépend des circonstances exceptionelles, et non pas normales, et que, théoriquement, elle doit être négligée."

Perhaps his views on this and other points would have been more exact if he had considered the part which the "disutility" of labour—to use Jevons's phrase—plays as a factor of economic equilibrium, instead of confining his attention to "final utility." Another theory to which we ought to call attention is contained in the lesson on capitalization, which is added in the new edition. If the price of capital is determined by competition, it follows from the general theory of supply and demand that the maximum utility of all the parties concerned is realized in the same sense as in other markets. What is more than this in the newly-added theory has baffled us.

In the case just noticed and others, the argument is probably rendered obscure, or at least unattractive, by the use of symbols in excess of the modest requirements of elementary mathematical reasoning. The exuberance of algebraic foliage, rather than the fruit of economic truth, is the outcome of science thus cultivated. It is remarkable that the neatness which characterizes Prof. Walras's literary style, should not be reflected in his mathematical compositions. As an algebraist he has not attended to the maxim, *Il ne faut pas épuiser les choses.* We shall justify our criticism by referring to the chapters or "lessons," in which it is attempted to analyze what is called the "*tâtonnement*" of the market. The writer gives us three courses of this analysis. He diffuses over some thirty-five pages an idea which might have been adequately presented in a few paragraphs. For it is, after all, not a very good idea. What the author professes to demonstrate is the course which the higgling of the market takes—the path, as it were, by which the economic system works down to equilibrium. Now, as Jevons points out, the equations of exchange are of a statical, not a dynamical, character. They define a position of equilibrium, but they afford no information as to the path by which that point is reached. Prof. Walras's laboured lessons indicate *a* way, not *the* way, of descent to equilibrium. This is not the only topic with respect to which the laboriousness of the investigation is out of proportion to its importance.

Agreeing, therefore, in the main with Prof. Walras in his plea for the use of mathematical reasoning in economics, we fear that he may have prejudiced the cause by his advocacy. The excessive elaboration of his reasoning, compared with the simplicity of his conclusions, is calculated to excite suspicion. Moreover, he traduces the mathematical method when he applies it in such a manner as to justify the popular prejudice against abstract reasoning. He is surely *ultra crepidam*, he goes beyond the little hard matter with which the craft of the mathematician is concerned, when he offers opinions on the living organism of the industrial body, and the complexion of practical problems. His scheme of dosing the circulation by a nicely calculated injection of supplementary currency reminds us of the tailors in Swift's Laputa, who went through laborious mathematical computations in order to determine the measurements of a suit of clothes, which after all fitted very ill. When Prof. Walras offers us "the solution of the Anglo-Indian monetary problem," we think of Fluellen in the heat of the battle discoursing about the "discipline of the wars." There is a discipline adapted to the schools, and which it is profitable to have studied, but which has no direct bearing upon action.

A minor ground of complaint is formed by the extreme severity of our author's criticism, especially those which relate to the English school. We cannot think that Mill's oversights deserve the "*horribili flagello*" which is administered. To dismiss in a few lines "comme nul et non avenu" so much of that philosopher's reasoning appears to us rather slashing. But we are sensible that in condemning the unceremonious treatment of great men, we are laying down a law which applies to our own criticism of Prof. Walras. We shall therefore forbear to reduce our initial encomium by invidious reservations. When all that could be made are summed and subtracted, there would still remain to Prof. Walras the undoubted glory of an original discovery. He may say of that, as Napoleon of his victories, "*Il y a là du solide que la dent de l'envie ne peut ronger.*" F. Y. E.

MUSICAL INSTRUMENTS AND THEIR HOMES.

Musical Instruments and their Homes. By Mary E. Brown and W. Adams Brown. (New York: Dodd, Mead, and Co., 1888.)

THIS work should prove very useful to all who are interested in music and musical instruments. Primarily it professes to be a catalogue of the collection of musical instruments made by Mrs. J. Crosby Brown, of New York; but its value has been greatly augmented by a series of essays on the music and musical instruments of Oriental and savage races. The "catalogue" portion is well illustrated with clever pen-and-ink sketches, which give, for the most part, an excellent idea of the instruments, though they do not exhibit a great amount of detail. A brief description with dimensions, and, where possible, the native name, accompanies each sketch. The catalogue is divided into geographical sections, and at the end of each is added an essay treating of the music of the country from an historical and theoretical point of view, with a general account of the native instruments. Though these essays contain little that is new or original, they nevertheless form extremely useful compilations from a large amount of scattered literature; the references are full, and the list of authorities is a very representative one.

The sections devoted to China and India are of special interest, as dealing with regions which were the birthplaces of so many of the instruments in use amongst ourselves, changed though these be from their original forms. There seems little doubt, for example, that we owe the harmonium to China, and that instruments played upon with a bow had their original home in India, whither, too, we must refer the original use of "sympathetic strings."

Musical instruments, like all other products of man's handiwork, are subject to the laws of evolution, and each arrived at its present state by gradual stages of improvement. If the genealogies could be all followed back to the earliest stages, all instruments could be referred to such simple original forms as, for example, hollow or solid logs, reeds, or hunters' bows. With the rapid disappearance of the more primitive native instruments, the difficulty of tracing the history of music backwards by means of primitive "survivals" increases year by year. Every effort should be made to collect and place on record these simple forms, as from these we greatly derive our ideas of the "dawn" of music. The magnificent work by Hipkins and Gibb furnishes us with beautiful illustrations of *beautiful* instruments, but does not deal with the humbler kinds. The illustrations in the present work, therefore, are especially valuable, as the primitive instruments receive equal attention with the more elaborate. A very common error has crept into the pages of this otherwise excellent work—in the terminology. Nothing is more distinct than instruments of the "oboe" type and those of the "clarionet" type are from each other. These, though somewhat similar in general aspect, belong to different classes—the "double-reed" and the "single-reed" classes respectively; and any relationship must date back to the time when they each probably took their origin from a section of corn-stalk, the one form being sounded through the *pinched* end of the stalk, and the other through a *slit* cut in the end, and forming a *vibrating* or *beating* tongue. We find, however, in several passages a confusion of these terms. Thus, the Corean, Greek, and Spanish "clarionets," so called, are evidently "oboes," with double reeds for mouth-pieces. Similarly, the "pandeiro" of Madeira, not having a tense membrane, cannot be a "tambourine," however much it looks like one. The "mogugyo," or "wooden fish," of Corea and China, is called a "drum" in one passage (p. 80). But a "drum," too, *must* have a tense membrane, and an instrument ceases to be one if lacking this addition. The "mogugyo" is really far more closely allied to the "bell" series, though there is no general term which expresses this class of wooden instrument. Such mistakes are, doubtless, mere slips, but they are apt to be misleading.

In the description of savage music it is stated (p. 240) that the Mincopies have no musical instruments. This is not quite true, as they have one, though a simple one, and consisting merely of a hard-wood board, of special shape, which is used for sounding a rhythmical time for dancing. It is used only as a musical instrument, and so illustrates a step in advance of the Australian, who taps with a stick upon his "casting-board" for the same purpose, without employing a separate instrument.

It is to be hoped that other collectors will follow the excellent example of the authors of this work, and publish illustrated catalogues of their collections. We can hardly expect many such beautifully produced "catalogues," but the scientific spirit and easy style of this book might well be a model for others.

OUR BOOK SHELF.

Heat. By H. G. Madan, M.A., F.C.S. (London: Rivingtons, 1889.)

THIS is an elementary treatise of exceptional merit, combining thoroughly practical work with sound theoretical conclusions. The course of instruction which it comprises has been found suitable by the author, in his capacity as instructor at Eton College, for boys who already have some acquaintance with physiography and elementary dynamics. Mathematical expressions are accordingly used as little as possible, and, when used at all, they are fully explained in ordinary language.

A very large number of experiments—many of them new—are described, and we have the author's assurance that they are all capable of successful performance with moderate skill and care. It is rightly observed that experiments which do not always succeed, even with the greatest care, are altogether unsuitable for young students, as they invariably tend to make them lose confidence in the science.

Particular attention is given throughout to the application of the general laws of heat to the arts and manufactures, and to the phenomena of every-day life. The subject of ventilation, for example, is very fully discussed and illustrated by experiments. There is also a beautiful experiment illustrating the intermittent action of geysers (p. 195). Perhaps the most important application of the laws of heat, however, is the steam-engine; and most of the various forms, including locomotive and marine engines, are described. Even the gas-engine is briefly referred to.

There are no less than 138 excellent diagrams distributed throughout the text, most of which have been specially prepared for the book.

British Rainfall, 1888. By G. J. Symons, F.R.S. (London: E. Stanford, 1889.)

THIS work is a general summary and epitome of a year's work, and contains a Report upon the progress of rainfall investigations.

The volume is divided into three parts: the first deals with the measurement of snow, experimental gauges, the Camden Square evaporation experiments, and concludes with a list of the staff of observers, showing that the staff is still on the increase, although very slowly, the chief increase being in England.

The second part treats of the rainfall and meteorology for the year, as reported from the various observing stations. One of the heaviest short-period rains recorded is that which fell on March 24 at Chepstow, Shirenewton Hall; it lasted two minutes, and in that time the ground was covered 2 inches deep with snow, the flakes being 3¾ inches in diameter, and only ¼ inch thick, 6 inches of this snow yielding 1 inch of water, so that, if the snow had lasted one hour, it would have reached an average depth of 5 feet.

Maps and tables indicate the monthly rainfall for the year, the greatest fall being at "The Stye," in Cumberland (175·40 inches), the least at Skegness, in Lincolnshire (17·50 inches).

Lastly, Part III. consists of general tables of the total rainfall at the 2500 places of observation.

Putting together all the above facts, we find that during the year there was much dry weather, although few droughts; there were hours and days of excessive rain, months with amounts of rain almost without precedent. Yet, on the whole, we get a result not at all remarkable, but decidedly below the average.

Rainfall observers will find in this book a collection of most interesting tables, maps, and articles upon the various branches of the work; and as the new decade begins with January 1 next year, we hope that the staff of observers will number many of our readers among them.

Ancient Art of the Province of Chiriqui. By W. H. Holmes. (Washington: Government Printing Office, 1888.)

THIS is an extract from the sixth Annual Report of the U.S. Bureau of Ethnology, and will be read with interest by all students of American antiquities. Chiriqui occupies a part of the Isthmus of Panama, and at the present time is inhabited chiefly by Indians and natives of mixed blood. Many ancient cemeteries have been discovered along the Pacific slope of the district, and explorers have found in them a great quantity of more or less valuable objects of art. These objects Mr. Holmes has classified, and in the present monograph he carefully describes the characteristics of typical specimens. He first deals with the graves and their human remains, then passes on to consider, in order, objects in stone, objects in metal, and objects in clay. His descriptions are concise and lucid, and their value is greatly increased by a large number of excellent illustrations. Mr. Holmes is careful to point out that there is no valid reason for assigning a very high antiquity to the works of art found in Chiriqui. The tribes by whom the graves were made may, he thinks, have been in possession of the country, or parts of it, at the time of the conquest. Their pottery appears to indicate that they were more closely related with the ancient Costa Rican peoples than with those of continental South America; but in their burial customs, in the lack of enduring houses and temples, and in their use of gold, they were, as Mr. Holmes shows, like the ancient peoples of middle and southern New Granada.

An Elementary Treatise on Dynamics. By Benjamin Williamson, F.R.S., and Francis A. Tarleton, LL.D. Second Edition. (London: Longmans, Green, and Co, 1889.)

THIS work has been thoroughly revised, and a considerable alteration has been made in the order of its arrangement. The first half of the book treats of the dynamics of a particle, while the latter part deals with kinematics and kinetics of rigid bodies.

Many portions of the subject have been developed, and in some cases rewritten, especially that on generalized co-ordinates in connection with Legrange's and Hamilton's methods; the general theory of oscillations is exhibited in a new form.

The work has been arranged from the most elementary conceptions, so that anyone acquainted with the conditions of equilibrium, and with the notation of the calculus, may commence the treatise without studying any other book on the subject.

LETTERS TO THE EDITOR.

On some Effects of Lightning.

DURING the thunderstorms of the 6th and 7th of June last, some twenty trees and buildings were struck within a 5-mile radius from Cranleigh. I have examined most of the trees struck, and have found a remarkable similarity in the effects, which are of two kinds: the first, by far the most common effect, is simply a score out of the bark up the trunk of the tree, out along one limb, and then by perhaps two or three smaller branches to the outer twigs; the other effect is the shattering of the tree, which occurs, as Mr. Griffith remarks in NATURE of August 15 (p. 366), when the lightning course leaves the outer surface of the tree and enters between the bark and the wood at the junction of some main branch with either the stem or with some other branch, when the shattering would probably occur from some obstruction at the junction, or from there being water in a cavity or in a collection of dead leaves in the fork.

I imagine that in general the course of the electricity is outside of the bark, following one or more lines of moisture or running water down the tree; when this conductor becomes insufficient a discharge takes place, and the stream of water is converted into steam so violently as to destroy the bark instantly along the line of strain. If the sap within be also converted into steam by communication through a knot-hole or by a flaw, the bark is blown off altogether.

If the tension be very great indeed, and especially if the air round the tree be dry, the sap may be violently exploded, and the trunk splintered and shattered as if by dynamite.

Most of the trees in this neighbourhood were struck while it was raining; but one tree, a Scotch fir, occupying a prominent position on the side of a hill, was struck before any rain fell. This tree divided out into two arms nearly in line with the stem; one arm was thrown to the ground, the other remained up for a few hours, and was then blown down by the wind, falling in the opposite direction to the first arm. At the junction there was a great deal of turpentine which was thoroughly blackened. The trunk below the arms was shivered, and the bark thrown out to a distance very similarly to the case related by Mr. Griffith. One curious feature in the present instance was that the roots of the tree could be traced to a considerable distance by the earth above them being thrown up as over a mole barrow.

Most of the trees struck here have been oak; but there were also two poplars, four elms, a chestnut, and the fir above mentioned. It is said that beech-trees are never struck: probably the smooth close-fitting bark makes a better conductor than the rough bark of the oak. J. P. MACLEAR.

Cranleigh, August 26.

Nose-Blackening as a Preventive of Snow-Blindness.

IN vol. xxxviii. of NATURE there were several interesting letters on this subject. Will you allow me to suggest a possible explanation?

For some years past I have interested myself in the choroidal circulation, and my observations have led me to believe that when light is absorbed by the choroidal pigment the blood-supply at that spot is increased. If the light is intense, this increase soon has the effect of blurring the image, and if at the same time the light is intense and the exposure to it prolonged, the sensitiveness of the retina may suffer for some time after from the same cause, *i.e.* an abnormally large blood-supply in the choroid.

In the course of the blood-vessels there is just such a connection between the retina and the skin as the nose-blackening preventive requires. My suggestion is that the blackening of the skin increases its demand for blood in some way, perhaps by its increase of temperature, and that thus a larger supply is drawn along the main branches of the ophthalmic artery, the naso-frontalis, the supra-orbitalis, and the lacrymalis, diminishing the quantity which finds its way into the small and almost independent system of the choroid. In this way nose-blackening would save the retina from being oppressed and injured in the way mentioned.

I may mention that if anyone after walking for an hour or so in the snow covers his eyes so as to exclude all external light, he will find his eyes filled with a very bright retinal light, and also if he is at all accustomed to see the blood corpuscles moving in his field of vision he will see them at such a time very distinctly and in great numbers by looking at the sky.

The theory which my observations have led me to form, that there is a very intimate connection between the retinal light and the circulation in the choroid is almost necessarily crippled by the fact that it rests largely upon subjective phenomena which are misleading, are not demonstrable, and depending on the constitution of the subject are not readily confirmed. Until, therefore, I can hear of another worker in the same field whose observations agree in the main with my own, I do not feel prepared to publish them. HENRY BERNARD.

Jena, August.

A Method of Mounting Dried Plants.

AN example of a very useful and expeditious method of mounting herbarium specimens adopted here is inclosed as worthy of attention. Short strips of lead, used in packing tea, are passed through slits in the paper on each side of the part of the plant to be fastened, and the ends then bent flat out on the back of the sheet. The many advantages of using this, or some other pliable metal, in certain cases, are very obvious. Has this method been hitherto suggested? JOHN WILSON.

University, St. Andrews.

COLOUR-BLINDNESS AND DEFECTIVE FAR-SIGHT AMONG THE SEAMEN OF THE MERCANTILE MARINE.

IN the House of Commons, recently, attention was called to this subject by Dr. Farquharson, who, in stating that he would take an early opportunity of discussing it next session, intimated that the efficiency of the Board of Trade regulations on this matter was open to grave suspicion. On making inquiry, we find his doubts are only too well founded. When, in the year 1852, the carrying of red and green side-lights by sailing-vessels was made compulsory, the subject of colour-blindness had not awakened the attention of practical observers. Had the fact that from 3 to 4 per cent. of the whole male population are colour-blind then been known, it is possible that some mode other than by showing red and green lights would have been devised to indicate the positions of vessels at sea at night. As there is generally but a hazy conception of what is meant by the term colour-blind, we will briefly indicate its exact significance.

When, in 1794, the distinguished chemist, Dalton, published a description of his sense of colour, the scientific world were surprised to find that there existed individuals whose perception of colour differed in a remarkable way from that of their fellow-man. To have said that an individual possessed the sense of sight was tantamount to saying that he possessed the sense of colour, the latter being considered an integral part of the former; but Dalton's report clearly showed that the two senses were separate and distinct, and that, while an individual might have a perfect appreciation of form, he might also be quite unable to perceive any distinction between two or three or more distinct and different colours. Further investigation showed that there were a few people who could discern no colour at all, every object appearing as black or white, or as shades of black and white (grey). This is total colour-blindness, and is very rare. The usual form, and that which we allude to when we speak of a colour-blind, is that in which the individual can distinguish the colours blue and yellow, but can see no difference between the colours red, green, and brown; and from the fact that one of these individuals, if given a vivid scarlet skein of wool, will select to match with it green skeins and brown skeins, it follows that he must see green and scarlet as he sees brown. Now, there being between 3 and 4 per cent.[1] of the whole male population afflicted with this variety, it follows that a very large section of the community are by nature disqualified for all those positions in which the correct interpretation of coloured lights is essential to safety. Clear as this fact must be, it was not until Dr. George Wilson, of Edinburgh, in the year 1855, published his admirable work, entitled "Researches on Colour-blindness," that public attention was invited to the subject. He showed with the greatest clearness how the safety of a vessel lay in the hands of men—"look-outs," officers, and pilots—who might be colour-blind, but were unconscious of this defect, or afraid to confess it; and he came to the definite conclusion, as the colour-blind were in a minority in the community, therefore, those destined to deal with signals should be selected solely from the majority whose vision was normal, and he earnestly urged upon those in authority the necessity of excluding colour-blind men from the sea profession.

One sentence was prophetic, that in which he says "the appalling yearly list of lost vessels which appears in our Wreck Returns awakens the suspicion that more than one of these fatal disasters may have resulted from the mistaken colour of a lighthouse beacon or harbour lamp, which on a strange coast, and with the accompaniments of a snow-storm or a thick fog, has been wrongly deciphered by a colour-blind pilot."[2] And if true of the pre-steamship days when vessels carolled along at the rate of a few miles an hour, what is to be said of the present time, when our "greyhounds" of the ocean flash along at the rate of twenty miles an hour, day and night? The regulation red and green lights of a steamer are

[1] Holmgren examined 32,165 men: 1019 colour-blind—3·168 per cent. Joy Jeffries examined 10,387 men: 431 colour-blind—4·149 per cent. London Committee examined 14,846 men: 617 colour-blind—4·156 per cent.

[2] Colour-blindness proved to be the cause of *Lumberman* and *Isaac Bell* collision: ten lives lost. Colour-blindness proved to be the cause of loss of *City of Austin*—colour of buoys was mistaken: money loss £40,000. Colour-blindness or defective sight was the cause of collision between *Carbet Castle* and *J. H. Ramier*: money loss £1900.

supposed to be seen at a distance of two miles. Take the case of two steamers going in opposite directions at the rate of twenty miles an hour. It follows that from the very moment of those on board being aware of each other's position, but three minutes will elapse before they meet. Is not this little enough time to alter a course? And this is premising a clear atmosphere. Should the night be hazy, the oil poor, the wick badly trimmed, or the glass dirty, the distance at which the light can be seen is lessened, and the time to alter a course correspondingly diminished. Add to this the presence of a colour-blind or defective far-sighted "look-out" or officer, and there is present every attribute for the accomplishment of those terrible tales of the sea which year after year greet us with an alarming regularity. The *Times* (February 5, 1889), in reporting the terrible collision which occurred in the channel, *in fine clear weather*, in which both vessels (s.s. *Nereid* and s. *Killochan*) went to the bottom in less than five minutes, carrying to a watery grave twenty-three men out of a total of forty-two, remarks: "All inquiries respecting the cause of this disaster lead to the same conclusion, that it was due to one of those astounding errors of judgment on the part of one or other of the navigators which seem to defy all attempts at reasonable excuse." Read in the light we suggest, and the cause is as clear as daylight.

The same may be said of the terrible collision, when, again on a *perfectly clear night*, the s.s. *Douro* and the s.s. *Yrurac Bat* both went to the bottom with more than two score of their living burden. And who can say that the loss of the s.s. *Ville du Havre*, with its appalling death-roll, was not directly due to the colour-blindness of "look-out" or officer on one of the colliding vessels? We know how the inquiry ended. The English Admiralty decided that the English vessel was free from all blame, and the French Admiralty declared that the French vessel could not be in any way incriminated. But no one thought of attributing the mistake to the very probable one of colour-blindness. Now, what are the precautions taken to guard against those dangers which the employment of "colour-blind" and defective far-sighted sailors renders possible? We reply advisedly and after careful inquiry, "Practically none." It is true that twenty-two years *after* Dr. Wilson had so graphically described these dangers, the Board of Trade authorities awoke from their long sleep of indifference, and said that they recognized "the serious consequences which might arise from an officer of any vessel being unable to distinguish the colour of the lights and flags which were carried by vessels," and they instituted "tests and regulations," the value of which will be indicated by the following facts. The regulations do not prevent colour-blind "look-outs," colour-blind pilots, colour-blind A.B.'s, or colour-blind apprentices remaining sailors to the end of their days. They do not prevent colour-blind first mates or colour-blind captains and masters retaining their positions also to the end of their days; nay, more, they actually give colour-blind officers certificates that they are not colour-blind.

Should anyone doubt these grave statements, let him read the Board of Trade Reports for 1885, 1887, and 1888. He will find there that no less than forty-five officers rejected for colour-blindness were eventually given unendorsed certificates, which is identical to saying these men were not colour-blind, and that they were perfectly capable of taking charge of the lives of hundreds of helpless passengers, and of property to the extent of thousands. Is not this little less than a public scandal? We who know that colour-blindness is congenital and incurable, know either that these forty-five men were not colour-blind when rejected, or that they are colour-blind to-day. Which contention is the more likely may be gathered from the fact that, of these legalized non-colour-blind men, according to the Board of Trade's own reports, four were unable to distinguish red from green, twenty-two more called the colour red green, five others called the colour green red, and the remainder made mistakes of a marked character.

The Board of Trade so-called "tests for the detection of colour-blindness," viz. the requiring candidates to give the *names* of coloured cards, and lights shown them—tests which are stated to be "sufficient to prevent anyone who is more or less (!) colour-blind escaping detection by the examiner"—may be tests of a man's education in the *names* of colours, but as tests of the colour sense, they are not trustworthy, and tests which are not trustworthy are worse than no tests at all. Practically, the "tests" are barely worth the paper they are printed on. And the "regulations" dealing with a colour-blind officer, should he be detected, are of a like character, a snare and delusion. The public and the shipowners believed, rightly or wrongly it matters not, that the regulations were framed to absolutely keep colour-blind officers out of the sea service. They do nothing of the sort. With regard to the far-sight of a sailor or officer, there are no tests at all; a man may be the subject of any of the various forms of eye-disease, may have any degree of blindness, or may be so shortsighted as to be unable to see distinctly more than a few inches in front of his nose, and yet be at perfect liberty to be a sailor to the end of his days, or to become an officer. Are the public going to allow this grave condition of affairs to remain as they are? We answer emphatically "No," and we feel sure that when Dr. Farquharson brings the subject forward, the House of Commons will insist that the Board of Trade authorities who have the duty and privilege of providing for the safety of the travelling community of the first maritime nation of the world, will take, even though thus late, such precautions as will insure to the sea traveller immunity from those dangers which the present employment of colour-blind and defective far-sighted sailors renders possible.

ST. ELMO'S FIRE ON BEN NEVIS.[1]

ST. Elmo's Fire as seen occasionally at the Ben Nevis Observatory takes the form of jets of light on the tops of all objects that stand any height above the general level of the roof of the Observatory, such as the chimneys, anemometers, lightning-rod, &c. In a very fine display the tops of the objects are quite ablaze with the phenomenon, which then glows and hisses in brilliant tongues of white and blue, from four to six, or even more, inches in length. Nor is the phenomenon confined to these objects alone in the finer displays, but if the observer stands on the roof his hair, hat, pencil, &c., glow with it as well, and when he raises a stick above his head the stick has also a long flame at the top. Further, however, than having a slight tingling in his head and hands he suffers no inconvenience. The hissing is a very marked characteristic of the phenomenon, being always heard during ordinary displays, though in the feebler displays, when the light can barely be seen, it cannot be distinguished from the hissing of the wind and the snow drift. On one occasion the sound was a very highly pitched note. In the finer and even in ordinary displays St. Elmo's Fire is an object of great beauty, and the stormy character of the weather—namely, squally winds with heavy showers of snow and hail, and with clouds of snow-drift flying all around—heightens rather than diminishes the effect, although at the same time it detracts from the convenience of observing with advantage.

Up till the summer of 1888 fifteen cases of St. Elmo's

[1] Abstract of a paper on "St. Elmo's Fire on Ben Nevis," by Angus Rankin in the Journal of the Scottish Meteorological Society, third series, No. v.

Fire were noted at the Observatory, and these occurred all in the night-time, and all during the winter months, beginning with September and ending with February. The feebleness of the light it gives forth, in comparison with ordinary daylight, makes it difficult if not impossible to see it during the day, which is probably the reason for its being a nocturnal phenomenon, and partly for its being a winter phenomenon, for the short summer nights greatly lessen the chances of seeing it. Other reasons for its being a winter phenomenon, and not a summer one as well, are that the high temperature in summer is not favourable to its appearance, and that the weather type in which it appears is far more common in winter than in summer. The fifteen cases are distributed throughout the winter months as follows: two in September, three in October, five in November, two in December, one in January, and two in February. An investigation of these cases, and of the meteorological observations made before and after each appearance of St. Elmo's Fire, has shown that the weather which precedes, accompanies, and follows it has very definite characteristics, not only on Ben Nevis but also over the whole west of Europe. What these characteristics are will be briefly explained in what follows.

To arrive at a knowledge of the conditions obtaining on Ben Nevis, the observations of pressure, temperature, wind direction, and rainfall, made at the Observatory, were tabulated for each hour from thirty hours before to twenty-four hours after the appearance of the phenomenon in each case. The general averages thus obtained for the whole fifteen cases for each element give very decided curves. They show that, as regards pressure, the barometer, from being 24·993 inches at thirty hours before St. Elmo's Fire is seen, steadily falls till the sixth hour before, when it is 24·771 inches, and thereafter rises till the twenty-fourth hour after the display, when it is 24·979 inches. At the hour at which St. Elmo's Fire is seen and the following hour, however, a slight dip is indicated in the ascending curve. Taking all the pressure averages into account, they indicate a well-defined depression, in which St. Elmo's Fire is seen six hours after the centre, or point of lowest barometer, has passed. It is important to note that all the pressure averages come out below 25·000 inches, because this indicates that the depression occurs while Ben Nevis is in an area of general low pressure—the mean barometric pressure at the Observatory for the four years ending 1887 being 25·296 inches.

The temperature averages show a broad maximum from twenty-four to sixteen hours before and a minimum sixteen hours after St. Elmo's Fire is seen—the range being 3°·7; and between these hours there is a continuous fall in the temperature. The rate of fall is greater before than after the display. In some of the cases the range is much greater than 3°·7—in one it is 13°·4. It was chiefly from the observations of temperature that we were able on several occasions to give successful forecasts of the appearance of the phenomenon several hours before it occurred.

The chief points shown by the wind-direction averages are, that they all belong to the western half of the compass; that till the tenth hour before St. Elmo's Fire is seen the wind blows from a south of west direction, and thereafter from north of west; and that from the twenty-fourth hour before St. Elmo's Fire is seen, when the direction is south-west, the wind steadily veers till the fourth hour before, when it is west-north west, which it continues to be till after the appearance of the phenomenon, and goes on veering again till the tenth hour following, when it is north by west. This veering of the wind before St. Elmo's Fire is seen is well marked in all the cases.

The rainfall averages show two distinct maxima, the first between ten and six hours previous to the display, and the other at the hour St. Elmo's Fire is seen and the following. The latter maximum is wholly due to the heavy showers of snow and snow-hail that accompany the displays. This snow-hail differs from the usual flaky snow crystals in being of the shape of small cones with spherical bases, and being hard and dry. During the finer displays this kind of snow was always present.

Thus, as far as local observation goes, we see that St. Elmo's Fire is seen on an average six hours after the lowest reading of the barometer has been recorded, in a depression that occurs in a general low-pressure area; that it is preceded, accompanied, and followed by a falling temperature; that before it is seen the wind has veered considerably, and goes on veering for some time after its appearance; and that it is attended by heavy precipitation in the form of snow-hail.

The averages are of some interest apart from their connection with St. Elmo's Fire, for they show the relations existing in this class of storms between the four elements here discussed. The averages of pressure and of the direction of the wind are sufficient to show that the depression comes in from the Atlantic, and that the centre passes eastwards somewhere to the north of Ben Nevis. Then it is seen that the temperature is at a maximum when the barometer is falling, and is still falling when the barometer is at its lowest; that is, at a time when the atmosphere is very unstable and ascending currents at their strongest, the temperature is falling on Ben Nevis, a state of matters that must necessarily result in a rapid condensation of vapour, and a consequent copious precipitation. The rainfall averages quite agree with this.

As to the prevailing weather over the British Isles and west of Europe in general, about the times of St. Elmo's Fire being seen on Ben Nevis, the weather charts of the London Meteorological Office show that, in almost all the cases, the following conditions obtained—namely, somewhere to the south or south-east of the British Isles, usually over the south of France and over the Spanish peninsula, there was a distinct high-pressure area, or anticyclone; and that to the west or north of Scotland there was a low-pressure area, or cyclone. Between these two positions the barometric gradient was chiefly for south-westerly to westerly winds, and was usually pretty steep. The charts also showed that, so long as the anticyclone maintained its position to the south-east, so long did cyclones sweep in from the Atlantic with the above gradient wind, and pass our islands in a north-easterly or easterly direction. Thunder and lightning were noted in Ireland on several of the nights that St. Elmo's Fire was seen on Ben Nevis. Only on one occasion was any thunder and lightning observed on Ben Nevis, about the times of St. Elmo's Fire appearing, and then the phenomenon was seen two hours before the thunderstorm came on.

It might be inferred, from what has been said, that as St. Elmo's Fire appeared at the change of weather, when the centre of the storm had passed, it would be a good prognostic of improving weather. Such is not the case, however, for almost invariably another cyclone is approaching, and another spell of bad weather is experienced soon after the St. Elmo's storm has passed.

A. R.

NOTE.—Since the paper, of which the foregoing is an abstract, was written, several additional cases of St. Elmo's Fire have been observed on Ben Nevis. On one occasion we were fortunate enough in securing a photograph of the phenomenon, which shows St. Elmo's Fire as three small spots of white on the top of the kitchen chimney, the chimney being but very faintly seen.

TELESCOPES FOR STELLAR PHOTOGRAPHY.[1]

I.

I WILL ask you to remember that the subject of this paper is not that of the proposed international photographic survey of the heavens itself, but of the instruments which are to be used for that survey. No doubt a communication on the survey itself, dealing with the results aimed at, the conditions under which it is considered the best results may be arrived at, and the general scheme under which it is proposed to measure, define, and catalogue the position of the stars obtained, would be more generally interesting than one on the mere instrumental equipment; but this part of the subject has already been amply and most efficiently dealt with in lectures by Mr. Common and Dr. Gill at the Royal Institution, while the subject of the instruments to be used has only as yet been discussed in the more scientific and technical journals or proceedings of Societies; besides which, I may be pardoned for saying that I think when actual work is commenced, the perfection of the instrumental equipment will be found to be a larger factor in the attainment of success than has ever been the case in any previous astronomical research. There is probably nothing which surprises and excites the admiration of the modern astronomer more than the work done in bygone times by some of the older astronomers—work which was the outcome of marvellous patience and ingenuity while working with tools which would excite the pity and contempt of the merest tyro in astronomy of the present day; but while I am by no means a sceptic as to the most important part of all telescopes being "the man at the small end," I do believe that never before in any system of astronomical observing has "the man at the small end" been so completely dependent on the excellence of his instrumental equipment, a disarrangement of any one part of which would leave him utterly helpless. I trust, therefore, you will bear with me while discussing and describing a few of the more important mechanical details of these instruments.

You are aware, probably, that an International Congress of Astronomers was held last year in Paris, and that it was decided to start a number of Observatories, in various parts of the world, each to take its share in producing photographs of the heavens, to be afterwards used in compiling a general chart, in which stars down to the 14th magnitude would be entered.

Before we go further, it may be well to explain the difference between this system of charting and the old system, and what circumstances have led to this proposed revolution in astronomical work.

The system of mapping stars which has been used up to the present time consists, as you are aware, in observing all the stars *seriatim*, in a transit circle, or similar instrument, and tabulating their declination (*i.e.* angular distance north and south of the equator), or Polar distance, as found by readings of the vertical centre, and their right ascension (*i.e.* their distance measured on the equator from an empirically fixed point in the heavens), as found by the difference of time of the sidereal clock between the passage of the star across the centre wire of the telescope and that of the fixed point above referred to. The essential point in the above system which I have to direct your attention to is, that every single star has to be examined *by itself*.

The magnitude of the work of such a survey as the Paris Congress has decided upon may be inferred from the fact that there are probably some 20,000,000 stars to be examined and catalogued. It is a good year's work of a transit circle to tabulate 5000 stars; supposing, therefore, thirty or forty Observatories divide the work between them, the survey would still occupy over 100 years, and by that time the proper motion of the stars would render a new survey necessary.

Now, ever since photography has been practised, it has been the dream of the astronomer to photograph the heavens, and obtain, at one and the same time, the positions not of one but of hundreds, or perhaps thousands, of stars in each operation. But then, it may be asked, why was not photography employed long since? The answer is, that until recently the amount of sensitiveness obtained was not sufficient to allow of the fainter stars impressing the plate within reasonable time, and consequently it was found impossible to produce satisfactory stellar photographs, except of the larger stars.

Dr. Warren De la Rue was the first to point out the use which might be made of photography for the purpose of star-charting, and, as far back as 1860 and 1861, produced photographs of star-clusters, &c.

In 1864 or 1865, Rutherford, of New York, obtained photographs of the larger stars, and while photographing the moon with the great Melbourne telescope in 1867 I took, for the purpose of adjustment, some photographs of "Castor"; but in an article which I wrote for the "British Journal Photographic Almanack" in 1869, I pointed out that for the development of celestial photographs we would have to look to the chemist and not to the optician—in other words, that until we obtained more suitable plates we could not expect much advance. This has proved to be the fact, for with the advent of the gelatine plates, and consequent increase of sensitiveness, celestial photography received that impetus which has eventuated in this proposition of an international photographic survey. I also pointed out in that same article nineteen years ago that if by any possibility the exposures could be reduced so far as to render the unsteadiness of the image insensible—a rapidity which I said there was no reason to suppose might not be obtained in the case of the sun—we might expect great results, a prediction which has since been verified by Prof. Jansen's magnificent pictures of the sun, with which you are all familiar.

It is almost superfluous to remind you also of the magnificent picture of the nebula in Orion by Mr. Common, an example of celestial photography never yet surpassed.

In 1882, Dr. Gill sent home to the Royal Astronomical Society, and to the Paris Academy of Sciences, a photograph of the great comet of that year, and called attention to the large number of stars photographed on the same plate. This photograph was obtained with an ordinary photographic lens and camera attached to a clock-driven equatorial.

It was this, perhaps, that influenced the Paris Observatory to construct the photographic telescope of about 13 inches aperture, 11 feet focal length, specially corrected for the chemical rays, with which the splendid star charts of the Messrs. Henry were obtained. Meanwhile, others were not idle, and while Dr. Gill, through the munificence of Mr. Nasmyth, obtained a 9-inch achromatic, which I corrected of course for the chemical rays, Mr. Roberts, of Liverpool, had a 20-inch reflecting telescope constructed for the same purpose.

It soon became evident that this new departure in the system of star-charting was likely to be of very great importance, and consequently an International Congress of Astronomers assembled last year in Paris to discuss the whole question. This Congress defined the size and focus of the object glasses to be used, and laid down a certain standard for the correction of the chromatic aberration suitable to the nature of the work; but left almost all other points free for individual astronomers to deal with as they thought best. In fact, the Congress wisely defined only just such points as were necessary for securing uniformity in the scale of the photographs, all of which it is proposed shall be sent to some central bureau to be examined, discussed, and made use of in compiling the chart.

[1] A Paper read by Sir Howard Grubb, F.R.S., before the Society of Arts, on April 18, 1888.

But it may be asked where is the great difference between this system and the old, as the positions of the star images on these photographs have to be measured *seriatim*, just as the stars themselves have to be measured *seriatim* in the old system. This is no doubt true, but under what different conditions are the measurements made.

None but those who have worked in this field know the labour represented by a volume of 5000 star places under the old system.

How many times does that wretched bit of cloud come across the field just as the star reaches the centre wire of the micrometer, and how many nights, beautiful and clear as they may look to ordinary individuals, prove utterly worthless for observing purposes; but under the new system, once a single good plate has been obtained, there is a permanent record of some hundreds, or in some cases thousands, of stars, which can be measured at leisure by day or by night, in good weather or bad weather, and in comfort in your office or study, and there also is that photograph as a permanent record which can be referred to at any time as a check on errors which might possibly creep in to some of the final reductions.

In fact, this new system gives us the means of taking advantage of the very few really favourable opportunities of observing, and of producing, during those favourable moments, a *facsimile*, so to speak, of any portion of the heavens which we can examine and survey at our leisure without any of the difficulties or discomforts attendant upon direct astronomical observations, and under conditions far more favourable to the obtaining of accuracy in the results.

Let us now consider what are the chief points to be attended to in the construction of the instrument. It is evident that what is required is an instrument which—

(1) Can be accurately pointed at any given object.

(2) That when pointed in the desired direction the clockwork shall cause it to follow that object as steadily as possible.

(3) That as the meridian is the best position for observation, the instrument should be capable of working for some distance on each side of the meridian without reversing.

(4) That means should be supplied by which the observer can watch and verify the accuracy of the clock-driving, or making any change in position rendered necessary by refraction.

The first point involves delicate and accurate slow motions in right ascension and declination.

The second involves great steadiness and rigidity of the mounting, great smoothness of motion of the polar axis in its bearings, and above all most accurate clock-driving motion.

The third point involves either the adoption of the old English form of mounting, or a modification of the German form, as the latter does not generally allow of motion for any considerable extent beyond the meridian without reversal.

The fourth merely involves a very powerful finder—or, rather, guiding—telescope with suitable micrometric eye-piece arrangements.

Respecting the relative merits of refractors and reflectors for this purpose, I shall speak just now; for the present I wish to direct your attention to the instrumental part only, and, for the better understanding the peculiarities of the various mountings, I will now throw photographs of some of them on the screen.

The first illustration is that of the Paris equatorial, with which the well-known and deservedly praised star pictures of the Messrs. Henry were produced. You see it is of the construction generally known as the "English" equatorial,—a long split polar axis, with bearings for carrying the telescope at the centre (its weakest point). This form of equatorial has many advantages, which at first seem to render it peculiarly fit for this special work. With good slow motion, and a large finder telescope, it admirably fulfils the first, third, and fourth of the above conditions; but, owing to its peculiar form, and the difficulty of using a driving sector of long radius, it is not well calculated to fulfil the second and most important of all conditions, viz. the accurate following. No doubt excellent work has been done with it by what is called the "eye and hand" guiding. That is, the star is watched in a powerful finder, and when it is seen to err sensibly in position, it is brought right again by the slow motion handle. I think it is generally allowed that the undoubted excellence of the work done by the Messrs. Henry is due more to extraordinary patience and skill in the "eye and hand" guiding than to any unusual perfection of the clock-driving. This form of instrument also possesses a disadvantage in being very difficult to arrange for work near the Pole.

The second illustration is of Dr. Gill's 9-inch photo telescope, with which he took his star pictures. There is nothing peculiar about the mounting of this, being in fact an old equatorial which I sent him some years since. In this case also the excellence of his results is to be attributed to the skill of the observer, and not to any inherent excellence of the clockwork; but that excellent work has been done with it is apparent from the perfection of some of his photographs.

The next illustration is that of the telescope of Mr. Isaac Roberts, of Liverpool, for whom I mounted a 20-inch reflector to experiment with. As you see, it is mounted on what I call the twin form, as I mounted Dr. Huggins's instrument, by the adoption of which the observer always has a second telescope available for visual work, if anything interesting should appear in the heavens. With this instrument Mr. Roberts, working in the exceptionally wretched atmosphere of Liverpool, has secured some most admirable work, a few specimens of which I now throw on the screen.

This is the first instrument, as far as I know, in which a successful attempt has been made to drive, for any considerable time, without "eye and hand guiding." The special system of clockwork used I will describe further on. So far as the general form of the instrument is concerned, it would appear that the balance of advantage lies with the German form (so called) — that usually adopted in this country. It is capable of being made of great stability, and it admirably fulfils all the conditions except the third, but that also, by a little modification, can be managed.

The next illustration shows the general form which I have adopted, the principal feature of which is great stability. The stand being cast all in one piece contributes to this, but the peculiarity of the system of equipoise probably has more to do with it. In designing these instruments, I proposed that the fulcrum of the levers which support the greater part of the weight of the polar axis, should be attached, not to the frame of the instrument, but to an independent pillar, so that only a very small portion of the weight of the moving parts should be carried by the main framing. Dr. Gill then proposed that I should also allow the levers to act in a purely vertical direction, instead of, as usual, in a direction at right angles to the polar axis, and to let the point of support be vertically under the centre of gravity of the whole moving part. This I have carried out, and the result is that only as much of the weight of the whole instrument as is necessary to insure steadiness will rest on the bearings (lateral or end bearings) of the polar axis; all the rest is transferred to the base of the stand.

We now come to consider the all-important part of the photographic equatorial—that is, the driving clock.

All clocks used for driving equatorials (which must of course move uniformly, and not step by step as pendulum clocks), may be divided into two classes—(*a*) those in which uniform motion is obtained, or sought to be obtained, by some variable friction or resistance which increases as the speed increases; and (*b*) those in which some such similar contrivance is supplemented by a system of electric control from a pendulum clock, which is itself incapable of being re-acted upon by the uniform motion clock.

For all ordinary observing, and even for micrometric work, clocks of the class *a* are made, which answer admirably, but for photographic equatorials I believe it will be found necessary to employ clocks of the *b* type, and for this reason: the tendency of the compensation in uncontrolled clocks (class *a*) is to correct the *rate* of the clock when from any momentary cause it is disturbed. The best it can do is to bring the *rate* absolutely right again, but it cannot act till an error has actually occurred, and therefore, although the rate is corrected, the *position* of the star on the plate is shifted by the amount of the error. I have heard it stated by the designers of some of these clocks that errors were corrected *before* they existed! It is hardly necessary to stop to show the fallacy of this, but it is evident that the increased or diminished resistance, or friction, or whatever it is, that checks the speed, can only exist from, and in consequence of, the error itself.

In the case of micrometric measures, it is not of very much consequence if a minute error occasionally creeps in, provided the speed keeps constant during the few seconds or minutes required for making the bisections, but in the case of the photographic telescopes, if the image of the star takes up a new position any time during the exposure, it is of course fatal.

Let us try now and get an idea of what amount of accuracy is really necessary for this work. We often hear of a perfect equatorial clock, but the word perfect is, I fear, as loosely used in this connection as in others.

I have heard in days gone by a perfect clock defined as one which drove the instrument so accurately that if you set the telescope on a star and went to dinner you would find the star still in the field when you resumed your observations after dinner. Allowing, say, two hours between the ante-prandial and the post-prandial observations, and assuming the eye-piece to be (as we may fairly do) a low one of about 20′ of arc field, this would mean that the clock did not vary more than 600″ of arc or 40 seconds of time an hour. The accuracy we now require for these photographic telescopes is something very different. The image of a 12th magnitude star impresses itself on the plate, with moderate exposure, in the form of a circular disk of about $\frac{1}{700}$ inch diameter. If the clock vary one-tenth of a second during the exposure, the disk will be elongated by $\frac{1}{1000}$ inch, producing a very sensible distortion.

We must not therefore have any errors over one-tenth of a second, and if possible it should be reduced to one-twentieth.

It will not be necessary that the clock keep within this one-twentieth of a second for more than ten or fifteen minutes, because it is always necessary to watch the image occasionally through the guiding telescope, and correct whenever refraction becomes apparent; but what I do urge as absolutely necessary is that the clock shall go so perfectly as not to require more than the occasional attention of the observer, instead of the constant and never-ceasing watching with ordinary clockwork. No one who has not tried it can imagine the strain required to keep a constant watch on a star image for 30 or 40 minutes, but if attention be only required for a second or so every few minutes there is no difficulty or irksomeness whatever.

Even the most enthusiastic admirers of various forms of equatorial clocks will not venture to assert that they will go for fifteen minutes without one-tenth of a second of error. There is now, however, no difficulty in controlling a uniform motion clock from a pendulum so that it will never vary one-twentieth of a second from it. It may therefore, I think, be assumed that some form of electrical control is necessary. There are, as far as I know, four forms of control to choose from.

First, Dr. Gill's, as applied to the 15-inch equatorial at Dun Echt with admirable success.

In this an electric current is sent once a second from an independent pendulum, which may be any distance away. That current passes through a certain wheel in the clock, with contacts so arranged that if the clock be going exactly with the pendulum the current is sent in a direction which keeps one of two rubbers rubbing on a

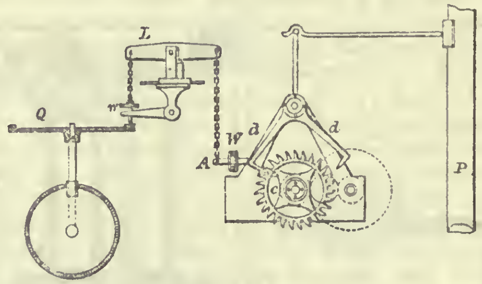

FIG. 1.

quick-moving wheel of the clock. If the clock, however, goes the least quantity too fast, the wheel has revolved a little further than it should at the moment the next current comes from the pendulum, and the current is sent in such a direction as to cause both rubbers to rub on the clock wheel. If, on the contrary, the clock has gone a shade slower, the current is sent in a third direction, which lifts both rubbers off. This control, so far as it goes, acts almost perfectly, but it is open to this objection, that as it only corrects the errors of whatever shaft in the clock the contact-wheel is attached to, any error in wheels between that and the telescope screw are unaffected by it; also I find in practice that when it is attempted to control a clock by alteration of friction, on any heavy quick-moving part, it takes some little time to act, and

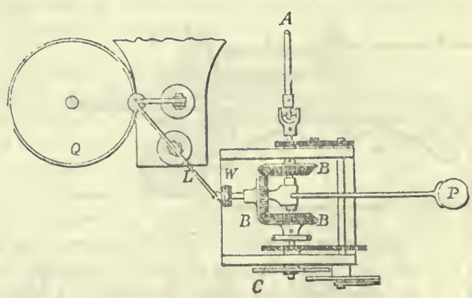

FIG. 2.

then generally overdoes the correction, causing what is generally termed "hunting." The second form of control is the first which I introduced.

Fig. 1 is an elevation, and Fig. 2 a plan, of the arrangement which is attached to the back of the main clockwork, and can be seen in Fig. 3 at E, but on too small a scale for description; A is a portion of one of the uniform clock motion spindles, or any shaft coupled thereto; B, B, B, are the three wheels of an ordinary mitre *remontoire* train driving by weights, W, the scape-wheel, C, into the teeth of which gear the pallets, D D, which pallets are driven by the electric pendulum, P.

The electric pendulum is connected to and driven by a current from any independent clock. To the weight-carrying arm of the *remontoire* is attached a small chain or wire, which communicates any motion it may have to the lever, L, from the other end of which lever hangs a weight, *w*, smaller than W, which weight is therefore raised when the *remontoire* arm is lowered, and lowered when the *remontoire* arm is raised; Q is a disk of metal

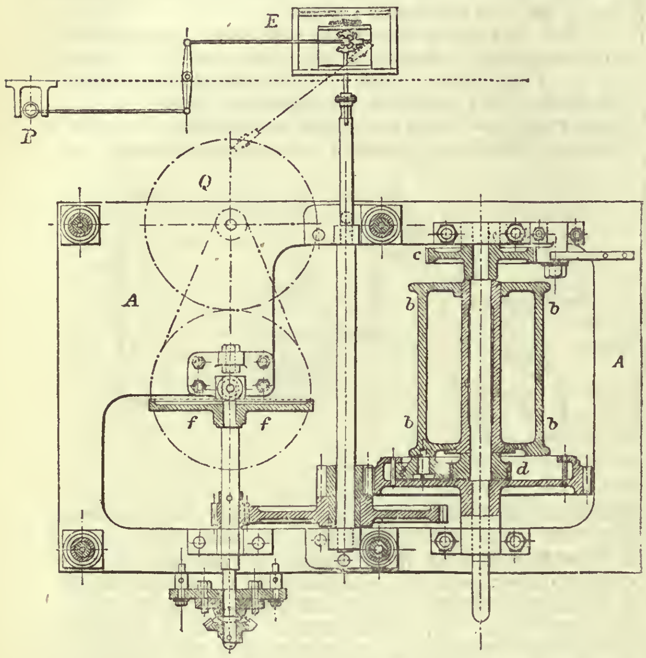

FIG. 3.

on a vertical spindle of a uniform motion clock, and revolving rapidly (say 300 per minute). When the weight, W, is below its mean position, it is in contact with the disk Q, and (the lower end of it being coated with leather) produces a considerable amount of friction, and therefore tends to retard the speed of the clock; when the weight, W,

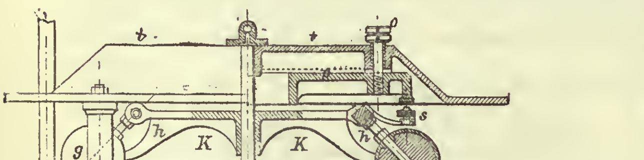

FIG. 4.

is above its mean position, it is altogether out of contact with the disk Q. The action is as follows: Supposing the shaft, A, to be revolving exactly one per minute, the pendulum to be vibrating exactly 60 per minute, and that there are 30 teeth in the scape-wheel, it is evident that the *remontoire* arm, and therefore, the weights, W and *w*, will vibrate backwards and forwards the same distance each second, and that the mean position of all will be the same each second. Under these circumstances, the weight, W, will be alternately 0·5 second in contact with the disk Q, and 0·5 second out of contact, and the uniform motion clock is rated, *per se*, just so much fast, that the resting of the weight, W, for 0·5 second in each second, will bring the rate right.

Now, suppose an error of acceleration to arise in the uniform motion clock, the mean position of *remontoire* arm will rise; therefore W will fall, and, instead of rubbing in contact with Q for 0·5 second, it will rub for 0·6 or 0·7 second, according to the extent of the error. This will tend to check the rate, and this check will continue till the relative position of the uniform motion shaft becomes as it was when the clock was going correctly.

If a retardation occurs, the reverse effect will take place, and the weight, W, will rub only for 0·4 or 0·3 second, instead of 0·5, until the error be corrected.

So far as described, there was no particular novelty, as most of this arrangement, in principle, had been tried before, the failure that had resulted being due to the fact that it was found impossible to prevent the pendulum being influenced by the difference of force on the pallets, under varying circumstances, the pendulum being in the former case driven by the scapement; not by electricity, as in this case.

This difficulty was got rid of by:—

(1) Making the pallets (as they are not required to drive the pendulum) of such form that the teeth of the scape-wheel impinge upon them nearly at the angle of repose.

(2) By driving the pendulum by electric current from another clock, thus virtually rendering the pendulum not a pendulum at all, but a lever worked backward and forward by electricity, and not subject to alteration in its rate by slightly varying force on the pallets.

An arrangement is also attached (but not shown in the figure, to avoid confusion) by which, if either portion of the clock fails to do its duty from want of winding, want of electric current, or other cause, the connection between the two systems is instantly severed, automatically.

(*To be continued.*)

NOTES.

MR. GRIESBACH, of the Geological Survey of India, who has lately been engaged in geological work in Afghanistan, and who was geologist to the Afghan Boundary Commission, has been appointed to Beloochistan, "to carry on geological investigations into the mineral deposits of the country."

AT the meeting of the British Association at Newcastle there will be a joint discussion by Sections B and G of a paper to be read in the latter Section by Sir I. Lowthian Bell, F.R.S., President of Section B, on "Blast Furnace Practice."

THE International Astronomical Congress will hold its sittings in Brussels from the 10th to the 12th inst., and at Liége on the 13th. The attendance from all European countries and America will, it is anticipated, be very large.

IT is reported from Brussels that M. Dutoit, the Transvaal Minister of Public Instruction, is now endeavouring in Belgium and Holland to recruit the necessary staff for organizing a Dutch University in Pretoria, the capital of the Transvaal.

COLONEL THUILLIER'S report on the progress of the Survey of India for the past year shows that the party employed on the trigonometrical surveys has completed the 370 miles remaining of the secondary triangulation along the east coast of India. The secondary triangulation was also carried out for an aggregate length of 270 miles by parties employed in Beloochistan as a basis for topographical surveys in that region. The work of the geodetic party comprised measurement of seven arcs of longitude in Southern India, and the tidal survey party continued its observations with self-registering tide-gauges at several stations along the coast, where tidal observatories are established, and connected with the operations of spirit levelling. Geographical surveys have been carried out vigorously in Upper Burmah, nearly 21,000 square miles having been surveyed and mapped on a half-inch scale. Reconnaissance along the Nepal boundary has supplied a rough basis for a more accurate and detailed survey of the northern frontier when an opportunity offers. Interesting additional information regarding Bhootan and Tibet has been obtained from the adventurous travels of native explorers trained and sent thither by the Department. Of the new maps 4062 were published during the year, and heavy demands continue for trans-frontier maps, and maps of Upper Burmah. The photographic and lithographic offices show the large out-turn of 1,203,861 copies during the year, including high class illustrations for archæological and other reports.

A RECENT mail from New Guinea brings information that the Italian naturalist Signor Lorie had landed in that country, and was proceeding to carry out arrangements for a scheme of scientific investigation which he proposed to himself. His present intention is to remain for several years in New Guinea, where he intends, in addition to following his favourite scientific pursuits, to devote some of his time to exploration work. Signor Lorie is described as a great enthusiast, and a man of determination and courage.

THE *American Meteorological Journal* for August contains an instructive article, by Prof. W. Ferrel, on decrease of temperature with increase of altitude. The author reviews the cases of rapid decrease which would occur were the atmosphere without aqueous vapour and in a stable state; of the very low temperature that would exist a little above the earth, if there were no atmosphere; of the low temperature of the upper atmosphere, owing to radiation into space, if the earth were surrounded by a clear atmosphere, not heated by the solar rays. The very rapid decrease of temperature with height is prevented by the ascending currents, caused by unstable equilibrium, and by the heat of condensation given out after the vapour has ascended to the altitude where condensation commences. The average vertical gradient is less in the cloud region than in the lower strata of the atmosphere, and less in the lower strata in cloudy than in clear weather, as shown by the results of Glaisher's balloon observations. He also refers to the more frequent unstable state of the atmosphere in spring and early summer, owing to the lower strata at that season being warmed up faster than the upper strata; in the fall of the year the unstable state is not so readily produced, and more settled weather prevails. Mr. H. H. Clayton has a paper on diurnal and annual oscillations of the barometer. It is pointed out, in the report of the expedition to Lady Franklin Bay, that if the diurnal pressure at five Arctic stations differing largely in longitude be plotted in simultaneous time, the epochs of maxima and minima show a striking coincidence with each other; the author traces the probable cause of the occurrence of the maxima to the expansion and overflow of air from Asia and America to the Pole; and of the minima at the Pole to the fact that the outflow from the Pole towards those continents is not replaced by an influx in that direction from the oceans. The retardation of the annual maximum from the Arctic region to the Equator, and of the minimum from the southern parts of the continents to the Arctic region, is also attributed to the relative heating and cooling of the continents and oceans. The remaining articles are: on the mineral waters of Gratiot County, Michigan, by Dr. Brainerd, giving an analysis of the waters and the virtues of the substances contained in them; the State tornado charts of Kansas and Indian Territory, by Lieut. Finley; a translation of a paper, by Saussure in 1796, on the use of the sling psychrometer, from which has resulted the modern use of that instrument; and, on atmospheric economy of solar radiation, by A. Searle, with comments by Prof. Ferrel (the principal point is that the earth is kept at a higher temperature than it would be, owing to the fact that heat is transferred upwards by conduction and convection instead of by direct radiation).

THE syllabus for the year 1889–90 of the Manchester Technical School has been issued. It shows the importance and magnitude of the work in which this institution is engaged. There are eight departments in the day and ten in the evening school, beginning with a manual training school for boys, which is the beginning of the whole course. This school is not intended to teach boys a trade, but to provide them with a complete education of both head and hand, in the belief that in this way their powers will best be developed and they themselves be best fitted for after-life. The syllabus this year has some new features. In manual training there is a special course on Saturday mornings for schoolmasters and teachers in the use of wood-working tools, with a view to enable them to introduce manual training among their own pupils. In commercial geography there is to be a special course of lectures of a practical character. Type-writing is another novelty. The chief feature is instruction in the use of the Remington and Caligraph machines. With a view to obtain the necessary skill, each student has three hours' practice per week. There is a special class for women in shorthand, in addition to increased facilities for male students. A special honours class has been formed for evening students in magnetism and electricity, telegraphy, and electric lighting. Especially it should be noted that facilities are offered for a comprehensive study of commercial subjects. There are now great facilities to evening students for the study of science and of art in their application to all the more important industries. The school staff consists of 52 teachers. Last session the school was attended by 3328 individual students.

WE have received the prospectus of the day classes in arts and science and of the evening lectures for the session 1889–90 of the University College, Liverpool.

THE Colonial Board of Viticulture in Melbourne recently proposed the establishment at public expense of an experimental vineyard and school of viticulture for the colony. The suggestion has now been accepted by the Minister of Lands, and a site has been selected for the purpose at Rutherglen. The area selected is 200 acres, and it will be permanently reserved for the purpose. Instruction will be imparted at the institution by capable teachers in the most approved methods of vine cultivation, and experiments will be conducted with the view of testing the value of new plants said to be suitable for growth in Victoria. Funds for conducting the school will be provided in the present year's estimates, but pending the formal vote the Minister has authorized the expenditure of a sum sufficient to at once plant 20 acres of the reserve, and so expedite the work. This will enable the Board of Viticulture to take advantage of the present favourable season.

IN his last Report, the British Vice-Consul at Nisch mentions the terrible havoc which is being made by disafforestation in Servia since its independence. He says that during the Turkish occupation Servia was covered with magnificent forests of oak, beech, chestnut, and walnut trees, by means of which the country was assured of a regular and plentiful supply of water, and in the recesses of which the natives found shelter and refuge from their foreign conquerors. From the date of her independence a destruction of these invaluable treasures commenced which has been carried on with remorseless and unreflecting perseverance, and it appears as though there were at the present day a race against time to complete the havoc. From time to time the consciences of Ministers and Governments have roused them to interfere, but, beyond passing laws which remain a dead letter, hardly anything has been done to arrest the evil. Floods in winter and drought in summer were declared by Mr. Borchgrave, in 1883, to have already begun to exact the penalty which carelessness or want of foresight must be called upon to pay; but the peasant and his goats continue their work of destruction, whilst the authorities are apparently more anxious to avoid occasions of discontent which restrictive measures would create than of applying such remedies as legislation has placed in their hands. Whole mountains may be seen completely denuded of timber, with the exception of a low worthless scrub, which were, a few years ago, covered with woods, but which have fallen victims to the innumerable herds of goats which are allowed to browse at will. The peasants amongst whom the land was divided at the time of the Servian independence have cleared vast tracts for the purposes of agriculture, and possess the right of cutting timber for firewood in those forests which are under the management of the different *communes*. Very little coal is used for household purposes, and the amount of wood required for daily consumption adds enormously to the drain on the national resources. The best-wooded parts of Servia are the districts of the south and south-east, but especially the department of Toplitza, which may be said to contain the only remaining virgin forests of Servia, and whence are annually drawn large supplies of walnut trunks and oak staves for casks. The heights of the Nischava Valley, Stalatz, and Krushevatz furnish excellent building timber. Oak forests are abundant on the Turkish frontier of Vrania. Walnut trees, which attain to an enormous growth, have been mercilessly dealt with, the value of this timber having attracted the attention of Austrian merchants, who send agents to choose and cut the wood for exportation. The fir and juniper are found in the central and western valleys, and on the great Kopavnik Range on the south-east, the pine on the heights of Zlatibor.

HERR TROGNITZ contributes to the last issue of *Petermann's Mitteilungen* the results of calculations which he has made of the areas of the various South American States. These are based on the maps in the latest edition of Stieler's Atlas, which are compiled from the latest official and other information. The figures are in square kilometres.

Brazil	8,361,350
French Guiana	78,900
Dutch ,, ...	129,100
British ,, ...	229,600
Venezuela	1,043,900
Columbia	1,203,100
Ecuador	299,600
Peru	1,137,000
Bolivia	1,334,200
Chili	776,000
Argentine	2,789,400
Uruguay	178,700
Paraguay	253,100
Total	17,813,950

THE *Colonies and India* reports from Tasmania that a movement is on foot in Hobart for the creation of a University. A notice of motion directing attention to the desirability of such a step was given in the Council of Education by the Minister of Education, and the subject was to be considered at a meeting on June 19. "We hope to hear that it has been favourably considered, as the colony is quite prosperous enough to maintain such an institution, and it would be one which would be extremely useful, as well as being to some extent an adornment to the picturesque capital of the Island Colony."

MR. G. W. ROOSEVELT, American Consul at Bordeaux, in a report on the treatment of diseases of vines in France, says that in spite of the numerous inventions meant to destroy Phylloxera, it still continues its ravages. One of the most recent plans is that of an American, Mr. L. H. Davis, who inoculates the vine, through a carefully made excision, with a preparation which he claims is destructive to the Phylloxera, while it leaves the vine uninjured. It is too soon yet to speak of the results of this plan. Dr. Griffin advocates a distribution by a machine constructed by him of a substance which can be used in either a dry or a liquid state. Last spring he operated on a vineyard placed at his disposal by the French Government, and had the satisfaction of seeing the vines treated by him sound and healthy, while other plants in the same vineyard were perishing. The most generally employed remedy has been found to be very serviceable, and free from the danger that was thought to follow it—that is, the submersion for not less than forty days in carbon of sulphur dissolved in water. In light permeable soils a strong mixture is used, but on hard soils a weaker solution is better. Within the past few years the actual area of the vines destroyed by this pest is 1,200,000 hectares, or, roughly speaking, one-half of the vineyards of France; and if we remember that a hectare of vines is worth about 6000 francs we can see what a terrible loss France has suffered. In the case of Oïdium, as in that of Phylloxera, no positive remedy has yet been discovered, but the usual mode—that is, the application of sulphur, pure or mixed—checks the disease, and at the same time helps the growth of the vine. In fact, so great have been the good results of the use of sulphur, that it will for the future be used in most vineyards, even where Oïdium does not exist. Till the year 1885 no remedy was known for mildew. Since that year, however, salts of copper have been successfully employed, though there is some doubt whether that substance is really beneficial to the vineyards. The most general method is to pluck off the diseased leaves and burn them. Besides these there are other methods, such as the use of *bouillie bordelaise*, *eau céleste*, ammoniate of copper, and verdigris with powdered sulphate of copper. On account of the recent appearance of the disease called black rot, no satisfactory remedy has yet been tried. With regard to anthracnose, if steps are taken early in the spring, the disease may be brought under control. Perhaps the best remedy is a mixture of lime and sulphur. A first sulphuring is given when the shoots are four or five inches long; then, if lesions appear, the operation is repeated in about a fortnight with a mixture of lime and sulphur, the proportion being one part of sulphur to three of lime. A mixture of plaster and sulphate of iron has also been very successful. The only really efficacious remedy for pourridie is by removing and burning all roots showing traces of the disease. Erinnose may be treated like mildew—that is, by repeated applications of sulphur.

A REPORT on the appearance of the Hessian fly in this country, by Mr. Charles Whitehead, the Agricultural Adviser, has been issued by the Agricultural Department of the Privy Council. The fly was first seen in 1886 in Great Britain, and in that year did some harm to wheat and barley plants in England and Scotland. In 1887 it was noticed in twenty counties in England and ten in Scotland, wheat and barley crops being considerably damaged by its action. The weather during the summer of 1887 was hot and dry, like that which normally prevails in America, and was presumably favourable to the development and progress of the fly. During 1888, when the summer was unusually wet and cold, very little was heard or seen of the Hessian fly either in England or Scotland. But during the early months of the present year the temperature was high and the rainfall small, and from the reports received by the Agricultural Department the infested area has largely increased in England. In Scotland it does not appear to have made so much progress. Still it is present in many Scotch counties. The actual amount of injury to the crops is slight, and, so far as can be ascertained, is not in any instance so important as that caused in some cases in 1887. It is most probable that the injurious operations of the insect have been checked by the wet, cold weather which has followed the abnormal heat of May, and the warmth and dryness of June. When a cycle of hot summers occurs, it may happen that the ravages of the Hessian fly may be general and calamitous. Mr. Whitehead therefore urges the desirability of careful watching and the prompt adoption of simple methods, which he describes, for preventing the increase of the pest.

THE *Industrie Textile* has a long account of the treatment of wild silks (that is, those which are furnished by silkworms other than those of the domesticated *Bombyx mori*) in their native countries. In India there are no less than fifty varieties of silk-bearing insects, the most important of which is called tussur, that is, "the weaver's shuttle." The caterpillar, like the moth, is of a great size, and feeds upon more than thirty species of plants. The cocoons of the tussur, which make their appearance twice in the year, are found attached to the branches of trees in the jungle in large oval masses. The caterpillar lives from thirty to forty days, and then weaves its cocoon. In four or six weeks from this time the moth comes out and lays eggs from which comes a second generation of caterpillar. These wrap themselves in the cocoon, and remain hanging to the trees throughout the rainy season—that is, for seven or eight months. The cocoon, which is about four times the size of that of the mulberry silkworm, is composed of a double and interrupted thread of about 1400 metres in length. The thread is impregnated with uric acid of sodium, which must be removed by the aid of an alkaline wash before the thread is unwound. The tussur is tended with great care; in fact, for centuries various religious usages have been employed in rearing it. The moth, which is a large insect of a brownish colour, having its wings beautified by four transparent eyes, is venerated, and may be only approached by people of a certain caste. Unlike the tussur, which has been domesticated in India for some thousands of years, the cocoons of the other species are collected in the jungle. Amongst these is the *Attacus cynthea*, which feeds on the castor-oil plant, and of which the cocoon is white. Other species are the *Antheræa assama* and the *Cricula trifenestra*, which lives on the mangrove tree and spins a cocoon of a bright golden colour. The most important Chinese species is the *Antheræa pernyi*, which is cultivated in the province of Sze-chuan. In China also is found the most beautiful of all moths, the *Attacus altas*, which spins an enormous cocoon, covered at both ends with a very thick silk, known as Fagara silk. In Japan are the *Ailanthus* caterpillar, and the *Yamanai*, which till lately was reserved for the exclusive use of the Mikado, and the exportation of the eggs was an offence punishable with death. At present attempts are being made to cultivate this species in France, and it is believed they will be successful.

MESSRS. BLACKIE AND SON will publish immediately a translation of the well-known "Organische Chemie" of Prof. Bernthsen, of Heidelberg. The translation is by Dr. George McGowan, University College, Bangor, and the original text has been specially brought up to date for this edition by the author, who has throughout shown keen practical interest in the perfecting of the English edition.

THE Royal Meteorological Institute at Utrecht has just published a valuable atlas of twenty-two charts, containing the results of observations in the Indian Ocean, for the separate months of December, January, and February. Some portions of the ocean are naturally without data, but the amount of material dealt with may be judged of from the fact that 51,799 observations have been used in the construction of the wind chart for December. The temperature of the sea-surface is represented by isotherms drawn for every 2° C., and shows in certain regions, *e.g.* near the Cape of Good Hope, considerable differences of temperature in the various months. The currents are plotted in 1° squares, in two colours, showing the resultants of the currents setting towards the west and of those towards the east, separately, together with the number of observations from which they are calculated. Atmospheric pressure is represented by isobars drawn for every 2·5 mm. They show an area of high pressure between lat. 30° and 35° S. and long. 80° and 90° E.; in January there are two centres of high pressure, at long. 55° and 85°. The temperature of the air is exhibited by isotherms for every 2° C. The difference between the air and sea temperature is generally small, but the excess of the latter sometimes amounts to 5° C. The wind is represented by roses showing the relative frequency for direction (only), arranged according to homogeneous areas, combining the same prevalent winds in irregular spaces. Other charts show specific gravity, rain, percentages of storms, and other interesting information.

THE third session of the Edinburgh University Extension Summer Vacation Course was held, as before, during August, at Granton Marine Station, through the kindness of Dr. Murray, Director of the *Challenger* Expedition, and of Mr. Irvine, of Royston. The courses of botany and zoology were conducted, as last year, by Prof. Geddes and Mr. G. A. Thomson. This year each course was divided into an elementary and an advanced section, the former dealing with Vertebrates and Phanerogams, the latter with Invertebrates and Cryptogams. Prof. Geddes also delivered a course of twenty lectures on sociology. Some twenty-five or thirty students attended. All the courses were supplemented by demonstrations in the field and on the shore, and by visits to public and private gardens and to the Museum.

IN the abstract of Dr. Stefan's paper on "Ice Growth" (NATURE, August 22, p. 400), the third paragraph should read as follows:—"The theory gives for the thickness (h) of ice formed in the time (t) the following formula, which is approximately correct—

$$h^2\left(1 + \frac{cf}{3\lambda}\right) = \frac{2k\mathrm{T}}{\lambda\sigma}.$$

In this formula (c) is the specific and (λ) the latent heat of ice; (k) is the coefficient of conduction, (σ) is specific gravity, (f) is the temperature at the surface of the ice at the time (t), (T) the sum of cold for the same time; the last is the sum of the temperatures counted downwards from 28° F., or the freezing-point of sea-water, from the commencement of ice formation up to the time (t)."

THE additions to the Zoological Society's Gardens during the past week include a Common Peafowl (*Pavo cristatus* ♂, white variety) from India, presented by Mr. Richard Hunter; a Manx Shearwater (*Puffinus anglorum*) from Essex, presented by Mr. J. M. Wood, C.E.; a Lesser Razor-billed Curassow (*Mitua tomentosa*) from Guiana, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Louisianian Meadow Starling (*Sturnella ludoviciana* ♀) from North America, presented by Mr. Newton Hayley; a Turtle Dove (*Turtur communis*), European, presented by Mr. C. W. Cousins; five Herring Gulls (*Larus argentatus*), British, presented by Sir Richard Nicholson.

OUR ASTRONOMICAL COLUMN.

YALE COLLEGE OBSERVATORY.—The report of this Observatory for the year ending June 1889 has recently appeared. Mr. Brown, the Secretary, records the carrying out of several improvements in the grounds of the Observatory, and the continuation of the work of the Thermometric Bureau, 7475 thermometers having been received for verification during the year. Dr. Elkin, the astronomer in charge of the heliometer, completed the measures for the triangulation of the region near the North Pole during the summer of 1888, and the necessary reductions are well advanced. In October 1888 a series of observations for the parallax of Iris was commenced in connection with similar series to be effected at the Cape and at Leipzig, but measures were only obtained on thirty-four instead of sixty-five nights. In addition to these, however, 168 sets, each consisting of sixteen pointings, were obtained by Messrs. Elkin and Hall, for the diurnal parallax of the same planet. The discussion of the whole series of measures has been undertaken by the Yale astronomers, and the work has already been commenced. A series of measures for the parallaxes of Victoria and Sappho are now being undertaken, and it is expected that two additional observatories, those of Bamberg and Göttingen, will co-operate in the work. The heliometer has also been employed in further researches on stellar parallax; Procyon and Altair having been taken up by Mr. Hall, Vega and Regulus by Dr. Elkin. During the winter Mr. Hall completed the reductions of his work on the orbit of Titan; whilst Dr. Elkin took part in the observation of the total solar eclipse of January 1, 1889, which he observed from Winnemucca, Nevada, under very favourable circumstances.

NEW MINOR PLANET.—A new minor planet, No. 287, was discovered by Prof. Peters at the Clinton Observatory, on August 25.

Should the two planets discovered on August 3 both be confirmed as new bodies, that discovered by M. Charlois will be No. 285, whilst Herr Palisa's will be No. 286; the former having been discovered at 10h. 46m. G.M.T., and the latter at 11h. 27m.

COMET 1889 *d* (BROOKS, JULY 6.)—Dr. K. Zelbr has found elliptic elements for this comet, with a period of 12⅓ years. The ephemeris from these elements compares as follows with Herr Knopf's ephemeris which is given below:—

Zelbr-Knopf.

1889.	R.A. m. s.	Decl. ′
Sept. 8	−2 17	+1·7
Oct. 2	−5 49	+5·1

Herr Knopf's Ephemeris for Berlin Midnight.

REDUCTION OF RUTHERFURD'S PHOTOGRAPHS OF THE PLEIADES AND PRÆSEPE.—Two papers by Dr. B. A. Gould have recently been published in the memoirs of the National Academy of Sciences, which possess a very special interest at the present time, for they show that in the very dawn of astronomical photography, it was possible to determine the relative places of the members of a star-cluster from a series of photographs with a precision comparable to that attained even with a heliometer. In 1865, Rutherfurd had obtained a number of photographs of the Pleiades, and early in 1866 he placed the results of his measurements of these plates in the hands of Dr. B. A. Gould, who deduced from them the R.A.'s and Decls. of nearly fifty stars of the group, and who, further, compared these results with the heliometer measures of Bessel, made more than a quarter of a century earlier. The comparison, even as it stood, was a most satisfactory one, for, in spite of imperfections in the method of measuring the photographs, such as naturally occurred in a first essay, the probable error of a measure, either of distance or position, appeared as small for the photograph as for the heliometer, and the general agreement of the two methods was most gratifying. The paper in which this discussion was given, though presented to the Academy on August 11, 1865, has only recently appeared—a regrettable delay, for it might well have been that so striking a demonstration of the possibilities of the photographic method might have insured its adoption by astronomers a decade, or even two, earlier than has actually been the case. Dr. Elkin has now (*Astron. Jour.* No. 197) compared Dr. Gould's places of the Pleiades with values interpolated between the Königsberg heliometer places for 1840, and the Yale places for 1885, and after clearing the photographic results for some systematic errors thus disclosed, he finds the residuals very small indeed. Of sixty-eight values, only one exceeds 0″·38, and forty-seven are less than 0″·20, nor do they show any systematic character depending on distance or direction from the centre of the field. The probable error of a co-ordinate from the photographic measurements, he deduces as:—

For the brighter stars, ± 0″·079,
,, fainter ,, ± 0″·101.

Dr. Elkin concludes, therefore, that "the smallness of these probable errors must be convincing proof that in photography we have really a means of investigation for micrometric work at least on a par with any existing methods as regards magnitude, and doubtless far surpassing them in ease of measurement and output of work."

The paper on Rutherfurd's photographs of the Præsepe was presented to the Academy on April 14, 1870, and the central star to which the others were referred being a small one, instead, as in the Pleiades, of a very bright one, which had been, therefore, always much over-exposed, the results were even more satisfactory.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 SEPTEMBER 8–14.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 8

Sun rises, 5h. 26m.; souths, 11h. 57m. 27·9s.; daily decrease of southing, 20·6s.; sets, 18h. 29m.: right asc. on meridian, 11h. 8·4m.; decl. 5° 32′ N. Sidereal Time at Sunset, 17h. 41m.

Moon (Full on September 9, 13h.) rises, 18h. 37m.; souths, 23h. 35m.; sets, 4h. 44m.*: right asc. on meridian, 22h. 47·7m.; decl. 12° 20′ S.

GEOGRAPHICAL NOTES.

FROM advices just received from Queensland the *Colonies and India* understands that Sir William MacGregor left Port Moresby, for the ascent of Mount Owen Stanley, on April 19, in an open boat, with a party of fourteen for Vanapa River, 30 miles westward. He arrived safely, and pushed the boat up river for eight days, during which period he encountered many difficulties in crossing rapids and dragging the boat over rocks. When he could get no further he camped on the left bank of the river and sent Mr. Cameron (his secretary) back to Port Moresby for supplies, with native carriers to cross the mountain. Mr. Cameron returned with two boats loaded with provisions, thirty natives, and six Polynesians. All being ready, on May 17 the party, comprising forty-two men, left the camp, all packing, and the Governor taking the heaviest load. There were only four whites in the party. They crossed Mount Gleason at Eyton Junction, and then shaped a course north-east by east. At a height of 175 feet they crossed Mount Gunbar, next Mount Kulwald. Mount Belford was crossed at the Joseph River, after which they descended to the Goodwin Spur, and saw the first native house at Goodwin's village, Mount Musgrave, where they camped, the Governor going ahead with four Polynesians and seven natives; then ascended Mount Musgrave for over 7000 feet to Vanapa River and Mount Knutsford Range, over rough country; they followed a spur leading west. After three days' march they descended the spur, and began the ascent of Mount Owen Stanley on June 9, reaching the top on June 11 and 12, returning to Mount Musgrave on June 16. All hands started homewards and arrived at River Camp on June 22. They left on June 23, visited a mountain village on June 24, and met the steam launch from the *Merrie England*, which was searching for the Governor's party, and took them in tow. They arrived at Mana Mana on the 25th, and were taken on to Port Moresby, where the party landed after two months, all well. The only death that occurred was that of a native. The country traversed was very mountainous, and no table-land was discovered. Of the geological formation the country is mainly decomposed slate, granite, and quartz, with no sign of gold. Specimens of rock were collected by the Governor. The climate to 8000 feet is moist, above that dry and bracing. Natives were met on only two occasions, and were extremely friendly. They were stout well-built men, but no women were ever seen. Cultivation paddocks were fenced in. Potatoes, yams, and sugar-cane were plentiful, as also was tobacco. Natives, who were devoid of warlike implements, paid particular attention to head-dresses made of shells procured from the natives on the eastern coast of German New Guinea, who were showing friendly communication. Across the Owen Stanley Range the Governor collected many specimens of new plants, among others being some beautiful yellow rhododendrons, which he has since sent to Melbourne to Baron Von Mueller for report. A great number of new grasses in large patches were discovered. At Mount Victoria (Goodwin) he secured several new birds and one animal, which was something like a native bear, but had a long tail and dusty-brown collar and black extremities. The extreme length was 3 feet 6 inches, of which the tail was 1 foot 6 inches. There were five claws on all the feet, the tail was bushy, and it was estimated that the weight of the animal was 40 pounds. The birds of the lower altitudes were the same as those before seen, except as to a new paradise bird similar to the Great Epimachus. Sir William procured a female *Astrachia stephania*, the only male bird of that species being in the Museum, Berlin. The Governor procured several new small birds at Mount Victoria, including the identical English lark. Unfortunately, they were eaten by the Polynesians. Entomological specimens were obtained, including a milk butterfly. Only a few were captured.

ACCORDING to a *Times* telegram from Zanzibar, the Sultan has signed a concession to the British East Africa Company, of Lamu and the Ben-Adir coast, embracing all his territory from Kipini to Mruti. The concession embraces the administration and government of the island and port of Lamu, and of the northern mainland ports of Kismayu, Brava, Magadisho, and Warsheikh. The company's jurisdiction is thereby extended from the River Umba, in the south, to the port of Warsheikh in the north, an extent of about 700 miles of coast-line. Lamu is, next to Zanzibar and Mombasa, the most important port on the East African coast, and commands the trade of the mainland south of Kismayu, and that of the fine waterway of the Tana. It has been for years past the seat of a flourishing commerce, which is mostly in the hands of British Indian subjects, and it is a port of call for the British India Company's steamers.

OUR SENSATIONS OF MOTION.[1]

WE may distinguish two quite different kinds of sensation of motion, active and passive. When we walk or run or row, we use our muscles, and this use of our muscles is the cause of our motion, and also the cause of special sensations which may in a sense be called active sensations of motion. But we have other sensations than these connected with motion. For, if we are carried, or rocked in a boat, or dropped from a height, we are not only moved, but we are conscious of a very well marked sensation which we may call a passive sensation of motion. When we move ourselves we feel both kinds, and it is difficult for us to analyze what we feel and distinguish between our sensations as movers and our sensations as moved. It is to our passive sensations of motion that I wish to direct your attention to-night, and as these can best be examined in cases where they are not complicated with the other kind, we shall confine our attention almost exclusively to passive motion—that is, to cases wh.re we are moved without any exertion of our own muscles. Now the first thing I have to say is in at all events apparent contradiction to the title of this lecture: it is that we have no direct sensation of motion as such. That this is so will be at once obvious if we consider the fact known to all, that we are at this moment being moved with very great velocity through space. We know that this is so, astronomers can prove it, but we are so perfectly unconscious of it that I dare say most of us here could not point the direction in which we are moving; in fact, as we are ignorant of the direction and rate of motion of the great system of which our solar system is a part, no one can say how fast and towards what point in space we are travelling. What we are conscious of is change of motion. It is because the motion of the earth is so steady, because, although very rapid, its changes are very slow, that we do not feel it.

There are two altogether different ways in which a body can be moved. These have been called respectively translatory and rotational. In translatory motion the body is always similarly oriented. Thus, if we consider motion within so small a part of the earth's surface that we may neglect the earth's curvature, such an object as this desk is subjected to purely translatory motion if we move it thus, so that the same side always looks up, and the same side always looks east. Rotational motion involves a change of orientation, and is rotation about an axis. This axis may always be the same, or it may change, and the change of axis may be abrupt or may be continuous. Most of the motions which we observe are made up of both kinds. When we travel by rail—always supposing that we sit still in the carriage—we are subjected to a purely translatory motion only when the train is running along a perfectly straight piece of the line. When it goes round a curve, we are—always supposing we sit still—subjected to rotation as well as to translation; because our face no longer continues to look in the same direction, but, as long as the train is running on the curve, continuously changes the direction in which it looks.

Let us examine what we feel when we are passively subjected to purely translatory motion. As long as the motion is steady,

[1] Armitstead Lecture delivered in Dundee, by Prof. A. Crum Brown.

unchanged in speed or in direction, we feel nothing, as has been pointed out already. Let us look at the case when the speed changes, the direction remaining the same. We have to consider separately three different directions: (1) horizontal, (2) up, and (3) down, because we shall see that our sensations are different in these three cases. With change of speed in horizontal motion we are all familiar. The starting and the stopping of a train or of a steamer give us ample means of studying it. We all know the jolt of a badly started train. What we feel in such a case is, mainly at all events, due to our body being jerked forward or backward, according as we are sitting with our back or our face to the engine. But if the train is carefully started we find that our rate of motion may in a very short time be changed from nothing (relatively to the earth) to, say, thirty or forty miles an hour, without our feeling anything but the up and down rattle due to the slight unevenness of the rails. And the same was the case till comparatively lately with stopping. Now, however, since the introduction of the continuous brake, a train can be so rapidly stopped—its rate of motion, that is our rate of motion when we are in it, can be so very quickly changed from, say, sixty miles an hour, to nothing—that we do feel a strange, not altogether pleasant sensation. Experience has taught us what that sensation means, but at first it was so novel that experience was necessary to interpret it. It is not a sensation of jolt, the change though rapid is not abrupt. What we really feel, although it takes some amount of careful observation and some thought to see this clearly, is that the direction of the vertical, the direction in which a body falls, the direction in which our body presses has been changed. We feel this most distinctly if we are standing when the brake is applied; we feel that if we do not take means to prevent it, we shall fall over, and we prevent this by bringing our body into the line of the new vertical. Our feeling of unsteadiness depends on our uncertainty how long the new state of matters is to last. It lasts as long as the speed is being changed at the same rate, and the deviation of the new from the real vertical depends on the rate at which the speed is being changed. Our perception of deviation from the vertical is pretty acute. Most of us can tell a line to be off the vertical when it is inclined only a few degrees to it. In ordinary cases we have extraneous help in judging. We have walls or chimneys, known to be vertical, or surfaces known to be level, with which to compare, but even when we have no assistance of this kind we are not often far wrong. It might be supposed that it is the pressure of our body on the floor or ground that gives us the idea of the vertical, but that idea still exists in cases where we can feel no such pressure. If our body is supported in water, or entirely submerged, as in diving, we still have a very distinct, and fairly accurate notion of up and down, although in such cases, as our body is very nearly of the same density as water, the resultant pressure on it is small. We shall see in a little a possible explanation of our sense of the vertical. When the train in which we are travelling runs quickly round a sharp curve, we feel something very like the sensation just described. And indeed it is due to a perfectly similar cause; the apparent vertical is the direction of the resultant of the force of gravity and the centrifugal force, and is, as every engineer knows, more inclined to the real vertical as the curve is sharper and the speed of the train greater. In this case the sensation is complicated, because the motion is not one purely of translation, but, as already pointed out, is compounded of translatory and rotational motion.

Let us now look at cases of up and down motion. As we can study horizontal motion in the railway train, so we can up and down motion in a lift. Here also we see that it is change of motion which we really perceive. For, once the lift is started, and is moving smoothly and uniformly, either up or down, we are quite unconscious of the motion. It is the start and the stop, or the quickening or slowing of the motion only that we feel. And the stopping of the upward motion produces exactly the same feeling as the starting of the downward motion, provided they are equally smooth and free from jerk. It is easy to see what are the physical conditions here. Just as the acceleration in a horizontal direction inclines the apparent direction of gravity, so acceleration up increases, and acceleration downwards diminishes, the apparent intensity of gravity. If the lift *fell* down, unrestrained, its inmates, during the short time the experiment would last, would have no sense of the force of gravity at all. An object dropped from the hand would not fall down to the floor, because the floor itself would be falling at the very same rate as the object. And what is true in this extreme case is true also in a measure in all cases of downward acceleration. But only in cases of *acceleration*, for, however fast the lift goes down, if it moves uniformly, without change of speed, the bodies of those in it press on its floor exactly as if it were at rest. Similarly, upward acceleration increases the apparent force of gravity. The physical conditions, then, of our perception of acceleration of translatory motion in any direction are change in the apparent direction, intensity, or both, of the force of gravity. It is a strange and interesting fact that our perception of downward acceleration—that is, of diminished force of gravity—is more acute than that of acceleration upward or in a horizontal direction. We feel the starting of the lift as it goes down, and its stoppage when it has come up, much more distinctly than the start on the way up or the stop at the end of the journey down. And when we are rocked in a rolling steamer, it is the beginning of the downward move that is most perceived.

Having now discussed the phenomena of our sensations connected with translatory motion, let us examine what our experience is when we are turned round, or subjected to rotational motion. We execute such movements every minute of our waking life. But as with translational motion, so, and even more, with rotational motion, it is impossible to analyze our sensations when they are complicated with what we feel we do. And in the case of rotation a very serious complication is introduced by our seeing how we are being moved. So that, to make a strict examination of our sensations in this matter, the observer must place himself blind-folded on the rotating apparatus, and be passively turned round. Or, as in Prof. Mach's very ingenious experiments, a small hut with translucent paper windows may be placed on the turn-table for the reception of the observer. Just as we can move, or be moved, right or left, backwards or forwards, up or down, so we can be spun round about a fore-and-aft, a right-and-left, or an up-and-down axis, and about each of these axes either the one or the other way round. It is plain, however, that we can get simple results only in the case of rotation about a vertical axis, because otherwise a great complication would be introduced by the varying position of our body relatively to the direction of gravity. We shall see that we can get everything we require with rotation about a vertical axis. Here we find, as in the former case, that it is only change of motion that is perceived. The observer sits on a chair on the turn-table, his eyes are bandaged, and an assistant gives the table a steady, uniform rotation. At first the observer feels the turning quite distinctly, but after less than a whole revolution the sensation becomes very indistinct, and, while the turning still continues at the same rate, soon disappears altogether. If the rate of turning is now increased, he feels it begin again, all that he perceives being the increase; his perception of that also soon dies away, so that in a short time he may be spinning rapidly round, while he feels completely at rest, and is only aware that he has been gently turned round a little, two or three times. But if you now stop him he feels a turning round in the opposite way to that in which he really was turning, the fancied rate of turning being, at the moment of stopping, that of the real turning which has just been stopped. This imaginary rotation dies away, exactly as the sensation of the real rotation did. Now, *very nearly* the same thing takes place, whatever is the position in which the head is placed during the experiment, *if the head is kept rigidly in the same position during the whole of the experiment.* Let us look at a case in which the position of the head is not kept the same during the experiment. The observer sits on the table, with his head inclined to one side, so that the line from ear to ear is vertical. He is now turned uniformly round; as before, he feels the turning at first, but as the uniform turning goes on the sensation dies away. When he feels perfectly at rest, let him give the word to stop, and at the same instant raise his head into the ordinary position. He will now feel as if he were being turned about the line from ear to ear—that is, now, about a horizontal axis. If his right ear was down when he was actually being rotated, and if the turning was with the hands of a watch lying with its face up, then the imaginary rotation will be the opposite way round—he will feel as if his head were going forward and his feet back. This sensation will last only a short time, but there is a risk in trying the experiment, that the observer may try to correct this alarming overturn by throwing himself backwards; if he is nervous it may therefore be as well to have him strapped to the chair. Whatever line in the head we make vertical while the real rotation is going on—that is, whatever line in the head we make the axis of the real rotation—that line is the axis of the apparent rotation which we feel when the real rotation stops, however we may move our head at the time of the stoppage. There is a practical joke depending on this principle, which I have seen played. The subject of the joke, who ought, of course, to be a person not conversant with the laws of the sensation of motion, is asked to hold a poker upright on the floor, and, placing his forehead on the top of it, to walk three times round it, rise up, and walk across the room. His march round the poker is a rotation about the fore-and-aft axis of his head; when he rises up he feels the contrary imaginary rotation, about the same axis, now, of course, horizontal, so that, if he went round with the sun, he falls to the right, and to the left if he went round the other way. In a very interesting experiment with the turn-table we have a combination of real and apparent rotation. Lie down on the table, say on the left side, so that the left ear is vertically under the right ear, so making the right-and-left axis of the head the axis of rotation; let the table be turned round at a uniform rate, wait until all sensation of rotation has ceased, and then, while the uniform turning is still going on, roll yourself over on your back. You will then experience a very startling sensation. The new axis of rotation of the head is the fore-and-aft one; there was no rotation about it before, therefore you feel that real rotation, the real rotation about the old axis—right-and-left—has just ceased, therefore you feel the imaginary opposite rotation. The sudden occurrence of the combination of these motions, felt as real, resulting from a cause so seemingly inadequate, rolling from your side to your back, gives rise to an almost dreadful sense of insecurity.

Thus then in rotational as in translational motion it is change of motion, what is technically called acceleration, which we perceive. There are two questions which naturally arise in this connection: (1) What is the use of this sense? and (2) What is the organ of this sense, and how does it work? What is the use of it? Everyone will, I am sure, admit that it must be of great use to us to have a constant knowledge of the direction of the vertical; to have, as it were, a private level of our own, which we cannot mislay. As to our sense of rotation, it is to it chiefly that we owe what we call our knowledge of the airts; it enables us, as we walk about on winding roads, or through narrow crooked streets, to retain some idea of the real directions. But the chief use, no doubt, of the sense of rotation is to enable us to control and regulate the rotatory movements of our head—movements we are constantly making as we look about us. It may be asked, in these short quick movements of the head, where is the secondary sensation of turning the other way which I described? We never experience it at all. Mach has very clearly, and with great penetration, explained how this comes about. These quick movements, our habitual movements of rotation, are so short in their duration, that during them we do not come to feel that our head is at rest. The sense of the original real rotation is still vivid when the rotation is stopped, so that the secondary sensation of an imaginary motion the other way round merely annuls the primary sensation, puts an end to it when the real rotation stops. Without such a stopper of sensation we should go on feeling the rotation for a short time after it was done.

What is the organ of this sense? There is in our head a very remarkable organ which has been for long a puzzle to physiologists, an organ which is found not only in our heads, but also in the heads of all mammals, of all birds, and of all but the very lowest fishes (and even in the very lowest fishes it occurs in a less developed form). This organ is so closely related in position to the organ of hearing, that it was long supposed to be a part of it, and we shall see what attempts were made to explain it as an organ of hearing. I shall give as short a description of it as is compatible with making it plain how it can act as the organ of the sense we have been considering. I must at the same time confess that in some points our knowledge of the matter is still imperfect, and that much has still to be done before we can explain its action as fully as we can that of the eye, for instance.

The organ in question is lodged in a bony cavity continuous with that which contains the organ of hearing, and for this reason was long, and perhaps by some is still, regarded as itself having something to do with the perception of sound. This cavity in the hardest bone in our head consists of four parts—the vestibule, and the three semicircular canals. The vestibule is an irregular chamber, in man about $\frac{1}{5}$ of an inch long and $\frac{1}{7}$ of an inch broad and deep. In its walls are five openings leading to the semicircular canals. These are tunnels in the bone having an elliptical or circular section, and opening at each end into the vestibule. The central line of each canal lies nearly in one plane, which we may call the plane of the canal. At one end of each canal there is an enlargement called the ampulla. The planes of the three canals are approximately at right angles to one another. The canals are named from their position—the horizontal, the superior, and the posterior; the two latter unite at their non-ampullary ends before joining the vestibule, so that there are five and not six openings into the vestibule from the canals—three ampullary, one for each canal, and two non-ampullary, one for the horizontal, and one common to the superior and the posterior canals. The plane of the horizontal canal is nearly horizontal in the ordinary position of the head in all animals, and is therefore at right angles to the mesial plane: the planes of the two other canals make nearly equal angles with the mesial plane.

In the bony labyrinth just described there is inclosed a membranous labyrinth of a generally similar form. It consists of the utricle, lodged in the vestibule, and of three membranous canals, each furnished with a membranous ampulla. The membranous labyrinth does not fit tight into its bony case. The utricle is much smaller than the vestibule, which contains, besides, the saccule, an organ connected with the cochlea; and the diameter of the membranous canals, except at the ampullæ, is much less than that of the bony canals. The membranous ampullæ, on the other hand, nearly fill the bony ampullæ. The entire cavity is thus divided into two spaces, one within, the other around, the membranous labyrinth; each is filled with a liquid, the endolymph and the perilymph. The nerves are distributed to one spot in the utricle, and to a crescent-shaped ridge near the middle of each ampulla. The nerves end in hair-cells, the hairs of which project into the endolymph. The *macula acustica*, the spot in the utricle to which nerves are distributed, is covered with a gelatinous layer in which are embedded small crystals of carbonate of lime.

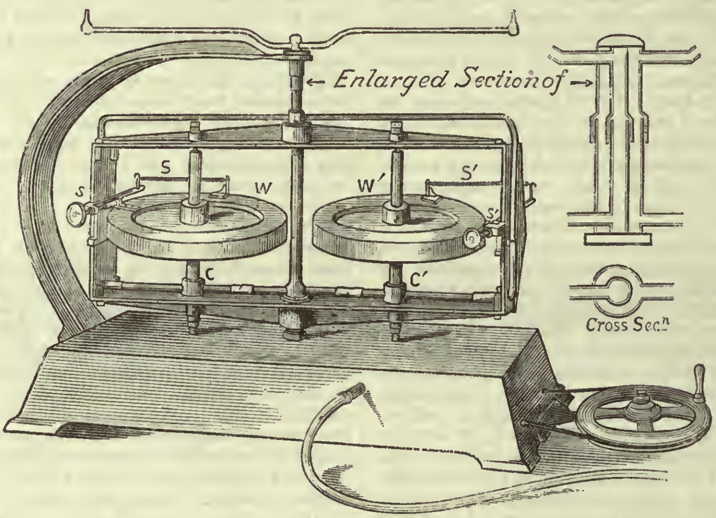
Everyone must see that an apparatus so purpose-like in its arrangement must have a use, and this use must be one applicable to all the higher animals.

It was long supposed that it had to do with our perception of the direction from which sounds come to us. The idea is not unnatural, and is obviously derived from the nearness of the apparatus to the organ of hearing, and from the relation of its form to the three dimensions of space. No explanation has ever been given how it could serve this purpose; and we can easily show that it does not do so by experimentally showing that we have no means of ascertaining the direction from which a sound comes except by two or more simultaneous or successive observations. If a sound is heard louder in the right ear than in the left we conclude that it comes from the right, and by turning round the head we soon get a sufficient number of observations to enable us to judge of the exact direction. If a short sharp noise is made at a point equidistant from the two ears, we do *not* know the direction from which it comes unless we see what causes it.

But the apparatus is admirably fitted to act as the organ of the sense of rotation, or rather of the sense of acceleration of rotatory motion. Let us first consider the action of one canal. If the head is rotated about a line at right angles to the plane of the canal, with the ampulla leading, you will see from looking at the diagram that there will be a tendency of the endolymph to go from the utricle into the ampulla, and of perilymph to go from the space between the bony and the membranous canals into the utricle. These will conspire to stretch the membranous ampulla where the nerve-endings are, and we can easily see how this will stimulate the nerves, and send a message to the brain. But this stretching will not take place if the head be rotated the other way about. In that case the tendency of the fluids will be in the opposite directions, and will rather make the ampulla less tightly stretched, and we can readily suppose that this may not stimulate the nerves, and no message will be sent to the brain. One canal will thus be able to give indications of rotation about one axis, in one of the two ways round. But for each axis we have two canals, one turned the one way and the other the other. And as by means of three rectangular axes we can represent any rotation, so any rotation will be perfectly recognized by means of the six canals. That this is actually the function of this organ is further proved by the effects of injury or disease. One ear is sometimes attacked by inflammation while the other ear is unaffected. In such cases the patient suffers from persistent vertigo—that is, sense of rotation where no real rotation occurs. This is, at least, one form of what is known as Ménière's disease, so-called from the name of the physician who first drew the attention of medical men to it. Now it is obvious that, if the six canals act in the way I have indicated, the pathological irritation of the three canals of one ear will produce a sensation of rotation about an axis the position of which we can foretell from the relative positions of the planes of these three canals. And clinical observations on persons suffering from this disease show that the vertigo actually is about this axis. Deaf-mutes are persons who from a very early age have had no sense of hearing at all. This condition may arise from the imperfect development of the organ of hearing, or from its early destruction by disease. In either case it often happens that the organs we have been discussing, from their nearness to the organ of hearing, are involved in the mischief, and are also imperfectly developed, or destroyed by disease. Deaf-mutes have therefore not unfrequently the semicircular canals in a state unfit for use. Experiments have been made on deaf-mutes with the object of testing the accuracy of their sense of rotation. Those who have made these experiments report that many deaf-mutes are insensitive to rotation. If these observations are confirmed, the theory I have just been explaining will receive a very great support.

In order to illustrate this theory, and to show that the principle on which it is based is a sound one, I have devised a sort of working model which I shall now show you. I may say that when I accepted your invitation to lecture here, and had selected the subject of our sensations of motion, the idea occurred to me of making a sort of working model of the semicircular canals. The difficulty was to find an instrument-maker who could help me over the obstacles which always lie in the way of a designer who is not himself an engineer. I take this opportunity of thanking Mr. Alex. Frazer for his help in this matter. He at once understood what I wanted, and so gave me the use of his skill and experience that the instrument here is exactly what I intended it to be, and a great deal better than my most sanguine hopes.

The model, as perhaps you will better see from this somewhat diagrammatic drawing than from the machine itself, consists essentially of two heavy wheels, placed side by side, with their axes parallel, in a frame which itself can be turned round about an axis parallel to that of the wheels. These heavy wheels correspond to two parallel canals, say the two horizontal canals. As it is the inertia of the fluid in the canals which enables them to work, so here it is the inertia of the heavy wheels. Each wheel has a stop, which altogether prevents its turning, in one way round, beyond a certain point. The one wheel is thus checked in turning the one way, the other in turning the other way. Each wheel is just held against its stop by a spring which is stretched when the wheel turns away from the stop. Each wheel with its stop and spring is as nearly the mirror image of the other as it could be made. When I turn round the frame, both wheels tend to lag behind the rotation of the frame, on account of their inertia. One of them cannot lag behind at all because of its stop, and the other cannot lag much behind because of its spring; the stronger we make the spring the less can it lag behind. This lagging behind is, of course, a turning of the wheel on its axis, relatively to the frame, in the opposite sense to that in which the frame is turned. As we continue to turn the frame with uniform speed, the spring brings the wheel back to its original place against the stop, and further rotation at the



same rate makes no change in the relative position of the parts of the machine. But if we now quickly bring the frame to rest, both wheels in virtue of their inertia tend to continue their rotation: one, that one which made the relative movement before, cannot continue its rotation because of its stop; the other can rotate a little, not much, because of its spring—it turns a little, but is soon brought back to its original position against its stop by the spring. You will easily see that just as in the model the inertia of the wheel corresponds to the inertia of the fluid, so here the stretching of the spring corresponds to the stretching of the ampulla. All that we want to make the model complete is to find some way of making the stretching of the spring visible, something which shall correspond to the message sent to the brain. You cannot easily see the stretching of the spring while the frame is turning round, and it was necessary to devise some way of making it visible. We must here leave the analogy of the living organ. The brain turns with the labyrinth, but we are the brain of this machine, and we do not turn with it. After a good deal of consideration, and after thinking of and rejecting a good many plans, I fell upon the one I shall now show you. In the lower end of the axle of each wheel there is fixed a stop-cock, through which gas can pass from one pipe to another. When the wheel is against the stop only a very little gas passes—just enough to prevent the jet going out. When the wheel turns away from its stop, the stop-cock is opened, and the stop-cock is so adjusted that the quantity of gas passing shall be roughly in proportion to the stretching of the spring. By a contrivance indicated in the diagram, the two gas pipes, one from each stop-cock, are brought through the axle of the frame and led each to a gas jet.

Now, when I begin to turn the frame one jet flares up, but as I continue the turning, as nearly uniformly as I can, you see the jets remain at their minimum, which I shall call zero of sensation. Of course I could have made this zero the zero of gas too, but then we should have needed a subsidiary flame to light the gas when the stop-cock opened. I now stop the frame, and you see the other jet flare up for a little. That corresponds to the secondary imaginary rotation which we feel when a real rotation is stopped. I ought to apologize for so often calling this a secondary or imaginary rotation. I hope you all see now that it is as really an *acceleration* in the strict meaning of the word as the original start from rest.

I have taken this question—What is the organ by means of which we perceive acceleration of *rotatory* motion?—first, because it has been most fully worked out. We now come to the question, How do we perceive acceleration of translatory motion? This, as we have seen, is the same as the question, How do we by our senses recognize the direction and estimate the intensity of what is to us at the moment the force of gravity? A very natural suggestion as to the way in which we perceive the intensity of this force is that it is a skin sensation; that it is by the greater or less pressure which we feel on that part of our body which rests on our support. Prof. Mach, to whose experiments I have had often to refer, and to whom we owe, more than to any other investigator, our knowledge of the whole subject of the sensation of motion, has very clearly proved that this is not the case. Everything we know as to this sense leads us to look for its organ in the head. And there is an organ which, to some extent, at all events, seems to be what we are in search of. The *macula acustica* in the utricle is a spot well furnished with nerves, and we have not found out any special function for it. There is a similar *macula* in the saccule, that other membranous bag contained in the vestibule. Mach has suggested that the *macula* of the utricle may be the organ by means of which we perceive acceleration of translatory motion. Let us look at it, and see how far it is fitted to act as a level. Its length is stated by Prof. Schwalbe to be about $\frac{1}{8}$ of an inch, and its breadth a little less. According to the same observer, it covers a part of the floor, the anterior wall, and a part of the external wall of that part of the utricle called the "recess." Its nerves end, as has already been stated, in hair-cells, and these are covered by a gelatinous substance filled with a fine powder of crystals of carbonate of lime. What is interesting to us in this description is that it looks in three directions, and that the whole of it is covered with a powder of considerably greater density than the fluid (the endolymph) with which the utricle is filled.

Let us try to imagine a model of this structure. Let us take a box of glass, so that we may see what goes on in the inside of it. Let us put on a part of the bottom of the box, on the end of it, and on a part of the side of it, a layer of thin jelly mixed with fine sand. Fill up the box with water, and put on a lid. We shall find that we have an apparatus that does to some extent answer the purpose of a level. When we change its inclination, the jelly but for the sand would indeed have very little tendency to change its position, but the sand, being specifically heavier than the water will, and will either move through the jelly if that is thin enough, or pull the jelly with it. In any case, a change of position of the box will involve a change in the relative position of its contents. In the actual case of the *macula acustica* such a change in the relative position of the sand and the hair-cells must give rise to an irritation of the terminations of the nerves, and send a message to the brain. We cannot as yet work out all this in detail, as we can the way in which the canals give us information as to the acceleration of rotational motion, but we know enough to turn our attention to the subject; and we may hope that, by more accurate study of the sensation phenomena, and by comparison of them with the anatomical facts, this important and interesting physiological question may be satisfactorily answered.

ON THE GEOLOGICAL HISTORY OF THE PREHISTORIC FLORA OF SWEDEN.

FIFTY years have passed since the Danish Professor, Japetus Steenstrup, presented to the world his masterly researches on the history of Denmark's peat-bogs. These researches clearly demonstrated that the forests of Denmark had suffered remarkable variations. The oldest forests had consisted chiefly of aspen (*Populus tremula*), next, for a long period, of Scotch fir (*Pinus sylvestris*), then of oak, and, finally, of alder (*Alnus glutinosa*). Remains of the beech—now Denmark's chief species of tree—are, however, entirely absent from the peat-bog. Consequently, it must have been the last to immigrate. It was a natural surmise—and one even advanced by Steenstrup—that the changes referred to were connected with a gradual softening of the climate, a view defended, too, by Prof. Forchhammer.

But Steenstrup's researches were in advance of their time; glacial geology was only in its infancy, and voices were therefore raised both in Denmark and Sweden claiming to interpret these changes in the forest vegetation as one of Nature's great systems of evolution, whereby one variety, so to speak, prepared the soil for the next comer, without any reference to climate. However, this view has now but an historical interest. For, since our knowledge of the geology of the Glacial age has become more and more enlarged, and since remains have been found in Scania of a true Arctic flora embedded in the fresh-water clay deposits of that province, a return to Steenstrup's theory that the changes of climate and forest vegetation were related was but natural. Indeed, the same Arctic flora was shortly discovered underneath the aspen layer in the Danish peat-bogs, so that the aspen flora cannot be regarded as the first after the Glacial age. By degrees, as the ice melted, the denuded soil was invaded by the Arctic flora from the south. First, when the climate became still milder, and a forest vegetation could flourish, the aspen and the birch immigrated, and in turn the pine, oak, and alder. Each one formed in its day the forest of Denmark, and they were naturally accompanied each by its own peculiar undergrowth of shrubs and plants. Enormous ages elapsed between these events. The remains of the peat-bogs show that generations upon generations of grand firs flourished before the oak immigrated and before the pine flora was at last ousted. And in its turn the oak reigned supreme during countless ages, until that, too, was extinguished by the alder and the beech. During the fir period, the men of the Stone Age spread themselves over the land; when the fir was supplanted by the oak, the Bronze Age began. If we bear in mind how exceedingly slow the extension of the oak and the beech is, we can form some idea of the immense time that must have elapsed since the Ice age.

Therefore the flora of Denmark consists entirely of the offspring of immigrated plants. Many of the species which appeared in the country did not remain; to them Denmark was only a station on the road towards higher latitudes. This was, for instance, the case with the greater portion of the Arctic flora, as well as with the fir. From the beginning of the historical period the beech has flourished throughout the whole country.

In Sweden, in districts rich in calcareous matter, tuff strata are deposited from springs which, by their contents of carbonic acid, contain carbonate of lime. When calcareous water is exposed to the air, the carbonic acid gas evaporates, and the carbonate of lime is precipitated in the form of a white deposit, which soon hardens to stone. Such a deposit is therefore particularly natural around the mouth of a spring or in some pool into which the calcareous water is discharged. Consequently the leaves or other remains of plants growing around are covered, soon after falling into the water, with a thin coating of chalk, and although they are by degrees destroyed, this imprint in the chalk remains—often so distinctly that the finest fibres of a leaf may be traced.

A necessity for the formation of calcareous tuff is therefore the presence of calcareous rocks, whence the water may draw the lime. And, indeed, with us all calcareous tuff deposits, as far as we know, are confined to where the chalk formations are richest, as, for instance, Scania, Western and Eastern Gothia, Jemtland, Ångermanland, and Åsele Lappmark.

The greatest in extent and richest in leaf imprints are the old well-known tuff strata at Benestad, in Scania, north of the town of Ystad. They were formerly largely worked for building purposes, as, for instance, for several churches. The tuff is referred to by early writers as rich in leaf imprints, but in their writings a serious error crept in, viz. that even leaves of the beech were imprinted. This is wholly without foundation.

In consequence of the quantity of stone removed, it is now impossible to fix precisely the nature of the stratification, and what we know on this point is due to the particulars supplied by Baron Claes Kurck, who carefully examined the strata. His researches fully confirm the views of the writer, expressed as far back as 1872, viz. that the oldest strata were deposited whilst the aspen was the predominating tree in the districts, and before the fir had immigrated. Kurck has also found here traces of birch, grey sallow (*Salix cinerea*), and possibly the common sallow (*Salix caprea*). Above this stratum we come to the fir, deposited when that predominated. The imprints of the fir, in the shape of needles, branches, bark, and cones, show that this tree grew close by the springs. Most of the tuff dates from the fir period, but during the same age other species of trees gradually immigrated, of which indications are found in the lower parts of the fir deposit. From these the National Museum possess a rich collection, chiefly made by Nordenskiöld in 1873. It contains several rare species of plants, and the imprints of leaves are so remarkably clear that the collection is one of the greatest ornaments of the palæontological section.

Of the trees which flourished contemporaneously with the fir, we learn from Kurck that the birch, mountain ash (*Sorbus aucuporia*), *Salix caprea*, and *Salix aurita*, were the oldest, and the hazel but little younger. To somewhat later strata he refers dog-wood (*Cornus sanguinea*) and berry alder (*Rhamnus frangula*), and he believes that the remains found of Dutch rush (*Equisetum hyemale*), and the guelder rose (*Viburnum opulus*) also date from the same period. If this be the case, it is probable that some leaves in the Nordenskiöld collection of hawthorn (perhaps *Cratægus monogyna*) also belong to this stratum.

Naturally, the species named also appear in this collection. The later strata from the fir period are, according to Kurck, distinguished by a quantity of leaves of the mountain elm (*Ulmus montana*). Leaves of hazel, birch, aspen, &c., are also found; whilst, for the first time, leaves of the lime (*Tilia parvifolia*) are met with, but very rarely. In this stratum Kurck has also found the common bracken (*Pteris aquilina*) and meadow-sweet (*Spiræa ulmaria*). Some leaves of the alder he believes to be still younger.

Besides the species named—which are all found with remains of the fir—are some others. Already in Nordenskiöld's collection notice was attracted to portions of a stratum in which the fir was absent, and which in a measure differs in appearance somewhat from the rest of the tuff. These portions contain leaves of the mountain ash, the common oak (*Quercus pedunculata*), viz. hazel, lime, salix, and birch. This stratum has been re-discovered by Kurck, and is, as might be expected, younger than those named. It may be added that, according to earlier writers, leaves of the maple (*Acer platanoides*) have also been found at Benestad, but latterly none have been discovered.

It would seem, then, that there is at Benestad a counterpart to the Danish aspen, fir, and oak periods; but we cannot quite say that as regards the second period. There is, for instance, nothing to prevent the fir having vegetated, through some accidental causes, at Benestad, even during a part of the oak period. This is the more likely as we find the tree at the present day in Northern Scania. If, therefore, on the one hand, it is certain that the elder pine strata at Benestad belong to the true fir period—the time before the immigration of the oak—it cannot, on the other, be denied that the younger section of the fir strata may have been deposited already when the oak immigrated thither. That some of the fir-bearing strata must have been deposited relatively late seems evident from the presence of such plants as dogwood, hawthorn, elm, &c. However, the problem will no doubt be finally solved when once the peat-bogs of the province have been palæontologically examined.

Of the beeches and hornbeams (*Carpinus betulus*), now common in the district, there are no traces in the strata, and although the springs still yield plenty of water, there appears to be no deposit of calcareous tuff whatever. Thus, all we are really able to say respecting the palæontological remains in the fir period at Benestad is that these plants immigrated before the beech, and, most probably, even before the oak, and that all of them came from the south-west.

Respecting the flora which flourished in Scania previous to the aspen and fir periods, we know its characteristics through the vegetable remains in the fresh-water clays of the province. They display a rich Arctic flora, comprising *Dryas octopetala*, *Salix polaris*, *herbacea*, *reticulata*, *Betula nana*, *Oxyria digyna*, &c. An animal fossil must also be mentioned, only recently found among them, viz. *Apus glacialis*, now common in Spitzbergen lakes, but which in Scandinavia is not found south of the lakes in the Dovre Mountains.

In proportion as the inland ice melted, the Arctic flora, so rich in varieties, advanced, but as the climate became milder this flora was replaced by the forest vegetation immigrating from the south, and, at all events at Benestad, the trees followed each other in the same succession as in Denmark, viz. aspen, fir, oak, whilst the beech immigrated considerably later. It is most probable that the forest vegetation followed in the same order in the whole of Southern Sweden, but we do not know this with certainty. For we still know too little respecting the remains of plants in the peat-bogs of Southern Sweden. That we are far behind in this respect is chiefly due to the circumstance that in Denmark the peat-bogs are turned largely to profitable account.

Of the calcareous tuff strata in the province of West Gothia we know unfortunately very little. They are, however, small in extent, and contain only remains of trees still found in the neighbourhood, viz. hazel, salix, and aspen. Near the Eskedal railway station there is certainly a very large deposit, but not formed of continuous tuff, but of loose calcareous *débris*, which does not retain imprints.

In East Gothia we have two calcareous formations, one near Vreta cloister, which appears to be of a rather recent date, as it contains salix, hazel, oak, and lime. The other, north of Vadstena, is, however, much older, and therefore of great interest. This contains, among other remains of a pure Alpine plant, *Dryas octopetala* (L.), which we already know from the Scania fossil glacial flora, besides dwarf birch (*Betula nana*), and perhaps also *Betula intermedia*. There are also leaves of several varieties of willow, birch (*Betula odorata*), crowberry (*Empetrum*), *Vaccinium uliginosum*, and fir needles. The discovery of Dryas in this locality is of the highest interest and importance, as it leads us to hope that we may discover in other parts of Sweden between Scania and Jemtland remains of an Arctic flora, which, judging from the discovery referred to, must, at all events partly, have advanced from the south through the whole country. Formerly we did not possess a single palæontological proof from this part of Sweden in support of this assumption. The discovery is also of great interest in another respect, inasmuch as it shows that Lake Vettern must have become separated from the Baltic, with which it was once connected, at a time when the climate was Arctic—an assumption in full accord with Prof. S. Lovén's discoveries respecting the Arctic Sea fauna that to the present day is found at great depths in this lake.

The Jemtland strata have of late been examined by Herr A. F. Carlson. This province is rather rich in calcareous tuff deposits, some twenty localities having already been discovered. Here, too, the first forests appear to have consisted of aspen, birch, chiefly *Betula odorata*, and fir, of which latter remains have been found in several places. In four localities *Dryas octopetala* have been found, and in two *Salix reticulata*, both of the Arctic flora. As the former were found at Fillsta and Digernäs, in Sunne parish, and the other at Semla, in Mörsils parish, it would appear to be proved that the Alpine flora of Jemtland formerly had a far greater extension within the province than at present, and that at that period it reached as far as the basin of Lake Storsjö. Without doubt an examination of the fresh-water clays of the province would go to show that the Alpine flora formerly covered the whole of Jemtland. The tuff strata which contain such remains were deposited a little later, whilst the Alpine flora was in process of being displaced by the forest vegetation.

The remaining plants that have been found in Jemtland are Dutch rush (*Equisetum hyemale*), salix, several varieties of willow, dwarf birch, *Betula intermedia* and *alpestris*, *Alnus incana*, crowberry, mountain ash, *Sorbus aucuporia*, *Vaccinium uliginosum*, and sea buckthorn (*Hippophaë rhamnoides*).

From the province of Ångermanland we know two tuff deposits, near each other, but the palæontological remains are few and badly preserved. Here have hitherto been found only some lichen, fir, birch, salix, and willow.

In Åsele, Lappmark, between Långfors and Långsile, there are two deposits—as far as we know the northernmost in Sweden. Both are rich in leaf imprints, and thanks to Colonel N. Sjöberg, of Åsele, the National Museum has obtained specimens. The species are certainly not numerous, but they are well preserved, and consist of lichen, leaves of fir, birch, aspen, salix, some willows, and *Hippophaë rhamnoides*.

As I have already stated, leaves of this plant have also been found in a spot in Jemtland situated more than 1500 feet above sea-level. Here the leaves are found in common with remains of Dryas, but whilst the latter now has to be sought high up in the mountains, the former is, on the contrary, only found by the coast. It is found along the shores of the Baltic, from Roslagen (near Stockholm) to Vesterbotten in the north, and the thorny shrub, with its whitish silvery leaves, and yellow or chrome-coloured sour berry-like fruit, here goes by the name of *haf-thorn* (*i.e.* sea thorn). In other parts of Central and Northern Europe where this shrub grows, it is also a coast plant, but it is found beside the glacial rivers of the Alps; and its former existence in the localities named in Norrland—right in the heart of the country, high above the sea, together with other Arctic plants—shows indisputably that here also it was originally an Arctic plant. But whilst *Dryas*, *Salix reticulata*, &c., were forced northwards by the immigrating forest flora, this plant, on the contrary, found a place of refuge on the sea-shore, where it flourishes to the present day. It seems, indeed, hardly credible that two plants now so widely separated, geographically, as Dryas in the high mountains and Hippophaë by the Baltic shore, once grew side by side in the heart of the country.

Having dealt with the proofs respecting the former extension of the Swedish flora furnished by the palæontological remains of the calcareous tuff strata, I purpose to touch upon an equally important point, viz. that the spruce immigrated comparatively late. In no single tuff deposit has trace been found of this tree, and this circumstance is too uniform throughout to be a matter of accident. Especially peculiar are the conditions in

Jemtland, where several of the localities in which the palæontological discoveries were made are surrounded by spruce forests, and where the tree grows higher up on the mountains than the fir, which is the reverse of what is generally the case. In Jemtland, therefore, the spruce clearly immigrated after the fir, and first when the principal tuff formation had ceased. Whence did the spruce immigrate into Sweden? It cannot have been from the south or from Denmark, for remains of the tree are totally absent in that country's well-explored peat-bogs, neither does it belong to Denmark's present wild flora. Neither can the spruce have come from the British Isles. Certainly it appears from palæontological evidence that the spruce existed in England before the Ice age, but it appears to have been extinguished during that age, as it is absent from the post-glacial deposits as well as from the British flora of the present day. Finally, the scarcity of the spruce in the western parts of South-Eastern Norway fully proves that it did not immigrate from the west. There cannot, therefore, be the slightest doubt that the spruce immigrated into Sweden from the east. This assumption corresponds entirely with the present extension of the tree east of the Baltic. But this immigration cannot have taken place *viâ* Northern Sweden around the Gulf of Bothnia, as this part can be supposed to have had only at a later period a climate mild enough for its existence. It is more probable that the immigration took place *viâ* the Island of Gothland on the south-east coast, or *viâ* the Aland Islands, off Central Sweden, and that the spruce afterwards spread north, west, and southwards.

It may be mentioned, by the way, that the spruce existed in the neighbourhood of Enköping at the time when Lake Mälaren was a bay of the Baltic, and the sea covered the spot where the town is now situated. Of great importance with regard to this point is the discovery recently made by Dr. H. Munthe, that the spruce was found in Gothland at a time so far remote that the division of land and sea then was wholly different from that which at present exists. This seems to speak for the immigration of the spruce by this road. Further, Dr. R. Hult, of Helsingfors, last summer discovered in West Nyland, in Finland, sub-fossil remains of spruce in a stratum which he estimates to be older than the remains of spruce found in Scandinavia, and he therefore considers that the spruce immigrated from Finland.

Considering the present and past extension of the spruce in Europe, one might be inclined to assume that the true home of this tree was Scandinavia, whence it was driven in the Glacial age, but this, it is now being demonstrated, was not the case.

Now, the spruce, in spite of its relatively late immigation, has in Sweden spread greatly, forming huge forests; and we might be disposed to conclude that in its turn it would extinguish other species. Experience from our forests goes to prove that this is really the case. Thus, from Southern Sweden we know from the researches of Dr. R. Hult in Blekinge that the spruce (except in dry localities) generally extinguishes the fir. And reports by Herr C. G. Holmerz and Herr Th. Örtenblad show that this is also the case in Norrbotten, where "the spruce in all more favoured localities wedges itself in between firs and birches, and finally exterminates its predecessors in occupation." Even the oak is ousted by the spruce. Prof. Elias Fries states that "the spread of our noblest foliage tree is being arrested in recent times. In a primæval spruce forest, where there is no more oak in the locality, I have found below an immense layer of moss oak trunks of such dimensions that I doubt whether there are their equal in all Sweden." In Blekinge also similar facts have been brought to light, and recently Prof. F. R. Kjellman expressed the opinion that "the oak flora formerly had a greater extension in our country, but has been thrust aside by the spruce."

Although the spruce is victorious over some species, it is unable to conquer the beech. Therefore there is little chance that the spruce will take possession of our southern counties.

In conclusion, as the result of the known palæontological facts respecting the immigration of our flora, we are able to express the opinion that the greatest part of the Arctic flora, as the inland ice melted, immigrated from the south; and that, of the various forest trees, the birch, aspen, and fir came by the same road, forming the country's oldest forests. From the south, too, we must assume that salix, mountain ash, mountain elm, hazel, lime, with accompanying shrubs, certain willows, guelder rose, *Rhamnus frangula*, *Cornus sanguinea*, and the hawthorn came, and from the same quarter, at a later period, the common ash, oak, and ivy. Furthermore, later still, the beech and the hornbeam, with accompanying shrubs, came from this quarter. The spruce and the beech both immigrated late, but the former from the east. These two forest trees are at present, in different localities, the two most favoured, the beech in the south, and the spruce in all other parts as far as the northern limit of coniferous trees. But the contest between the different species of trees is no longer undisturbed. For since man settled in the land a new factor has arisen, and this factor participates both directly and indirectly in the contest. Originally slight, his influence has grown greater and greater, and the time may come when he will be the arbiter as to the trees that are to form the forests of the future.

A. G. NATHORST.
Geological Survey of Sweden.

AGRICULTURAL EXPERIMENTAL STATIONS IN THE UNITED STATES.

THE following interesting information in reference to the establishment of agricultural experimental stations in the United States is given in a memorandum recently issued by the Agricultural Department of the Privy Council, and laid before Parliament. An "Office of Experiment Stations" has been instituted as a special branch of the United States Department of Agriculture. For the expense in connection therewith a sum of £2000 was voted by Congress in 1888, to enable the Commissioner of Agriculture to carry out Section 3 of the Act of Congress of March 1887, by which experimental stations were established. This said section provides that, "in order to secure, as far as practicable, uniformity of methods and results in the work of the said stations, it shall be the duty of the United States Commissioner of Agriculture to furnish forms, as far as practicable, for the tabulation of results of investigation or experiments; to indicate, from time to time, such lines of inquiry as to him shall seem most important; and in general to furnish such advice and assistance as will best promote the purposes of this Act. It shall be the duty of each such station annually, on or before February 1, to make to the Governor of the State or Territory in which it is located, a full and detailed report of its operation, including a statement of receipts and expenditure to the said Commissioner of Agriculture, and to the Secretary of the Treasury of the United States." In 1888 an Act was passed by Congress making an appropriation for the Department of Agriculture for the fiscal year ending June 30, 1889, and for other purposes, appropriating £119,000, including the £2000 specially reserved for the Commission of Agriculture, for the purpose of endowing and assisting agricultural and experimental stations throughout the country. Besides this sum, the several States have contributed £25,000, making a total sum of £144,000 given from public funds for the support of these stations. There are now forty-six of these stations in the United States, so that, taking an average, each station will receive over £3000 this year. It is said, however, that several of these stations have sub-stations under them, and that there are 370 trained men connected with the stations in the prosecution of scientific and practical agricultural experiments. The first agricultural experiment station in America was established in 1875 in Connecticut, and the next in California in the year following. In 1879 the well-known Cornell University Station was founded, which has done so much good work, and the equally valuable Wisconsin Station in 1883. No less than twenty-six stations were founded last year, in consequence of the inducements set forth by the Act of 1887. In a recent Report as to the organization of these experimental stations, a list of the staff of each is given, from which list a few examples may be taken to show the extent of work that is performed, or may be performed. At the Connecticut Agricultural Station there is a director who is a Master of Arts, a vice-director who is a Doctor of Philosophy, and a chemist. There are three other chemists who are Doctors or Bachelors of Philosophy, a mycologist, and a practical farmer in charge of grounds and buildings. The staff of the Dakota Station is still more extensive, consisting of a director, a superintendent of the farm, a superintendent of forestry and horticultural experiments, an entomologist, an analytical chemist, a veterinarian, an accountant and stenographer, and a librarian. Upon the staff of the Iowa Station there are two chemists, one for ordinary and one for special work, a botanist for ordinary and special work, an entomologist, a veterinarian, a horticulturist, and a practical farmer. The Cornell University Station staff comprises a chemist, veterinarian, botanist, and arboriculturist, a horticulturist, an entomologist, a cryptogamic botanist, besides an assistant in entomology, chemistry, veterinary science, and horticulture. Among the operations of these agricultural experiment stations are "fertilizer control," or the analyses of manures, the analyses of fodder and feeding-stuffs drainage experiments, feeding experiments with farm animals, observations on milk, the determination of injurious insects, with remedies against their attacks, fruit culture experiments, drinking-water analyses, ensilage experiments, meteorology, seed-testing, analyses of soils and rocks, the culture of various plants for fodder and corn, with other useful work.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 26.—M. Des Cloizeaux, President, in the chair.—On the molecular tactics of the artificial macle of Iceland spar produced by Baumhauer by means of a knife, by Sir William Thomson. The substance of this paper has already been communicated to the Royal Society of Edinburgh, and will shortly be published, under the title of "Molecular Tactics of Crystals," in the Proceedings of the Society. The author also contributes a paper on the equilibrium of atoms, and the elasticity of solids in Boscovich's theory of matter.—Note on the orbits of shooting-stars, and on stationary radiant points, by M. F. Tisserand. A calculation of the elements (mostly parabolic) of their several orbits leads to the inference that the meteoric showers encountered by the earth at different times of the year do not all emanate from the same radiating centre, but belong to different systems proceeding from quite independent radiant points. A series of essays based on the assumption that the orbits are not parabolic, but elliptic, lead to the same conclusion.—On the relations of atmospheric nitrogen to vegetable soil, by M. Th. Schlœsing. This is a reply to M. Berthelot's recent strictures on the author's negative results. These results are here maintained, and M. Schlœsing again argues on fresh grounds that there is no fixation of nitrogen by vegetable humus except through the actual process of vegetation.—Pathogenic properties of the microbes present in malignant tumours, by M. Verneuil. The author still adheres to the opinion already enunciated in 1883, that these parasites have nothing to do with the initial stage of boils, ulcers, cancer, and the like. At the same time he does not regard their presence as a matter of indifference, but admits that in certain cases they may themselves possess special pathogenic properties, in virtue of which they act on the system like septic poisons.—On the progress of the zoological station at Roscoff, by M. de Lacaze-Duthiers. The author speaks in satisfactory terms of the present condition of this station, and of the complementary establishment at Banyuls, which have now been placed in connection with the Sorbonne. The electric light, introduced at Roscoff by the aid of private munificence, is now in perfect working order.—The Eiffel Tower struck by lightning, by M. Mascart. A correct account is given of this occurrence, which took place on August 19, and exaggerated reports of which appeared in the daily papers. The conductor was struck, with the normal results, showing perfect communication with earth, and consequently complete safety of the structure from any danger on this score.—Observations with the pendulum effected in Russia, by General Steibnitski. The author reports that the Russian Imperial Geographical Society is now in possession of three Repsold pendulums, with which the latitude and longitude of Karmakul in Novaya Zemlya and Archangel, the two northernmost stations in European Russia, have been accurately determined.—Occultation of Jupiter by the moon, August 7, 1889, by M. Ch. André. The results are given of the three observations taken at the Observatory of Lyons by MM. André, Le Cadet, and Marchand. None of the satellites disappeared instantaneously, as is the case with stars of the same magnitude (seventh). The disappearance of satellites III., II., and IV. occupied $1''\cdot5$, $1''\cdot1$, and $0''\cdot5$ respectively, giving for their several diameters $0''\cdot46$, $0''\cdot30$, and $0''\cdot15$.—On the angle of polarization of the moon, by M. J. J. Landerer. A method is described by means of which this element has been determined at $33° 17'$, a mean value resulting from eleven series of observations with probable error $\pm 7'$. The same process is equally applicable to the planet Venus.—On the solar spots, by M. G. Spoerer. Besides some brilliant protuberances, the large spot visible from June 16 to 18 was observed on the last day at 10.43 a.m. at Potsdam. But a photograph of the same taken a few minutes before the observation shows no trace of the spot, which is replaced by an even depression on the solar rim, exactly where the spot had been observed. An explanation is suggested of this phenomenon.—Specific heat of aqueous vapour under constant volume, by M. Ch. Antoine. For Regnault's curves of the form $x = A + Mt_s - Nt_s^2$, the author substitutes functions of the temperature t and of the tension p, such as $x = B + ct_s = \phi(p)$, deducing for aqueous vapour two determinations for specific heat under constant pressure and constant volume. Analogous formulas may be obtained for other vapours, such as ether, chloroform, acetone, benzene, chloride, and sulphide of carbon.—Papers were contributed by M. Léo Vignon on the action of water on stannic chloride; by M. G. Raulin, on the action of phosphates on the growth of cereals; by M. C. Timiriazeff, on the relation between the intensity of solar radiation and the decomposition of carbonic acid by plants; and by M. Armand Sabatier, on the zoological station at Cette.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, SEPTEMBER 12, 1889.

THE TECHNICAL INSTRUCTION ACT.

IN the Speech from the Throne at the close of the session, Her Majesty is made to express satisfaction, *inter alia*, with "the steps you have taken towards the establishment of technical education in England and Wales," and perhaps the words here placed in the Queen's mouth will do as well as any others to express the feeling with which the Government Bill was regarded by the friends of technical instruction all over the country, and by those who for years past have laboured in the cause. Steps have been taken "towards" the establishment of technical education in England and Wales, not very complete or large steps, but still steps which show that the Government, when time and opportunity arise, are prepared to go further, and which pledge the present Ministry, at any rate, to secondary technical instruction. That the new Act goes no further is not necessarily due to any lukewarmness on the part of the Vice-President of the Council or of his colleagues. The circumstances of the past few years were such that a very large amount of legislation had to be proposed, and if possible carried, during the session just ended; and any Government would naturally desire to avoid all contentious subjects except those which imperatively called for treatment. Unfortunately, nothing is easier than to revive in certain quarters in the House of Commons the heated educational controversies of twenty years ago; there are still some men whose blood is fired by these antique battle-cries, and who think it their duty to ride forth to a war in which there is nowadays no real enemy. We think that the friends of technical instruction have every reason to be grateful to a Government which, with many inducements to do nothing, have yet brought in and passed a Bill which, with Sir Henry Roscoe's amendments, was supported by all the members of the Royal Commission on Technical Instruction who had seats in the House of Commons. But, we hear it said, the Bill is a very poor and small measure, while the subject is one to be dealt with by a large, comprehensive, and elaborate enactment; the principle of the administration is all wrong, for it divides technical education from the ordinary education of the country,—it should be administered by the School Boards and by the School Boards only; it is mere paltry, tinkering legislation where it might be heroic, and so on. No doubt in the best of all possible worlds the matter would be different, but here below we have to take things as we find them; and amongst the things which we find, is a legislative machine which labours heavily and slowly, and which has to be manipulated with a hundred and one different considerations in view. The House of Commons is far, indeed, from being an ideally perfect assembly for dealing with technical education or any subject of the kind; but in this, as in most other matters in this country, where compromise governs in all things, from the position of the Queen on the throne downwards, the question is not what we ought to have, but what we can get. Things do not spring full-grown from the brain of the British Jove; we do not get complete, exhaustive, elaborate legislative enactments from the British Parliament; finality is never written on any of its proceedings; it never seeks theoretical perfection. First we get one small inadequate measure; by and by this is enlarged, amended, improved, supplemented, by a succession of Acts, spread, it may be, over years, and perplexing lawyers and administrators by their inconsistent and contradictory provisions; then last of all comes a reforming official who elaborates all these scattered Acts into one homogeneous statute, which he succeeds in getting through Parliament just as the whole becomes useless in consequence of some new policy or wave of public opinion; and then the process is all gone through again. As to the objection respecting the authority administering the Act, we must confess we cannot attach any weight to it, in comparison with the substantial concession to the demand for technical instruction which it makes. It seems to us that it can matter very little which particular one of our numerous local authorities is to be the medium for passing on to the public the benefits conferred by the Act. No doubt the work is more within the scope of the School Boards; but to refuse those benefits because, for reasons which are perfectly well understood by those who have followed the discussion, they come from County and Borough Councils and rural sanitary authorities, would be absurd pedantry—almost a crime. One member of the House of Commons was filled with dismay at the prospect of the rural and urban sanitary authorities raising technical institutes out of the public funds, although he quite approved of technical instruction. It does not appear that a technical institute will be any the worse because the money with which it is maintained will be raised by a number of men with one long name rather than a number with another long name: the public gets the institute all the same. Moreover, this point is rendered of little or no importance, even in itself, by the present position of local government in this country. It is now in a transition stage; most of the existing machinery which has not already been taken to pieces will certainly have to undergo that process in the course of the next few years, and we feel no assurance at all that School Boards themselves will not shortly disappear, to be replaced by Education Committees of County and Borough Councils, as existing sanitary authorities will be supplanted by Sanitary Committees and sub-committees. From this point of view, even if a great question of principle were otherwise involved, it would not matter much which set of authorities undertook the task, seeing that all are likely to be equally short-lived, and to be merged soon in the County or Borough Councils, as the case may be. What satisfies those true friends of our national progress who have made this subject their own in Parliament, and who are in specially favourable positions for judging what is attainable, will probably satisfy most other sensible advocates of technical instruction. In common phrase, the Act is "something to go on with"; it is even more, because it is a pledge that the Government will go further in due time. In an excellent and well-considered article on the subject, the *Times* (September 4) says it "remains for us to make the best use of the system about to be established, to take note of the dangers and drawbacks incidental to it, but not to forget the limitless possibilities for good which it offers," and further, "almost without a struggle is established the possibility of a complete national system of technical instruction." It is for this that we have reason to be thankful to the Government: it has placed the instrument in our hands, and it is for us now to use it efficiently.

CAMBRIDGE MATHEMATICS.

A History of the Study of Mathematics at Cambridge. By W. W. Rouse Ball. (Cambridge: University Press, 1889.)

AUGUSTUS DE MORGAN, writing more than fifty years ago, says that "the literary history of this country requires separate and minute accounts of the rise of science in Oxford, in Cambridge, and in the north of England, which should severally end (if it might be no later) with Wallis, Newton, and Thomas Simpson."[1] To what extent this long-felt want has been supplied by other publications, we cannot tell; but we know of none readily accessible to the student of mathematical history, and therefore hail with satisfaction the appearance of the small octavo volume which is the subject of our review.

What we should call the study of mathematics at Cambridge is of comparatively recent origin: for, although Seth Ward "brought mathematical learning into vogue in the University, . . . where he lectured his pupils in Master Oughtred's 'Clavis,'"[2] the first Mathematical Professor there was Isaac Barrow (Ward's junior by about twelve years), and the lectures of his illustrious successor were so ill attended that M. Bertrand says: "Il professa trente ans à Cambridge sans y former un disciple digne de lui; la salle du cours restait souvent déserte le jour de sa leçon, et Newton retournait alors tranquillement à ses travaux."[3] Oughtred, whose "Clavis Mathematica" was published in 1631, did not reside long at Cambridge: his secluded life is thus described by our author:—

"Although living in a country vicarage he kept up his interest in mathematics. Equally with Briggs he received one of the earliest copies of Napier's 'Canon' on logarithms, and was at once impressed with the great value of the discovery. Somewhat later in life he wrote two or three works. He always gave gratuitous instruction to any who came to him, provided they would learn to 'write a decent hand.' He complained bitterly of the penury of his wife, who always took away his candle after supper, 'whereby many a good motion was lost and many a problem unsolved'; and one of his pupils who secretly gave him a box of candles earned his warmest esteem. He is described as a little man, with black hair, black eyes, and a great deal of spirit. Like nearly all the mathematicians of the time, he was somewhat of an astrologer and alchemist. He died at his vicarage of Albury in Surrey on June 30, 1660."[4]

Mr. Ball leaves us in doubt as to the nature of the "two or three works" written "somewhat later in life" by Oughtred. Fortunately we are able to supply this omission from an old book[5] on our shelves, which says that

"Lord Napier, in 1614, publishing at Edinburgh his 'Mirifici logarithmorum canonis descriptio, ejusque usus in utraque trigonometria, &c.,' it presently fell into the hands of Mr. Briggs, then geometry-reader of Gresham College in London; and that gentleman, forming a design to perfect Lord Napier's plan, consulted Oughtred upon it; who probably wrote his 'Treatise of Trigonometry' about the same time, since it is evidently formed upon the plan of Lord Napier's 'Canon.' In prosecuting the same subject, he invented, not many years after, an instrument, called 'The Circles of Proportion.' . . . All such questions in arithmetic, geometry, astronomy, and navigation, as depended upon simple and compound proportion, might be wrought by it; and it was the first sliding rule that was projected for those uses, as well as that of gauging."

Authorities differ as to the day of Oughtred's death: thus the "Penny Cyclopædia" makes it happen on "Jan. 30th" (a misprint, probably, for the same day of June); in the article just quoted it is "about the beginning of May"; and in the historical introduction to Hammond's "Algebra"[6] we read that "he lived to the Age of Fourscore and Seven, and died then of Joy, on May 1, 1660, at hearing the House of Commons had voted the King's Return."

One circumstance compels us to reject this account: we cannot understand how Oughtred, living in the neighbourhood of Guildford, could know what took place in Parliament, on May 1, before the next day. But the mere fact of his death being currently attributed to such a cause illustrates so well the intense political excitement of the times in which he lived that it ought not to be passed over in silence. It is of more value than many boxes of candles.

From the time of Newton down to the beginning of the present century, mathematics (though diligently studied) made very little progress, either at Cambridge or in other parts of England. In Cambridge this was due to the excessive reverence paid to authority; at first by all, and afterwards by those "senior members of the senate, who regarded any attempt at innovation as a sin against the memory of Newton,"[7] and who were the worthy successors of the Cambridge dons described by Pope, in 1742, as

"A hundred head of Aristotle's friends."[8]

We may be mistaken, but we strongly suspect that one of them was William Farish (b. 1759, d. 1837), whose memory is embalmed in the following extract:—

"He is celebrated in the domestic history of the University for having reduced the practice of using Latin as the official language of the schools and the University to a complete farce. On one occasion, when the audience in the schools was unexpectedly increased by the presence of a dog, he stopped the discussion to give the peremptory order, *Verte canem ex.* At another time one of the candidates had forgotten to put on the bands which are

[1] "Notices of English Mathematical and Astronomical Writers between the Norman Conquest and the Year 1600." This important article appeared anonymously in the Companion to the Almanac for 1837, but was undoubtedly written by De Morgan, and in fact was claimed by him six years afterwards.

[2] Ball, p. 37. In referring to the work before us, both here and subsequently, for brevity we cite only the author's name and the number of the page.

[3] "Les Fondateurs de l'Astronomie Moderne" (8vo, Paris, n.d.) p. 303.

[4] Ball, p. 30.

[5] As no edition of this work is mentioned by De Morgan in his "References for the History of the Mathematical Sciences," we give its title in full, as follows: "A New and General Biographical Dictionary; containing an Historical and Critical Account of the Lives and Writings of the Most Eminent Persons in every Nation; particularly the British and Irish; from the Earliest Accounts of Time to the present Period. Wherein Their remarkable Actions and Sufferings, Their Virtues, Parts, and Learning, are Accurately Displayed. With a Catalogue of their Literary Productions. A New Edition, in Twelve Volumes, greatly enlarged and improved" (8vo, London, 1784).

[6] The third edition, 8vo. London, 1764.

[7] Ball, p. 117.

[8] "Dunciad," iv. 192. A note to this verse reads thus:—"The Philosophy of *Aristotle* had suffered a long disgrace in this learned University: being first expelled by the *Cartesian*, which, in its turn gave place to the *Newtonian*. But it had all this while some faithful followers in secret, who never bowed the knee to *Baal*, nor acknowledged any strange God in Philosophy."

still worn on certain ceremonial occasions. Farish, who was presiding, said, *Domine opponentium tertie, non habes quod debes. Ubi sunt tui. . . .* (with a long pause) *Anglice bands?* To whom with commendable promptness the undergraduate replied, *Dignissime domine moderator, sunt in meo* (*Anglice*) *pocket.* Another piece of scholastic Latin quoted by Wordsworth is, *Domine opponens non video vim tuum argumentum.*"[9]

In the last sentence "his scholastic Latin" would read better than "scholastic Latin": perhaps, however, this alteration could not be made without violating historic truth; in which case it might be difficult (but we hope not impossible) to substitute some other Latin sentence belonging undoubtedly to Farish, and anything like as good as his exquisite "*Verte canem ex.*" It is recorded, to the credit of Farish, that he resided and taught; a rare instance of virtue in a Professor of that period. Strange abuses were prevalent in his time; among them the practice of "huddling" the disputations in the schools may be mentioned.

"By the Elizabethan code every student before being admitted to a degree had to swear that he had performed all the statutable exercises. The additional number thus required to be performed were kept by what was called *huddling*. To do this a regent took the moderator's seat, one candidate then occupied the respondent's rostrum, and another the opponent's. *Recte statuit Newtonus*, said the respondent. *Recte non statuit Newtonus*, replied the opponent. This was a disputation, and it was repeated a sufficient number of times to count for as many disputations. The men then changed places, and the same process was repeated, each maintaining the contrary of his first assertion—an admirable practice, as De Morgan observed, for those who were going to enter political life. Jebb asserts that in his time (1772) a candidate in this way could, as a respondent, read two theses, propound six questions, and answer sixteen arguments against them, all in five minutes."

The above is extracted from the chapter devoted to the exercises in the schools. This and the one on the mathematical tripos (ix. and x.) are the two best chapters in the book, and contain a large mass of interesting matter; but since the substance of both is reprinted from the author's "Origin and History of the Mathematical Tripos" (Cambridge, 1880), with which many of our readers are doubtless acquainted, we refrain from making any further quotations from either. We need only say that together with chapter viii. (under the heading "The Organization and Subjects of Education") and chapter xi. ("Outlines of the History of the University") they constitute the second of the two well-defined portions into which the present work is divided, and give a clear though succinct account of the history of Cambridge and of the principal object of study there, from the earliest times to the date of the repeal of the Elizabethan statutes (1858), with which the history is made to terminate. The first seven chapters, which (see the preface) "are devoted to an enumeration of the more eminent Cambridge mathematicians, arranged chronologically," embrace the same period of time. Their style is somewhat similar to that of the author's "History of Mathematics" published last year, but is still more concise. In them, with the assistance afforded by the introductory paragraphs prefixed to each, we are enabled to trace the rise of mathematical science from the earliest times to the death of Newton (i. to iv.), and its subsequent decadence in Cambridge (v. and vi.), until we come to chapter vii., which is mainly occupied with those mathematical reforms (initiated by Robert Woodhouse, and carried out by Peacock, Herschel, Babbage, and others) which inaugurated the great modern revival of learning in England, spoken of by Mr. Ball in his concluding paragraph as the "new renaissance." The first portion of the work terminates with this chapter, which also contains notices of some of the more prominent mathematicians who graduated at Cambridge since the time of the above-mentioned reformers, but not later than the Tripos of 1859. Except in the ninth and tenth chapters, the style is too condensed, and conciseness is sometimes attained by the suppression of interesting facts; but this is not an unmixed evil, since the cost of publication is thereby kept down, and we have every reason to believe that those who are content to pay a moderate price for a general view of the subject will find in this little volume a very useful compendium of Cambridge mathematical history.

We ought to add that, in its externals, the book is all that most attracts the fastidious purchaser. It is neatly bound, in general correctly printed, in clear type, and on good paper. The table of contents and index are also good.[10]

[9] Ball, p. 106.

[10] In this note we append a few disjointed remarks for the sake of pointing out certain trivial *errata*, and small emendations, or what we believe to be such:—

P. 17, "belated traveller." A man who had travelled no farther than from St. James's Park to Whitefriars (see "The Fortunes of Nigel," ch. xvi. and xvii.) and who had remained in sanctuary there for some days, can hardly be called a belated traveller because he asks for "a book—any sort of book—to pass away the night withal," and we can discover no other reason. The passage we allude to occurs in ch. xxiv. of Scott's novel, and in the version from which we quote runs thus:—"*She heard with interest Lord Glenvarloch's request to have a book—any sort of book—to pass away the night withal, and* returned for answer, that she knew of no other books in the house than her young mistress's (*as she always denominated Mistress Martha Trapbois*) Bible, which the owner would not lend; and her Master's Whetstone of Witte, *being the second part of Arithmetic*, by Robert Record, *with the Cossike Practice and Rule of Equation; which promising volume Nigel declined to borrow.*" This is quoted both by De Morgan and Mr. Ball, of whom the latter omits the italicized words, and the former those only that are also underlined. Both of them omit the comma between "answer" and "that"; and both spell "Bible" with a small "b," "Master's" with a small "m," and "Record" with a final "e." From this we infer that both of them quoted from a version of Scott differing from the one on our shelves in the above particulars, unless Mr. Ball copied his quotation from De Morgan's. The fact that De Morgan makes no allusion to a "belated traveller" seems to favour the former theory. Our author deals with Recorde just as he has done with Scott: he takes a passage from him, gives certain portions of it, and modernizes the spelling (see the quotations from Recorde on pp. 16–18, and compare them with those given in the article by De Morgan, referred to in note [1], which contains all of them and is easily procurable). The ghost of an old author has a right to complain of the alteration of a single letter in his work, and to say "Interpretation will misquote our *b*ooks" (Hen. IV., Part I., act v., sc. 2). There! we have committed the very offence we felt called upon to condemn, and have changed Shakespeare's "l" into a "b."

P. 31. For "*circle of proportion*" read "*circles of proportion.*"

P. 41. The first volume of Marie's "Histoire des Sciences mathématiques" was published in 1883: this date is changed into 1833 by an obvious misprint.

P. 72. The correct title of Dr. Sloman's work (which lies open before us as we write) is, "The claim" (not claims) "of Leibnitz to the invention of the differential calculus."

P. 91. Smith's "Compleat System of Opticks" was published in 1738 (not 1728). An advertisement dated "*London*, Apr. 25, 1738," speaks of it as "Printing at *Cambridge* in Quarto, and will be published by the latter end of *May* or the beginning of *June*" (we quote *literally*).

P. 93. It is not easy to identify books whose titles are not given, but we know of no text-book by Humphry Ditton "on the infinitesimal calculus" of an earlier date than 1706, when his "Institution of Fluxions" was published. We therefore conclude that the date 1704 must be a misprint for 1706, and shall continue to think so until we actually see an edition dated 1704.

On this page also, for "Robert Smith (1728)" read "Robert Smith (1738)."

P. 257. In the index, insert the reference "Commercium Epistolicum, 72"; for "Creswell" read "Cresswell;" and in the third line of the references to De Morgan, *dele* 180.

We have given the above list in compliance with the words, "I shall thankfully accept notices of additions or corrections which may occur to any of my readers," with which Mr. Ball's preface terminates.

DE LAPPARENT'S "MINERALOGY."

Cours de Minéralogie. Par A. de Lapparent. 2me édition. (Paris: F. Savy, 1890.)

SIX years have elapsed since our announcement in NATURE of the appearance of this book, and now the call for a second edition indicates the continually increasing popularity of the work, not only in France, but especially abroad, where more than half of the first edition has been sold. This popularity must be ascribed mainly to the fact that M. de Lapparent's "Cours de Minéralogie" was the first educational work in which the crystallographic theories of Bravais and Mallard were expounded as a system, and constituted, one may say, the basis of his lectures.

Now that these theories are continually obtaining a more favourable reception, it must be recognized that their diffusion has been largely effected by the present "Cours de Minéralogie," owing mainly to the remarkable power of exposition possessed by M. de Lapparent, of which he gave us a new proof when he published his lectures on mineralogy in 1884. The same quality is eminently conspicuous in this edition; but let us hasten to remark that the present is in reality a new work, which contains nearly 100 pages more than the first edition and a large number of new figures. A glance is sufficient to show that the author has not been content with revision, but has entirely reconstructed the book. He has so developed the optical portion that the volume becomes a sufficient introduction to the study of petrography, this chapter now containing a description of the refractometer, the quarter-wave-length mica, and Bertrand's plate; attention may also be directed to the paragraph on complex molecules (p. 22), and to the demonstration of the terquaternary system (p. 55); he has, moreover, grouped in a series of chapters, which constitute a homogeneous and strikingly uniform treatise on the subject, the elegant theories of Mallard upon twinning, isomorphism, and polymorphism. The description of species has been considerably increased, especially by the extended account of the rock-forming minerals; and the characters in microscopic sections of the minerals which are most important in lithology are illustrated by figures selected from the best authorities. In his own words, the author, taught by experience and knowing how necessary it is that numbers should be verified, has revised all the crystallographic data; he has given for each species the corresponding axial ratios after imposing upon himself the task of verifying by trigonometrical calculation the agreement of these ratios with the fundamental angles; and he has selected from the latest and best publications the optical data, such as double refraction, dispersion, principal indices of refraction, and the numbers which indicate the positions of the optic axes and bisectrices.

Finally the index has been subjected to careful revision, and has been augmented by 200 names which represent the progress of descriptive mineralogy during the last six years. Since, moreover, the chapter on calculation has been developed and contains all the formulæ in common use, the practical value of the book has been largely increased, and it should satisfy every requirement of the University student; it will prove of special service to geologists occupied with the study of rocks, the class of readers whom the author appears to have continually had in his mind in the composition of a treatise in which the geological bias is discernible both in the classification adopted, and in the manner in which the description of the rock-forming minerals has been developed.

In a word, this work not only affords a good general idea of all that constitutes modern mineralogy, but is also a useful introduction to the study of lithology.

We are convinced that the book, written with the remarkable lucidity and elegance which characterize the works of M. de Lapparent, is destined to occupy the same position in the study of mineralogy which in geology has been held by the same author's "Traité de Géologie."

A. F. RENARD.

OUR BOOK SHELF.

Key to Higher Algebra. By H. S. Hall, M.A., and S. R. Knight, B.A. (London: Macmillan and Co., 1889.)

THIS work forms a key to the higher algebra, and contains solutions fully worked out of nearly all the examples. More than one solution of a problem is given in some cases, and throughout the book repeated references are made to the text and illustrative examples of the algebra. The volume will prove most useful to teachers, and we strongly recommend it to students who are beginning the study of algebra without the aid of a teacher, for, by first of all trying to work out the examples without the key, they may learn much by a careful and judicious use of the solutions afterwards.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Use of the Word Antiparallel.

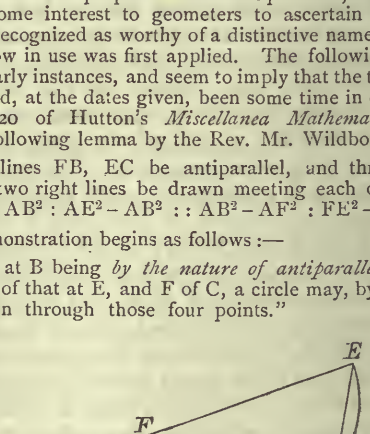
So much of the "recent geometry of the triangle" is connected with the properties of "antiparallels," that it is a matter of some interest to geometers to ascertain when they came to be recognized as worthy of a distinctive name, and when the name now in use was first applied. The following extracts afford two early instances, and seem to imply that the term "antiparallel" had, at the dates given, been some time in existence.

On p. 220 of Hutton's *Miscellanea Mathematica* (1775) occurs the following lemma by the Rev. Mr. Wildbore:—

"If two lines FB, EC be antiparallel, and through their extremities two right lines be drawn meeting each other in A, it will be as $AB^2 : AE^2 - AB^2 :: AB^2 - AF^2 : FE^2 - BC^2$";

and the demonstration begins as follows:—

"The $<$ at B being *by the nature of antiparallel lines* the supplement of that at E, and F of C, a circle may, by Eucl. III. 22, be drawn through those four points."

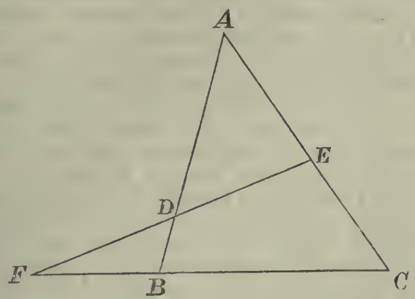


After the lemma occurs this "Scholium":—

"The reader may from hence correct an error in 'Clark's Dictionary' under the word *antiparallels*, where it is said that the sides AE, AC are cut reciprocally proportional by the line FB; that is, AF : FE :: BC : AB, which is evidently wrong."

In Hutton's "Mathematical and Philosophical Dictionary" (1796) we find:—

"ANTIPARALLELS, in geometry, are those lines which make equal angles with two other lines but contrary ways; that is, calling the former pair the 1st and 2nd lines, and the latter pair the 3rd and 4th lines, if the angle made by the 1st and 3rd lines be equal to the angle made by the 2nd and 4th, and, contrariwise, the angle made by the 1st and 4th equal to the angle made by the 2nd and 3rd; then each pair of lines are antiparallels with respect to each other, viz. the 1st and 2nd, and the 3rd and 4th.



"So if AB and AC be any two lines, and FC, FE two others cutting them so that the angle B is equal to the angle E and the angle C is equal to the angle D; then BC and DE are antiparallels with respect to AB, AC; also these latter are antiparallels with respect to the two former."

It is curious also to note an error as regards the ratios of the segments of the sides, similar to but not identical with the one pointed out by the contributor to the *Miscellanea Mathematica* as occurring in "Clark's Dictionary"; for the next paragraph states:—

"It is a property of these lines that each pair cuts the other into proportionate segments, taking them alternately;

viz. AB : AC :: AE : AD :: DB : EC
and FE : FC :: FB : FD :: DE : BC."

Here the third ratio in each line is wrongly stated to be equal to the two which precede it; for keeping the triangle ABC and therefore also the direction of FE fixed, it is clear that the ratios AB : AC, AE : AD remain fixed, while DB : EC may range from zero to infinity.

E. M. LANGLEY.

The Force of "Example" in Animals.

SOME years ago we had two cats—a tabby, and a powerful tom perfectly white all over. One day I happened to be in the attic, and noticed them go out on the slates, when Tom jumped across the yard to the next roof. It appeared to me a splendid leap, considering the width of the yard and the height of the roof. When Tabby came to the edge of the slates her courage failed, and she uttered a cry of distress, whereupon Tom turned round and leaped back, and giving a cheerful mew as much as to say, "Look how easily it can be done," jumped across again, this time followed by Tabby, to my great delight.

φ.

"Astrarchia stephaniæ."

IN the interesting "Geographical Notes" from New Guinea, published in NATURE of September 5 (p. 449), it is stated that Sir William MacGregor procured, among others, "a female *Astrachia stephania*, the only male bird of that species being in the Museum, Berlin." Will you permit me to rectify this in communicating to you that the only male *Astrarchia stephaniæ* is in the Zoological Museum of Dresden. The bird was described and figured by Dr. Finsch and myself in the year 1885, and the name is correctly written as I have just given it.

Dresden, September 8.

A. B. MEYER.

THE RECENT GREAT EARTHQUAKES IN JAPAN.

FULL details have now been received of the recent earthquakes in Japan. According to the report of the Governor of the Kumamoto district, in the Island of Kiushiu, the centre of the earthquake was a mountain situated to the west of Kumamoto, the chief town in the province of Higo. Knipo is one of a chain of volcanoes connected with Mount Aso, one of the most noted volcanoes in the country, which was visited and described a few years ago by Prof. Milne, who regards it as one of the two or three largest volcanoes in the world. No eruption, however, has ever as yet taken place there, but fears are now entertained of a terrible eruption; rumblings have been heard, and the mountain has discharged lava in several places. Aso Yama, or Mount Aso, has for many years been known as the only active volcano on the Island of Kiushiu. This mountain rises to a height of nearly 5000 feet. Its last eruption was in 1874, when a large quantity of grayish-white pumice ashes was discharged. It would seem, however, that more or less constant discharges have taken place at intervals ever since the premonitory signs. On the morning of July 28, the day of the destructive shock, the weather was agreeably cool, but at twilight the sky was clothed with a dark cloud tinged with a pale reddish colour, and the atmosphere became quite close. About ten minutes past eleven p.m. a noise as of thunder was heard. Simultaneously a strong earthquake movement commenced. As the nature of the shock was unusual, some of the inhabitants dressed, whilst others with scarcely any clothing, rushed from their houses, a number of them only to be crushed to death by falling walls and trees. The Castle of Kumamoto, which was the scene of the memorable siege by General Saigo at the time of the Kagoshima rebellion, and is noted for the solidity of its structure, was damaged in several parts. In the streets fissures appeared in several places, some of the cracks measuring six feet in width. In other parts of the town subsidences occurred; in some instances water was seen spouting from the fissures created by the seismological disturbance. There were several incipient fires caused by the overturning of lamps, but they were speedily extinguished, and much additional loss of property was thus avoided. Houses were overturned and the occupants killed. The first shock was soon followed by several smaller and two severe ones. With the break of day the dull cloud moved off, to leave the sky covered with yellowish little patches. The most severe shock was the first one, when even unusually strong houses were almost displaced from their foundations. Old houses and those not very strongly built were brought to the ground with sufficient force to kill, and in other cases injure numbers of persons. The losses sustained by chemists and china-ware merchants were large, owing to the breakage among their brittle stock. All wells in Kumamoto have either been rendered so foul with mud as to make them useless, or are dry by reason of the escape of water. The city is being temporarily forsaken by those who can afford to remove their families. In the town of Kumamoto the list of casualties is three persons crushed to death and six wounded. Twenty-two houses were thrown down and sixteen partially wrecked. In the neighbouring district of Akita, however, the force of the shock seems to have been felt more severely. Fifteen lives were lost, thirteen persons were injured, and thirty-two dwellings were overthrown, while many farmhouses were more or less damaged. In Sage, also a district of Kiushiu, there were underground sounds as of many cannons; then ensued prolonged vibrations from south to north-west, dwellings leaning over at inclinations varying from 70° to 80°, accompanied by loud crackling of posts and walls. The ground quivered so that pedestrians stumbled and fell. This shock continued for about four minutes. During the night there were two other disturbances, the last being the most severe. The greatest disorder and fright prevailed, and a night of terror was passed in the open air by the unclad population. In the districts of Sakanami and Kami-Tunaki the ground for a space of 9 acres began to crack on July 28, and the phenomenon continued until the whole surface was covered with a network of fissures. According to the latest accounts, fifty-three distinct shocks had been felt, only two or three of them being severe. Within twelve hours on August 3, thirty-five earthquakes were experienced at Kumamoto, one of which caused the ground to open in no fewer than twelve places.

THE UNITED STATES ECLIPSE EXPEDITION.

THE Navy Department in Washington is now fitting out an Expedition to Angola, on the west coast of Africa, to observe the total eclipse of the sun which will be visible there on the afternoon of December 22 next. Prof. Todd, of Amherst College, has been appointed chief of the party, a position similar to that which he held two years ago in conducting the Eclipse Expedition to Japan.

The party, which will be a large one, will leave New York about October 1, in a Government cruiser. The natural history department of the Expedition will be under the charge of Dr. Wm. J. Holland, of Pittsburg, who will make large collections and extensive investigations, especially in entomology, which is his special department. He filled a similar position in the Expedition to Japan in 1887. Work will be done in many directions, and even if the weather or any accident should render a successful observation of the eclipse impossible, the Expedition will have a great amount of valuable information and collections when it returns.

After landing at St. Paul de Loanda, 250 miles south of the mouth of the Congo, the Expedition will go about one hundred miles into the interior, in order to be on higher land, and out of the fever belt on the coast. The eclipse, which will occur on December 22, 1889, at about 3 p.m., will be total for a little over three minutes at the station south-east of Loanda. The whole length of the eclipse will be between two and three hours. In photographing its different phases, if the sky is clear, it is hoped that about 150 photographs will be taken, with the largest telescope ever used for photographing an eclipse. This will give an image of the sun about 4½ inches in diameter. Owing to the number of fine instruments which have to be carefully transported and adjusted, about two months will be spent at the observation station, and the party will be absent about five or six months altogether. The particular point where it is hoped a settlement may be made is Muxima on the Quanza River. In reply to a question as to the instruments he would take with him, Prof. Todd is reported to have said:—

"Some of them will be the same as I had in Japan, especially the great telescope, forty feet long, to get pictures of the different stages of the eclipse with. It is the same sort of a telescope that I used in photographing the transit of Venus in 1882 at the Lick Observatory. But photographing the corona is not the main thing nowadays in eclipses. All that has gone by. There are other questions of much more importance than merely to find out how the corona looks. It is a very complex phenomenon. The sources of its light are not known, and the streamers of light are in parts superposed or overlapping. The most important thing to do is to take photographs in such a way that the intensity of the light in every part can be accurately measured, and to photograph the spectrum of as many separate portions of the coronal light as possible. We are making much progress in this direction, but the old methods of eclipse photography in use ten or fifteen years ago yielded very insufficient results, and there is relatively little use in following them up if the more advanced and specialized work is not undertaken. Of course they are good as far as they go. Then I shall have several new devices, which my previous experience, particularly in Japan, has led to the invention of. Among other things I have devised a revolving plate holder, which will enable us to get the largest possible number of pictures at the critical moments."

URANIUM.

EXACTLY a century ago—namely, in 1789—Klaproth succeeded (says the *Times*) in isolating from a dark-coloured mineral known as pitchblende a yellow oxide, which, after carefully testing, he pronounced to be the oxide of a new metal. To this metallic substance he gave the name of uranium, so calling it after the planet Uranus, then recently discovered by Herschel, and it was at once classed among the rare metals, and still remains so. Its rarity is indicated by its market price, which is about £2400 per ton. There are several oxides of this metal; but the best known and most important is the sesquioxide, which forms a number of beautiful yellow salts. This oxide is largely employed for imparting delicate golden and greenish yellow tints to glass, while the protoxide is much used in producing the costly black porcelain. Uranium is also found to be useful in certain photographic processes as a substitute for the chloride of gold; but its rarity and consequent high price have hitherto caused its application to be very limited, although there are uses other than those already named to which it could be put if it were less scarce and less costly. It is found in Cornwall, Saxony, and Bohemia; but up to the present time it has only been met with in isolated pockets and patches. The centenary of its discovery by Klaproth has, however, been marked by the finding of a continuous lode at the Union Mine, Grampound Road, Cornwall, which is believed to be the only known lode in the world. This discovery is regarded as unique in the history of the metal, for the lode is what is known as a true fissure vein, and the ore is found to contain an average of 12 per cent. of the pure metal, the assays going up as high as 30 per cent. in some parts of the lode. Several tons of the ore have already been raised and sold, fetching high prices. The lode traverses the mine from north to south, and the uranium occurs in it chiefly as a sesquioxide. It is anticipated that the present discovery will enable two important applications of the metal to be followed up. The first is as a substitute for gold in electroplated ware, inasmuch as with platinum and copper it forms two beautiful alloys, each having the appearance of gold, and the former also resisting the action of acids. The second application is in connection with electric installations, where its usefulness consists in its high electrical resistance. The mineral deposits generally at the Union Mine are of an exceptional character, comprising, in addition to uranium, magnetic iron, silver lead, tin, copper, ochre, and umber.

THE BRITISH ASSOCIATION.

NEWCASTLE, *Tuesday Night.*

IT is impossible at this stage to say what will be the character of the third Newcastle meeting, so far as numbers are concerned. In one quarter I am informed it is not expected that the attendance will be above the average, while another authority, who ought to know, assures me the numbers will be greater than was the case even at the Manchester meeting. For it should be remembered that, until that meeting, Newcastle topped the record so far as numbers go. To judge from the aspect of the Reception Room, not many people have yet arrived, though doubtless they will come in by later trains, and tomorrow morning. So far as I have been able to learn, very few foreign men of science of distinction are expected. Universal regret is expressed that the serious illness of Dr. Burdon Sanderson will prevent his taking his place as President of Section D; his address, which promises to be one of much interest, will be read by one of the Vice-Presidents. The proceedings in this Section, it is expected, will be somewhat lively; more than one paper will be read on certain aspects of Darwinism, and, as vigorous controversialists of different schools will be present, some strong speaking may be looked for.

So far as the efforts of the Local Committee go, the meeting ought to be a success. It is evident that everything has been done, so far as the accommodation of Newcastle permits, for the convenience and comfort of the visitors. The Durham College of Medicine makes very excellent Reception and Reading Rooms. Smoking Rooms, Luncheon Rooms, and other conveniences that conduce to the comfort of visitors, have been provided and well equipped. The St. George's Drill Hall is large enough for the opening address and the lectures, but the quality of its acoustic properties is feared. One of the great social events of the meeting will be the banquet given by Lord Armstrong, on Thursday night, to 200 guests; while the favourite excursion is that to Durham on Saturday, when the Warden and Professors of the University will entertain 200 at lunch. Regret is expressed that the excursion to the Roman Wall has not been fixed for the Saturday instead of the Thursday. Indeed, the Thursday excursions—to Berwick, Bamburgh, Holy Island, Barnard Castle, and other places—are likely to induce many visitors to stay over that day.

Geologists are looking forward with much interest to Dr. A. Geikie's paper on his recent visit to Norway, as well as to Prof. James Geikie's address as President of the Section. Prof. Flower's address will be devoted mainly to the arrangement of Museums.

It may be worthy of note that the Economical Section will be conducted on much more scientific lines than has been hitherto the case.

Inaugural Address by Prof. W. H. Flower, C.B., LL.D., F.R.S., F.R.C.S., Pres.Z.S., F.L.S., F.G.S., President.

It is twenty-six years since this Association met in Newcastle-upon-Tyne. It had then the advantage of being presided over by one of the most distinguished and popular of your fellow-townsmen.

Considering the age usually attained by those upon whom the honour of the presidency falls, and the length of time which elapses before the Association repeats its visit, it must have rarely happened that anyone who has held the office is spared, not only to be present at another meeting in the town in which he has presided, but also to take such an active part in securing its success, and to extend such a hospitable welcome to his successor, as Lord Armstrong has done upon the present occasion.

The address which was delivered at that meeting must have been full of interest to the great majority of those present. It treated of many subjects more or less familiar and important to the dwellers in this part of the world, and it treated them with the hand of a master, a combination which always secures the attention of an audience.

When it came to my knowledge that in the selection of the President for this meeting the choice had fallen upon me, I was filled with apprehension. There was nothing in my previous occupations or studies from which I felt that I could evolve anything in special sympathy with what is universally recognized as the prevailing genius of the district. I was, however, somewhat reassured when reminded that in the regular rotation by which the equal representation in the presidential office of the different branches of science included in the Association is secured, the turn had come round for some one connected with biological subjects to occupy the chair, which during the past seven years has been filled with such distinction by engineers, chemists, physicists, mathematicians, and geologists. I was also reminded that the Association, though of necessity holding its meeting in some definite locality, was by no means local in its character, but that its sphere was co-extensive, not with the United Kingdom only, but with the whole of the British Dominions, and that our proceedings are followed with interest wherever our language is understood—I may say, throughout the civilized world. Furthermore, although its great manufacturing industries, the eminence of its citizens for their skill and intelligence in the practical application of mechanical sciences, and the interesting and important geological features of its vicinity, have conferred such fame on Newcastle as almost to have overshadowed its other claims to distinction in connection with science, this neighbourhood is also associated with Bewick, with Johnson, with Alder, Embleton, Hutton, Atthey, Norman, the two Hancocks, the two Bradys, and other names honoured in the annals of biology; it has long maintained a school of medicine of great repute; and there has lately been established here a natural history museum, which in some of its features is a model for institutions of the kind, and which, I trust, will be a means of encouraging in this town some of the objects the Association was designed to promote.

There can be no doubt that among the various methods by which the aims of the British Association (as expressed in its full title, *the advancement of science*) may be brought about, the collection and preservation of objects available for examination, study, and reference—in fact, the formation of what are now called "museums"—is one of very great practical importance; so much so, indeed, that it seems to me one to the consideration of which it is desirable to devote some time upon such an occasion as this. It is a subject still little understood, though, fortunately, beginning to attract attention. It has already been brought before the notice of the Association, both in Presidential and Sectional addresses. A committee of our members is at the present time engaged in collecting evidence upon it, and has issued some valuable reports. During the present year an association of curators and others interested in museums has been founded for the purpose of interchange of ideas upon the organization and management of these institutions. It is a subject, moreover, if I may be allowed to mention a personal reason for bringing it forward this evening, which has more than any other occupied my time and my attention almost from the earliest period of my recollection, and I think you will agree with the opinion of one of my distinguished predecessors in this chair, "that the holder of this office will generally do better by giving utterance to what has already become part of his own thought than by gathering matter outside of its habitual range for the special occasion. For," continued Mr. Spottiswoode, "the interest (if any) of an address consists not so much in the multitude of things therein brought forward as in the individuality of the mode in which they are treated."

The first recorded institution which bore the name of museum, or temple or haunt of the Muses, was that founded by Ptolemy Soter at Alexandria about 300 B.C.; but this was not a museum in our sense of the word, but rather, in accordance with its etymology, a place appropriated to the cultivation of learning, or which was frequented by a society or academy of learned men devoting themselves to philosophical studies and the improvement of knowledge.

Although certain great monarchs, as Solomon of Jerusalem and Augustus of Rome, displayed their taste and their magnificence by assembling together in their palaces curious objects brought from distant parts of the world—although it is said that the liberality of Philip and Alexander supplied Aristotle with abundant materials for his researches—of the existence of any permanent or public collections of natural objects among the ancients there is no record. Perhaps the nearest approach to such collections may be found in the preservation of remarkable specimens, sometimes associated with superstitious veneration, sometimes with strange legendary stories, in the buildings devoted to religious worship. The skins of the gorillas brought by the navigator Hanno from the West Coast of Africa, and hung up in the temple at Carthage, afford a well-known instance.

With the revival of learning in the Middle Ages, the collecting instinct, inborn in so many persons of various nations and periods of history, but so long in complete abeyance, sprang into existence with considerable vigour, and a museum, now meaning a collection of miscellaneous objects, antiquities as well as natural curiosities, often associated with a gallery of sculpture and painting, became a fashionable appendage to the establishment of many wealthy persons of superior culture.

All the earliest collections, comparable to what we call museums, were formed by and maintained at the expense of private individuals: sometimes physicians, whose studies naturally led them to a taste for biological science; often great merchant princes, whose trading connections afforded opportunities for bringing together things that were considered curious from foreign lands; or ruling monarchs in their private capacity. It every case they were maintained mainly for the gratification of the possessor or his personal friends, and rarely, if ever, associated with any systematic teaching or public benefit.

One of the earliest known printed catalogues of such a museum is that of Samuel Quickelberg, a physician of Amsterdam, published in 1565 in Munich. In the same year Conrad Gesner published a catalogue of the collection of Johann Kentmann, a physician of Torgau in Saxony, consisting of about 1600 objects, chiefly minerals, shells, and marine animals. Very soon afterwards we find the Emperor Rudolph II. of Germany busily accumulating treasures which constituted the foundations of the present magnificent museums by which the Austrian capital is distinguished.

In England the earliest important collectors of miscellaneous objects were the two John Tradescants, father and son, the latter of whom published, in 1656, a little work called "Musæum Tradescantianum; or, a Collection of Rarities preserved at South Lambeth neer London." The wonderful variety and incongruous juxtaposition of the objects contained in this collection make the catalogue very amusing reading. Under the first division, devoted to "Some Kindes of Birds, their Egges, Beaks, Feathers, Clawes and Spurres," we find "Divers sorts of Egges from Turkie, one given for a Dragon's Egge"; "Easter Egges of the Patriarch of Jerusalem"; "Two Feathers of the Phœnix Tayle"; "The Claw of the bird Rock, who, as Authors report, is able to trusse an Elephant." Among "whole birds" is the famous "Dodar from the Island Mauritius; it is not able to flie, being so big." This is the identical specimen, the head and foot of which have passed through the Ashmolean into the University Museum of Oxford; but we know not what has become of the claw of the Rock, the Phœnix tayle, and the Dragon's egg. Time does not allow me to mention the wonderful things which occur under the head of "Garments, Vestures, Habits, and Ornaments," or the "Mechanick, Artificial Workes in Carvings, Turnings, Sowings, and Paintings," from Edward the Confessor's knit gloves, and the famous "Pohatan, King of Virginia's habit, all embroidered with shells or Roanoke," also still at Oxford, and lately figured and described by Mr. E. B. Tylor, to the "Cherry-stone, upon one side S. George and the Dragon, perfectly cut, and on the other side 88 Emperours' faces," or the other "cherry-stone, holding ten dozen of tortoisshell combs made by Edward Gibbons." But before leaving these private collections I cannot forbear mentioning, as an example of the great aid they often were in advancing science, the indebtedness of Linnæus in his early studies to the valuable zoological museums, which it was one of the ruling passions of several Kings and Queens of Sweden to bring together.

Upon the association of individuals together into societies to promote the advancement of knowledge, these bodies in their corporate capacity frequently made the formation of a museum part of their function. The earliest instance of this in our country was the museum of the Royal Society in Crane Court, of which an illustrated catalogue was published by Dr. Grew in 1681.

The idea that the maintenance of a museum was a portion of the public duty of the State or of any municipal institution had, however, nowhere entered into the mind of man at the beginning of the last century. Even the great teaching bodies, the Universities, were slow in acquiring collections; but it must be recollected that the subjects considered most essential to the education they then professed to give were not those which needed illustration from the objects which can be brought together in a museum. The Italian Universities, where anatomy was taught as a science earlier and more thoroughly than anywhere else in Europe, soon found the desirability of keeping collections of preserved specimens, and the art of preparing them attained a high degree of excellence at Padua and Bologna two centuries ago. But these were generally the private property of the professors, as were nearly all the collections used to illustrate the teaching of anatomy and pathology in our country within the memory of many now living.

Notwithstanding the multiplication of public museums during the present century, and the greater resources and advantages which many of these possess, which private collectors cannot command, the spirit of accumulation in individuals has happily not passed away, although generally directed into rather different channels than formerly. The general museums or miscellaneous collections of old are now left to Governments and institutions which afford greater guarantee of their permanence and public utility, while admirable service is done to science by those private persons with leisure and means who, devoting themselves to some special subject, amass the materials by which its study can be pursued in detail either by themselves or by those they know to be qualified to do so; which collections, if they fulfil their most appropriate destiny, ultimately become incorporated, by gift or purchase, in one or other of the public museums, and then serve as permanent factors in the education of the nation, or rather of the world.

It would be passing beyond the limits of time allotted to this address, indeed going beyond the scope of this Association, if I were to speak of many of the subjects which have pre-eminently exercised the faculties of the collector and formed the materials of which museums are constructed. The various methods by which the mind of man has been able to reproduce the forms of natural objects or to give expression to the images created by his own fancy, from the rudest scratchings of a savage on a bone, or the simplest arrangement of lines employed in ornamenting the roughest piece of pottery, up to the most lovely combinations of form and colour hitherto attained in sculpture or in painting, or in works in metal or in clay, depend altogether on museums for their preservation, for our knowledge of their condition and history in the past, and for the lessons which they can convey for the future.

Apart from the delight which the contemplation of the noblest expressions of art must produce in all cultivated minds, apart also from the curiosity and interest that must be excited by all the less successfully executed attempts to produce similar results, as materials for constructing the true history of the life of man, at different stages of civilization, in different circumstances of living, and in divers regions of the earth, such collections are absolutely invaluable.

But I must pass them by in order to dwell a little more in detail upon those which specially concern the advancement of the subjects which come under the notice of this Association—museums devoted to the so-called "natural history" sciences, although much which will be said of them will doubtless be more or less applicable to museums in general.

The terms "*natural history*" and "*naturalist*" have become deeply rooted in our language, but without any very definite conception of their meaning or the scope of their application. Originally applied to the study of all the phenomena of the universe which are independent of the agency of man, natural history has gradually narrowed down in most people's minds, in consequence of the invention of convenient and generally understood and accepted terms for some of its various subdivisions, as astronomy, chemistry, geology, &c., into that portion of the subject which treats of the history of creatures endowed with life, for which, until lately, no special name had been invented. Even from this limitation botany was gradually disassociating itself in many quarters, and a "naturalist" and a "zoologist" have nearly become, however irrationally, synonymous terms. The happy introduction and general acceptance of the word "biology," notwithstanding the objections raised to its etymological signification, has reunited the study of organisms distinguished by the possession of the living principle, and practically eliminated the now vague and indefinite term "natural history" from scientific terminology. As, however, it is certain to maintain its hold in popular language, I would venture to suggest the desirability of restoring it to its original and really definite signification, contrasting it with the history of man and of his works, and of the changes which have been wrought in the universe by his intervention.

It was in this sense that, when the rapid growth of the miscellaneous collections in the British Museum at Bloomsbury (the expansion of Sir Hans Sloane's accumulation in the old Manor House at Chelsea) was thought to render a division necessary, the line of severance was effected at the junction of what was natural and what was artificial; the former including the products of what are commonly called "natural" forces, unaffected by man's handiwork, or the impress of his mind. The departments which took cognizance of these were termed the "Natural History Departments," and the new building to which they were removed the "Natural History Museum."

It may be worth while to spend a few moments upon the consideration of the value of this division, as it is one which concerns the arrangement and administration of the majority of museums.

Though there is very much to be said for it, the objection has been raised that it cuts man himself in two. The illustrations of man's bodily structure are undoubtedly subjects for the zoologist. The subtile gradations of form, proportion, and colour which distinguish the different races of men, can only be appreciated by one with the education of an anatomist, and whose eye has been trained to estimate the value of such characters in discriminating the variations of animal forms. The subjects for comparison required for this branch of research must therefore be looked for in the zoological collections.

But the comparatively new science of "anthropology" embraces not only man's physical structure: it includes his mental development, his manners, customs, traditions, and languages. The illustrations of his works of art, domestic utensils, and weapons of war are essential parts of its study. In fact it is impossible to say where it ends. It includes all that man is or ever has been, all that he has ever done. No definite line can be drawn between the rudest flint weapon and the most exquisitely finished instrument of destruction which has ever been turned out from the manufactory at Elswick, between the rough representation of a mammoth, carved by one of its contemporary men on a portion of its own tusk, and the most admirable production of a Landseer. An anthropological collection, to be logical, must include all that is in not only the old British Museum but the South Kensington Museum and the National Gallery. The notion of an anthropology which considers savages and prehistoric people as apart from the rest of mankind may, in the limitations of human powers, have certain conveniences, but it is utterly unscientific, and loses sight of the great value of the study in tracing the gradual growth of our complex systems and customs from the primitive ways of our progenitors.

On the other hand, the division first indicated is as perfectly definite, logical, and scientific as any such division can be. That there are many inconveniences attending wide local disjunctions of the collections containing subjects so distinct yet so nearly allied as physical and psychical anthropology must be fully admitted; but these could only have been overcome by embracing in one grand institution the various national collections illustrating the different branches of science and art, placed in such order and juxtaposition that their mutual relations might be apparent, and the resources of each might be brought to bear upon the elucidation of all the others—an ideal institution, such as the world has not yet seen, but into which the old British Museum might at one time have been developed.

A purely "Natural History Museum" will then embrace a collection of objects illustrating the natural productions of the earth, and in its widest and truest sense should include, as far as they can be illustrated by museum specimens, all the sciences which deal with natural phenomena. It has only been the difficulties, real or imaginary, in illustrating them which have excluded such subjects as astronomy, physics, chemistry, and physiology from occupying departments in our National Natural History Museum, while allowing the introduction of their sister sciences, mineralogy, geology, botany, and zoology.

Though the experimental sciences and those which deal with the laws which govern the universe, rather than with the materials of which it is composed, have not hitherto greatly called forth the collector's instinct, or depended upon museums for their illustration, yet the great advantages of collections of the various instruments by means of which these sciences are pursued, and of examples of the methods by which they are taught, are yearly becoming more manifest. Museums of scientific apparatus now form portions of every well-equipped educational establishment, and under the auspices of the Science and Art Department at South Kensington a national collection illustrating those branches of natural history science which have escaped recognition in the British Museum is assuming a magnitude and importance which brings the question of properly housing and displaying it urgently to the front.

Anomalies such as these are certain to occur in the present almost infantile though rapidly progressive state of science. It may be taken for granted that no scientific institution of any complexity of organization can be, except at the moment of its birth, abreast of the most modern views of the subject, especially in the dividing lines between, and the proportional representation of, the various branches of knowledge which it includes.

The necessity for subdivisions in the study of science is continually becoming more apparent as the knowledge of the details of each subject multiplies without corresponding increase in the power of the human mind to grasp and deal with them, and the dividing lines not only become sharper, but as knowledge advances they frequently require revision. It might be supposed that such revision would adjust itself to the direction taken by the natural development of the relations of the different branches of science, and the truer conceptions entertained of such relations. But this is not always so. Artificial barriers are continually being raised to keep these dividing lines in the direction in which they have once started. Difficulties of readjustment arise not only from the mechanical obstacles caused by the size and arrangements of the buildings and facilities for the allocation of various kinds of collections, but still more from the numerous personal interests which grow up and wind their meshes around such institutions. Professors and curatorships of this or that division of science are founded and endowed, and their holders are usually tenacious either of encroachment upon or of any wide enlargement of the boundaries of the subject they have undertaken to teach or to illustrate; and in this way, more than any other, passing phases of scientific knowledge have become crystallized or fossilized in institutions where they might least have been expected. I may instance many European Universities and great museums in which zoology and comparative anatomy are still held to be distinct subjects taught by different professors, and where, in consequence of the division of the collections under their charge, the skin of an animal, illustrating its zoology, and its skeleton and teeth, illustrating its anatomy, must be looked for in different and perhaps remotely placed buildings.

For the perpetuation of the unfortunate separation of palæontology from biology, which is so clearly a survival of an ancient condition of scientific culture, and for the maintenance in its integrity of the heterogeneous compound of sciences which we now call "geology," the faulty organization of our museums is in a great measure responsible. The more their rearrangement can be made to overstep and break down the abrupt line of demarcation which is still almost universally drawn between beings which live now and those which have lived in past times, so deeply rooted in the popular mind and so hard to eradicate even from that of the scientific student, the better it will be for the progress of sound biological knowledge.

But it is not of the removal of such great anomalies and inconsistencies which, when they have once grown up, require heroic methods to set them right, but rather of certain minor defects in the organization of almost all existing museums which are well within the capacity of comparatively modest administrative means to remedy, that I have now to speak.

That great improvements have been lately effected in many respects in some of the museums in this country, on the Continent, and especially in America, no one can deny. The subject, as I have already indicated, is, happily, exciting the attention of those who have the direction of them, and even awakening interest in the mind of the general public. It is in the hope of in some measure helping on or guiding this movement that I have ventured on the remarks which follow.

The first consideration in establishing a museum, large or small, either in a town, institution, society, or school, is that it should have some definite object or purpose to fulfil; and the next is that means should be forthcoming not only to establish but also to maintain the museum in a suitable manner to fulfil that purpose. Some persons are enthusiastic enough to think that a museum is in itself so good an object that they have only to provide a building and cases and a certain number of specimens, no matter exactly what, to fill them, and then the thing is done; whereas the truth is the work is only then begun. What a museum really depends upon for its success and usefulness is not its building, not its cases, not even its specimens, but its curator. He and his staff are the life and soul of the institution, upon whom its whole value depends; and yet in many—I may say most—of our museums they are the last to be thought of. The care, the preservation, the naming of the specimens are either left to voluntary effort—excellent often for special collections and for a limited time, but never to be depended on as a permanent arrangement—or a grievously under-salaried and consequently uneducated official is expected to keep in order, to clean, dust, arrange, name, and display in a manner which will contribute to the advancement of scientific knowledge, collections ranging in extent over almost every branch of human learning, from the contents of an ancient British barrow to the last discovered bird of paradise from New Guinea.

Valuable specimens not unfrequently find their way into museums thus managed. Their public-spirited owners fondly imagine that they will be preserved and made of use to the world if once given to such an institution. Their fate is, unfortunately, far otherwise. Dirty, neglected, without label, their identity lost, they are often finally devoured by insects or cleared away to make room on the crowded shelves for the new donation of some fresh patron of the institution. It would be far better that such museums should never be founded. They are traps into which precious—sometimes priceless—objects fall only to be destroyed; and, what is still worse, they bring discredit on all similar institutions, make the very name of museum a byword and a reproach, hindering instead of advancing the recognition of their value as agents in the great educational movement of the age.

A museum is like a living organism—it requires continual and tender care. It must grow, or it will perish; and the cost and labour required to maintain it in a state of vitality is not yet by any means fully realized or provided for, either in our great national establishments or in our smaller local institutions.

Often as it has been said, it cannot be too often repeated, that the real objects of forming collections, of whatever kind (apart, of course, from the mere pleasure of acquisition—sometimes the only motive of private collectors), and which, although in very different degrees, and often without being recognized, underlie the organization of all museums, are two, which are quite distinct, and sometimes even conflicting. The first is to advance or increase the knowledge of some given subject. This is generally the motive of the individual collector, whose experience shows him the vast assistance in forming definite ideas in any line of research in which he may be occupied that may be derived from having the materials for its study at his own command, to hold and to handle, to examine and compare, to take up and lay aside whenever the favourable moment to do so occurs. But unless his subject is a very limited one, or his means the reverse, he soon finds the necessity of consulting collections based on a larger scale than his own. Very few people have any idea of the multiplicity of specimens required for the purpose of working out many of the simplest problems concerning the life-history of animals or plants. The naturalist has frequently to ransack all the museums, both public and private, of Europe and America in the endeavour to compose a monograph of a single common genus, or even species, that shall include all questions of its variation, changes in different seasons, and under different climates and conditions of existence, and the distribution in space and time of all its modifications. He often has to confess at the end that he has been baffled in his research for want of the requisite materials for such an undertaking. Of course this ought not to be, and the time will come when it will not be, but that time is very far off yet.

We all know the old saying that the craving for riches grows as the wealth itself increases. Something similar is true of scientific collections brought together for the purpose of advancing knowledge. The larger they are the more their deficiencies seem to become conspicuous; the more desirous we are to fill up the gaps which provokingly interfere with our extracting from them the complete story they have to tell.

Such collections are, however, only for the advanced student, the man who has already become acquainted with the elements of his science, and is in a position, by his knowledge, by his training, and by his observing and reasoning capacity, to take advantage of such material to carry on the subject to a point beyond that at which he takes it up.

But there is another and a far larger class to whom museums are or should be a powerful means of aid in acquiring knowledge. Among such those who are commencing more serious studies may be included; but I especially refer to the much more numerous class, and one which it may be hoped will year by year bear a greater relative proportion to the general population of the country, who, without having the time, the opportunities, or the abilities to make a profound study of any branch of science, yet take a general interest in its progress, and wish to possess some knowledge of the world around them and of the principal facts ascertained with regard to it, or at least some portions of it. For such persons museums may be, when well organized and arranged, of benefit to a degree that at present can scarcely be realized.

To diffuse knowledge among persons of this class is the second of the two purposes of museums of which I have spoken.

I believe that the main cause of what may be fairly termed the failure of the majority of museums—especially museums of natural history—to perform the functions that might be legitimately expected of them is that they nearly always confound together the two distinct objects which they may fulfil, and by attempting to combine both in the same exhibition practically accomplish neither.

In accordance with which of those two objects, which may be briefly called *research* and *instruction*, is the main end of the museum, so should the whole be primarily arranged; and in accordance with the object for which each specimen is required, so should it be treated.

The specimens kept for research, for advancement of knowledge, for careful investigations in structure and development, or for showing the minute distinctions which must be studied in working out the problems connected with variations of species according to age, sex, season, or locality; for fixing the limits of geographical distribution, or determining the range in geological time, must be not only exceedingly numerous (so numerous, indeed, that it is almost impossible to put a limit on what may be required for such purposes), but they must also be kept under such conditions as to admit of ready and close examination and comparison.

If the whole of the specimens really required for enlarging the boundaries of zoological or botanical science were to be displayed in such a manner that each one could be distinctly seen by any visitor sauntering through the public galleries of a museum, the vastness and expense of the institution would be quite out of all proportion to its utility; the specimens themselves would be quite inaccessible to the examination of all those capable of deriving instruction from them, and, owing to the injurious effects of continued exposure to light upon the greater number of preserved natural objects, would ultimately lose a large part of their permanent value. Collections of this kind must, in fact, be treated as the books in a library, and be used only for consultation and reference by those who are able to read and appreciate their contents. To demand, as has been ignorantly done, that all the specimens belonging to our national museums, for instance, should be displayed in cases in the public galleries, would be equivalent to asking that every book in a library, instead of being shut up and arranged on shelves for consultation when required, should have every single page framed and glazed and hung on the walls, so that the humblest visitor as he passes along the galleries has only to open his eyes and revel in the wealth of literature of all ages and all countries, without so much as applying to a custodian to open a case. Such an arrangement is perfectly conceivable. The idea from some points of view is magnificent, almost sublime. But imagine the space required for such an arrangement of the national library of books, or, indeed, of any of the smallest local libraries; imagine the inconvenience to the real student, the disadvantages which he would be under in reading the pages of any work fixed in an immovable position beneath a glass case; think of the enormous distances he would often have to traverse to compare a reference or verify a quotation, and the idea of sublimity soon gives place to its usual antithesis. The attempt to display every bird, every insect, shell, or plant, which is or ought to be in any of our great museums of reference would produce an exactly similar result.

In the arrangement of collections designed for research, which, of course, will contain all those precious specimens called "types," which must be appealed to through all time to determine the species to which a name was originally given, the principal points to be aimed at are—the preservation of the objects from all influences deleterious to them, especially dust, light, and damp; their absolutely correct identification, and record of every circumstance that need be known of their history; their classification and storage in such a manner that each one can be found without difficulty or loss of time; and, both on account of expense as well as convenience of access, they should be made to occupy as small a space as is compatible with these requirements. They should be kept in rooms provided with suitable tables and good light for their examination, and within reach of the necessary books of reference on the particular subjects which the specimens illustrate. Furthermore, the rooms should be so situated that the officers of the museum, without too great hindrance to their own work, can be at hand for occasional assistance and supervision of the student, and if collections of research and exhibited specimens are contained in one building, it is obvious that the closer the contiguity in which those of any particular group are placed the greater will be the convenience both of students and curators, for in very few establishments will it be possible to form each series on such a scale as to be entirely independent of the other.

On the other hand, in a collection arranged for the instruction of the general visitor, the conditions under which the specimens are kept should be totally different. In the first place, their numbers must be strictly limited, according to the nature of the subject to be illustrated and the space available. None must be placed too high or too low for ready examination. There must be no crowding of specimens one behind the other, every one being perfectly and distinctly seen, and with a clear space around it. Imagine a picture gallery with half the pictures on the walls partially or entirely concealed by others hung in front of them: the idea seems preposterous, and yet this is the approved arrangement of specimens in most public museums. If an object is worth putting into a gallery at all it is worth such a position as will enable it to be seen. Every specimen exhibited should be good of its kind, and all available skill and care should be spent upon its preservation and rendering it capable of teaching the lesson it is intended to convey. And here I cannot refrain from saying a word upon the sadly neglected art of taxidermy, which continues to fill the cases of most of our museums with wretched and repulsive caricatures of mammals and birds, out of all natural proportions, shrunken here and bloated there, and in attitudes absolutely impossible for the creature to have assumed while alive. Happily there may be seen occasionally, especially where amateurs of artistic taste and good knowledge of natural history have devoted themselves to the subject, examples enough—and you are fortunate in possessing them in Newcastle—to show that an animal can be converted after death, by a proper application of taxidermy, into a real life-like representation of the original, perfect in form, proportions, and attitude, and almost, if not quite, as valuable for conveying information on these points as the living creature itself. The fact is that taxidermy is an art resembling that of the painter, or rather the sculptor; it requires natural genius as well as great cultivation, and it can never be permanently improved until we have abandoned the present conventional low standard and low payment for "bird-stuffing," which is utterly inadequate to induce any man of capacity to devote himself to it as a profession.

To return from this digression, every specimen exhibited should have its definite purpose, and no absolute duplicate should on any account be permitted. Above all, the purpose for which each specimen is exhibited, and the main lesson to be derived from it, must be distinctly indicated by the labels affixed, both as headings of the various divisions of the series, and to the individual specimens. A well-arranged educational museum has been defined as a collection of instructive labels illustrated by well-selected specimens.

What is, or should be, the order of events in arranging a portion of a public museum? Not certainly, as too often happens now, bringing a number of specimens together almost by haphazard, and cramming them as closely as possible in a case far too small to hold them, and with little reference to their order or to the possibility of their being distinctly seen. First, as I said before, you must have your curator. He must carefully consider the object of the museum, the class and capacities of the persons for whose instruction it is founded, and the space available to carry out this object. He will then divide the subject to be illustrated into groups, and consider their relative proportions, according to which he will plan out the space. Large labels will next be prepared for the principal headings, as the chapters of a book, and smaller ones for the various subdivisions. Certain propositions to be illustrated, either in the structure, classification, geographical distribution, geological position, habits, or evolution of the subjects dealt with, will be laid down and reduced to definite and concise language. Lastly will come the illustrative specimens, each of which as procured and prepared will fall into its appropriate place. As it is not always easy to obtain these at the time that they are wanted, gaps will often have to be left, but these, if properly utilized by drawings or labels, may be made nearly as useful as if occupied by the actual specimens.

A public exhibition which is intended to be instructive and interesting must never be crowded. There is, indeed, no reason why it ever should be. Every such exhibition, whether on a large or small scale, can only contain a representative series of specimens, selected with a view to the needs of the particular class of persons who are likely to visit the gallery, and the number of specimens exhibited should be adapted to the space available. There is, therefore, rarely any excuse for filling it up in such a manner as to interfere with the full view of every specimen shown. A crowded gallery, except in some very exceptional circumstances, at once condemns the curator, as the remedy is generally in his own hands. In order to avoid it he has nothing to do but sternly to eliminate all the less important specimens. If any of these possess features of historical or scientific interest demanding their permanent preservation, they should be kept in the reserve collections; if otherwise, they should not be kept at all.

The ideal public museums of the future will, however, require far more exhibition space than has hitherto been allowed; for though the number of specimens shown may be fewer than is often thought necessary now, each will require more room if the conditions above described are carried out, and especially if it is thought desirable to show it in such a manner as to enable the visitor to realize something of the wonderful complexity of the adaptations which bring each species into harmonious relation with its surrounding conditions. Artistic reproductions of natural environments, illustrations of protective resemblances, or of special modes of life, all require much room for their display. This method of exhibition, wherever faithfully carried out, is, however, proving both instructive and attractive, and will doubtless be greatly extended.

Guide-books and catalogues are useful adjuncts, as being adapted to convey fuller information than labels, and as they can be taken away for study during the intervals of visits to the museum, but they can never supersede the use of labels. Anyone who is in the habit of visiting picture galleries where the names of the artists and the subject are affixed to the frame, and others in which the information has in each case to be sought by reference to a catalogue, must appreciate the vast superiority in comfort and time-saving of the former plan.

Acting upon such principles as these, every public gallery of a museum, whether the splendid saloon of a national institution or the humble room containing the local collection of a village club, can be made a centre of instruction, and will offer interests and attractions which will be looked for in vain in the majority of such institutions at the present time.

One of the best illustrations of the different treatment of collections intended for research or advancement of knowledge, and for popular instruction or diffusion of knowledge, is now to be seen in Kew Gardens, where the admirably constructed and arranged herbarium answers the first purpose, and the public museums of economic botany the second. A similar distinction is carried out in the collections of systematic botany in the natural history branch of the British Museum, with the additional advantage of close contiguity; indeed, as an example of a scheme of good museum arrangement (although not perfect yet in details), I cannot do better than refer to the upper story in the east wing of that institution. The same principles, little regarded in former times in this country, and still unknown in some of the largest Continental museums, are gradually pervading every department of the institution, which, from its national character, its metropolitan position, and exceptional resources, ought to illustrate in perfection the ideal of a natural history museum. In fact, it is only in a national institution that an exhaustive research collection in all branches of natural history, in which the specialist of every group can find his own subject fully illustrated, can or ought to be attempted.

As the actual comparison of specimen with specimen is the basis of zoological and botanical research, and as work done with imperfect materials is necessarily imperfect in itself, it is far the wisest policy to concentrate in a few great central institutions, the number and situation of which must be determined by the population and the resources of the country, all the collections, especially those containing specimens already alluded to as so dear to the systematic naturalist, known as authors' "types," required for original investigations. It is far more advantageous to the investigator to go to such a collection and take up his temporary abode there, while his research is being carried out, with all the material required at his hand at once, than to travel from place to place and pick up piecemeal the information he requires, without opportunity of direct comparison of specimens.

I do not say that collections for special study, and even original research, should not, under particular circumstances and limitations, be formed at museums other than central national institutions, or that nothing should be retained in provincial museums but what is of a directly educational or elementary nature. A local collection, illustrating the fauna and flora of the district, should be part of every such museum; and this may be carried to almost any amount of detail, and therefore in many cases it would be very unadvisable to exhibit the whole of it. A selection of the most important objects may be shown under the conditions described above, and the remainder carefully preserved in cabinets for the study of specialists.

It is also very desirable in all museums, in order that the exhibited series should be as little disturbed as possible in arrangement, and be always available for the purpose for which it is intended, that there should be, for the use of teachers and students, a supplementary set of common objects, which, if injured, could be easily replaced. It must not be forgotten that the zealous investigator and the conscientious curator are often the direst antagonists: the one endeavours to get all the knowledge he can out of a specimen, regardless of its ultimate fate, and even if his own eyes alone have the advantage of it; the other is content if a limited portion only is seen, provided that can be seen by everyone both now and hereafter.

Such, then, is the primary principle which ought to underlie the arrangement of all museums—the distinct separation of the two objects for which collections are made; the publicly exhibited collection being never a store-room or magazine, but only such as the ordinary visitor can understand and profit by, and the collection for students being so arranged as to afford every facility for examination and research. The improvements that can be made in detail in both departments are endless, and to enter further into their consideration would lead me far beyond the limits of this address. Happily, as I said before, the subject is receiving much attention.

I would willingly dwell longer upon it—indeed I feel that I have only been able to touch slightly and superficially upon many questions of practical interest, well worthy of more detailed consideration—but time warns me that I must be bringing this discourse to a close, and I have still said nothing in reference to subjects upon which you may expect some words on this occasion. I mean those great problems concerning the laws which regulate the evolution of organic beings, problems which agitate the minds of all biologists of the present day, and the solution of which is watched with keen interest by a far wider circle—a circle, in fact, coincident with the intelligence and education of the world. Several communications connected with these problems will be brought before the Sectional meetings during the next few days, and we shall have the advantage of hearing them discussed by some of those who by virtue of their special attention to and full knowledge of these subjects are most competent to speak with authority. It is therefore for me rather delicate ground to tread upon, especially at the close of a discourse mainly devoted to another question. I will, however, briefly point out the nature of the problems and the lines which the endeavour to solve them will probably take, without attempting to anticipate the details which you will doubtless hear most fully and ably stated elsewhere.

I think I may safely premise that few, if any, original workers at any branch of biology appear now to entertain serious doubt about the general truth of the doctrine that all existing forms of life have been derived from other forms by a natural process of descent with modification, and it is generally acknowledged that to the records of the past history of life upon the earth we must look for the actual confirmation of the truth of a doctrine which accords so strongly with all we know of the present history of living beings.

Prof. Huxley wrote in 1875:—"The only perfectly safe foundation for the doctrine of evolution lies in the historical, or rather archæological, evidence that particular organisms have arisen by the gradual modification of their predecessors, which is furnished by fossil remains. That evidence is daily increasing in amount and in weight, and it is to be hoped that the comparisons of the actual pedigree of these organisms with the phenomena of their development may furnish some criterion by which the validity of phylogenic conclusions deduced from the facts of embryology alone may be satisfactorily tested."

Palæontology, however, as we all know, reveals her secrets with no open hand. How can we be reminded of this more forcibly than by the discovery announced scarcely three months ago by Prof. Marsh of numerous mammalian remains from formations of the Cretaceous period, the absence of which had so long been a source of difficulty to all zoologists? What vistas does this discovery open of future possibilities, and what thorough discredit, if any were needed, does it throw on the value of negative evidence in such matters! Bearing fully in mind the necessary imperfection of the record we have to deal with, I think that no one taking an impartial survey of the recent progress of palæontological discovery can doubt that the evidence in favour of a gradual modification of living forms is still steadily increasing. Any regular progressive series of changes of structure coinciding with changes in time can of course only be expected to be preserved and to come again before our eyes under such a favourable combination of circumstances as must be of most rare occurrence; but the links, more or less perfect, of many such series are continually being revealed, and the discovery of a single intermediate form is often of immense interest as indicating the path along which the modification from one apparently distinct form to another may have taken place.

Though palæontology may be appealed to in support of the conclusion that modifications have taken place as time advanced, it can scarcely afford any help in solving the more difficult problems which still remain as to the methods by which the changes have been brought about.

Ever since the publication of what has been truly described as the "creation of modern natural history," Darwin's work on the "Origin of Species," there has been no little controversy as to how far all the modifications of living forms can be accounted for by the principle of natural selection or preservation of variations best adapted for their surrounding conditions, or whether any, and if so what, other factors have taken part in the process of organic evolution.

It certainly cannot be said that in these later times the controversy has ended. Indeed those who are acquainted with scientific literature must know that notes struck at the last annual meeting of this Association produced a series of reverberations, the echoes of which have hardly yet died away.

Within the last few months also, two important works have appeared in our country, which have placed in an accessible and popular form many of the data upon which the most prevalent views on the subject are based.

The first is, "Darwinism: an Exposition of the Theory of Natural Selection, with some of its Applications," by Alfred Russel Wallace. No one could be found so competent to give such an exposition of the theory as one who was, simultaneously with Darwin, its independent originator, but who, by the title he has chosen no less than by the contents of the book, has, with rare modesty and self-abnegation, transferred to his fellow-labourer all the merit of the discovery of what he evidently looks upon as a principle of overwhelming importance in the economy of Nature; "supreme," indeed, he says, "to an extent which even Darwin himself hesitated to claim for it."

The other work I refer to is the English translation of the remarkable "Essays upon Heredity and Kindred Biological Problems," by Dr. August Weismann, published at the Oxford Clarendon Press, in which is fully discussed the very important but still open question—a question which was brought into prominence at our meeting at Manchester two years ago—of the transmission or non-transmission to the offspring of characters acquired during the lifetime of the parent.

It is generally recognized that it is one of the main elements of Darwin's, as well as of every other theory of evolution, that there is in every individual organic being an innate tendency to vary from the standard of its predecessors, but that this tendency is usually kept under the sternest control by the opposite tendency to resemble them, a force to which the terms "heredity" and "atavism" are applied. The causes of this initial tendency to vary, as well as those of its limits and prevailing direction, and the circumstances which favour its occasional bursting through the constraining principle of heredity offer an endless field for speculation. Though several theories of variation have been suggested, I think that no one would venture to say we have passed beyond the threshold of knowledge of the subject at present.

Taking for granted, however, as we all do, that this tendency to individual variation exists, then comes the question, What are the agents by which, when it has asserted itself, it is controlled or directed in such a manner as to produce the permanent or apparently permanent modifications of organic structures which we see around us? Is "survival of the fittest" or preservation by natural selection of those variations best adapted for their surrounding conditions (the essentially Darwinian or still more essentially Wallacian doctrine) the sole or even the chief of these agents? Can isolation, or the revived Lamarckian view of the direct action of the environment, or the effects of use or disuse accumulating through generations, either singly or combined, account for all? or is it necessary to invoke the aid of any of the numerous subsidiary methods of selection which have been suggested as factors in bringing about the great result?

Anyone who has closely followed these discussions, especially those bearing most directly upon what is generally regarded as the most important factor of evolution—natural selection, or "survival of the fittest"—cannot fail to have noticed the appeal constantly made to the advantage, the utility, or otherwise of special organs, or modifications of organs or structures to their possessors. Those who have convinced themselves of the universal application of the doctrine of natural selection hold that every particular structure or modification of structure must be of utility to the animal or plant in which it occurs, or to some ancestor of that animal or plant, otherwise it could not have come into existence; the only reservation being for cases which are explained by the principle which Darwin called "correlation of growth." Thus the extreme natural selectionists and the old-fashioned school of teleologists are so far in agreement.

On the other hand, it is held by some that numerous structures and modifications of structures are met with in Nature which are manifestly useless; it is even confidently stated that there are many which are positively injurious to their possessor, and therefore could not possibly have resulted from the action of natural selection of favourable variations. Organs or modifications when in an incipient condition are especially quoted as bearing upon this difficulty. But here, it seems to me, we are continually appealing to a criterion by which to test our theories of which we know far too little, and this (though often relied upon as the strongest) is, in reality, the weakest point of the whole discussion.

Of the variations of the form and structure of organic bodies we are beginning to know something. Our museums, when more complete and better organized, will teach us much on this branch of the subject. They will show us the infinite and wonderful and apparently capricious modifications of form, colour, and of texture to which every most minute portion of the organization of the innumerable creatures which people the earth is subject. They will show us examples of marvellously complicated and delicate arrangements of organs and tissues in many of what we consider as almost the lowest and most imperfectly organized groups of beings with which we are acquainted. But as to the use of all these structures and modifications in the economy of the creatures that possess them, we know, I may almost say, nothing, and our museums will never teach us these things. If time permitted I might give numerous examples in the most familiar of all animals, whose habits and actions are matters of daily observation, with whose life-history we are as well acquainted almost as we are with our own, of structures the purposes of which are still most doubtful. There are many such even in the composition of our own bodies. How, then, can we expect to answer such questions when they relate to animals known to us only by dead specimens, or by the most transient glimpses of the living in a state of nature, or when kept under the most unnatural conditions in confinement? And yet this is actually the state of our knowledge of the vast majority of the myriads of living beings which inhabit the earth. How can we, with our limited powers of observation and limited capacity of imagination, venture to pronounce an opinion as to the fitness or unfitness for its complex surroundings of some peculiar modification of structure found in some strange animal dredged up from the abysses of the ocean, or which passes its life in the dim seclusion of some tropical forest, and into the essential conditions of whose existence we have at present no possible means of putting ourselves in any sort of relation?

How true it is that, as Sir John Lubbock says, "we find in animals complex organs of sense richly supplied with nerves, but the functions of which we are as yet powerless to explain. There may be fifty other senses as different from ours as sound is from sight; and even within the boundaries of our own senses there may be endless sounds which we cannot hear, and colours as different as red from green of which we have no conception. These and a thousand other questions remain for solution. The familiar world which surrounds us may be a totally different place to other animals. To them it may be full of music which we cannot hear, of colour which we cannot see, of sensations which we cannot conceive."

The fact is that nearly all attempts to assign purposes to the varied structures of animals are the merest guesses and assumptions. The writers on natural history of the early part of the present century, who "for every why must have a wherefore," abound in these guesses, which wider knowledge shows to be untenable. Many of the arguments for or against natural selection, based upon the assumed utility or equally assumed uselessness of animal and vegetable structures, have nothing more to recommend them. In fact, to say that any part of the organization of an animal or plant, or any habit or instinct with which it is endowed, is useless, or still more injurious, seems to me an assumption which, in our present state of knowledge, we are not warranted in making. The time may come when we shall have more light, but infinite patience and infinite labour are required before we shall be in a position to speak dogmatically on these mysteries of Nature—labour not only in museums, laboratories, and dissecting-rooms, but in the homes and haunts of the animals themselves, watching and noting their ways amid their natural surroundings, by which means alone we can endeavour to penetrate the secrets of their life-history. But until that time comes, though we may not be quite tempted to echo the despairing cry of the poet, "Behold, we know not anything," a frank confession of ignorance is the most straightforward, indeed the only honest position we can assume when questioned on these subjects.

However much we may be convinced of the supreme value of scientific methods of observation and of reasoning, both as mental training of the individual and in the elucidation of truth and advancement of knowledge generally, it is impossible to be blind to the fact that we who are engaged with the investigation of those subjects which are commonly accepted as belonging to the domain of physical science are unfortunately not always, by virtue of being so occupied, possessed of that most precious gift, "a right judgment in all things."

No one intimately acquainted with the laborious and wavering steps of scientific progress (I can answer at least for one branch of it) can look upon that progress with a perfect feeling of satisfaction.

Can it be said of any of us that our observations are always accurate, the materials on which they are based always sufficient, our reasoning always sound, our conclusions always legitimate? Is there any subject, however limited, of which our knowledge can be said to have reached finality?

Or if it happens to any of us as to

> A man who looks at glass
> On it may stay his eye,
> Or if he pleases through it pass
> And then the heavens espy,

are not those heavens which are beyond the immediate objects of our observation coloured by our prejudices, prepossessions, emotions, or imagination, as often as they are defined by any profound insight into the depth of Nature's laws? In most of these questions an open mind and a suspended judgment appear to me the true scientific position, whichever way our inclinations may lead us.

For myself, I must own that when I endeavour to look beyond the glass, and frame some idea of the plan upon which all the diversity in the organic world has been brought about, I see the strongest grounds for the belief, difficult as it sometimes is in the face of the strange, incomprehensible, apparent defects in structure, and the far stranger, weird, ruthless savagery of habit, often brought to light by the study of the ways of living creatures, that natural selection, or survival of the fittest, has, among other agencies, played a most important part in the production of the present condition of the organic world, and that it is a universally acting and beneficent force continually tending towards the perfection of the individual, of the race, and of the whole living world.

I can even go further and allow my dream still thus to run:—

> Oh yet we trust that somehow good
> Will be the final goal of ill,—
>
> That nothing walks with aimless feet,
> That not one life shall be destroyed
> Or cast as rubbish to the void
> When God hath made the pile complete.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY CAPTAIN W. DE W. ABNEY, C.B., R.E., F.R.S., F.R.A.S., PRESIDENT OF THE SECTION.

THE occupant of this chair has a difficult task to perform, should he attempt to address himself to all the various subjects with which this Section is supposed to deal. I find that it has very often been the custom that some one branch of science should be touched upon by the President, and I shall, as far as in me lies, follow this procedure.

This year is the jubilee of the practical introduction of photography by Daguerre and Fox Talbot, and I have thought I might venture to take up your time with a few remarks on the effect of light on matter. I am not going into the history of photography, nor to record the rivalries that have existed in regard to the various discoveries that have been made in it. A brand-new history of photography, I dare say, would be interesting, but I am not the person to write one; and I would refer those who desire information as to facts and dates to histories which already exist. In foreign histories perhaps we English suffer from speaking and writing in a language which is not understanded of the foreign people; and the credit of several discoveries is sometimes allotted to nationalities who have no claim to them. Be that as it may, I do not propose to correct these errors or to make any reclamations. I leave that to those whose leisure is greater than mine.

I have often asserted, and I again assert, that there should be no stimulus for the study of science to be compared to photography. Step by step, as it is pursued, there will be formed a desire for a knowledge of all physical science. Physics, chemistry, optics, and mathematics are all required to enable it to be studied as it should be studied; and it has the great advantage that experimental work is the very foundation of it, and results of some kind are always visible. I perhaps am taking an optimist view of the matter, seeing there are at least 25,000 living facts against my theory, and perhaps not 1 per cent. of them in its favour. I mean that there are at least 25,000 persons who take photographs, and scarcely 1 per cent. who know or care anything of the "why or wherefoie" of the processes, so far as theory is concerned. If we call photography an applied science, it certainly has a larger number who practise it, and probably fewer theorists, than any other.

He would be a very hardy man who would claim for Nièpce, Daguerre, or Fox Talbot the discovery of photographic action on matter. The knowledge that such an action existed is probably as old as the fair-skinned races of mankind, who must have recognized the fact that light, and particularly sunlight, had a tanning action on the epidermis, and the women then, as now, no doubt took their precautions against it. As to what change the body acted upon by light underwent it need scarcely be said that nothing was known, and perhaps the first scientific experiment in this direction was made rather more than a hundred years ago by Scheele, the Swedish chemist, who found that when chloride of silver was exposed to light chlorine was given off. It was not till well in the forties that any special attention was given to the action that light had on a variety of different bodies; and then Sir John Herschel, Robert Hunt, Becquerel, Draper, and some few others carried out experiments which may be termed classical. Looking at the papers which Herschel published in the Philosophical Transactions and elsewhere, it is not too much to say that they teem with facts which support the grand principle that without the absorption of radiation no chemical action can take place on a body; in other words, we have in them experimental proofs of the law of the conservation of energy. Hunt's work, "Researches on Light," is still a text-book to which scientific photographers refer, and one is sometimes amazed at the amount of experimental data which is placed at our disposal. The conclusions that Hunt drew from his experiments, however, must be taken with caution in the light of our present knowledge, for they are often vitiated by the idea which he firmly held, that radiant heat, light, and chemical action, or actinism, were each of them properties, instead of the effects, of radiation. Again, we have to be careful in taking seriously the experiments carried out with light of various colours when such colours were produced by absorbing media. It must be remembered that an appeal to a moderately pure spectrum is the only appeal which can be legitimately made as to the action of the various components of radiation, and even then the results must be carefully weighed before any definite conclusion can be drawn. No photographic result can be considered as final unless the experiments be varied under all the conditions which may possibly arise. Coloured media are dangerous as enabling trustworthy conclusions to be drawn, unless the characters of such media have been thoroughly well tested and the light they transmit has been measured. An impure spectrum is even more dangerous to rely upon, since the access of white light would be sure to vitiate the results.

Perhaps one of the most puzzling phenomena to be met with in photography is the fact that the range of photographic action is spread over so large a portion of the spectrum. The same difficulty of course is felt in the matter of absorption, since the one is dependent on the other. Absorption by a body we are accustomed, and indeed obliged by the law of the conservation of energy, to consider as due to the transference of the energy of the ether wave-motion to the molecules and atoms comprising the body by increasing the vibrations of one or both.

In the case where chemical action takes place we can scarcely doubt that it is the atoms which in a great measure take up the energy of the radiation falling on them, as chemical action is dependent on the liberation of one or more atoms from the molecule, whilst, when the swings of the molecules are increased in amplitude, we have a rise in temperature of the body. I shall confine the few remarks I shall make on this subject to the case of chemical action. The molecule of a silver salt, such as bromide of silver, chemists are wont to look upon as composed of a limited and equal number of atoms to form the molecule. When we place a thin slab of this material before the slit of the spectroscope we find a total absorption in the violet and ultra-violet of the spectrum, and a partial absorption in the blue and green, and a diminishing absorption in the yellow and red. A photographic plate containing this same salt is acted upon in exactly the same localities and in the same relative degree as where the absorption takes place. Here, then, we have an example of, it may be, the vibrations of four atoms, one of which at least is isochronous, or partially so, with the waves composing a large part of the visible spectrum. The explanation of this is somewhat obscure. A mental picture, however, may help us. If we consider that, owing to the body acted upon being a solid, the oscillations of the molecules and atoms are confined to a limited space, it probably happens that between the times in which the atoms occupy, in regard to one another, the same relative positions, the component vibrations of, say, two of the atoms vary considerably in period. An example of what I mean is found in a pendulum formed of a bob and an elastic rod. If the bob be made to vibrate in the usual manner, and at the same time the elastic rod be elongated, it is manifest that we have a pendulum of ever-varying length. At each instant of time the period of vibration would differ from that at the next instant, if the oscillations were completed. It is manifest that increased amplitude would be given to the pendulum swings by a series of well-timed blows differing very largely in period; at the same time there would be positions of the pendulum in which some one series of well-timed blows would produce the greatest effect. In a somewhat similar manner we should imagine that the ethereal waves should produce increased amplitude in the swing of the atoms between very wide limits of period, and, further, that there should be one or more positions in the spectrum when a maximum effect is produced.[1] I would here remark that the shape of the curves of sensitiveness, when plotted graphically, of the different salts of silver to the spectrum have a marked resemblance to the graphically drawn curves of the three colour-sensations of the normal eye, as determined by Clerk Maxwell. May not the reason for the form of the one be equally applicable for the other? I only throw this out as evidence, not conclusive indeed, that the colour-sensitiveness of the eye is more probably due to a photographic action on the sensitive retina than to a merely mechanical action. That this is the case I need scarcely say has several times been propounded before.

The ease with which a silver salt is decomposed is largely, if not quite, dependent on the presence of some body which will take up some of the atoms which are thrown off from it. For instance, in chloride of silver we have a beautiful example of the necessity of such a body. In the ordinary atmosphere the chloride is, of course, coloured by the action of light; but if it be carefully dried and purified, and placed in a good vacuum, it will remain uncoloured for years in the strongest sunlight. In this case the absence of air and moisture is sufficient to prevent it discolouring.

If in the vacuum, however, a drop of mercury be introduced, the coloration by light is set up. We have the chlorine liberated from the silver and combining with the mercury vapour, and a minute film of calomel formed on the sides of the vessel.

Delicate experiments show that not only is this absorbent almost necessary when the action of light is so strong or

[1] The effect of perfect and nearly perfect synchronism of one oscillation upon another is also to be found exemplified in my "Treatise on Photography" ("Text-book of Science Series").

so prolonged that its effect is visible, but also when the exposure or intensity is so small that the effect is invisible and only to be found by development. The reason for this absorbent is not far to seek. If, for instance, silver chloride be exposed to light *in vacuo*, although the chlorine atoms may be swung off from the original molecule, yet they may only be swung off to a neighbouring molecule which has lost one of its chlorine atoms, and an interchange of atoms merely takes place. If, however, a chlorine absorbent be present which has a greater affinity for chlorine than has the silver chloride which has lost one of its atoms; then we may consider that the chlorine atoms will be on the average more absorbed by the absorbent than by the subchloride molecules. The distribution of the swung-off atoms between the absorbent and the subchloride will doubtless be directly proportional to their respective affinities for chlorine, and so for the other salts of silver. If this be so, then it will be seen that the greater the affinity of the absorbent for the halogen the more rapid will be the decomposition of the silver salt. This, then, points to the fact that if any increase in the sensitiveness of a silver salt is desired it will probably be brought about by mixing with it some stronger halogen absorbent than has yet been done.

The question as to what is the exact product of the decomposition of a silver salt by the action of light is one which has not as yet been fully answered. For my own part, I have my strong beliefs and my disbeliefs. I fully believe the first action of light to be a very simple one, though this simple action is masked by other actions taking place, due to the surroundings in which it takes place. The elimination of one atom from a molecule of a silver salt leaves the molecule in an unsatisfied condition, and capable of taking up some fresh atom. It is this capacity which seemingly shrouds the first action of light, since when exposure is prolonged the molecules take up atoms of oxygen from the air or from the moisture in it. Carey Lea, of Philadelphia, has within the last three years given some interesting experiments on the composition of what he calls the photochloride of silver, which is the chloride coloured by light, and Prof. Hodgkinson has also taken up the matter. The conclusions the former has drawn are, to my mind, scarcely yet to be accepted. According to the latter experimentalist the action of light on silver chloride is to form an oxidized subsalt. This can hardly be the case, except under certain conditions, since a coloured compound is obtained when the silver chloride is exposed in a liquid in which there is no oxygen present.

This coloration by light of the chloride of silver naturally leads our thoughts to the subject of photography in natural colours. The question is often asked when photography in natural colours will be discovered. Photography in natural colours not only has been discovered, but pictures in natural colours have been produced. I am not alluding to the pictures produced by manual work, and which have from time to time been foisted on a credulous public as being produced by the action of light itself, much to the damage of photography and usually of the so-called inventors. Roughly speaking, the method of producing the spectrum in its natural colours is to chlorinize a silver plate, expose it to white light till it assumes a violet colour, heat till it becomes rather ruddy, and expose it to a bright spectrum. The spectrum colours are then impressed in their natural tints. Experiment has shown that these colours are due to an oxidized product being formed at the red end of the spectrum and a reduced product at the violet end. Photography in natural colours, however, is only interesting from a scientific point of view, and, so far as I can see, can never have a commercial value. A process to be useful must be one by which reproductions are quickly made ; in other words, it must be a developing and not a printing process, and it must be taken in the camera, for any printing process requires not only a bright light but also a prolonged exposure. Now it can be conceived that in a substance which absorbs all the visible spectrum the molecules can be so shaken and sifted by the different rays that eventually they sort themselves into masses which reflect the particular rays by which they are shaken ; but it is almost—I might say, quite—impossible to believe that when this sifting has only been commenced, as it would be in the short exposure to which a camera picture is submitted, the substance deposited to build up the image by purely chemical means would be so obliging as to deposit in that the particular size of particle which should give to the image the colour of the nucleus on which it was depositing. I am aware that in the early days of photography we heard a good deal about curious results that had been obtained in negatives, where red brick houses were shown as red and the blue sky as bluish. The cause of these few coincidences is not hard to explain, and would be exactly the same as when the red brick houses were shown as bluish and the sky as red in a negative. The records of the production of the latter negatives are naturally not abundant, since they would not attract much attention. I may repeat, then, that photography in natural colours by a printing-out process—by which I mean by the action of light alone—is not only possible but has been done, but that the production of a negative in natural colours from which prints in natural colours might be produced appears, in the present state of our knowledge, to be impossible. Supposing it were not impracticable, it would be unsatisfactory, as the light with which the picture was impressed would be very different from that in which it would be viewed. Artists are fully aware of this difficulty in painting, and take their precautions against it.

The nearest approach to success in producing coloured pictures by light alone is the method of taking three negatives of the same subject through different-coloured glasses, complementary to the three colour-sensations which together give to the eye the sensations of white light. The method is open to objection on account of the impure colour of the glasses used. If a device could be adopted whereby only those three parts of the spectrum could be severally used which form the colour-sensations, the method would be more perfect than it is at present. Even then perfection could not be attained, owing to a defect which is inherent in photography, and which cannot be eliminated. This defect is the imperfect representation of gradation of tone. For instance, if we have a strip graduated from what we call black to white (it must be recollected that no tone can scientifically be called black, and none white) and photograph it, we shall find that in a print from the negative the darkness which is supposed to represent a grey of equal mixtures of black and white by no means does so unless the black is not as black nor the white as white as the original. The cause of this untruthfulness in photography has occupied my attention for several years, and it has been my endeavour to find out some law which will give us the density of a silver deposit on a negative corresponding with the intensity of the light acting. I am glad to say that at the beginning of this year a law disclosed itself, and I find that the transparency of a silver deposit caused by development can be put into the form of the law of error.

This law can be scarcely empiric, though at first sight it appears that the manipulations in photography are so loose that it should be so. It is this very looseness, however, which shows that the law is applicable, since in all cases I have tried it is obeyed. That there are theoretical difficulties cannot be denied, but it is believed that strictly theoretical reasoning will eventually reconcile theory with observation.

This want of truth in photography in rendering gradation, then, puts it out of the range of possibility that photography in natural colours can ever be exact, or that the three negatives system can ever get over the difficulty.

One of the reproaches that in early days was cast at photography was its inability to render colour in its proper monochromatic luminosity. Thus whilst a dark blue was rendered as white in a print—that is, gave a dense deposit in a negative—bright yellow was rendered as black in a print, or nearly so—that is, as transparent or nearly transparent glass in the negative. To the eye the yellow might be far more luminous than the blue, but the luminosity was in the photograph reversed. I need scarcely say that the reason of this want of truth in the photograph is due to the want of sensitiveness of the ordinarily used silver salts to the least refrangible end of the spectrum. Some fifteen years ago Dr. H. W. Vogel announced the fact that when silver salts were stained with certain dyes they became sensitive to the colour of the spectrum, which the dyes absorbed. This at once opened up possibilities, which, however, were not at once realized, owing perhaps to the length of exposure required when the collodion process was employed. Shortly after the gelatine process was perfected, the same dyes were applied to plates prepared by this method, which, although they contained the same silver salts as the old collodion process, yet *per se* were very much more sensitive. A new era then dawned for what has been termed isochromatic and orthochromatic photography. The dyes principally used are those belonging to the eosin group and cyanine—not the ordinary cyanine dye of commerce, but that discovered by Greville Williams. For a dye to be of use in this manner it may be taken as an axiom—first propounded by the speaker, it is believed—that it must be fugitive, or that it must be capable of forming a silver compound. The more stable a dye is the less effective it is. If we take as an example cyanine, we find that it absorbs in the orange and slightly in the red. If paper or collodion stained with this colouring-matter be exposed to the action of the spectrum, it will be found that the dye bleaches in exactly the same part of the spectrum as that in which it absorbs, following, indeed, the universal law I have already alluded to. If a film containing a silver salt be dyed with the same, it will be found that, whilst the spectrum acts on it in the usual manner—viz. darkening it in the blue, violet, and ultra-violet—the colour is discharged where the dye absorbs, showing that in one part of the spectrum it is the silver salt which is sensitive, and that in the other it is the colouring-matter. If such a plate, after exposure to the spectrum, be developed, it will be found that at both parts a deposit of silver takes place; and further, when the experiment is carefully conducted, if a plate with merely cyanine-coloured collodion be exposed to the spectrum and bleached in the orange, and after removal to the dark room another film containing a silver salt be applied and then a developer, a deposit of silver will take place where the bleaching has occurred. This points to the fact that the molecules of a fugitive dye, when altered by light, are unsatisfied, and are ready to take up an atom or atoms of silver, and other molecules of silver will deposit on such nuclei by an action which has various names in physical science, but which I do not care to mention. This is the theory which I have always advocated, viz. that the dye by its reduction acts as a nucleus on which a deposit of silver can take place. It met with opposition; a rival theory which makes the dye an "optical sensitizer"—an expression which is capable of a meaning which I conceive contrary to physical laws—being run against it. The objection to what I may call the nucleus theory is less vigorous than it has been, and its diminution is due perhaps to the more perfect understanding of the meaning of each other by those engaged in the controversy. To my mind, the action of light on fugitive dyes is one of the most interesting in the whole realm of photography, as eventually it must teach us something as to the structure of molecules, and add to the methods by which their coarseness may be ascertained. Be the theory what it may, however, a definite result has been attained, and it is now possible to obtain a *fair* representation of the luminosity of colours by means of dyed films. At present the employment of coloured screens in front of the lens, or on the lens itself, is almost an essential in the method when daylight is employed, but not till some dye is discovered which shall make a film equally sensitive for the same luminosity to the whole visible spectrum will it be possible to make orthochromatic photography as perfect as it can be made. The very fact that no photograph of even a black and white gradation will render the latter correctly must of necessity render any process imperfect, and hence in the above sentence I have used the expression "as perfect as it can be made."

The delineation of the spectrum is one of the chief scientific applications to which photography has been put. From very early days the violet and ultra-violet end of the spectrum have been favourite objects for the photographic plate. To secure the yellow and red of the spectrum was, however, till of late years, a matter of apparently insurmountable difficulty; whilst a knowledge of that part of the spectrum which lies below the red was only to be gained by its heating effect. The introduction of the gelatine process enabled the green portion of the spectrum to impress itself on the sensitive surface; whilst the addition of various dyes, as before mentioned, allowed the yellow, the orange, and a portion of the red rays to become photographic rays. Some eight years ago it was my own good fortune to make the dark infra-red rays impress themselves on a plate. This last has been too much a specialty of my own, although full explanations have been given of the methods employed. By preparing a bromide of silver salt in a peculiar manner one is able so to modify the molecular arrangement of the atoms that they answer to the swings of those waves which give rise to these radiations. By employing this salt of silver in a film of collodion or gelatine the invisible part of the spectrum can be photographed and the images of bodies which are heated to less than red heat may be caused to impress themselves upon the sensitive plate. The greatest wave-length of the spectrum to which this salt is sensitive so far is 22,000 λ, or five times the length of the visible spectrum. The exposure for such a wave-length is very prolonged, but down to a wave-length of 12,000 it is comparatively short, though not so short as that required for the blue rays to impress themselves on a collodion plate. The colour of the sensitive salt is a green blue by transmitted light; it has yet to be determined whether this colour is all due to the coarseness of the particles or to the absorption by the molecules. The fact that a film can be prepared which by transmitted light is yellow, and which may be indicative of colour due to fine particles, together with an absorption of the red and orange, points to the green colour being probably due to absorption by the molecules. We have thus in photography a means of recording phenomena in the spectrum from the ultra-violet to a very large wave-length in the infra-red—a power which physicists may some day turn to account. It would, for instance, be a research worth pursuing to photograph the heavens on a plate prepared with such a salt, and search for stars which are nearly dead or newly born, for in both cases the temperature at which they are may be such as to render them below red heat, and therefore invisible to the eye in the telescope. It would be a supplementary work to that being carried out by the brothers Henri, Common, Roberts, Gill, and others, who are busy securing photographic charts of the heavens in a manner which is beyond praise.

There is one other recent advance which has been made in scientific photography to which I may be permitted to allude, viz. that from being merely a qualitative recorder of the action of light it can now be used for quantitative measurement. I am not now alluding to photographic actinometers, such as have been brought to such a state of perfection by Roscoe; but what I allude to is the measurement and interpretation of the density of deposit in a negative. By making exposures of different lengths to a standard light, or to different known intensities of light, on the same plate on which a negative has to be taken, the photographic values of the light acting to produce the densities on the different parts of the developed image can be readily found. Indeed, by making only two different exposures to the same light, or two exposures to two different intensities of light, and applying the law of density of deposit in regard to them, a curve is readily made from which the intensities of light necessary to give the different densities of deposit in the image impressed on the same plate can be read off. The application of such scales of density to astronomical photographs, for example, cannot but be of the highest interest, and will render the records so made many times more valuable than they have hitherto been. I am informed that the United States astronomers have already adopted the use of such scales, which for the last three years I have advocated, and it may be expected that we shall have results from such scaled photographs which will give us information which would before have been scarcely hoped for.

One word as to a problem which we may say is as yet only qualitatively and not quantitatively solved. I refer to the interchangeability of length of exposure for intensity of light. Put it in this way. Suppose that with a strong light, L, a short exposure, E, be given, a chemical change, C, is obtained: will the same change, C, be obtained if the time is only an *n*th of the light L, but *n* times the exposure? Now this is a very important point, more particularly when the body acted upon is fairly stable, as, for instance, some of the water-colour pigments, which are known to fade in sunshine, but might not be supposed to do so in the light of an ordinary room, even with prolonged exposure. Many experiments have been made at South Kensington as regards this, more especially with the salts of silver, and it is found that, for any ordinary light, intensity and exposure are interchangeable, but that when the intensity of light is very feeble, say the $\frac{1}{1000000}$ of ordinary daylight, the exposure has to be rather more prolonged than it should be, supposing the exact interchangeability always held good; but it has never been found that a light was so feeble that no action could take place. Of course it must be borne in mind that the stability of the substance acted upon may have some effect; but the same results were obtained with matter which is vastly more stable than the ordinary silver salts. It may be said in truth that almost all matter which is not elemental is, in time and to some degree, acted upon by light.

I should like to have said something regarding the action of light on the iron and chromium salts, and so introduced the subject of platinotype and carbon printing, the former of which is creating a revolution in the production of artistic prints. I have, however, refrained from so doing, as I felt that the President of

Section A should not be mistaken as the President of Section B. Photogravure and the kindred processes were also inviting subjects on which to dwell, more especially as at least one of them is based on the use of the same material as that on which the first camera picture was taken by Nièpce. Again, a dread of trenching on the domains of art restrains me.

Indeed, it would have been almost impossible, and certainly impolitic, in the time which an address should occupy, to have entered into the many branches of science and art which photography covers. I have tried to confine myself to some few advances that have been made in its theory and practice.

The discovery of the action of light on silver salts is one of the marvels of this century, and it is difficult to overrate the bearing it has had on the progress of science, more especially physical science. The discovery of telegraphy took place in the present reign, and two years later photography was practically introduced; and no two discoveries have had a more marked influence on mankind. Telegraphy, however, has had an advantage over photography in the scientific progress that it has made, in that electrical currents are subject to exact measurement, and that empiricism has no place with it. Photography, on the other hand, has laboured under the disadvantage that, though it is subject to measurement, the factors of exactitude have been hitherto absent. In photography we have to deal with molecules the equilibrium of whose components is more or less indifferent according to the process used; again, the light employed is such a varying factor that it is difficult to compare results. Perhaps more than any other disadvantage it labours under is that due to quackery of the worst description at the hands of some of its followers, who not only are self-asserting, but often ignorant of the very first principles of scientific investigation. Photography deserves to have followers of the highest scientific calibre; and if only some few more real physicists and chemists could be induced to unbend their minds and study the theory of an applied science which they often use for record or for pleasure, we might hope for some greater advance than has hitherto been possible.

Photography has been called the handmaid of Art; I venture to think it is even more so the handmaid of Science, and each step taken in perfecting it will render it more worthy of snch a title.

SECTION B.

CHEMISTRY.

Opening Address by Sir Lowthian Bell, Bart., F.R.S., F.C.S., D.C.L., M.Inst.C.E., President of the Section.

It has occasionally been the practice of former occupants of this chair to devote a considerable portion of the Presidential address to the more recent discoveries in chemical science. This branch of learning advances now with such rapid strides and covers so wide a field, that no one who has not made it the business of his life can hope to discharge this duty with even a moderate share of success.

My immediate predecessor, indeed, discouraged any further attempts in this direction on the ground of the impossibility of doing it justice within the limits of a short discourse, and his remarks were consequently directed to the best methods of teaching the science with which Section B is more directly concerned. I propose this morning to add my testimony to the importance of Dr. Tilden's recommendation by comparing the rate of progress of one of our great national industries as it has been advanced with and without the aid which chemistry is capable of affording. For this purpose I have selected the metallurgy of iron, not only from my greater familiarity with its details, but because, in my judgment, it affords a suitable example for the object I have in view.

It is needless to insist on the disadvantage attending the application of a science to practical work, without a fair knowledge of the principles which regulate its action. At the same time it would be unfair to those who were engaged in the manufacture of iron during the first half of the present century to deny the value of the services rendered to their art, without giving much thought to the laws of Nature upon which their processes depended. The work so performed sufficed nevertheless to place the world in possession of the metal in such abundance and at so low a cost, that no engineering works have been delayed on account of the high price of or absence of the required quality in the produce of our ironworks during the period in question. On the other hand, it is not to be denied that since the ironmasters have allied themselves with the chemist, they have made more progress in thirty years than their predecessors did in three centuries.

No one unacquainted with the archæology of the iron trade could suppose that the colossal furnaces pouring forth their streams of molten metal, followed by the rapid action of the Bessemer converter, were the modern representatives of the iron-making appliances of former days. Out of the latter, in a low hearth not larger than a domestic fire-place, often dependent on the wind for their blast, a few pounds of ore were, at a considerable cost for labour, fuel, and waste of metal, converted into malleable iron. By means of a modern furnace in an hour and a half a ten-ton converter can be filled with liquid cast iron, which in twenty minutes may be run into ingots cheaper, stronger, and more malleable than the best wrought iron of our ancestors, or indeed of our own manufacture.

How out of the small fire of the ancient ironworks the German *Stück-Ofen* was evolved is a matter of conjecture. In both, owing to the conditions under which the fuel was burnt, carbon dioxide was largely the product of its combustion. The oxidizing property of this gas was in each the cause of the waste of metal just spoken of. Probably, and for other reasons than avoiding this loss of iron, attempts were made to increase the dimensions of the *Stück-Ofen*. If this addition were one of limited extent, the smelter would find to his cost that a substance was obtained which no longer possessed the malleable property of that obtained from the lesser furnace. This change would be due to the absorption of carbon, but not in sufficient quantity to constitute that valuable form of the metal known as cast iron. With a material useless for the smith and incapable from its difficult fusibility of being run into moulds, we can understand the delay which took place in the introduction of the blast furnace, which about the middle of the sixteenth century gave to cast iron a recognized and valuable position in the arts.

In those days there was no very exact science to appeal to, for two hundred and fifty years after the "high furnace" of the Germans and French had been set to work, Fourcroy, in his "General System of Chemical Knowledge and its Application to the Phenomena of Science and Art," arrived at the conclusion that cast metal was erroneously supposed to be a mixture of slag and iron or a compound of arsenic or manganese and iron. This was written in 1804, in a work of 5000 pages, when he leant to the opinion that Monge and Berthollet were more correct in considering the product of the blast furnace as consisting of iron, oxygen, and carbon.

When the malleable iron-maker had placed in his hands a material containing, as the pig did, more than 90 per cent. of metal, he found it greatly to his advantage to avoid having to deal with all the earthy matter contained in the ores, for it was the presence of silica and alumina which helped to add to the waste incurred in the old hearths. The object sought for in the old Catalan fires, as they were called, in treating ore was one of a reducing or deoxidizing character, whereas the reverse of this was required when ore was replaced by pig-iron. In the first oxygen had to be removed from the oxide of iron, in the latter oxygen had to be united with the metalloids found in the pig. These were distinctions unknown in the days we are considering, and therefore did not trouble the minds of the ironmasters. In both cases there was a large formation of oxide of iron, and when pig-iron was handed over to the Catalan furnace man, it was the oxide of iron so generated which performed the desired duty, and thus this simple mode of procuring malleable iron remained undisturbed for upwards of two hundred years.

The discovery which led to the discontinuance of the low blast furnace as a means of procuring iron in its malleable form was that of puddling made by Cort in 1784. In point of fact Cort's process was merely doing in a reverberatory furnace that which was previously effected by means of compressed air. In an economic point of view, however, the difference is great, and its consequences were of immense importance, for to the puddling furnace we were first indebted for an ample supply of cheap iron by which, in a variety of well-known ways, the interests of the human race have been so largely promoted. As an indication of the indifference of those formerly engaged in industrial pursuits to the scientific aspect of their calling, may be mentioned the fact that puddling had been largely followed for upwards of half a century before it occurred to anyone to examine the chemistry of the process.

Down to the beginning of the seventeenth century the only fuel used in the blast furnace, and, indeed, in the manufacture of iron generally, was charcoal. In 1620, Dudley made several attempts to substitute mineral coal for vegetable fuel in his smelting works, which, by the exhaustion of timber, had become very expensive. He failed in this, and in consequence the British iron trade gradually fell until it was not equal to the production of one modern blast furnace. This happened in 1740, when Darby, by treating pit coal in the same fashion as the charcoal burners had done with wood, *i.e.* by charring it, restored vitality to an expiring industry. It is true the restoration must have been of a languid character, for in half a century afterwards it is said the weekly produce of a furnace did not exceed fifteen or sixteen tons.

Various changes were introduced into the manufacture of iron in the first quarter of the present century, but these were rather of a mechanical than of a chemical nature. They chiefly owed their origin to the lessons taught by the chemist Black to James Watt, who profited by them in the application of steam as a motive power. This brings us to the year 1828, a year which will always be distinguished in the annals of the iron trade by the discovery of Neilson of the value of heated air in smelting the ores of this metal. I never heard it pretended that the inventor had any pretensions to be considered a man of sciencee Had it been otherwise, the knowledge of the virtues of the hot blast might have been indefinitely postponed, and this opinion is founded on the fact that for many a long year no satisfactory explanation was given why heat obtained by burning coal in the hot air apparatus was capable of saving three or four times its weight in the fuel consumed in the furnace itself. I propose, with your permission, to consider this subject with more attention than I shall devote to other portions of this address, and I am led to do this, not only because it is one of some scientific interest, but because its study seems to afford a solution to some questions in respect to which great differences of opinion prevailed among those whose daily work led them to pay much attention to their details. These questions have all a reference to the quantity of fuel consumed in smelting the ore, as this may be affected by the temperature of the blast and the dimensions of the furnaces employed for this purpose.

As is well understood, the heat excited in an iron furnace may be classified under three heads :—

First, that derived from the combustion of the coke at the point where the blast enters the furnace, the ultimate product being carbonic oxide.

Second, the conversion of a portion of this carbonic oxide into carbon dioxide.

Third, the heat carried into the furnace by the blast.

For the better illustration of the relations which the heat derived from these sources bear to each other, a table (No. I.) has been prepared in which the quantities of each are given in Centigrade calories, and reckoned upon 20 units of iron to correspond with English weights. The information upon which the calculations are based is derived from actual observation gathered from furnaces of different sizes and fed with air at different temperatures.

TABLE I.

—	A	—	—	—
Height of furnace in feet ...	48	48	80	80

,, slag per ton of metal ...	34	31	29	28

A second table contains statements showing the manner in which the heat so generated is appropriated in the various divisions of the duty the furnaces had to perform, and for facility of comparison, alongside the quantities of heat so required, their equivalents in the coke used have been added.

In the table No. II. the appropriation of the heat is separated into *Constants* and *Variables*. The first consists of items where the quantity of heat in making a particular quality of iron is only liable to alterations of trifling amount. On the other hand, the variables exhibit in A and B differences so considerable that work which in the furnace blown with cold air absorbed 73,388 calories per 20 cwts. of pig-iron, was done with 58,645 calories by merely raising the blast to 485°.

The cause of this great variation in the amount of heat required for a given weight of pig-iron, produced under different circumstances as to temperature of blast and size of furnace, depends on changes in the actual amount of work to be performed. How this arises will be best seen in the description of the four examples set forth in the two tables.

Beginning with A, which is a furnace 48 feet in height, blown with cold air and consuming 45 cwts. of coke and 18 cwts. of limestone per ton of metal, the volume of gas produced may be taken at 14,460 cubic yards at ordinary temperatures and pressures. At the temperature at which they escape we may assume the volume per ton of iron to be about 36,000 cubic yards, passing out of the furnace at the rate of 357 cubic yards per minute.

In comparing the consumption of coal formerly burnt in the hot-air stoves with the saving of coke in the furnace, account must be taken of the different conditions of the combustion. In Table I., owing to the small quantity of carbon dioxide formed, the heat evolved is only 2638 calories per unit of coke, whereas each unit of the coal consumed in heating the air afforded three times this quantity of heat. Doubtless there was a great loss in the operation of heating the air, for it would not appear that much above one-fourth of the theoretical quantity of heat capable of being generated by the coal reached the furnace through the *tuyères*.

We have now to consider the nature of the change which is effected in a furnace where, for every 2638 calories generated by the combustion of the coke, 508 calories are carried in by the blast. It will be readily understood that with the velocity at which the gases are passing out of the cold-blast furnace they have but little time to impart their heat to the incoming solids, or to have the carbonic oxide they contain converted into carbon dioxide. The withdrawal of so much coke, and its place taken by heat contained in the blast, means that the 14,460 cubic yards of escaping gases are reduced to about 12,120 cubic yards. The effect of this is not only to alter the speed at which the gases are passing through the materials, but to alter the relation in point of quantity which the ironstone present in the furnace bears to the coke, so that, in point of fact, a larger space is occupied by the ore than was before, and a lesser one by the fuel. We have thus the carbonic oxide passing more slowly over the oxide of iron at the same time that there is a greater quantity of the oxide exposed to the influence of the reducing gas. To illustrate how this operates, a table has been prepared, showing how each 1000 cubic feet of furnace space is occupied in the four cases we are considering :—

	A 48-feet cold blast.	B 48-feet hot blast.	C 80-feet blast.	D 80-feet blast.
Coke cubic feet ...	736	686	590	590
Limestone ,, ...	63	75	86	77
Ironstone ,, ...	201	239	324	333
	1000	1000	1000	1000

The immediate effect of the introduction of the hot blast is to alter the spaces filled by the three minerals from those given in

Column A to coke 686, limestone 75, and ore 239 cubic feet. This is followed by a twofold advantage. Volume for volume, ore and limestone possess double the heat-intercepting power of coke, and there is 19 per cent. more ore ready to oxidize the carbonic oxide passing over it at a reduced speed of 16 per cent. than there was when using cold air. The increased efficiency of the coke, due to a more perfect cooling of the gases and higher oxidation of the carbonic oxide, permits its further suppression until the relative spaces filled by the materials are those shown under Column B. These advantages would not of themselves suffice to save 16 cwts. of coke or thereabouts out of 45 cwts., but the reduction in the coke consumed is followed by a diminution in the quantity of air used and in the weight of gases and slag produced. A reference to the appropriation of heat classified under the head of "Variables" will show in consequence diminution from 73,338 to 54,643 calories.

It may be asked whether this prolonged exposure of the ore to the reducing gases could not be secured by driving the furnace at a slower speed. There is, however, a point which may be regarded as one of equilibrium, in which the quantity of cold materials charged at the top just suffices to reduce the temperature of the gases, leaving it as far as is possible consistent with the dimensions of the furnace. If the volume of blast entering at the *tuyères* is lowered one-half, it would mean that the materials would be exposed for twice the time to the hot gases that they were previous to the alteration in the rate of driving. The elevation in the temperature of the coke would enable its carbon to act on the carbon dioxide, so that there would ensue as great a loss under the second head of heat evolution in Table I. as there is gained by a more perfect interception of the heat contained in the gases.

There is, however, another way of securing this prolonged exposure of the ore to the action of the reducing gas without incurring the inconvenience just referred to, viz. by increasing the dimensions of the furnace blown with cold air. When this was done by raising the height from 48 to 71 feet, it was found that the duty performed by the coke, apart from the heat contained in the blast, was just about the same as that in the hot-blast furnace.

With regard to the position of equilibrium above referred to, it is worthy of remark that, while this was reached when a furnace of 48 feet ran 100 tons per week when driven with cold air, it was not arrived at in one of similar dimensions using heated air until the make was increased to about 220 tons.

When we proceed to examine the composition and weight of the gases given off by a 48-feet furnace blown with air at 485° C., it will be found that about 20 per cent. of the carbon as dioxide has disappeared, due no doubt to the still excessive temperature of the upper zone and too rapid a current of the reducing agent. An obvious way to remedy this evil would be by an addition to the capacity of the furnaces. This was done by raising them to a height of 80 feet, with a cubical space three or four times greater than those of 48 feet. In such a furnace, almost the full theoretical quantity of carbon as dioxide has been obtained, but, while the larger furnace held three or four times as much ore, &c., the production was only about double that of the lesser. On referring to Table II., it will be seen that a further economy of 6·6 cwts. of coke has been effected in Furnace C as compared with B, due solely to an enlargement of space, for the temperature of the blast was exactly the same in both. This improvement, it will also be perceived, is due to an extension of those causes which acted so beneficially when hot air was applied to B.

If 6·6 cwts. of carbon or thereabouts is the full quantity per ton of iron which can be found in the gases as dioxide, and if, in a furnace working under the conditions of C, it requires 22·32 of coke to furnish this carbon and that in the carbonic oxide, it is clear we cannot withdraw any coke without disturbing the position of equilibrium supposed to have been established in the case of the furnace in question. Suppose into such a furnace the blast, instead of 485°, is admitted at 695°, as happened under Column D. The additional heat, 732 calories, instead of 534 as in C, will make itself felt throughout the entire height of the furnace, including, of course, the upper zone. Immediately this happens, the carbon dioxide generated by the reduction of the ore attacks the coke and escapes as carbonic oxide. If Table I. is examined, it will be seen that almost the whole of the additional heat carried into the furnace D, as compared with C, has been absorbed by the disappearance of carbon dioxide, so that the net power of the coke unit in both cases is practically the same. Nevertheless it will be remarked that there is still a small saving of coke due to a reduced amount of blast, escaping gases, &c.

From what has preceded, it has been concluded that a furnace of 80 feet affords sufficient opportunity for the gases being as fully saturated with oxygen as the nature of the process of deoxidizing the ore will permit. The sensible heat in the escaping gases, however, still represents a considerable loss, reduced as they have been from 29,482 to 11,043 calories.

According to estimate, it was believed that the reduction of oxide of iron ought to be attended by an increase of temperature—in other words, the conversion of carbonic oxide into carbonic dioxide produced more heat than that absorbed by splitting up oxide of iron into its constituent parts. The estimated difference not being a large one, an experiment was made by substituting in the furnace inert substances having about the same specific heat as the ore. The results confirmed the correctness of the calculation—the temperature of the escaping gases fell, and rose to their normal point when the use of ore was recommenced. A more expensive experiment was subsequently made in the same direction by building, at Ferry Hill, a pair of furnaces having a height of 103 feet, without any substantial benefit being derived from the large additional expenditure incurred.

It was Scheerer, I think, who first divided the blast furnace into zones. The first division, beginning at the top and extending twelve feet downwards, was designated the preheating zone, the following eighteen feet downwards was distinguished as the reducing zone, the next eight feet the carburizing zone, followed by four feet which constituted the zone of fusion. The lowest of all, having a depth of about six feet, was named the zone of combustion. The author of this mapping out, as it were, of the interior of the furnace, does not wish to be understood as confining its various functions within the respective spaces assigned to them; on the contrary, he admits the existence of considerable variations of position. My own observations, however, have led me to conclusions varying considerably from those adopted by Scheerer.

The fundamental cause of these differences seems to depend on the temperature considered as being required for a commencement of the reduction of the ore. By Scheerer the reducing zone is considered to require a temperature of 1000° to 1200° C. This change undoubtedly is not the same with all kinds of ores, but my experiments were conducted when using almost every variety of the mineral. According to the trials made, a mixture of one volume of carbon dioxide and two volumes of carbonic oxide at a temperature of 410°, removed 10 per cent. only of the oxygen in Cleveland ore, and 37·8 per cent. from an artificially prepared oxide. The composition of the gases at the different depths, however, indicates in an unmistakable manner the nature of the action which is going on at any particular point. A table has been prepared from actual analyses of the gases which gives the quantity of oxygen present for every 1000 parts of metal produced; and to this is added the weight of carbon they contained. The results vary, but the general inference to be drawn from the observations made on furnaces of 80 feet, is that by the time the minerals have passed through a space of eight feet of the depth they have to travel, all the oxygen susceptible of removal from the ore in the upper region is found in the gases, the remainder being retained until it reaches the zone of fusion. The same is the order of action in a somewhat modified form which was found to prevail in the case of furnaces 48 feet in height.

TABLE III.—*Showing the quantity of Oxygen and Carbon in gases per* 1000 *parts of pig-iron produced. The 8 feet immediately below charging plates is occupied by charging apparatus.*

NOTE.—Nos. 3 and 4 were using partially calcined limestone, hence the deficiency of O and C until the lower depths are reached.

On casting the eye along the lines of figures a somewhat remarkable circumstance is apparent, viz. that the quantity of oxygen per 1000 of pig-iron gradually decreases as the gases ascend, until they approach the upper region, when it commences to increase. This had been the subject of observation for many years without any complete explanation being given of its cause. Dr. Percy, among others, bestowed some attention to the circumstance without arriving at any opinion satisfactory to himself. It is a little extraordinary that, so far as I have seen, no notice has ever been taken of the fact that the carbon in the gases followed the same law. While engaged in investigating the action of furnace gases on the ore a peculiarity was observed previously unknown to me, viz. that large quantities of carbon were deposited by the dissociation of the reducing gas, the action being $2CO = CO_2 + C$. Experimentally I ascertained that spongy iron, as well as oxide of iron, was capable of producing the change, and that 30 per cent. of carbon dioxide, mixed with the carbonic oxide, arrested the reaction, the temperature at the time being 420°. Dr. C. A. Wright, who subsequently became chief chemist of our laboratory, was asked to continue the examination. The conclusion arrived at was the impossibility of effecting the complete reduction of E_2O_3, or of any oxide by CO. On the contrary, when metallic iron known to contain no oxygen was exposed to a current of this gas, carbon was deposited and oxygen absorbed. It would seem, therefore, that this absorption of oxygen by the iron and precipitation of carbon suffice to explain the disappearance of these two elements from the gases, and that they remain in this condition until the fusion of the iron, in contact with intensely heated carbon, liberates the oxygen as well as that portion of the carbon which is not absorbed by the metal in order to produce pig-iron.

So far, then, as the analyses given in Table III. enable us to judge, instead of the upper two-thirds of a furnace being required for the purposes of reduction, no material change is effected after passing through eighteen feet in a modern furnace of 80 feet in height. After this the composition of the gases, and, therefore, of the minerals, remains pretty steady until the vicinity of the *tuyères* is reached, with the consequences already referred to.

Of the excess of oxygen at the zone of combustion it is highly probable that a portion is due to the reduction of P_2O_5, S_1O_2, SO_3, and CaO. In the case of Cleveland iron I have estimated this at 54 parts per 1000 of pig-iron produced, but the average total oxygen beyond that furnished by the blast in the first two instances given was 130 parts. At this rate there must have been 76 parts of oxygen liberated from the oxide of iron, which is equal to 19 per cent. of that originally combined with the iron in the ore.

It may be appropriate here to refer to what may be taken as a typical expression of the working of a blast furnace in respect to the presence of carbon dioxide. An analysis of the gases is therefore inserted, drawn from an 80-feet furnace at various levels, with the simple remark that it is improbable that carbon dioxide can exist for any length of time when exposed to incandescent coke at the temperature which prevails at the depths mentioned in the last two columns.

TABLE IV.—*Showing what may be regarded as a typical instance of the absence of Carbon Dioxide in the gases taken from a furnace of* 80 *feet. Measurements taken from the highest level of the minerals*, i.e. 8 *feet below charging plates.*

Something like forty years ago the escaping gases from the blast furnaces, rich as they were in carbonic oxide, were permitted to burn wastefully on the surface of the minerals charged at the throat. This meant a loss of about 54 per cent. of the heating power of the coke. For reasons already given it was of course impossible to utilize much of this heat in the actual smelting of the ore because of the necessity of preserving a large excess of carbonic oxide in the gases. This, however, constituted no reason why, apart from the furnace work itself, this vast quantity of gaseous fuel should not have been utilized, as it no doubt would earlier have been, had the ironmakers known, as they now do, its full value. To-day all the blast and other engines are driven and the air is heated at our blast furnaces by fuel formerly wasted, and this without any labour for stoking being required. In Great Britain alone the annual saving is fully equal to four million tons of coal.

In connection with the other volatile products which accompany the iron smelters' work I will only mention ammonia. Some qualities of coal admit of being used in the raw state. In this case, as in distilling coal for illuminating purposes, ammonia is generated and may be collected. Instead, however, of the ammoniacal vapour being all contained in the hydrocarbons as in gas-making, it is diluted in addition with all the fixed carbon as oxides and all the nitrogen of the atmospheric air used in its combustion. Nevertheless, Messrs. Bairds, of the Gartsherrie Works, and others, are manufacturing large quantities of ammonia sulphate from the ammonia so obtained. A similar object is achieved by attaching the necessary condensers to the apparatus for coking coal. The process of distillation is then carried on in hermetically closed ovens heated by the combustion of the gases evolved. These, before reaching the fireplace where they are burnt, are deprived of their ammoniacal vapours by passing through condensers provided for the purpose. Previous, however, to this being done, the waste heat from the coking process had been applied for generating steam, so that at certain collieries in the county of Durham all the mechanical power is obtained without any coal being specially burnt for this purpose.

Before speaking of the next and last great improvements in connection with my subject, I should like to say a few words, and a few words only, respecting steel, a well-known and most valuable compound of iron and carbon. Let me first observe that it seems improbable that this substance was not earlier known to the ancients, as was at one time supposed. The facility with which the metal combines with carbon renders it very unlikely that acieration would not occasionally take place when iron itself was the object of the manufacturer. Certain it is that Agricola, who wrote in 1556, describes in Latin a mode, apparently as well known as that of making iron itself, of making *Acie.* The engraving in his "De re metallica" shows bars of malleable iron placed upright in a charcoal fire resembling that of a Catalan hearth. These, after an exposure of several hours to the incandescent charcoal and hot carbonic oxide, were found changed to steel and employed as such.

After the invention of the blast furnace, pig-iron was placed in a similar hearth, and while in a melted state a blast of air was directed upon the molten metal, until just as much carbon remained with the iron as constituted steel. This mode of procedure continued to be practised long within my own recollection, and may, for what I know, still be followed in some districts. The subject of steel-making occupied the attention of Hassenfratz, of Réaumur, and others, but practically the only process followed until 1865 was the well-known one of cementation.

Since the days of Fourcroy it was ascertained that in addition to the iron, carbon was an essential ingredient in cast metal, bu invariably accompanied by more or less silicon, and wheneve the minerals contained sulphur or phosphorus these metalloid were also present. The nature of the actions employed fo ridding the product of the blast furnace of these substances so a to render it malleable had also been carefully examined and explained by the light of scientific investigation. The manufacturer had, it is true, learnt by experience and observation how to produce an article of excellence without much knowledge of the science of his art. Among other things he ascertained that to obtain a ton of wrought iron he required the heat of an equal weight of coal in the puddling furnace; but he did not know, (nor did even men of science, I think, ever dream, that the oxidation of the metalloids in the pig-iron, and that of a small portion of the metal itself, would afford heat enough to enable the workmen to dispense with the use of all coal in the process of conversion. When, therefore, the iron trade was informed, in a paper read before the British Association in 1856, entitled "A Mode of making Iron without the use of Fuel," its author, Henry Bessemer, was set down by the iron trade as a deluded enthusiast. At that period I doubt whether ten pounds of wrought iron had ever been seen in a state of fusion at one time. Bessemer, in his description, however, spoke of melting tons of it with no more heat than that afforded by the rapid oxidation of about 5 or 6 per cent. of the weight of the pig-iron used. Not only, therefore, was the subject one of economic but also of high scientific interest. Nevertheless, a mere statement of the title of the paper was all the notice bestowed by our predecessors in their Transactions on a discovery which has revolutionized the art of making iron. It is quite true that for some time it appeared as if the scientific aspect of the question were to constitute its only recommendation, for the malleable iron made in a Bessemer converter proved unmanageable when hot, and destitute of strength when cold. Finally it was ascertained that phosphorus was the source of the evil, and, further, that while carbon and silicon could be almost entirely removed from the molten metal, this third metalloid remained unaffected by the treatment. The extent to which the hurtful influence of phosphorus makes itself felt in the wrought iron obtained by the Bessemer process is somewhat remarkable, because while two- to three-tenths per cent. is often present in puddled bars of fair quality, probably no consumer would accept Bessemer steel when it contains half of this amount. The first success was obtained in Sweden, where by using pig-iron containing a mere trace of the objectionable substance a product was obtained which was satisfactory. For many years the beneficial effect produced by manganese on steel had been well known, and it occurred to R. F. Mushet, son of David Mushet, one of, if not the earliest scientific metallurgist in the United Kingdom, to try its influence in the converter on iron made from the hæmatite iron of the west of England which contained from 0·05 to 0·1 per cent. of phosphorus. This addition, apparently by its removing occluded or combined oxygen in the molten iron, afforded the necessary relief, and the operation being one of extreme simplicity enables steel or wrought iron to be produced at a greatly reduced cost. To such an extent has this been carried, that ore is brought by sea over a distance of 1000 miles to Middlesbrough, and from it steel rails are made more cheaply than a greatly inferior article of iron can be produced from the abundant and economically wrought bed of ironstone found within a couple of miles of that town. As an example of the facility of conversion may be adduced the fact that the molten metal is brought direct from the blast furnace, turned into steel or ingot iron as the case may be, and the heat evolved by the operation is sufficient to enable the product in many cases, without further use of fuel, to be taken direct to the mill and rolled into a finished bar.

We have just seen that 0·1 per cent., or thereabouts, of phosphorus renders steel or ingot iron valueless; in like manner very insignificant variations in the quantities of carbon or silicon materially affect their quality. Now the blow, as it is termed, in a Bessemer converter may be accomplished in from twelve to fifteen minutes. It is clear, therefore, the opportunity of ascertaining the precise quality of the steel is one of very short duration. It is, I think, not disputed that a product can be obtained by this process possessed of very high, if indeed not of the highest excellence; but it is also pretended that the quality is not sufficiently uniform for certain purposes. The ordinary reverberatory furnace is incapable of affording the necessary temperature for melting steel or wrought iron, but by employing the fuel in a gaseous state, and by heating the air and gas before they are brought together, as is done in the valuable furnace suggested by the Messrs. Siemens, the heat is so intensified that wrought iron in it is rapidly fused. Steel is now largely made in such furnaces, either by mixing wrought and cast iron, as proposed by M. Pierre Martin, or by means of cast iron alone, when the carbon is removed by the addition of iron ore and some limestone, in which case, by the agency of the ore, the metalloids are oxidized and removed from the bath of iron. Some hours being required for this, sufficient opportunity is afforded for ascertaining the progress of the operation.

The cause of the iron in the Siemens furnace as well as in the Bessemer converter retaining its associated phosphorus, in time began to attract the attention of chemists. In each case the expulsion of the metalloids is effected by oxidation. The carbon is gasified, and the silicium on being acidified is absorbed, and forms a slag containing usually 40 to 50 per cent. of silicic acid. In the presence of such an excess of this substance, any phosphoric acid, if formed, could not be absorbed by the slag. It was the late M. Grüner, of Paris, who, in 1867, first pointed out this fact, and he it was who first recommended the use of lime in order to render the slag basic instead of acid. Further, in order to avoid the presence of silica, he recommended at the same time that the converter should be lined with lime instead of with fire-clay.

The same subject engaged my own attention, when guided by the fact that, as oxide of iron in the puddling furnace was capable of acidifying and removing a large quantity of the phosphorus as iron phosphate, it might be possible by keeping the temperature of the metal below that required for the process of puddling to make this removal more complete. The result of these experiments was communicated to the Iron and Steel Institute in March 1877, when it was shown that pig-iron containing 1·75 per cent. of P could in a few minutes have this reduced to 0·2 per cent.

The rapid destruction of the ordinary Bessemer converter led Mr. G. I. Snelus to consider the practicability of using a lime lining, and on experimenting with this on a working scale he confirmed the opinions previously enunciated by Grüner, by observing that the presence of lime had removed a considerable quantity of the phosphorus. These discoveries constitute the foundation of the very important basic process of Messrs. Thomas and Gilchrist, which consists in adding lime to the molten steel in a converter constructed on the principle described by Mr. Snelus. Considerable difficulty had, however, been experienced by this metallurgist in the attachment of the lime lining to the walls of the converter. This important question was solved by Mr. Edw. Riley by exposing dolomite to a very high temperature in order to prevent further shrinking, and then grinding and mixing the powder with coal tar. This formed a species of cement which is applied to the sides and bottom of the converter in the form of bricks or as cement.

The acidification and subsequent transference to the slag of the phosphorus by the basic treatment has led to its application to agriculture. For this purpose the slag is ground to a fine powder, and sprinkled over the land without any further preparation. By this operation an indispensable element of animal life is derived from the remains of living creatures which, ages ago, found a grave in the ferruginous mud destined to become the great Cleveland bed of ironstone.

Before closing this portion of my official duty, I cannot refrain from tendering to chemists an assurance of the great advantage the manufacturers of iron feel they have derived from the lessons taught them by chemical science. I am the more anxious to do this because we, among others, have been reminded that we are losing the supremacy among industrial nations we once enjoyed for want of that knowledge of chemistry which is more assiduously cultivated abroad than it is in our own country. I am not prepared to deny that the opportunities for acquiring a scientific education are less generally spread here than is the case in France, Germany, or Belgium, but for this the nation, and not the iron trade in particular, is responsible. It must also be admitted that as manufacturers we no longer stand so far above other lands as we formerly did. In this result any differences of education are in no way concerned, for if I were to classify the nationalities of the various inventions enumerated in the course of my remarks, the fears of those who are alarmed at the appearance of a Belgian girder or a German steam-engine on our shores would, I think, be allayed. Perhaps I might be allowed to offer a very few words on the technical side of this important question of education. Much I shall not be able to say, because I have not yet been able to learn the precise position the subject occupies in the minds of its most earnest advocates. If it means, as is sometimes alleged, a system by which, along with scientific instruction, manual dexterity in the use of tools, or a practical knowledge of various manufacturing processes has to be acquired, I confess I am not sanguine as to the results. Certain I am that if foreign workmen are more skilful in their trades, which, as a rule, I doubt, and which in the iron trade I deny, this superiority is not due to scientific training in the manner proposed, for in this they possess, so far as I have seen, no advantage over our own workmen. My objection to the whole system is the impossibility of anything approaching a general application being practicable. I have not a word to say against the rudiments of science being taught wherever this is possible. The knowledge so obtained may often give the future workman a more intelligent interest in his employment than he at present possesses; but I think they who expect much good to attend such a thin veneer of chemistry or physics do not take sufficient account of the extent of the knowledge already possessed by more highly educated men who are now directing the great workshops of the world. It is by extending and enlarging this that substantial aid has to be afforded to industry and science, and not by teaching a mere smattering in our primary or any other schools. In the case of young people who from necessity must leave the school-room at an early age, my own leaning is towards the present system, with the addition of drawing and some natural science. By it certain important lessons are taught, which, if not followed under the discipline of the schoolmaster, run some risk of being entirely neglected. After this, probably, the playground will be found more useful and much more popular with school-boys than trying to learn a trade by means of tools which, before he has to use them in earnest, may be thrown into the scrap heap.

As a national question the attention of the Government, Imperial or municipal, ought to be directed to the importance of establishing in all great manufacturing centres institutions resembling that of the Physical College of this city. These should consist of appropriate and even handsome buildings, properly furnished with all the instruments and appliances required for teaching the sciences in their practical bearings on industrial pursuits. In Newcastle, as well as in other places, this has been done on a fairly ample scale, and the advantages the College of Science in this city are capable of affording are offered on such terms that no one can plead expense being a barrier to mental improvement.

Bearing in mind the importance of the subject, and remembering, as my colleagues and myself do, the difficulties we have had to encounter and those we have still before us, I am strongly of opinion that the erection and maintenance of colleges of science should not be left to the accidental liberality of the few, but should be taken in hand by the nation at large.

NOTES.

AMONGST the recent scientific missions undertaken by order of the French Government are: one by Prof. Viault, of Bordeaux, in the table-lands of Peru, Ecuador, and Bolivia, to continue the investigations of the late M. Paul Bert into rarefied air; one by M. de Coubertin, Secretary of the Committee for the Encouragement of Physical Exercises in Education in the United States and Canada, to visit the Universities and Colleges, to study the working of the various athletic associations frequented by the young people of these countries; one by M. Jacques de Morgan, mining engineer, to explore those parts of Asia Minor lying between the south of the Caspian Sea, Armenia, the Gulf of Alexandria, and Anti-Taurus (this mission will occupy two years and three months); and one by M. Candelier, to Columbia, to make ethnographical researches and collections for the State.

MESSRS. LONGMANS have made arrangements with Dr. Nansen for the publication, both in London and New York, of an account of his recent expedition across Greenland. The book will be fully illustrated, and will probably be published in the spring of next year.

THE twenty-sixth annual meeting of the British Pharmaceutical Conference was opened at the Durham University College of Science, Newcastle, on the 10th inst., when the President, Mr. C. Umney, delivered the annual address.

THE Department of Botany, British Museum, has acquired the collection of microscopic slides made by the late Prof. de Bary.

A CORRESPONDENT of the *Daily Chronicle* states that particulars have reached Constantinople, of a volcanic eruption which occurred some days ago in the province of Erzeroum, destroying the village of Kantzorik, and the majority of its inhabitants. Kantzorik was a little village of 215 inhabitants, situated in the Caza of Tortoum, about 60 kilometres north of the city of Erzeroum. The village nestled in a narrow fertile valley about 1600 metres above the level of the sea, on the slope of the eastern mountains. Before the eruption the inhabitants were startled by subterranean noises, and they noticed at the same time that the springs on a mountain which stands at the eastern end of the valley were dried up. Alarmed at these phenomena they appealed to the nearest local authorities, and were advised at once to evacuate the village. The warning for the majority was too late. Towards midday, whilst the terrified peasants were preparing for flight, the eruption came. The torrent rushed down, bearing on its molten surface boulders and masses of earth torn from the surface or belched from the heart of the mountain. The whole village, with 136 persons, was engulfed in the stream.

IT is reported from Japan that Viscount Ennomoto, the new Minister of Education, is devoting special attention upon the introduction of technical education into the primary schools of the Empire, and that he has turned to Italy as a model. His scheme is to include technical education in the curriculum of the preparatory schools, and to give children technical training from the outset.

MR. BOTHAMLEY, Assistant Lecturer and Demonstrator in the Chemical Department of the Yorkshire College, has been unanimously elected President of the Photographic Convention of the United Kingdom for the meeting in 1890, which is to be held at Chester.

THE "Hand-book of Newcastle and District," compiled in view of the meeting of the British Association there this year, consists of three parts, a third being on the geology of the district. The volumes are very neatly got up and well printed. The general hand-book is by the Rev. Dr. Collingwood Bruce, the greatest living authority on the antiquities and history of the district, who has succeeded in making a highly readable and instructive volume. In a short introduction he shows the immense progress made by Newcastle since the last two visits of the Association, and especially since the introduction of railways. Dr. Bruce gives many reminiscences of the old life of Newcastle, and interesting details as to its historical buildings, as well as its modern institutions. In an appendix, brief descriptions are given of the places of interest in the vicinity of Newcastle arranged in alphabetical order. The second volume is devoted to the industries of Newcastle and the north-east coast, and is edited by Mr. Wigham Richardson. Each section is written by a specialist, and the whole is well illustrated by a fine series of maps and diagrams. We have chapters on agriculture, by Mr. Thomas Bell; railways from the Tweed to the Tees, by Mr. W. G. Laws; the harbours of the north-east coast, by Mr. P. J. Messent; mining and quarrying, by Mr. J. Boland Anderson; engineering, by Mr. W. Boyd; shipbuilding, by Mr. J. A. Rowe; electricity, by the Hon. C. A. Parsons; manufacture of iron and steel, by Mr. C. Lowthian Bell; lead, by Mr. N. C. Cookson; copper, by Mr. George Gatherall; antimony, by Mr. N. C. Cookson; zinc, by Mr. John Pattison; aluminium, by Mr. Curt Netto; chemical manufactures, by Mr. T. W. Stuart; gas-works, by Mr. W. Hardie; printing, by Mr. Sidney Reid; manufacture of paper, by Mr. W. H. Richardson; flour milling, by Mr. Edmund Procter; leather manufacture, by Mr. D. Richardson; tanning, by Mr. G. Angus; coachbuilding, by Mr. J. Philipson; earthenware, by Mr. H. Heath and Mr. C. T. Maling; photography, by Mr. Edwin Dodds; carpeting, by Mr. A. Henderson; cement, by Mr. J. Watson; the development of the Portland cement industry, by Mr. J. L. Spoor; ropemaking, by Mr. R. Dixon; the brewing trade, by Mr. T. W. Lovibond; tobacco, by Mr. J. Harvey; with a concluding section by the editor. The geology section is by Prof. Lebour, and is much above the average of similar hand-books.

DR. RUDOLPH KOENIG, the well-known constructor of standard acoustical apparatus in Paris, has just made a discovery of extreme importance in the theory of music, the details of which he will expound at the forthcoming meeting of the Naturforscher at Heidelberg. This is an extension of Helmholtz's theory of *timbre* to certain cases not represented in the elementary mathematical theory, and corresponding to the actual case of the *timbres* of certain musical instruments. The paper is certain to give rise to discussion, and will be of interest to musicians, who have never, as is notorious, taken kindly to Helmholtz's theory in its original form.

FROM an official summary of the proceedings at the German Anthropological Congress, which met at Vienna last month, it appears that after Prof. Ranke had read the year's report, in which the establishment of chairs of anthropology at German Universities was specially mentioned, Prof. Virchow read a paper on the progress of anthropology in the last twenty years. He thought in the next twenty years anthropologists would be able to explain the connection of the various races and peoples of Europe. Prof. Schaafhausen dealt with the present condition of the study of crania for anthropological purposes, and Prof. Ranke with the position of the ears in different races. Dr. Waldeyer described certain investigations of his into the placenta in the human species and in apes, while Prof. Zuckerkandl spoke of the physical qualities of the inhabitants of Styria and Carinthia. Amongst other papers were the following:—Dr. Hoernes, the present position of prehistoric studies in Austria; Herr Troeltsch, the protection of prehistoric antiquities; Dr. Woldrich, the Stone Age in Central Europe; Prof. Virchow, "Crania Americana"; and quite a number of writers described particular prehistoric discoveries, "finds" of bronzes, stone implements, &c.

On Thursday afternoon last a statue was erected at the Veterinary School at Alfort to the memory of Henri Bouley, who after being a professor there, held a chair at the Museum of Natural History, and who before the close of his career was President of the Academy of Sciences. He was the author of books on veterinary medicine and rural economy, which gave a great impulse to French agriculture. He made successful efforts to raise the education and social position of veterinary surgeons. The statue bears the words, "To Henri Bouley, 1814–1885; his pupils and his friends."

Recently we referred to an entomological tour about to be undertaken in Ceylon on behalf of certain German Museums, by Herr Frühstorfer, a Berlin naturalist. The Ceylon papers now contain an account of the tour in the island, and its results, from which it appears that he left Colombo at the beginning of April, and went *viâ* Ratnapura and Pelmadulla to Balangoda, in the neighbourhood of which place he stayed for some time, and then he took a trip over the hills to the low country round about Bintenne. In this neighbourhood he stayed altogether ten days, after which he made his way to Belihuloya, which he describes as most interesting country for naturalists, the hills round offering fine scope for the insect-trappers. Here he collected some very good specimens, principally dragon-flies of scientific interest. Beetles were also plentiful, and he was successful in obtaining some excellent specimens of the rare family of the *Cetonidæ*, and also captured one or two of the leaf-butterflies, which are so seldom seen, and so difficult to catch when seen, owing to the practice they have when pursued of flying to a bush or a tree, where their peculiar colour and shape, assimilating to the colour and shape of the leaves, render detection almost impossible. On May 6, Herr Frühstorfer went on, *viâ* Haldumulla and Koslande, to Wellaway, where he collected some beautiful butterflies, notably several specimens of the family known as *Papilios* (*montanus*). In the jungle near the Kottiyagalle estate, he captured some splendid butterflies, and an almost incredible number of grasshoppers. Here he collected, amongst other interesting specimens, a number of the insects which, from their red bodies and golden crests, are called "soldier" grasshoppers. Returning to Colombo for a time, he made an excursion to Panadura and the Bolgodde lakes, where he found centipedes of all kinds, including many rarities. On July 8 he journeyed to Kandy and Matale, and on to Dambool, where he stayed a week, and where he gathered his best specimens of *Orthopteras* or locusts, amongst them being some leaf-locusts of beautiful shape, and golden beetles, which are greatly in request by collectors and museums. While in the neighbourhood of Dambool he visited Anuradhapura, and thence he went on, over Habboorenna, to Kanthalai and Trincomalee, where he added to his store of butterflies.

Herr Frühstorfer, however, did not work alone. He employed altogether fourteen other collectors, who have been collecting for him in all parts of the island, and the result is that he has now a gigantic collection, the number of which he says it would be difficult to estimate; but he thinks he is well within the mark in saying that it includes 25,000 beetles, about 7000 butterflies, about 3000 *Orthopteras*, a like number of dragon-flies, and a thousand spiders and centipedes. He has a large number of butterflies and *Orthopteras* that are not to be found in the Colombo Museum; while, numerically speaking, he says he has more than three times the number of dragon-flies to be seen there. Amongst his most valuable specimens are the leaf-butterflies and locusts, and the long-horned beetles and *Mantidæ*. Besides all these, he has a good collection of snakes, amongst which are cobras, sea-snakes, and specimens of the *Uropeltidæ* and false snakes. Besides reptiles, Herr Frühstorfer has a valuable collection of shells. He describes Ceylon as being a very rich field for naturalists.

At the July meeting of the Anthropological Society of Bombay, Mr. Kitts, of the Indian Civil Service, read a paper on the early history of Northern India, in which the theory recently put forward by Mr. Hewitt, on the early history of India, was stated and discussed. The theory of Mr. Hewitt is briefly this:—That the first immigrants who settled in India and have left traces surviving were the so-called Kolarian races, who came from the north-east, and that their descendants, to the number of ten millions or thereabouts, are still occupants of Northern India. The Kolarians were succeeded and conquered by the Dravidians, who came from the north-west, and developed in India a very high state of civilization, both social and political. Large estates belonged to single owners, such as the *talukdari* tenures in Northern India, and the *zemindari* and *patidari* tenures in Southern India. "In short," says Mr. Hewitt, "it was the Dravidians who founded and consolidated the present land revenue system of India." The Dravidians also organized the *punchayet* and *chowkidar* system of village government, which has survived to the present day. All the manual arts and industries practised in the India of to-day were known to and practised by the Dravidians. The Aryans, migrating into a land occupied as India then was by the Dravidians, with a strongly-organized system of government, found great difficulty in obtaining a foothold, and even when they had secured a tract of country in the north-west for themselves, did not obtain supremacy over the rest of India by force of arms. The agents of their subsequent advance were three—religion, commerce, and military ability. Friendly alliances were concluded between the new-comers and the snake races of the Dravidians. The Aryans admitted the noble races of the Dravidians to be of royal blood, and accepted Siva or Lingam worship as not dishonouring to their religion. The Dravidians, thus recognized as of noble blood, were the ancestors of the modern Rajpoots and the Kshatriya caste. Intellectually the Aryans were far superior to the Dravidians, and the Aryan tongue was accordingly adopted as the *lingua franca* for commercial purposes. So, too, the Aryan became a necessary element in every court and in every commercial enterprise, and from this time forward (about six centuries B.C.) their supremacy was assured.

A recent issue of the Japanese *Official Gazette* contains an elaborate table showing the number of earthquake shocks felt in Tokio, and registered at the Central Observatory, from 1875 to 1889. The *Official Gazette* says that a large part of the area on which the city of Tokio stands, being of the character of alluvial deposit, is exceptionally sensitive to shocks of earthquake. These statistics, covering a period of fifteen years, unmistakably indicate the three closing and the three opening months of the year as the period of maximum seismic activity for Tokio. March is *the* month, *par excellence*, and next to it comes December. The order in respect to frequency of shocks is March, December, February, May, January, November, October, April, June, July, September, August.

In a special article of some length on the new Welsh Intermediate Education Act, the *Times* says that, while it recognizes, without supplanting, the higher elementary schools which were so warmly fostered by the Education Department half a dozen years ago, it takes power, not only to deal with intermediate or secondary education, properly so called, but also to become for Wales and Monmouth a Technical Education Act in everything but name. As a Secondary Education Act it will promote instruction in "Latin, Greek, the Welsh and English languages and literature, modern languages, mathematics, natural and applied science, . . . and generally in the higher branches of knowledge." As an Act for furthering technical education, it will promote the teaching of (1) any of the branches of science and art with respect to which grants are, for the time being, made by the Department of Science and Art; (2) the use of tools, and modelling in clay, wood, or other material; (3) commercial arithmetic, commercial geography, book-keeping, and shorthand; (4) any other subject applicable to the purposes of agriculture, industries, trade, or commercial life and practice, which may be specified in a scheme . . . as a form of instruction suited to the needs of the (particular) district. The only restriction to the fullest development of technical science to be aimed at under this Act is set forth in the proviso to the effect that any proposed course of technical instruction "shall not include teaching the practice of any trade, or industry, or employment."

A RECENT issue of the French *Journal Officiel* contains the Report which M. Bouchon-Brandely, Inspector-General of Marine Fisheries in France, has made to the Minister of Marine, on the subject of the cultivation and condition of the natural oyster-banks of Brittany. He visited St. Malo, where he reports the Roma, a river in which oysters have grown for the last fifty years, as being a spot eminently favourable for experiments, on a large scale, in the improved cultivation of this shell-fish. The oysters have been wastefully neglected in the Roma, and at the present time the industry appears to be almost ruined, but to be capable, with a little care, of being restored to a condition of very great importance. Proceeding westward, he found the Bay of St. Brieuc, once a rich oyster-field, entirely destroyed by the reckless use of the dredge. A little further, at Tréguier, he found the oyster-beds still existing which produce the famous Breton oyster, a fish rather larger than the Ostend variety, and not a whit inferior to it in flavour. The fishermen have fished to excess, in spite of all official warnings; they have left the beds no rest or time for growth. The Report suggests a return to the regulations of 1750, by which oyster-fishing in the creek of Tréguier was permitted only once in six years; or, if this be considered too long a close season for practical purposes, to prohibit the fishing for two years at least, during that period to cleanse and tend the beds, to check the wastefulness of the people of the locality, who are in the habit of helping themselves freely to oysters, and to arrange that an ordinary tide, and not the lowest tide in the year, should be chosen for the periodical general fishery. The Report speaks with considerable bitterness of the total destruction of the once flourishing oyster-beds of the Roads of Brest, ruined by every kind of wasteful and improvident fishing. M. Bouchon-Brandely is of opinion that these beds deserve to be replanted, and that, if proper care be taken to protect them, there is no reason why they should not flourish. But it will be necessary, by some penal regulation, to check poaching; and he believes that the expense of maintaining keepers on the oyster-beds would be amply repaid by the profits which would result from the prevention of poaching. Along the coast of the Morbihan the oyster-beds were found to be in a condition much less exhausted than in Finistère, and to be recovering. In the neighbourhood of Vannes a little steamer goes to and fro, watching the oyster-beds, and seeing that they are not disturbed by poachers—a proceeding which has been found to be of excellent service in preserving the fish. At every point, M. Bouchon-Brandely found that the rapacity of the dredgers and the constant disturbance of the young shells had been the principal causes of the rapid decline in the value of the Breton oyster-beds—a decline which has induced the Ministry of Marine to intrust him with these investigations.

THE following observations on the subject of agricultural laboratories in Belgium are taken from a report recently issued by the Agricultural Department of the Privy Council. Every person living in Belgium who purchases not less than a ton of feeding stuffs can have samples of these analyzed, free of cost, at the agricultural laboratory which exercises jurisdiction in the province in which the purchaser resides. In the last number of the *Bulletin de l'Agriculture*, published by the Minister of Agriculture in Belgium, there is a valuable report from the Commissioners appointed to superintend the establishment of agricultural laboratories and to inspect them periodically. From this it appears that there are now seven agricultural laboratories in Belgium where gratuitous analyses of manures and feeding stuffs are made. By a Royal decree, dated August 1887, the agricultural station at Gembloux was reorganized and a distinct agricultural laboratory was attached to it. Besides this there are agricultural laboratories at Gand, Liége, Hasselt, Anvers, Mons, and Louvain. Not only are analyses supplied by these institutions, but information is furnished to agriculturists upon the rational employment of manures, and the best modes of using various feeding stuffs as well as upon other agricultural points. At the station of Gembloux alone there were 227 consultations with agriculturists upon divers questions of agronomy.

A MEMORANDUM by Mr. Charles Whitehead, Agricultural Adviser to the Privy Council, on the subject of the introduction of insects injurious to corn and corn crops in wheat imported from India, has recently been issued. Mr. Whitehead says that the foreign matter mixed with wheat imported from India into this country serves as a medium for the wholesale transportation of insects injurious to crops. From the cleaning of Indian wheat several categories are formed at the flour-mills. One consists of short pieces of straw of from one inch to two inches and a half long, with pieces of wheat ears. This is sold for litter, and is distributed among various farms in the neighbourhood of the mills. In this straw the most dangerous corn insects might be introduced—insects of the type of the Hessian fly, of the *Isosoma Hordei*, the joint worm whose appearance in Great Britain is feared by agricultural entomologists. Another comprises light and misshapen grains of corn with weed seeds, known in this country as "screenings," and which ought to have been taken out of the bulk by the Indian producers. This is purchased for pigs' and chickens' food, being therefore scattered over the face of the land. In this, corn weevils especially and other insects may easily be conveyed. It is well known that weevils are most destructive to wheat and other grains in India. It is also equally well known that they are brought over to British ports and granaries in abundant quantities with Indian wheat. One species of weevil, the *Calandra oryzæ*, the rice weevil, does enormous harm to wheat in Indian granaries, and to wheat while it is being transported in vessels to this country. The admixture of dirt, seeds, and rubbish causes the wheat to heat, which of course is detrimental to its quality, and at the same time causes weevils to propagate unusually and to materially damage it. Sometimes the cargoes of wheat that have been heated are nearly alive with weevils, causing great waste and heavy loss to importers. This loss continues when the bulk is taken to granaries or warehouses where the heat is still evolved, and the weevils revel in it. The amount of loss occasioned by this weevil is estimated at an average of 2½ per cent. Taking the value of wheat exported at £6,000,000, the amount of loss due to this insect in exported wheat alone equals £150,000. Another weevil, the *Calandra granaria*, closely allied to

Calandra oryzæ, is also brought over with Indian wheat. This weevil is known in British and other European granaries, but it is presumed that the heat and surrounding circumstances of cargoes of Indian wheat favour its development and stimulate its powers of destruction. As it breeds freely in this country, the danger of its distribution is great. Besides the actual money loss occasioned by these weevils, it is stated that the flour made from wheat much infested by them is injurious to health.

THE French Consul-General to Bolivia, in a recent Report to his Government, gives some interesting remarks on the population of that remote State. The population, he says, consists of about 1,300,000 persons, and is not homogeneous; it consists of the white race, descendants of Europeans, the Indian, the original inhabitants of the country, and the Mestizos, called Cholos, a mixture of Europeans and Indians. The Indians form more than half the population, and the white race about one-quarter. The manners and customs of the Bolivians vary according to the social group; the white race have much the same customs as Europeans. Special mention is made of a national spice probably little known in Europe. This is pimento (*agi*) which burns the palate, and is largely used in all Bolivian food, and forms an important article of commerce. The continual use of such a hot condiment hardens the mouth, and explains the ease with which nearly all Bolivians can take the strongest spirits. The Indian has very different customs. He sustains himself during work or when hunting by chewing the leaves of the coca, and always carries a quantity with him wherever he goes. As he is addicted to drink, he gets drunk whenever he can. His favourite drink is pure alcohol. On high ground the Indian wears a particular dress summer and winter. This consists of loose drawers, made of coarse linen, which leave the lower part of the legs and feet bare, over these a linen tunic, and a poncho which is used as a mantle. He is accustomed to a hard life, and sleeps in the open air, covered only by a piece of linen, no matter what the weather may be. The morals of the Indian are more than doubtful. His black and glossy hair never receives attention, his red skin acquires a dark colour from the dust which accumulates on his body and becomes part of his epidermis. On *fête* days, men and women cover themselves with tinsel, skins of wild beasts, feathers of every shade, and dance and drink until exhausted by fatigue and drunkenness they throw themselves on the ground. This race, which is interesting from the novel spectacle it presents to the stranger, has but little apprehension of the benefits of civilization; it carries on, however, the agriculture of the country. The Cholo or half-castes already mentioned belong to the least estimable part of the population. They get drunk frequently and work little; they wear trousers and a vest, over which is thrown a poncho. They are almost always immoral and dishonest; wherever there is a disturbance there they are to be found. They are the handicraftsmen of Bolivia, and are not without some skill.

THE *Meteorologische Zeitschrift* for August contains a discussion of the daily period of the humidity in Christiania, by J. F. Schrœter, based upon an old series of hourly observations made at the Observatory between 1841 and 1847. The vapour-tension exhibits the usual periods of double maxima and minima. The relative humidity shows a strongly-marked maximum in the morning, and minimum in the afternoon; the epoch of the maximum occurs earlier from the winter to the summer solstice, and *vice versâ*. Dr. A. Wachlowski contributes a paper on the rainfall of Galicia. The yearly period is a very simple one; there is a maximum in July, and a minimum in January and February. The country is divided into seven districts, in which the annual rainfall varies from 24½ to 26½ inches.

THE additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mr. James Waddell; three Bengal Foxes (*Canis bengalensis*) from India, presented by Colonel Creek; a Common Badger (*Meles taxus*), British, presented by Mr. G. H. Hulme; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Miss Colvin; a Crested Porcupine (*Hystrix cristata*) from Ceylon, presented by Captain Rose; a Ringed Plover (*Ægialitis hiaticula*), British, presented by Mr. H. M. Upcher; a Red-billed Tree Duck (*Dendrocygna autumnalis*) from India, presented by Mrs. Alfred Oakes; five Hobbies (*Falco subbuteo*) from Spain, deposited; two Upland Geese (*Bernicla magellanica*, var. *dispar*, ♂ ♀) from Patagonia, two Spur-winged Geese (*Plectropterus gambensis*) from West Africa, two Black-backed Geese (*Sarcidiornis melanonota*) from India, purchased.

OUR ASTRONOMICAL COLUMN.

THE TRIPLE STAR Σ 2400.—In the year 1884 a third star was discovered by M. Perrotin, lying nearly midway between the two components which had been discovered by Struve in 1829. Mr. Burnham, writing to the *Observatory* under date July 31, 1889, now points out that the observations made of the three stars show that the change in position of the two companion stars is wholly due to the proper motion of the principal star, that the two fainter stars are substantially fixed with regard to each other, and may possibly prove to be physically connected, though with but slow motion, and that, thirdly, Struve's observation in 1872 was of the new, and not of the old, companion. It appears curious that the inner companion was not discovered earlier, as it is almost as bright as the outer one. The large star is moving away from the fainter, so that measurements will be rendered easier in the future.

THE POTSDAM OBSERVATORY.—The second part of the fourth volume of the Publications of this Observatory has just appeared. It is given up to solar physics, the heliographic latitudes and longitudes of the sun-spots from 1880–84 forming the first section; Herr Wilsing's research (see NATURE, vol. xxxviii. p. 206, June 28, 1888) on the rotation period of the sun as derived from the observation of faculæ, the second; and a description of Dr. Lohse's photoheliograph, and of the method employed at the Observatory for the measurement of the solar photographs, the remainder of the volume.

THE OBSERVATION OF SUDDEN PHENOMENA.—Prof. Langley, in the *Sidereal Messenger* for August, proposes a method for greatly diminishing personality in the observation of sudden phenomena, such as the disappearance of a star when occulted by the moon. The principle of the method, which is susceptible of a wide application, consists in associating a motion, real or apparent, of the object with intervals of time, so that the apparent position of the object at any occurrence being noted, the time of the occurrence will be known. For the apparent position, say, of a star at occultation is an integral part of the phenomenon observed, and does not depend for its correct estimation upon the rapidity with which the mind can pass from one order of impressions, as the sight of a star in the field of a telescope, to another, such as the estimation of the interval that has elapsed from the last beat of a pendulum. Some preliminary experiments with an eyepiece, in which the star under observation was made to appear to revolve once in a second, showed that it was quite possible to observe an occultation with a probable error of only one-fortieth of a second.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 SEPTEMBER 15–21.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 15

Sun rises, 5h. 37m.; souths, 11h. 55m. 1·0s.; daily decrease of southing, 21·2s.; sets, 18h. 13m.: right asc. on meridian, 11h. 33·6m.; decl. 2° 52′ N. Sidereal Time at Sunset, 17h. 53m.

Moon (at Last Quarter September 17, 5h.) rises, 20h. 41m.*; souths, 4h. 18m.; sets, 12h. 7m.: right asc. on meridian, 3h. 55·3m.; decl. 17° 7′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′
Mercury..	8 9	13 26	18 43	13 5·1	9 8 S.
Venus.....	2 7	9 36	17 5	9 13·9	16 11 N.

GEOGRAPHICAL NOTES.

The Indian Survey Department has just issued the second edition of an elaborate coloured map of India in six sheets, fully corrected up to 1888. The scale is 32 miles to the inch, and the details are most minute. British territory is clearly marked as well as dependent and subordinate native States, and independent countries and foreign possessions. Main and minor roads too are clearly noted, and railways open and in progress are indicated, while the position of lighthouses, passes, forts, and canals, is shown in a most precise manner ; another feature is that the altitudes above sea-level of the chief stations throughout India are given. The map was first issued under the direction of Lieut.-General J. T. Walker, C.B., R.E., and is now reissued under instructions from Colonel H. R. Thuillier, R.E.

It is reported from Honolulu that H.M.S. *Espiègle* arrived there on August 28, after annexing Humphrey and Rierson Islands, in the Manihiki Group, a cluster of small islands in the Eastern Pacific to the north of Cook Islands.

The following letter is published from Captain Grombchevsky, who started last spring for Kafiristan :—"I left Marghilan on July 13, and was compelled to halt owing to the overflow of the River Isfaran and the destruction of the bridges. After vain efforts to cross the snow-covered ridge of Transalai, opposite to Altyn Mazar, I returned to Alai, and reached Kala-i-Khumb, through Karategin as far as Moumina, Lake Yashil, the pass of Gardami, Kafar Vakhia, and Passand. I purposed proceeding up the River Khuf, as far as Lake Shiva, but the borders of the lake were occupied by Afghan troops. I shall therefore go up the Panjah towards Roshan and Shugnan, where Ak Barsba, whose days are numbered, still holds his own. He lately made a bold *sortie* against the Afghans, and took the towns of Ishkashin and Zebac, but, being surrounded by superior and better-disciplined forces of Afghans, he was obliged to surrender both places and retreat on Shugnan. He sent his Afghan prisoners to Darvaz, whence they were sent home by the Bokharan authorities through Kouliab. In three days I shall be in the centre of military operations, and as the issue is certain to be favourable to the Afghans, I am sending a letter to Faizabad, to the Ameer's lieutenant, asking permission to pass through Kafiristan. The letter is carried by a native of Shugnan, who was sold as a slave for his devotion to the Afghans, and is owing his liberty to me. All well, in high spirits and full of energy. I have with me seven Cossacks, two Tekkes, two Kirghiz, one native of Shugnan, and one German."

The following account of M. Bonvalot's tour in Central Asia is taken by the Paris *Figaro* from a letter from the traveller himself. He is accompanied by Prince Henry of Orleans, the eldest son of the Duc de Chartres. They have safely reached the Russo-Chinese frontier, and when the traveller wrote were about to cross into Chinese territory. M. Bonvalot's present object is nothing less than to make his way into Tonquin across China. The following is his proposed itinerary : from Omsk to Semipalatinsk, then to Bakti, next to Chuguchak, and thence onwards in succession through Chicho, Manas, Urumtsi, Karashar, Korla, by the course of the Tarim and Lob Nor to Karkalik, across the Tchamuen Tai by the way of Naichi Gob to Koukon Sai, Tsamdo, Batang, Yunnanfor, and finally Tonquin. M. Bonvalot ends his itinerary with the following reflections :—"A sufficiently hazardous task, perhaps incapable of execution. In a word this is our ideal, but complications and accidents may perhaps compel us to modify it. For the present we hope to reach China as quickly as possible. The approach of winter on the higher plateaus of Tibet frightens me a little, and makes me long to be there."

The Indian mail brings intelligence of the death of Mr. William Watts M'Nair, of the Indian Survey. In 1883, Mr. M'Nair, disguised as a Mahometan doctor, succeeded in reaching the outlying valleys of Kafiristan, travelling by way of the Swat Valley and Chitral. For this adventurous journey, in the course of which he obtained much valuable information regarding the passes of the Hindoo Koosh and about the manners and customs of the Sirjah Push Kafirs, the Royal Geographical Society awarded the Murchison grant. Mr. M'Nair, in whom the Indian Government has lost an able and zealous servant, died at Mussoorie, on August 13, of fever contracted at Quetta.

In answer to telegraphic inquiries, addressed to Tromsö by the Bremen Geographical Society respecting the fate of Dr. Kukenthal, whom they had sent out to explore the North Polar regions, a reply was received a few days ago stating that, although the *Berntina*, on board which Dr. Kukenthal was, had stranded, yet the young explorer and his companion, Dr. Walter, with all their equipment, had been saved. Their voyage had not even been delayed, as they had not returned to Tromsö, but had proceeded in another sealer, the *Cæcilie Magdalena*. In July they intended to press forward on the north coast of Spitzbergen.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The result of the examination for certificates held in July last under the direction of the Oxford and Cambridge Schools Examination Board has been published. In the examination for higher certificates there were 1161 candidates, of these 64 girls were candidates for letters only. The number of higher certificates awarded was 785, and the number of letters given to girls was 51. The total number of candidates for lower certificates was 709, and the number of certificates awarded was 408. For the newly-established commercial certificates there were 66 candidates, and 25 certificates were awarded.

The following are the statistics so far as scientific subjects are concerned:—

Higher Certificates.

Subject.	No. of Candidates.	Total Passed.	Distinguished.
Mathematics, Elementary	1068	924	0
Mathematics, Additional	483	344	85
Natural Philosophy, Mechanical Division	102	96	47
Natural Philosophy, Physical Division	46	42	21
Botany	23	17	7
Physical Geography and Elementary Geology	46	44	16
Biology	4	3	2

Lower Certificates.

Subject.	No. of Candidates.	Second Class.	First Class.
Arithmetic	709	387	152
Additional Mathematics	638	243	244
Geography	386	153	44
Mechanics and Physics	62	22	14
Physics and Chemistry	60	19	20
Chemistry and Mechanics	44	16	6

Commercial Certificates.

Subject.	No. of Candidates.	Second Class.	First Class.
Arithmetic	66	40	19
Algebra	66	40	18
English	66	28	7
Shorthand	12	2	0
Geography	66	34	4
Inorganic Chemistry	25	6	8
Mechanics	12	8	4
Electricity and Magnetism	19	14	4
Sound, Light, and Heat	15	10	0

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 2.—M. Des Cloizeaux, President, in the chair.—Definitions adopted by the International Congress of Electricians, by M. Mascart.—On the results obtained at Bourganeuf (Creuse), in transmission of force by electricity, by M. Marcel Deprez. The force is conveyed 14 kilometres, from a waterfall, by a bare siliceous bronze wire on posts. Generator and receiver have each 100 nominal horse-power; electromotive force of former 3000 volts. Further details are promised.—On the analytic representation of perturbations of planets, by M. Hugo Gyldén.—Researches on the relations between the carbon of plants and the quantity of fertilizing agents in the soil, by M. Georges Ville. The coloration of leaves varies with the nature of the manure, nitrogen having most effect. The colours of liquids got by treating leaves with alcohol (after extraction of the colouring matter carotine) correspond with those directly observed, but the differences in intensity are less. The orange solutions of carotine (with carbon sulphide) show corresponding variations of intensity with those of chlorophyll.—A prize competition, from Spain, was announced, for a work commemorating the discovery of America (30,000 francs and 15,000 francs).—On Brooks's comet, July 6, 1889, by M. Charlois.—On the aspect and on a companion of Brooks's comet, by M. G. Bigourdan. This companion, observed since the 27th ult., is a small round nebulosity (of magnitude 13·3) on one side of the tail, and 20″ from the nucleus.—Unipolar and bipolar induction on a turning sphere, by M. Ch. V. Zenger. The poles of the electro magnet can be moved towards or from each other, by means of movable coils. The suspended copper sphere, rotated by torsion, with axis near that of magnet, has a spiraloid elliptic movement, which is recorded on smoked paper. M. Zenger seeks to explain the orbital motion of planets and comets, on principles here involved.—Electrodynamic laws and planetary motion, by the same.—New experiments on the poison of the terrestrial salamander, by M. C. Phisalix. The minimum fatal dose of chlorhydrate of salamandrine for a dog is about 1·8 milligrammes per kilogramme of the animal, with subcutaneous injection; 1 milligramme with intravenous injection; and 8 to 10 milligrammes by the stomach. By a series of preventive inoculations a dog can be gradually accustomed to doses otherwise fatal. A dose of 5 to 10 milligrammes subcutaneous, or 1 milligramme intravenous, is fatal to the salamander itself.—On the cardiac effects of centrifugal excitations of the vagus, indefinitely prolonged beyond return of the heart-beats, by M. F. Laulanié. The intracardiac arresting apparatus is not, as has been supposed, exhausted when the heart begins to beat again after stoppage through the vagus.—Catheterism of the ureters, by M. P. Poirier. The bladder is illumined with a cystoscope, containing a small incandescent lamp at the end of the sound, and an optical apparatus, whereby the mouth of the ureter can be easily found, and the small catheter (also included in the cystoscope) inserted.—On the ovogenesis, the structure of the ovary, and the regression of the parenchyma of Gordians, by M. A. Villot.—On the *Polyodontes maxillosus*, by M. Remy Saint-Loup. This relates to the rare capture of a gigantic annelid (2 metres long) in the Gulf of Marseilles. The animal is described.—The protophylline in etiolated plants, by M. C. Timiriazeff. He finds confirmatory evidence of his view that it is protophylline that, oxidizing in light, gives rise to chlorophyll in the living organism. Protophylline is obtained from chlorophylline (*i.e.* chlorophyll minus xanthophyll).

THURSDAY, SEPTEMBER 19, 1889.

THE BRITISH ASSOCIATION.

NEWCASTLE-ON-TYNE, *Tuesday Evening.*

AMID much that has been stale and dull, the present meeting has not been without excitement. The discussions on heredity and Darwinism in D, Mr. Du Chaillu's attempt to make the Vikings responsible for the English-speaking peoples, and Dr. Nansen's appearance in several Sections, have all helped to keep the Sectional work alive, not to speak of the considerable number of papers of special scientific interest. Of the Sectional addresses, those of Prof. Geikie, Mr. Anderson, and Mr. Edgeworth are most spoken of for novelty and interest, the latter, curiously, for the touches of fun, if not humour, that the author succeeded in imparting into what seems at first sight a dry subject.

As to Newcastle itself, everybody is satisfied with the treatment this young city has accorded to the Association, and everybody is pleased to see the footing which science is getting in the place in the splendid new Science and Medical Schools. It is, moreover, gratifying that, in a district where the practical applications of science are everything, distinct acknowledgment should have been made of the value and indispensability of pure scientific research. This was done on two occasions: first, in the admirable speech of the Mayor (of whom all speak well) at the magnificent banquet given by Lord Armstrong; and again before an audience of over 3000 working men in the Drill Hall, when the various trades associations presented an address to Prof. Flower, before Mr. Baker gave his lecture on the Forth Bridge, and thus recognized that only as the result of long series of complicated researches, undertaken solely for themselves, has the accomplishment of such a stupendous undertaking been possible. It goes without saying, that Mr. Baker's lecture was a marked success; it is difficult to describe the enthusiasm evoked from an enormous audience keenly capable of appreciating the points. It was stated that over 8000 applications had been made for tickets, when only 3500 could be allotted.

The social arrangements have been all that could be wished. It would be difficult to convey any idea of the thoughtful arrangements that have been made in many cases to secure the comfort and enjoyment of the visitors, and especially for the hard-worked officials of the Association. The banquets, receptions, *conversaziones*, and other similar features, have been many and excellent; while no fault could be found with the excursions: that to Durham on Saturday gave pleasure to all who joined it, especially to those who were privileged to sit down to the substantial luncheon in the grand old Castle. At the Cathedral service afterwards, it was interesting to see the Sectional Secretaries sitting humbly in the chancel, and a few eminent Presidents of Sections exalted to the stalls of Canons and Prebends.

At the General Committee Meeting yesterday there was unusual excitement. These meetings are generally scantily attended; but, from the crowd which filled the room and hovered around the doors, it was evident that mischief was brewing. After other business was transacted, it was announced, to the evident regret and pain of everyone, that Mr. Atchison could no longer, owing to ill-health, continue to discharge his duties as Secretary, and that a successor would have to be appointed. Mr. Atchison's popularity with the Association was evident from the enthusiasm exhibited in the proposed votes of thanks accorded him. The name of the candidate selected by the Council for the approval of the meeting was then announced, and supported by Prof. Garnett and others. But opposition to the selection was immediately announced. It is unnecessary to report in detail what will probably be found in the daily papers; but it was evident that there was widespread dissatisfaction with the conduct of the Council. No one had any especial objection to this candidate, although he had never had any connection with the Association; but it was felt that the Council had acted unwisely in passing over certain other candidates who were of eminence in science and had had long experience of the workings of the Association. After many proposals had been made, and much excitement manifested, it was at last, almost unanimously, decided to reappoint Mr. Atchison, and authorize the Council to provide whatever assistance should be necessary. Happily, Mr. Atchison said he was willing to agree to this proposal, and so the incident ends at present. But it was expected that the matter might have gone further, and the whole subject of the constitution of the Association discussed, and the advisability of conforming it to existing conditions. Happily, such a discussion has been postponed: it would have been unwise to continue it in connection with so personal a matter.

At the same meeting, the invitation from Cardiff was accepted for 1891, while that from Edinburgh will no doubt be accepted for 1892. The meeting at Leeds, beginning on September 3 next year, will be presided over by Sir Frederick Abel.

It is impossible not to state, what all feel, that the success of the present meeting has been largely due to Prof. Merivale, who has been ably supported by Dr. Bedson, Dr. Dunn, and other members of the Local Committee. That the attendance (2431) is something like a thousand below the last Newcastle meeting, and still less than the Manchester meeting two years ago, is not surprising. Not only are the Paris Exhibition and the many Conferences being held in connection therewith a powerful counter-attraction, but there were in 1863 special local reasons for raising the attendance to so high a figure.

The following is the list of grants to be submitted to the meeting of the General Committee to-morrow:—

A.—*Mathematics and Physics.*

	£
Differential Gravity Meter	10
Electro-optics	50
Calculating Mathematical Tables	25
Seismological Phenomena of Japan	75
Pellian Equation Tables	15
Electrical Standards	50
Electrolysis	5

B.—*Chemistry.*

Properties of Solutions	10
Analysis of Iron and Steel	10
Isomeric Naphthalene Derivatives	15
Silent Discharge of Electricity	5
Methods of Teaching Chemistry	10
Absorption Spectra	30
Recording the Results of Water Analysis	10
Oxidation of Hydracids in Sunlight	15

C.—*Geology.*

Erratic Blocks	10
Volcanic Phenomena of Vesuvius	20
Fossil Phyllopoda	20
Geological Record	100
Underground Waters	5
Excavations at Oldbury Hill	15
Cretaceous Polyzoa	10
Geological Photographs	10
Lias Beds of Northamptonshire	25

Y

D.—*Biology.*

Botanical Station at Peradeniya	£50
Deep-sea Tow-net	10
Naples Zoological Station	100
West India Islands	100
Marine Biological Association	30

F.—*Economic Science and Statistics.*

Monetary Standard	10
Precious Metals in use as Money	15

G.—*Mechanical Science.*

Waves and Currents in Estuaries	150
Graphic Methods in Mechanical Science	15

H.—*Anthropology.*

North-Western Tribes of Canada	100
Effect of Occupations on Physical Development	20
Anthropological Notes and Queries	50
Anthropometric Calculations	10
Nomad Tribes of Asia Minor	25
Natives of India	10
Corresponding Societies	20
Total	£1265

SECTION C.

GEOLOGY.

Opening Address by Prof. James Geikie, LL.D., F.R.SS. L. & E., F.G.S., President of the Section.

The President of this Section must often have some difficulty in selecting a subject for his address. It is no longer possible to give an interesting and instructive summary of the work done by the devotees of our science during even one year. So numerous have the students of geological science become—so fertile are the fields they cultivate—so abundant the harvests they reap—that one in my present position may well despair of being able to take stock of the numerous additions to our knowledge which have accumulated within the last twelve months. Neither is there any burning question which at this time your President need feel called upon to discuss. True, there are controversies that are likely to remain unsettled for years to come—there are still not a few matters upon which we must agree to differ—we do not yet see eye to eye in all things geological. But experience has shown that as years advance truth is gradually evolved, and old controversies die out; and so doubtless it will continue to be. The day when controversies shall cease, however, is yet, I hope, far in the future; for should that dull and unhappy time ever arrive, it is quite certain that mineralogists, petrologists, palæontologists, and geologists shall have died out of the world. Following the example of many of my predecessors, I shall confine my remarks to certain questions in which I have been specially interested. And in doing so I shall endeavour to steer clear, as far as I can, of controversial matters. My purpose, then, is to give an outline of some of the results obtained during the last few years by Continental workers in the domain of glacial geology.

Those who are not geologists will probably smile when they hear one declare that wielders of the hammer are extremely conservative—that they are slow to accept novel views, and very tenacious of opinions which have once found favour in their eyes. Nevertheless, such is the case; and well for us that it is so. However captivating, however imposing, however strongly supported by evidence a new view may appear to be, we do well to criticize, to sift the evidence, and to call for more facts and experiments, if such are possible, until the proofs become so strong as to approach as near a demonstration as geologists can in most cases expect such proofs to go. The history of our science, and indeed of most sciences, affords abundant illustration of what I say. How many long years were the views of sub-aërial erosion, as taught by Hutton and Playfair, canvassed and controverted before they became accepted! And even after their general soundness had been established, how often have we heard nominal disciples of these fathers of physical geology refuse to go so far as to admit that the river-valleys of our islands have been excavated by epigene agents? If, as a rule, it takes some time for a novel view to gain acceptance, it is equally true that views which have long been held are only with difficulty discarded. Between the new and the old there is a constant struggle for existence, and if the latter should happen to survive, it is only in a modified form. I have often thought that a history of the evolution of geological theories would make a very entertaining and instructive work. We should learn from it, amongst other things, that the advance of our science has not always been continuous—now and again, indeed, it has almost seemed as if the movement had been retrograde. Knowledge has not come in like an overwhelming flood—like a broad majestic river—but rather like a gently-flowing tide, now advancing, now retiring, but ever, upon the whole, steadily gaining ground. The history I speak of would also teach us that many of the general views and hypotheses which have been from time to time abandoned as unworkable are hardly deserving of the reproach and ridicule which we in these latter days may be inclined to cast upon them. As the Scots proverb says, "It is easy to be wise behindhand." It could be readily shown that not a few discarded notions and opinions have frequently worked for good, and have rather stimulated than checked inquiry. Such reflections should be encouraging to every investigator, whether he be a defender of the old or an advocate of the new. Time tries all, and each worker may claim a share in the final establishment of the truth.

Perhaps there is no department of geological inquiry that has given rise to more controversy than that which I have selected for the subject of this address. Hardly a single step in advance has been taken without vehement opposition. But the din of contending sides is not so loud now—the dust of the conflict has to some extent cleared away, and the positions which have been lost or maintained, as the case may be, can be readily discerned. The glacialist who can look back over the last twenty-five years of wordy conflict has every reason to be jubilant and hopeful. Many of those who formerly opposed him have come over to his side. It is true he has not had everything his own way. Some extreme views have been abandoned in the struggle—that of a great Polar ice-sheet, for example, as conceived of by Agassiz. I am not aware, however, that many serious students of glacial geology ever adopted that view. But it was quite an excusable hypothesis, and has been abundantly suggestive. Had Agassiz lived to see the detailed work of these later days, he would doubtless have modified his notion, and come to accept the view of large continental glaciers which has taken its place.

The results obtained by geologists, who have been studying the peripheral areas of the drift-covered regions of our continent, are such as to satisfy us that the drifts of those regions are not iceberg-droppings, as we used to suppose, but true morainic matter and fluvio-glacial detritus. Geologists have not jumped to this conclusion—they have only accepted it after laborious investigation of the evidence. Since Dr. Otto Torell, in 1875, first stated his belief that the "diluvium" of North Germany was of glacial origin, a great literature on the subject has sprung up, a perusal of which will show that with our German friends glacial geology has passed through much the same succession of phases as with us. At first icebergs are appealed to as explaining everything; next we meet with sundry ingenious attempts at a compromise between floating ice and a continuous ice-sheet. As observations multiply, however, the element of floating ice is gradually eliminated, and all the phenomena are explained by means of land-ice and *Schmelz-wasser* alone. It is a remarkable fact that the iceberg hypothesis has always been most strenuously upheld by geologists whose labours have been largely confined to the peripheral areas of drift-covered countries. In the upland and mountainous tracts, on the other hand, that hypothesis has never been able to survive a moderate amount of accurate observation. Even in Switzerland—the land of glaciers—geologists at one time were of opinion that the boulder-clays of the low grounds had a different origin from those which occur in the mountain valleys. Thus it was supposed that at the close of the Pleistocene period the Alps were surrounded by great lakes or gulfs of some inland sea, into which the glaciers of the high valleys flowed and calved their icebergs—these latter scattering erratics and earthy *débris* over the drowned areas. Sartorius von Waltershausen[1] set forth this view in an elaborate and well-illustrated paper. Unfortunately for his hypothesis, no trace of the supposed great lakes or inland sea has ever been detected; on the contrary, the character of the morainic accumulations, and the symmetrical grouping and radiation of the erratics and perched blocks over the foot-hills and low grounds, show that these last have been invaded and overflowed by the glaciers themselves. Even the most strenuous upholders of the efficacy of icebergs as originators of some boulder-clays admit that the boulder-clay or till, of what we may call the inner or central region of a glaciated tract, is the product of land-ice. Under this category comes the boulder-clay of Norway, Sweden, and Finland, and of the Alpine lands of Central Europe, not to speak of the hilly parts of our own islands.

When we come to study the drifts of the peripheral areas it is not difficult to see why these should be considered to have had a different origin. They present certain features which, although not absent from the glacial deposits of the inner region, are not nearly so characteristic of such upland tracts. I refer especially to the frequent interstratification of boulder clays with well-bedded deposits of clay, sand, and gravel; and to the fact that these boulder-clays are often less compressed than those of the inner region, and have even occasionally a silt-like character. Such appearances do seem at first to be readily explained on the assumption that the deposits have been accumulated in water opposite the margin of a continental glacier or ice-sheet; and this was the view which several able investigators in Germany were for some time inclined to adopt.

But when the phenomena came to be studied in greater detail, and over a wider area, this preliminary hypothesis did not prove satisfactory. It was discovered, for example, that "giants' kettles"[2] were more or less commonly distributed under the glacial deposits, and such "kettles" could only have originated at the bottom of a glacier. Again, it was found that preglacial accumulations were plentifully developed in certain places below the drift, and were often involved with the latter in a remarkable way. The "brown-coal formation" in like manner was violently disturbed and displaced, to such a degree that frequently the boulder-clay is found to underlie it. Similar phenomena were encountered in regions where the drift overlies the Chalk—the latter presenting the appearance of having been smashed and shattered—the fragments having often been dragged some distance, so as to form a kind of friction-breccia underlying the drift, while large masses are often included in the clay itself. All the facts pointed to the conclusion that these disturbances were due to tangential thrusting or crushing, and were not the result of vertical displacements, such as are produced by normal faulting, for the disturbances in question die out from above downwards. Evidence of similar thrusting or crushing is seen in the remarkable faults and contortions that so often characterize the clays and sands that occur in the boulder-clay itself. The only agent that could produce the appearances now briefly referred to is land-ice, and we must therefore agree with German geologists that glacier-ice has overflowed all the drift-covered regions of the peripheral area. No evidence of marine action in the formation of the stony clays is forthcoming—not a trace of any sea-beach has been detected. And yet, if these clays had been laid down in the sea during the retreat of the ice-sheet from Germany, surely such evidence as I have indicated ought to be met with. To the best of my knowledge the only particular facts which have been appealed to, as proofs of marine action, are the appearance of bedded deposits in the boulder-clays, and the occasional occurrence in the clays themselves of a sea-shell. But other organic remains are also met with now and again in similar positions, such as mammalian bones and fresh-water shells. All these, however, have been shown to be derivative in their origin—they are just as much erratics as the stones and boulders with which they are associated. The only phenomena, therefore, that the glacialist has to account for are the bedded deposits which occur so frequently in the boulder-clays of the peripheral regions, and the occasional silty and uncompressed character of the clays themselves.

The intercalated beds are, after all, not hard to explain. If we consider for a moment the geographical distribution of the boulder-clays, and their associated aqueous deposits, we shall find a clue to their origin. Speaking in general terms, the stony clays thicken out as they are followed from the mountainous and high-lying tracts to the low ground. Thus they are of inconsiderable thickness in Norway, the higher parts of Sweden, and in Finland, just as we find is the case in Scotland, Northern England, Wales, and the hilly parts of Ireland. Traced south from the uplands of Scandinavia and Finland, they gradually thicken out as the low grounds are approached. Thus in Southern Sweden they reach a thickness of 43 metres or thereabout, and of 80 metres in the northern parts of Prussia, while over the wide low-lying regions to the south they attain a much greater thickness—reaching in Holstein, Mecklenburg, Pomerania, and West Prussia a depth of 120 to 140 metres, and still greater depths in Hanover, Mark Brandenburg, and Saxony. In those regions, however, a considerable portion of the "diluvium" consists, as we shall see presently, of water-formed beds.

The geographical distribution of the aqueous deposits which are associated with the stony clays is somewhat similar. They are very sparingly developed in districts where the boulder-clays are thin. Thus they are either wanting, or only occur sporadically in thin irregular beds, in the high grounds of Northern Europe generally. Further south, however, they gradually acquire more importance until in the peripheral regions of the drift-covered tracts they come to equal and eventually to surpass the boulder-clays in prominence. These latter, in fact, at last cease to appear, and the whole bulk of the "diluvium" along the southern margin of the drift area appears to consist of aqueous accumulations alone.

The explanations of these facts advanced by German geologists are quite in accordance with the views which have long been held by glacialists elsewhere, and have been tersely summed up by Dr. Jentzsch (*Jahrb. d. königl. preuss. geologischen Landesanstalt für* 1884, p. 438). The northern regions, he says, were the feeding-grounds of the inland ice. In those regions melting was at a minimum, while the grinding action of the ice was most effective. Here, therefore, erosion reached its maximum—ground-moraine or boulder-clay being unable to accumulate to any thickness. Further south melting greatly increased, while ground-moraine at the same time tended to accumulate—the conjoint action of glacier-ice and sub-glacial water resulting in the complex drifts of the peripheral area. In the disposition and appearance of the aqueous deposits of the "diluvium" we have evidence of an extensive sub-glacial water-circulation—glacier-mills that gave rise to "giants' kettles"—chains of sub-glacial lakes in which fine clays gathered—streams and rivers that flowed in tunnels under the ice, and whose courses were paved with sand and gravel. Nowhere do German geologists find any evidence of marine action. On the contrary, the dovetailing and interosculation of boulder-clay with aqueous deposits are explained by the relation of the ice to the surface over which it flowed. Throughout the peripheral area it did not rest so continuously upon the ground as was the case in the inner region of maximum erosion. In many places it was tunnelled by rapid streams and rivers, and here and there it arched over sub-glacial lakes, so that accumulation of ground-moraine proceeded side by side with the formation of aqueous sediments. Much of that ground-moraine is of the usual tough and hard-pressed character, but here and there it is somewhat less coherent and even silt-like. Now a study of the ground-moraines of modern glaciers affords us a reasonable explanation of such differences. Dr. Brückner[1] has shown that in many places the ground-moraine of Alpine glaciers is included in the bottom of the ice itself. The ground-moraine, he says, frequently appears as an ice-stratum abundantly impregnated with silt and rock-fragments—it is like a conglomerate or breccia which has ice for its binding material. When this ground-moraine melts out of the ice—no running water being present—it forms a layer of unstratified silt or clay, with stones scattered irregularly through it. Such being the case in modern glaciers, we can hardly doubt that over the peripheral areas occupied by the old northern ice-sheet boulder-clay must frequently have been accumulated in the same way. Nay, when the ground-moraine melted out and dropped here and there into quietly-flowing water it might even acquire in part a bedded character.

The limits reached by the inland ice during its greatest extension are becoming more and more clearly defined, although its southern margin will probably never be so accurately determined

[1] "Untersuchungen über die Klimate der Gegenwart und der Vorwelt," &c. (*Natuurkundige Verhandelingen v. d. Holland. Maatsch. d. Wetensch. te Haarlem*, 1865).

[2] These appear to have been first detected by Prof. Berendt and Prof. E. Geinitz.

[1] "Die Vergletscherung des Salzachgebietes, &c.," *Geographische Abhandlungen herausgegeben v. A. Penck*, Band i. Heft 1.

as that of the latest epoch of general glaciation. The reasons for this are obvious. When the inland ice flowed south to the Harz and the hills of Saxony, it formed no great terminal moraines. Doubtless many erratics and much rock-rubbish were showered upon the surface of the ice from the higher mountains of Scandinavia, but owing to the fanning-out of the ice on its southward march, such superficial *débris* was necessarily spread over a constantly widening area. It may well be doubted, therefore, whether it ever reached the terminal front of the ice-sheet in sufficient bulk to form conspicuous moraines. It seems most probable that the terminal moraines of the great inland ice would consist of low banks of boulder-clay and aqueous materials—the latter, perhaps, strongly predominating, and containing here and there larger and smaller angular erratics which had travelled on the surface of the ice. However that may be, it is certain that the whole region in question has been considerably modified by subsequent denudation, and to a large extent is now concealed under deposits belonging to later stages of the Pleistocene period. The extreme limits reached by the ice are determined rather by the occasional presence of rock-striæ and *roches moutonnées*, of boulder-clay and northern erratics, than by recognizable terminal moraines. The southern limits reached by the old inland ice appear in this way to have been tolerably well ascertained over a considerable portion of Central Europe. Some years ago I published a small sketch-map ("Prehistoric Europe," 1881) showing the extent of surface formerly covered by ice. On this map I did not venture to draw the southern margin of the ice-sheet in Belgium further south than Antwerp, where northern erratics were known to occur; but the more recent researches of Belgian geologists show that the ice probably flowed south for some little distance beyond Brussels (see a paper by M. E. Delvaux, *Ann. de la Soc. géol. de Belg.*, t. xiii. p. 158). Here and there in other parts of the Continent the southern limits reached by the northern drift have also been more accurately determined, but, so far as I know, none of these later observations involves any serious modification of the sketch-map referred to.

I have now said enough, however, to show that the notion of a general ice-sheet having covered so large a part of Europe, which a few years ago was looked upon as a wild dream, has been amply justified by the labours of those who are so assiduously investigating the peripheral areas of the "great northern drift." And perhaps I may be allowed to express my own belief that the drifts of Middle and Southern England, which exhibit the same complexity as the "lower diluvium" of the Continent, will eventually be generally acknowledged to have had a similar origin. I have often thought that whilst politically we are happy in having the sea all round us, geologically we should have gained perhaps by its greater distance. At all events we should have been less ready to invoke its assistance to explain every puzzling appearance presented by our glacial accumulations.

I now pass on to review some of the general results obtained by Continental geologists as to the extent of area occupied by inland ice during the last great extension of glacier-ice in Europe. It is well-known that this latest ice-sheet did not overflow nearly so wide a region as that underneath which the lowest boulder-clay was accumulated. This is shown not only by the geographical distribution of the youngest boulder-clay, but by the direction of rock-striæ, the trend of erratics, and the position of well-marked moraines. Gerard de Geer has given a summary (*Zeitschrift d. deutsch. geolog. Ges.*, Bd. xxxvii. p. 177) of the general results obtained by himself and his fellow-workers in Sweden and Norway; and these have been supplemented by the labours of Berendt, Geinitz, Hunchecorne, Keilhack, Klockmann, Schröder, Wahnschaffe, and others in Germany, and by Sederholm in Finland.[1] From them we learn that the end-moraines of the ice circle round the southern coasts of Norway, from whence they sweep south-east by east across the province of Gottland in Sweden, passing through the lower ends of Lakes Wener and Wetter, while similar moraines mark out for us the terminal front of the inland ice in Finland—at least two parallel frontal moraines passing inland from Hango Head on the Gulf of Finland through the southern part of that province to the north of Lake Ladoga. Further north-east than this they have not been traced; but, from some observations by Helmersen, Sederholm thinks it probable that the terminal ice-front extended north-east by the north of Lake Onega to the eastern shores of the White Sea. Between Sweden and Finland lies the basin of the Baltic, which at the period in question was filled with ice, forming a great Baltic glacier, which overflowed the Åland Islands, Gottland, and Öland, and which, fanning-out as it passed towards the south-west, invaded, on the south side, the Baltic provinces of Germany, while, on the north, it crossed the southern part of Scania in Sweden and the Danish islands to enter upon Jutland.

The upper boulder-clay of those regions is now recognized as the ground-moraine of this latest ice-sheet. In many places it is separated from the older boulder-clay by interglacial deposits, some of which are marine, while others are of fresh-water and terrestrial origin. During interglacial times the sea that overflowed a considerable portion of North Germany was evidently continuous with the North Sea, as is shown not only by the geographical distribution of the interglacial marine deposits, but by their North Sea fauna. German geologists generally group all the interglacial deposits together, as if they belonged to one and the same interglacial epoch. This perhaps we must look upon as only a provisional arrangement. Certain it is that the fresh-water and terrestrial beds which frequently occur on the same or a lower level, and at no great distance from the marine deposits, cannot in all cases be contemporaneous with the latter. Possibly, however, such discordances may be accounted for by oscillations in the level of the interglacial sea—land and water having alternately prevailed over the same area. Two boulder-clays, as we have seen, have been recognized over a wide region in North Germany. In some places, however, three or more such boulder-clays have been observed overlying one another throughout considerable areas, and these clays are described as being distinctly separate and distinguishable the one from the other.[1] Whether they with their intercalated aqueous deposits indicate great oscillations of one and the same ice-sheet—now advancing, now retreating—or whether the stony clays may not be the ground-moraines of so many different ice-sheets, separated the one from the other by true interglacial conditions, future investigations must be left to decide.

The general conclusions arrived at by those who are at present investigating the glacial accumulations of Northern Europe may be summarized as follows:—

1. Before the invasion of Northern Germany by the inland ice the low grounds bordering on the Baltic were overflowed by a sea which contained a boreal and arctic fauna. These marine conditions are indicated by the presence under the lower boulder-clay of more or less well-bedded fossiliferous deposits. On the same horizon occur also beds of sand, containing fresh-water shells, and now and again mammalian remains, some of which imply cold and others temperate climatic conditions. Obviously all these deposits may pertain to one and the same period, or more properly to different stages of the same period—some dating back to a time when the climate was still temperate, while others clearly indicate the prevalence of cold conditions, and are therefore probably somewhat younger.

2. The next geological horizon in ascending order is that which is marked by the "lower diluvium"—the glacial and fluvio-glacial detritus of the great ice-sheet which flowed south to the foot of the Harz Mountains. The boulder clay on this horizon now and again contains marine, fresh-water, and terrestrial organic remains, derived undoubtedly from the so-called preglacial beds already referred to. These latter, it would appear, were ploughed up and largely incorporated with the old ground-moraine.

3. The interglacial beds which next succeed contain remains of a well-marked temperate fauna and flora, which point to something more than a mere partial or local retreat of the inland ice. The geographical distribution of the beds and the presence in these of such forms as *Elephas antiquus*, *Cervus elephas*, *C. megaceros*, and a flora comparable to that now existing in Northern Germany, justify geologists in concluding that the interglacial epoch was one of long duration, and characterized in Germany by climatic conditions apparently not less temperate than those that now obtain. One of the phases of that interglacial epoch, as we have seen, was the overflowing of the Baltic provinces by the waters of the North Sea.

4. To this well-marked interglacial epoch succeeded another epoch of arctic conditions, when the Scandinavian inland ice

[1] For papers by Berendt and his associates see especially the *Jahrbuch d. k. preuss. geol. Landesanstalt*, and the *Zeitschr. d. deutsch. geol. Ges.* for the past few years. once more invaded Germany, ploughing through the interglacial deposits, and working these up in its ground-moraine. So far as I can learn, the prevalent belief among geologists in North Germany is that there was only one interglacial epoch; but, as already stated, doubt has been expressed whether all the facts can be thus accounted for. There must always be great difficulty in the correlation of widely-separated interglacial deposits, and the time does not seem to me to have yet come when we can definitely assert that all those interglacial beds belong to one and the same geological horizon.

I have dwelt upon the recent work of geologists in the peripheral areas of the drift-covered regions of Northern Europe, because I think the results obtained are of great interest to glacialists in this country. And for the same reason I wish next to call attention to what has been done of late years in elucidating the glacial geology of the Alpine lands of Central Europe —and more particularly of the low grounds that stretch out from the foot of the mountains. Any observations that tend to throw light upon the history of the complex drifts of our own peripheral areas cannot but be of service. It is quite impossible to do justice in this brief sketch to the labours of the many enthusiastic geologists who, within recent years, have increased our knowledge of the glaciation of the Alpine lands. At present, however, I am not so much concerned with the proofs of general glaciation as with the evidence that goes to show how the Alpine ground-moraines have been formed, and with the facts which have led certain observers to conclude that the Alps have endured several distinct glaciations within Pleistocene times. Swiss geologists are agreed that the ground-moraines which clothe the bottoms of the great Alpine valleys, and extend outwards sometimes for many miles upon the low grounds beyond, are of true glacial origin. Now these ground-moraines are closely similar to the boulder-clays of this country and Northern Europe. Like them, they are frequently tough and hard-pressed, but now and again somewhat looser and less firmly coherent. Frequently also they contain lenticular beds, and more or less thick sheets of aqueous deposits—in some places the stony clays even exhibiting a kind of stratification—and ever and anon such water-assorted materials are commingled with stony clay in the most complex manner. These latter appearances are, however, upon the whole best developed upon the low grounds that sweep out from the base of the Alps. The only question concerning the ground-moraines that has recently given rise to much discussion is the origin of the materials themselves. It is obvious that there are only three possible modes in which those materials could have been introduced to the ground-moraine: either they consist of superficial morainic *débris* which has found its way down to the bottom of the old glaciers by crevasses; or they may be made up of the rock-rubbish, shingle, gravel, &c., which doubtless strewed the valleys before these were occupied by ice; or, lastly, they may have been derived in chief measure from the underlying rocks themselves by the action of the ice that overflowed them. The investigations of Penck, Blaas, Böhm, and Brückner appear to me to have demonstrated that the ground-moraines are composed mostly of materials which have been detached from the underlying rocks by the erosive action of the glaciers themselves. Their observations show that the regions studied by them in great detail were almost completely buried under ice, so that the accumulation of superficial moraines was for the most part impossible; and they advance a number of facts which prove positively that the ground-moraines were formed and accumulated under ice. I cannot here recapitulate the evidence, but must content myself by a reference to the papers in which this is fully discussed.[1] These geologists do not deny that some of the material may occasionally have come from above, nor do they doubt that pre-existing masses of rock-rubbish and alluvial accumulations may have been incorporated with the ground-moraines; but the enormous extent of the latter, and the direction of transport and distribution of the erratics which they contain cannot be thus accounted for, while all the facts are readily explained by the action of the ice itself, which used its sub-glacial *débris* as tools with which to carry on the work of erosion.

Prof. Heim and others have frequently asserted that glaciers have little or no eroding power, since at the lower ends of existing glaciers we find no evidence of such erosion being in operation. But the chief work of a glacier cannot be carried on at its lower end, where motion is reduced to a minimum, and where the ice is perforated by sub-glacial tunnels and arches, underneath which no glacial erosion can possibly take place; and yet it is upon observations made in just such places that the principal arguments against the erosive action of glaciers have been based. If all that we could ever know of glacial action were confined to what we can learn from peering into the grottoes at the terminal fronts of existing glaciers, we should indeed come to the conclusion that glaciers do not erode their rocky beds to any appreciable extent. But as we do not look for the strongest evidence of fluviatile erosion at the mouth of a river, but in its valley- and mountain-tracks, so if we wish to learn what glacier-ice can accomplish, we must study in detail some wide region from which the ice has completely disappeared. When this plan has been followed, it has happened that some of the strongest opponents of glacial erosion have been compelled by the force of the evidence to go over to the other camp. Dr. Blaas, for example, has been led by his observations on the glacial formations of the Inn Valley to recant his former views, and to become a formidable advocate of the very theory which he formerly opposed. To his work and the memoirs by Penck, Brückner, and Böhm already cited, and especially to the admirable chapter on glacier-erosion by the last-named author, I would refer those who may be anxious to know the last word on this much-debated question.

The evidence of interglacial conditions within the Alpine lands continues to increase. These are represented by alluvial deposits of silt, sand, gravel, conglomerate, breccia, and lignites. Penck, Böhm, and Brückner find evidence of two interglacial epochs, and maintain that there have been three distinct and separate epochs of glaciation in the Alps. No mere temporary retreat and re-advance of the glaciers, according to them, will account for the phenomena presented by the interglacial deposits and associated morainic accumulations. During interglacial times the glaciers disappeared from the lower valleys of the Alps—the climate was temperate, and probably the snow-fields and glaciers approximated in extent to those of the present day. All the evidence conspires to show that an interglacial epoch was of prolonged duration. Dr. Brückner has observed that the moraines of the last glacial epoch rest here and there upon löss, and he confirms Penck's observations in South Bavaria that this remarkable formation never overlies the morainic accumulations of the latest glacial epoch. According to Penck and Brückner, therefore, the löss is of interglacial age. There can be little doubt, however, that löss does not belong to any one particular horizon. Wahnschaffe[1] and others have shown that throughout wide areas in North Germany it is the equivalent in age of the "upper diluvium," while Schumacher (*Hygienische Topographie von Strassburg i. E.*, 1885) points out that in the Rhine Valley it occurs on two separate and distinct horizons. Prof. Andreæ has likewise shown (*Abhandl. z. geol. Specialkarte v. Elsass-Lothringen*, Bd. vii. Heft 2) that there is an upper and lower löss in Alsace, each characterized by its own special fauna.

There is still considerable difference of opinion as to the mode of formation of this remarkable accumulation. By many it is considered to be an aqueous deposit; others, following Richthofen, are of opinion that it is a wind-blown accumulation; while some incline to the belief that it is partly the one and partly the other. Nor do the upholders of these various hypotheses agree amongst themselves as to the precise manner in which water or wind has worked to produce the observed results. Thus, amongst the supporters of the aqueous origin of the löss, we find this attributed to the action of heavy rains washing over and rearranging the material of the boulder-clays (Laspeyres, *Erläuterungen z. geol. Specialkarte v. Preussen*, &c., *Blatt Gröbzig, Zörbig, und Petersberg*). Many, again, have held it probable that the löss is simply the finest loam distributed over the low grounds by the flood-waters that escaped from the northern inland ice and the *mers de glace* of the Alpine lands of Central Europe. Another suggestion is that much of the material of the löss may have been derived from the denudation of the boulder-clays by flood-water, during the closing stages of the last cold period. It is pointed out that in some regions at least the löss is underlain by a layer of erratics, which are believed to be the residue of the denuded boulder-clay.

We are reminded by Klockmann (*Jahrb. d. k. preuss. geol. Landesanstalt für* 1883, p. 262) and Wahnschaffe (*op. cit.*, and *Zeitschr. d. deutsch. geol. Ges.* 1886, p. 367) that the inland ice must have acted as a great dam, and that wide areas in Germany, &c., would be flooded, partly by water derived from the melting inland ice, and partly by waters flowing north from the hilly tracts of Middle Germany. In the great basins thus formed there would be a commingling of fine silt-material derived from north and south, which would necessarily come to form a deposit having much the same character throughout.

From what I have myself seen of the löss in various parts of Germany, and from all that I have gathered from reading and in conversation with those who have worked over löss-covered regions, I incline to the opinion that löss is for the most part of aqueous origin. In many cases this can be demonstrated, as by the occurrence of bedding and the intercalation of layers of stones, sand, gravel, &c., in the deposit; again, by the not infrequent appearance of fresh-water shells; but, perhaps, chiefly by the remarkable uniformity of character which the löss itself displays. It seems to me reasonable also to believe that the flood-waters of glacial times must needs have been highly charged with finely-divided sediment, and that such sediment would be spread over wide regions in the low grounds—in the slack-waters of the great rivers, and in the innumerable temporary lakes which occupied, or partly occupied, many of the valleys and depressions of the land. There are different kinds of löss or löss like deposits, however, and all need not have been formed in the same way. Probably some may have been derived, as Wahnschaffe has suggested, from the denudation of boulder-clay. Possibly, also, some löss may owe its origin to the action of rain upon the stony clays, producing what we in this country would call "rain-wash." There are other accumulations, however, which no aqueous theory will satisfactorily explain. Under this category comes much of the so-called *Berglöss*, with its abundant land-shells, and its generally unstratified character. It seems likely that such löss is simply the result of sub-aërial action, and owes its origin to rain, frost, and wind acting upon the superficial formations, and rearranging their finer-grained constituents. And it is quite possible that the upper portion of much of the löss of the lower grounds may have been re-worked in the same way. But I confess I cannot yet find in the facts adduced by German geologists any evidence of a dry-as-dust epoch having obtained in Europe during any stage of the Pleistocene period. The geographical position of our continent seems to me to forbid the possibility of such climatic conditions, while all the positive evidence we have points rather to humidity than dryness as the prevalent feature of Pleistocene climates. It is obvious, however, that after the flood-waters had disappeared from the low grounds of the Continent, sub-aërial action would come into play over the wide regions covered by glacial and fluvio-glacial deposits. Thus, in the course of time, these deposits would become modified,—just as similar accumulations in these islands have been top-dressed, as it were, and to some extent even rearranged. I am strengthened in these views by the conclusions arrived at by M. Falsan, the eminent French glacialist. Covering the plateaux of the Dombs, and widely spread throughout the valleys of the Rhone, the Ain, the Isère, &c., in France, there is a deposit of löss, he says, which has been derived from the washing of the ancient moraines. At the foot of the Alps, where black schists are largely developed, the löss is dark grey; but west of the secondary chain the same deposit is yellowish, and composed almost entirely of siliceous materials, with only a very little carbonate of lime. This *limon* or löss, however, is very generally modified towards the top by the chemical action of rain, the yellow löss acquiring a red colour. Sometimes it is crowded with calcareous concretions; at other times it has been deprived of its calcareous element and converted into a kind of pulverulent silica or quartz. This, the true löss, is distinguished from another *lehm*, which Falsan recognizes as the product of atmospheric action—formed, in fact, in place, from the disintegration and decomposition of the subjacent rocks. Even this *lehm* has been modified by running water—dispersed or accumulated locally, as the case may be (Falsan, "La Période glaciaire," p. 81).

All that we know of the löss and its fossils compels us to include this accumulation as a product of the Pleistocene period. It is not of postglacial age—even much of what one may call the "remodified löss" being of Late Glacial or Pleistocene age. I cannot attempt to give here a summary of what has been learned within recent years as to the fauna of the löss. The researches of Nehring and Liebe have familiarized us with the fact that at some particular stage in the Pleistocene period a fauna like that of the alpine steppe-lands of Western Asia was indigenous to Middle Europe, and the recent investigations of Woldřich have increased our knowledge of this fauna. At what horizon, then, does this steppe-fauna make its appearance? At Thiede, Dr. Nehring discovered in so-called löss three successive horizons, each characterized by a special fauna. The lowest of these faunas was decidedly arctic in type; above that came a steppe-fauna, which last was succeeded by a fauna comprising such forms as mammoth, woolly rhinoceros, *Bos*, *Cervus*, horse, hyæna, and lion. Now, if we compare this last fauna with the forms which have been obtained from true postglacial deposits—those deposits, namely, which overlie the younger boulder-clays and flood-accumulations of the latest glacial epoch—we find little in common. The lion, the mammoth, and the rhinoceros are conspicuous by their absence from the postglacial beds of Europe. In place of them we meet with a more or less arctic fauna, and a high-alpine and arctic flora, which, as we all know, eventually gave place to the flora and fauna with which Neolithic man was contemporaneous. As this is the case throughout North-Western and Central Europe, we seem justified in assigning the Thiede beds to the Pleistocene period, and to that interglacial stage which preceded and gradually merged into the last glacial epoch. That the steppe-fauna indicates relatively drier conditions of climate than obtained when perennial snow and ice covered wide areas of the low ground goes without saying; but I am unable to agree with those who maintain that it implies a dry-as-dust climate, like that of some of the steppe-regions of our own day. The remarkable commingling of arctic and steppe-faunas discovered by Woldřich in the Böhmerwald (*Sitzungsb. d. kais. Akad. d. W. math. nat. Cl.*, 1880, p. 7; 1881, p. 177; 1883, p. 978) shows, I think, that the jerboas, marmots, and hamster-rats were not incapable of living in the same regions contemporaneously with lemmings, arctic hares, Siberian social voles, &c. But when a cold epoch was passing away the steppe-forms probably gradually replaced their arctic congeners, as these migrated northwards during the continuous amelioration of the climate.

If the student of the Pleistocene faunas has certain advantages in the fact that he has to deal with forms many of which are still living, he labours at the same time under disadvantages which are unknown to his colleagues who are engaged in the study of the life of far older periods. The Pleistocene period was distinguished above all things by its great oscillations of climate—the successive changes being repeated, and producing correlative migrations of floras and faunas. We know that arctic and temperate faunas and floras flourished during interglacial times, and a like succession of life-forms followed the final disappearance of glacial conditions. A study of the organic remains met with in any particular deposit will not necessarily, therefore, enable us to assign these to their proper horizon. The geographical position of the deposit, and its relation to Pleistocene accumulations elsewhere must clearly be taken into account. Already, however, much has been done in this direction, and it is probable that ere long we shall be able to arrive at a fair knowledge of the various modifications which the Pleistocene floras and faunas experienced during that protracted period of climatic changes of which I have been speaking. We shall even possibly learn how often the arctic, steppe-, prairie-, and forest-faunas, as they have been defined by Woldřich, replaced each other. Even now some approximation to this better knowledge has been made. Dr. Pohlig,[1] for example, has compared the remains of the Pleistocene faunas obtained at many different places in Europe, and has presented us with a classification which, although confessedly incomplete, yet serves to show the direction in which we must look for further advances in this department of inquiry.

During the last twenty years the evidence of interglacial conditions both in Europe and America has so increased that geologists generally no longer doubt that the Pleistocene period was characterized by great changes of climate. The occurrence at many different localities on the Continent of beds of lignite and fresh-water alluvia, containing remains of Pleistocene Mammalia, intercalated between separate and distinct boulder-clays, has

[1] Pohlig. *Sitzungsb. d. Niederrheinischen Gesellschaft zu Bonn*, 1884; *Zeitschr. d. deutsch. geolog. Ges.*, 1887, p 798. For a very full account of the diluvial European and Northern Asiatic mammalian faunas by Woldřich, see *Mém. de l'Acad. des Sciences de St. Pétersbourg*, Sér. vii, t. xxxv., 1887.

left us no alternative. The interglacial beds of the Alpine lands of Central Europe are paralleled by similar deposits in Britain, Scandinavia, Germany, and France. But opinions differ as to the number of glacial and interglacial epochs, many holding that we have evidence of only two cold stages and one general interglacial stage. This, as I have said, is the view entertained by most geologists who are at work on the glacial accumulations of Scandinavia and North Germany. On the other hand, Dr. Penck and others, from a study of the drifts of the German Alpine lands, believe that they have met with evidence of three distinct epochs of glaciation, and two epochs of interglacial conditions. In France, while some observers are of opinion that there have been only two epochs of general glaciation, others, as, for example, M. Tardy, find what they consider to be evidence of several such epochs. Others, again, as M. Falsan, do not believe in the existence of any interglacial stages, although they readily admit that there were great advances and retreats of the ice during the Glacial period. M. Falsan, in short, believes in oscillations, but is of opinion that these were not so extensive as others have maintained. It is, therefore, simply a question of degree, and whether we speak of oscillations or of epochs, we must needs admit the fact that throughout all the glaciated tracts of Europe, fossiliferous deposits occur intercalated among glacial accumulations. The successive advance and retreat of the ice, therefore, was not a local phenomenon, but characterized all the glaciated areas. And the evidence shows that the oscillations referred to were on a gigantic scale.

The relation borne to the glacial accumulations by the old river alluvia which contain relics of palæolithic man early attracted attention. From the fact that these alluvia in some places overlie glacial deposits, the general opinion (still held by some) was that palæolithic man must needs be of postglacial age. But since we have learned that all boulder-clay does not belong to one and the same geological horizon—that, in short, there have been at least two, and probably more, epochs of glaciation—it is obvious that the mere occurrence of glacial deposits underneath palæolithic gravels does not prove these latter to be postglacial. All that we are entitled in such a case to say is simply that the implement-bearing beds are younger than the glacial accumulations upon which they rest. Their horizon must be determined by first ascertaining the relative position in the glacial series of the underlying deposits. Now, it is a remarkable fact that the boulder-clays which underlie such old alluvia belong, without exception, to the earlier stages of the Glacial period. This has been proved again and again, not only for this country but for Europe generally. I am sorry to reflect that some twenty years have now elapsed since I was led to suspect that the palæolithic gravels and cave-deposits were not of postglacial but of glacial and interglacial age. In 1871–72 I published a series of papers in the *Geological Magazine*, in which were set forth the views I had come to form upon this interesting question. In these papers it was maintained that the alluvial and cave-deposits could not be of postglacial age, but must be assigned to preglacial and interglacial times, and in chief measure to the latter. Evidence was led to show that the latest great development of glacier-ice in Europe took place after the southern pachyderms and palæolithic man had vacated England; that during this last stage of the Glacial period man lived contemporaneously with a northern and alpine fauna in such regions as Southern France; and lastly, that palæolithic man and the southern Mammalia never revisited North-Western Europe after extreme glacial conditions had disappeared. These conclusions were arrived at after a somewhat detailed examination of all the evidence then available, the remarkable distribution of the palæolithic and ossiferous alluvia having, as I have said, particularly impressed me. I coloured a map to show at once the areas covered by the glacial and fluvio-glacial deposits of the last glacial epoch, and the regions in which the implement-bearing and ossiferous alluvia had been met with, when it became apparent that the latter never occurred at the surface within the regions occupied by the former. If ossiferous alluvia did here and there appear within the recently glaciated areas, it was always either in caves, or as infra- or interglacial deposits. Since the date of these researches our knowledge of the geographical distribution of Pleistocene deposits has greatly increased, and implements and other relics of palæolithic man have been recorded from many new localities throughout Europe. But none of this fresh evidence contradicts the conclusions I had previously arrived at; on the contrary, it has greatly strengthened my general argument.

Prof. Penck was, I think, the first on the Continent to adopt the views referred to. He was among the earliest to recognize the evidence of interglacial conditions in the drift-covered regions of Northern Germany, and it was the reflections which those remarkable interglacial beds were so well calculated to suggest that led him into the same path as myself. Dr. Penck has published a map (*Archiv für Anthropologie*, Bd. xv., Heft 3, 1884) showing the areas covered by the earlier and later glacial deposits in Northern Europe and the Alpine lands, and indicating at the same time the various localities where palæolithic finds have occurred. And in not a single case do any of the latter appear within the areas covered by the accumulations of the last glacial epoch.

A glance at the papers which have been published in Germany within the last few years will show how greatly students of the Pleistocene ossiferous beds have been influenced by what is now known of the interglacial deposits and their organic remains Profs. Rothpletz (*Denkschrift d. schweizer. Ges. für d. gesammt. Nat.*, Bd. xxviii., 1881) and Andreæ (*Abhandl. z. geolog. Specialkarte v. Elsass-Lothringen*, Bd. iv., Heft 2, 1884), Dr. Pohlig (*op. cit.*) and others, do not now hesitate to correlate with those beds the old ossiferous and implement-bearing alluvia which lie altogether outside of glaciated regions.

The relation of the Pleistocene alluvia of France to the glacial deposits of that and other countries has been especially canvassed. Rothpletz, in the paper cited above, includes these alluvia amongst the interglacial deposits; and in the present year we have an interesting essay on the same subject by the accomplished secretary of the Anthropological and Archæological Congress, which met last month in Paris. M. Boule correlates (*Revue d'Anthropologie*, 1889, t. i.) the palæolithic cave- and river-deposits of France with those of other countries, and shows that they must be of interglacial age. His classification, I am gratified to find, does not materially differ from that given by myself a number of years ago. He is satisfied that in France there is evidence of three glacial epochs and two well-marked interglacial horizons. The oldest of the palæolithic stages of Mortillet (CHELLÉENNE) culminated, according to Boule, during the last interglacial epoch, while the more recent palæolithic stages (MOUSTÉRIENNE, SOLUTRÉENNE, and MAGDALÉNIENNE) coincided with the last great development of glacier-ice. The palæolithic age, so far as Europe is concerned, came to a close during this last cold phase of the Glacial period.

There are many other points relating to glacial geology which have of late years been canvassed by Continental workers, but these I cannot discuss here. I have purposely, indeed, restricted my remarks to such parts of a wide subject as I thought might have interest for glacialists in this country, some of whom may not have had their attention directed to the results which have recently been attained by their fellow-labourers in other lands. Had time permitted I should gladly have dwelt upon the noteworthy advances made by our American brethren in the same department of inquiry. Especially should I have wished to direct attention to the remarkable evidence adduced in favour of the periodicity of glacial action. Thus Messrs. Chamberlin and Salisbury, after a general review of that evidence, maintain that the Ice Age was interrupted by one chief interglacial epoch, and by three interglacial sub-epochs or episodes of deglaciation. The same authors discuss at some length the origin of the löss, and come to the general conclusion that while deposits of this character may have been formed at different stages of the Glacial period, and under different conditions, yet that upon the whole they are best explained by aqueous action. Indeed a perusal of the recent geological literature of America shows a close accord between the theoretical opinions of many Transatlantic and European geologists.

Thus as years advance the picture of Pleistocene times becomes more and more clearly developed. The conditions under which our old palæolithic predecessors lived—the climatic and geographical changes of which they were the witnesses—are gradually being revealed with a precision that only a few years ago might well have seemed impossible. This of itself is extremely interesting, but I feel sure that I speak the conviction of many workers in this field of labour when I say that the clearing up of the history of Pleistocene times is not the only end which they have in view. One can hardly doubt that when the conditions of that period and the causes which gave rise to these have been more fully and definitely ascertained we shall have advanced some way towards the better understanding of the climatic conditions of still earlier periods. For it cannot be denied that our knowledge of Palæozoic, Mesozoic, and even early Cainozoic climates is unsatisfactory. But we may look forward to the time when much of this uncertainty will disappear. Meteorologists are every day acquiring a clearer conception of the distribution of atmospheric pressure and temperature, and the causes by which that distribution is determined, and the day is coming when we shall be better able than we are now to apply this extended meteorological knowledge to the explanation of the climates of former periods in the world's history. One of the chief factors in the present distribution of atmospheric temperature and pressure is doubtless the relative position of the great land and water areas; and if this be true of the present, it must be true also of the past. It would almost seem, then, as if all one had to do to ascertain the climatic condition of any particular period was to prepare a map, depicting with some approach to accuracy the former relative position of land and sea. With such a map could our meteorologists infer what the climatic conditions must have been? Yes, provided we could assure them that in other respects the physical conditions did not differ from the present. Now, there is no period in the past history of our globe the geographical conditions of which are better known than the Pleistocene. And yet when we have indicated these upon a map we find that they do not give the results which we might have expected. The climatic conditions which they seem to imply are not such as we know did actually obtain. It is obvious, therefore, that some additional and perhaps exceptional factor was at work to produce the recognized results. What was this disturbing element, and have we any evidence of its interference with the operation of the normal agents of climatic change in earlier periods of the world's history? We all know that various answers have been given to such questions. Whether amongst these the correct solution of the enigma is to be found time will show. Meanwhile, as all hypothesis and theory must starve without facts to feed on, it behoves us as working geologists to do our best to add to the supply. The success with which other problems have been attacked by geologists forbids us to doubt that ere long we shall have done much to dispel some of the mystery which still envelops the question of geological climates.

SECTION E.

GEOGRAPHY.

Opening Address by Colonel Sir Francis de Winton, K.C.M.G., F.R.G.S., President of the Section.

Geography has not inaptly been defined as "the science of distributions," and from whatever aspect we view it, whether from a large and comprehensive basis embracing all the conditions which surround it as a science, or from the narrower limits of simple physiography, we find certain well-defined principles, or one may term them natural laws, pervading everywhere, whose actions have, through their influences on the past, created the present, and according to the uses we now put them must largely govern the future.

The formation of our globe, unfolded to our vision by scientific discovery, brings us face to face with Nature in all her awful grandeur; and we learn how, under a beneficent and all-wise Providence, this world has been fashioned and made for the use of man during periods of time almost beyond man's calculations; and in the history of man upon earth—a mere drop in this ocean of time—we read of the rise and fall of nations, of great wars, of the discoveries of new routes (so ably described by my friend and talented predecessor in the address delivered by him in Section E last year), and we see what large and important developments have taken place as regards the commerce and trade of the world by the effect of these influences; and then, turning to more recent days, we enter upon the discovery of steam, and its application as a motive power,—a discovery which has given rise to extraordinary changes—changes by which the whole trade of the world and its industries have been stimulated and promoted. Add to this the inventions in electricity, by which almost instantaneous communication has been established to all parts of the globe, and we may well cease to wonder at the increase that has been manifested in what may be termed the motive power of the world, and the development of its larger activities.

Still the natural laws which govern this globe, in their relation to the science of geography, remain the same. It matters not how rapidly you travel from the pole to the equator, you will freeze at the one and perspire at the other; and while passing through the different zones of temperature lying between these regions—the frigid, temperate, and torrid zones—you will find each with its own products, varying with climate, soil, and peculiarity of position, and these variations pervade the whole realm of Nature. Take man as an example: with all his power of brain and reason, he is largely subject to his environment. Look at the toiling millions of the temperate zone, and the enormous activity they display, both mental and physical. Note their colour, form, nervous development; and then pass into the tropics, and the whole creature is changed: he is different in colour, and displays none of the energy or brain-power of the white species of his kind. Why is this? It is chiefly due to the environment in which the creature is living.

The effect of climate upon race is somewhat remarkably illustrated in recent times by noticing the physique and nerve-power of the present race of Americans. The wonderful tide of emigration which has raised them to being a nation of 60,000,000 people may have exercised certain influences as regards this change; but there are many true Americans still in existence. Two hundred years ago they were the same race as ourselves, but the difference between us now is marked. The climate of America has given them an individual stamp, and a perceptible difference in outward semblance has shown itself even in this short space of time.

Similar changes are manifested throughout the whole animal and vegetable kingdom; and while the geologist, zoologist, botanist, ethnologist, and entomologist, each and all are separate branches of science, yet each and all have a common ground in geography and its application to the shape and form of land and sea; to the wrinkled folds of the earth's surface which we call mountains and valleys; to the mighty ocean with its currents of air and water, and the influences they exert; to the huge inland seas and lakes; to the great rivers and small streams; to the endless varieties in the animal and vegetable kingdoms; and we find these great elements of Nature contributing each in its own sphere to questions relating to the commerce of the world and the development of new countries.

In this brief introduction to my paper I have designedly, though very briefly, drawn your attention to the science of applied geography before passing in review the most recent explorations and discoveries of the present day; and while doing this, I shall endeavour to draw attention to the great necessity for a more thorough study of this science, and the influences it exerts upon trade and commerce, as we gain a better knowledge of the products of one country and the industries of another, as well as the importance of such knowledge to the great manufacturing centres of this nation as new countries are discovered and developed.

It must be remembered that we no longer enjoy a monopoly of trade. Other nations are exhibiting large commercial activities; and if we desire a continuance of the trade of Great Britain we must put our shoulders to the wheel with the same energies and creative power that have produced such astonishing results during the present century.

In the paper to which I have already alluded, it was clearly shown how largely the rise and fall of the great emporiums of commerce in past centuries were influenced by the struggle for the Eastern trade. This struggle is still going on. The Russians in Central Asia are steadily advancing as each year goes by, and developing that system of absorption which has characterized their policy, especially in that region. Central Asia is the chosen field of their explorers, and the recent decease of General Prjevalsky has been a great loss in the scientific world. A full account of his remarkable discoveries and explorations appeared in the Proceedings of the Royal Geographical Society.

The principal work accomplished by the latest Russian explorers, Messrs. Grombchevski, Mr. Lidsky, and Mr. Grum-Grijmailo, in Central Asia have been in the region of the Pamir, and from thence across the Hindu Kush into Hunza. Also in Eastern Bokhara and in the upper waters of the Yarkand River, the Kalik Pass, and Kanjat. In the prosecution of these researches, which are all dangerously near our Indian frontier, very full reports are made, more especially as regards trade and commerce; and there is no doubt, since the completion of the Transcaspian railway to Samarcand, a great impetus has been given to Russian trade in Central Asia, even extending, by well-known routes, as far as the north-west provinces of China, where Russian goods are now found entering into competition with those of English manufacture.

By means of this railway, right into the heart of Asia, Russia has obtained the trade of a vast area, which formerly passed entirely through British hands. Both politically and commercially she is our rival in the East, and the question which nation is to be supreme must come sooner or later.

There is no more interesting country in the world than China. Her teeming and industrial population, her large mercantile centres, the geographical situation of her territory, her undeveloped mineral wealth, her individuality, and the magnitude of her trade with this country, all combine to invest her with a peculiar importance as regards our mercantile community. Coal has been discovered in all the seventeen provinces of the Chinese Empire, but the passive resistance offered by her rulers and her peoples to all attempts by foreign nations to obtain a footing in the interior have prevented any development of her resources. The day, however, cannot be far distant when railways, some of which are already projected, will open up the interior of China and make her better known; but we should be unworthy children of our forefathers if we permit the trade of this rich and widely-peopled country to pass from our hands, either from a want of energy, or from a departure from those principles of trade and commerce whose foundations are built upon the rocks of integrity and honest dealing. Nothing marks the individuality of the Chinese more than that, wherever you meet him, whatever his surroundings may be, he is John Chinaman still; he never adopts the dress, manners, or customs of other nations, but he remains constant to the pigtail, the quaint dress, and the umbrella; and if established in communities, you will find him with his joss-house, food, theatre, and his refreshment-places just as if he were in China.

Our knowledge of the latest acquisition in the East, Burmah, has been largely increased during the past eighteen months. Important surveys in North-Eastern Burmah by Colonel Woodthorpe, R.E., and Mr. Ogle have opened up an area of about 1500 square miles; and the fact of practicable routes between Assam and Burmah *viâ* the Palka Pass is now established. Burmah, with its large and intelligent population (numbering about 4,000,000), with its valuable minerals and precious stones, with its tropical products, is well worthy of the attention of the merchant adventurer; and as our knowledge of the physiography of the country is rapidly increasing, a study of its applied geography is strongly recommended to the student.

In our own territory of British India large and important surveys have been carried on under the able direction of Colonel Thuillier. These surveys are conducted in what is called the protected region; but very interesting additions, especially to the merchant, are made in the outlying territories bordering upon our Indian Empire, where no white man could go, by the employment of intelligent natives especially trained for the purpose. The information obtained by these men may be very profitably studied.

These Central Asian problems are full of deep significance to those desirous of developing and retaining the supremacy of the trade of this Empire in those regions; and I am happy to state that papers full of interest on these subjects will be presented to you during this meeting.

Turning to the northern parts of Asia, I feel some diffidence in speaking before a Newcastle audience on the subject of Siberia, for through your own townsmen, and Captain Wiggins, you are well acquainted with these regions. The exertions made by Captain Wiggins and those connected with him in this enterprise should receive the highest commendation; and that they have been so far successful is a matter for rejoicing. At the same time, I cannot but think that Russia, continuing the policy she has so steadily pursued for some years past, against the commercial development of Great Britain, would not object to the employment of British capital in opening up trade in her outlying dominions; for that trade, once fairly established on good business lines, would be absorbed on behalf of her own manufacturers. I do not attach any blame to Russia in this matter, but I am of opinion that more profits are to be gained when trade follows the British flag, for then British enterprise and money reap more certain reward. If the energy, talent, and perseverance which have been exhibited by Captain Wiggins and his partners had been utilized in the development of some of our own territories rather than in the territory of another nation, I feel sure they would command that success to which they are so justly entitled.

From the consideration of Siberia and the Northern Seas it is not a far step to Greenland, whose icy regions and eternal snows have been crossed for the first time in our history. The hero of this exploit, Dr. Frithjof Nansen, is a native of Norway, and the exploration which he has so recently conducted to a successful issue was rightly alluded to by the President of the Royal Geographical Society, in his annual address, as the most conspicuous achievement of the year.

Though young in years, Dr. Nansen proved himself to be a leader of men, and the account of his adventures will be found to be full of interest. The results of his expedition deal rather with the world of science than with commerce, as his discovery proved Greenland to be nothing more or less than a continent whose interior is a huge region of ice and snow. It, however, presents a most interesting study to those desirous of advancing our knowledge of glaciers and the glacial period. Dr. Nansen's description of this immense mass of frozen snow, forcing its way coastwards from the higher plateaus of the interior, by sheer weight and pressure, grinding, crushing, resistless in its slow but ever-moving power, gives one a faint idea of how the hills and valleys of the world were formed when, in remote periods of time, they too were under glacial influences.

Crossing from Greenland to North America, we still find ourselves in regions where ice and snow hold undisputed sway for a considerable portion of the year. The Canadian Government, with commendable activity, keep pushing forward their surveys into what is known as the old Hudson Bay Territory. The Mackenzie River has been found to be a far larger body of water than formerly supposed. More accurate surveys as regards the size of some of the great lakes of those regions are being made, and our knowledge of the climate and the isothermal variations of British North America is each year increasing.

Petroleum has been discovered, and, as the geological surveys advance, other discoveries of an important nature may reasonably be anticipated. I have been told of the existence of a huge bed of porous sandstone, saturated with mineral oil, which burns like coal.

Moving southwards, we pass through the prairie-lands of the North-West of Canada, traversed by the Canadian Pacific Railway. These rich lands are being rapidly developed, and should form a happy home for some of our surplus population. Colonization is a subject full of geographical considerations, but it demands a special paper, and I have neither space nor time to introduce it into this address. At the western edge of these prairie-lands are the Rocky Mountains, in whose foot-hills are now being reared large herds of cattle and horses, as well as flocks of sheep. Some cattle from these fertile regions were shipped last year to the English market, and no doubt a regular trade will soon follow this experiment.

Crossing the Rockies in a westward direction, you come to the Selkirk Range, then to the Gold Mountains, and lastly to the Cascades, whose wooded rocky sides plunge into the Pacific. Constant explorations are being carried on through these mountain ranges, chiefly in researches after gold and other precious metals, and our knowledge of their physiography is rapidly increasing. The Rev. Mr. Spotswood Green, in an interesting paper concerning these regions, tells us something of the configuration of the Selkirk Range, which offers alike to the mineralogist, sportsman, and Alpine explorer a field of great interest.

Continuing southward, we pass through the fertile plains and valleys of California, whose large industries in grape and orange culture are being fostered and developed. And from California you enter into Mexico, whose wonderful mineral resources are receiving a new impetus by the construction of railways, 4700 miles of which are now open to traffic. These railways will not only facilitate the transport of the wealth of Mexico from the coast to the sea, but they tend also to promote law and order among its restless and lawless population. As law and good government are established, so will trade and commerce and the natural riches of the country be promoted and encouraged.

Crossing over to South America, we find considerable progress in commercial activity, chiefly due to the increased means of communication.

In the smaller Republics upwards of 1500 miles of railway have been recently constructed; while in the larger States, Brazil has 6000 miles; Peru, 3000 miles; Chili, 1630; and the Argentine Republic, 4700—making a grand total in South America of 17,000 miles of railways. This allusion to railways may not be considered as bearing on the science of geography;

but railways are very important factors as regards the commerce and trade of the world, and by the facilities they afford they largely increase the power of exploration.

The southern portion of South America has been described by those who have visited and explored its savannahs and prairie-lands as possessing one of the richest grazing-lands of the world, and its development is only a question of time. In its present condition it offers a very interesting field of research to the explorer.

Time does not permit us to dwell long on the islands of the Pacific. Recent events concerning Samoa are fresh in your memories; and while some of these islands have developed commercially, it is when they lie in the great ocean tracks of the world that their real importance is manifested. Take for example the island of St. Vincent, of the Cape Verde Group. It is nothing but a barren rock, without any produce whatever; all its water has to be brought from a neighbouring island; yet it pays a large revenue to the Portuguese Government simply from coal dues, for it has a good harbour and lies directly in the line between Great Britain and the principal ports of South America; it has therefore become a most important coaling-station.

From the isles of the Pacific it is but a step to Australia, with its six great colonies of Queensland, Victoria, New South Wales, South Australia, Western Australia, and Tasmania, to which may be added New Zealand. Virgin fields untrodden by the foot of the white man are still awaiting the explorer to yield up their treasures to the science of applied geography; and when the marvellous progress that has been made in a few short years by our Australian colonies is weighed and considered, and as its vast interior is opened by exploration, and its mineral resources are developed, who could venture to predict the future that lies before it?

There are now nearly 11,000 miles of railway in operation, and many more miles are in course of construction throughout these various colonies—a sure and certain indication of their energy, wealth, material prosperity, and progress. Geographically speaking, some are not without their troubles. Take Queensland for instance. Her territory runs north and south for nearly 1500 miles, and lies both in the temperate and tropic zones. The Governments who during past years have administered her affairs have experienced some difficulties whilst endeavouring to reconcile the conflicting interests which arise out of her geographical position.

Laws relating to labour and capital in a temperate zone are not always in conformity with the industries and requirements of a tropical temperature, in which the white man is obliged to employ labour suitable to the climate. Hence we find a numerous section of the inhabitants of the northern part of this colony agitating in favour of separation. Australia has large coal-measures, and abounds in precious metals as yet hardly developed.

Attached to Australia are the great and lesser islands forming the Australasian archipelago. The most important of these is New Guinea, and quite recently a successful exploration of its highest mountain range has been accomplished by the present administrator, Mr. Macgregor, who reached an elevation of about 14,000 feet. A very interesting paper was read before the Royal Geographical Society by Mr. Paul Thomson concerning the D'Entrecasteaux and Louisiade Groups, adjacent to New Guinea; and though many of these islands and their inhabitants are quite new to us, still the knowledge we gain from a study of their geographical position may be turned to practical uses by the merchant adventurer.

Last but not least in this record of geographical progress of the world is the vast continent of Africa.

As General Strachey, late President of the Royal Geographical Society, in his address of this year, remarks:—

"The reflection can hardly be avoided that, great as has been the advance of exploration in Africa during the last twenty or thirty years, the interest of geographers will, in the immediate future, be more and more centred in that continent. Excluding the polar regions, there is no considerable portion of the earth's surface, unless it is in Africa, the essential outlines of which have not been delineated."

These words are, I think, absolutely true. Whether we consider Africa in regard to the extraordinary explorations and developments since the commencement of the work of David Livingstone; or from the fact that vast areas of its tropical portion remain untouched as yet by exploration, and are therefore unknown; or from a contemplation of the teeming millions of its inhabitants, of which the larger portion have never seen a white man; or from the uncompleted work of the late General Gordon, and the re-establishment of the power of a civilized Government over the whole of the Nile basin; or from the slavery question, in which our nation has taken the most active and leading part; or from the spectacle of a white man, Emin Pasha, establishing a settled form of government in the heart of the continent, between the two great slave-dealing communities of the Bahr-el-Ghazal and that of the Upper Congo and Lake Tanganyika; or from the expedition sent to convey to him the succour he so much needs, under the leadership of Mr. H. M. Stanley; or from the intense interest recently exhibited by the nations of Europe in portioning out Africa between each other—an interest that has led on the west coast to the establishment of the Congo Free State, and the German protectorate in the Cameroons, France and Portugal adding largely to the possessions they already hold, and England contenting herself with strengthening her grip upon the Niger, and on the east coast by the formation of the British and German spheres of influence; or to the colonies which Great Britain possesses in the southern extremity of this great continent; or to the struggle which sooner or later must be fought out between Christianity and Mohammedanism as regards the native races of Central Africa, in which the River Congo will play an important part: I say when we consider all these and the many other problems of this continent, the vast interests they represent, and the varied influences they may yet exert on the future history of this earth, as well as the extraordinary part which Great Britain has been permitted to play in lifting the veil of mystery and doubt which up to our own times enveloped these regions, we are forced to acknowledge that the country in which the civilized world takes the most active and absorbing interest is Africa, and that the Dark Continent still maintains its supremacy.

As regards Africa two very remarkable journeys have recently been brought to a successful conclusion—that of Count Teleki, an Austrian, on the north, and that of Mr. Arnot in the regions south of the equator.

The former, entering Africa at Mombasa, at the head of a numerous and well-equipped caravan, passed through the Masai country by what is known as Thompson's route, and, pushing northwards, discovered Lake Rudolph, a large inland salt lake, and by following its shores he was enabled to trace with commendable accuracy its shape, size, and position. The existence of a large lake, called Samburu, in the direction of Count Teleki's journey, had for some time been spoken of by the Arabs who traded in that region, but nothing definite was known concerning it. Count Teleki also obtained much valuable information of the region between Mount Kenia and Lake Rudolph, its inhabitants, its rivers, and its products; and the details of his most interesting and successful journey have yet to be published.

Mr. Arnot, on the other hand, started in 1883 from Pietermaritzburg with a very slender equipment and hardly any following. His object was to prove the existence of healthy plateaus in the interior of Africa, where white men could live and prosecute the work of missionary civilization without being exposed to the malarial influences which exist in so many parts of Central Africa.

Taking a northerly course, he reaches the Zambesi, whose waters he follows as far as Lealui. From this point his route trends to the west as far as Robongo, the capital of the Bihé country. From Robongo he continues his march to Bailundu, and from thence he reaches Benguela, on the west coast. Thus he crossed Africa in the same direction as Livingstone's first journey, though somewhat to the south of Livingstone's route. While at Bailundu he meets some messengers from Msidi, the chief of the Garangenze country, who beseech him to visit their king; and having replenished his stores, he retraces his steps to the interior.

From January 1885 to February 1886 he perseveres in his attempt to reach the capital of Msidi's country, and his efforts are at length crowned with success. After a sojourn among these people for two years, during which time he thoroughly succeeded in obtaining their confidence and that of their ruler Msidi, he returned to Europe in the latter part of last year, but not before he had established two other white missionaries at Mukururu to continue the work he had begun.

He also made several small expeditions during his residence at Mukururu, the most interesting of which was to the cave-dwellers of Urua, mentioned by Livingstone. This kingdom of Garangenze is situated to the east of Lake Moero; and Mr.

Arnot has recently published a book of his travels, giving a very clear and interesting account of these people, their manners, and their customs. Of all Livingstone's followers, Mr. Arnot very closely resembles the great leader in the patient earnestness, the quiet energy, and the scanty resources with which he prosecuted his remarkable journeys.

He has quite recently returned to the west coast of Africa with the intention of rejoining his friends at Garangenze.

The events which attended the expedition under Mr. H. M. Stanley to succour and relieve Emin Pasha are so well known to you all that I shall only attempt a brief recapitulation here.

We have learned from his own pen how, after much suffering and great hardships, he eventually overcame all the difficulties and obstacles which had to be encountered while conducting his caravan from the head waters of the Congo to the lake Albert Nyanza; that on reaching that lake he met Emin Pasha.

The value of Mr. Stanley's journey and the remarkable energy and courage he displayed, his high scientific attainments, and the information that will result from his labours, are, from a geographical point of view, of the highest interest. The desiccation of the lake Albert Nyanza, and its influences on the rise and fall of the Nile, are not the least remarkable of these problems. For my own part, I am of opinion that this rise and fall is mainly caused by the rapid growth of tropical water-plants. During the dry season this vegetation increases enormously, and at the first rains large masses of aquatic growth are loosened by the rising of the waters. These masses, in the form of floating islands, pass downwards on the bosom of the flowing waters, and on reaching a wide and shallow part of the river, such as we find at the Bahr-el Ghazal, they gradually but quickly collect till they form a dam of sufficient density to obstruct the progress of the river; and the water thus arrested finds a temporary lodgment in the lake Albert Nyanza, causing it to overflow its normal boundaries. At length the vegetable dam can no longer withstand the weight and pressure of the water bearing upon it; a portion gives way; a channel is opened; and the river, hurrying on to the sea, overflows the banks of the Lower Nile and drains the lake to a lower level. This is what happens to the Albert Nyanza, which is nothing more than a huge backwater of the Upper Nile basin, and it accounts for the lake being seen at two different levels by those two distinguished explorers Mr. H. M. Stanley and Sir Samuel Baker, and hence the difference of opinion as to its true extent and size that has arisen between them. We know that this phenomenon takes place on Lake Tanganyika, as Stanley found a marked difference in its level on the two occasions he rested upon its shores. He also followed the Lukuga River from the Tanganyika Lake to its junction with the Congo; and there is no doubt that a vegetable dam, such as I have described, forms at the point of departure of this river from the lake, and prevents its regular flow till the weight and pressure behind it sweeps all away. During the second year that I was on the Congo we had an unusually heavy flood at the time of the first rains. The river rose several feet in one night, and some months afterwards news came from the Upper Congo that the waters of the big lake had broken through, and this no doubt had reference to the Lukuga River and Lake Tanganyika.

Now, as regards the countries through which we have been passing, there are certain points of great interest connected with the science of applied geography, to which I desire to draw your special attention.

The first of these points is the study of the great railway systems of the world, and the application of railways to the development of new countries. Take our Indian possessions for example. What a change has been wrought, not only as regards the commerce of the country, but also with reference to the social condition of its inhabitants and their manners and customs! The introduction of Indian wheat, by means of these railways, into the markets of Europe has caused a revolution in the trade in that commodity. We find this especially in America, where it has upset the calculations of those gigantic combinations or rings which sought to obtain a monopoly in the supply of this universal article of food. Thus the construction of railways in the East exercises commanding influences over the markets of the West.

Consider also the traffic from China and Japan to America, with its 60,000,000 people, by means of the great Atlantic and Pacific railways, in tea and raw materials. Now, although railways cannot compete with direct traffic by sea, when the necessity for more rapid conveyance of certain goods arises, we find that a combination of sea and land transport is often adopted in preference to the longer route by sea alone.

The development of any country, no matter what its geographical position may be, is enormously increased by the construction of railways. Take the Congo Free State as an instance (which is undoubtedly the finest property in Central Africa). So long as the Upper Congo region, with its miles—measured by thousands—of navigable tributaries, was separated from the Lower Congo by the rapids extending from Stanley Pool to Matadi, this magnificent territory was practically shut to trade and commerce. Every piece of goods in the interior had to be carried on men's heads for more than 200 miles, and all ivory and other products were brought to the coast in the same way. Roughly speaking, such transport costs about £40 per ton.

The Congo Free State has wisely determined to build a railway, of some 250 miles in length, to cross this cataract region; and the moment it is completed the future of that country is assured.

H.M. the King of the Belgians has kindly given permission for a Belgian officer of distinction, Captain Thys, to read a paper at this meeting on this railway, which will afford a more detailed account of this wise and patriotic undertaking.

I have mentioned railways as the first point of interest because they are creations of our own time, and have therefore a special interest of their own; but the most important factor in the early history of the science of applied geography, and to which the establishment of our great colonial empire is mainly due, is the record of the merchant adventurers.

Their voyages and exploits, extending to every part of the globe, began at the end of the fourteenth century, in the reign of Henry VIII., when the Cabots (Venetians) sailed from England to Newfoundland, and afterwards to Florida. This expedition and those which followed it were fitted out at the expense of corporations of merchants, with the object of extending the commerce of the country by a search after trade in new and foreign lands. They were placed under the command of some well-known leader, and the results obtained were extraordinary.

In 1530 the merchant adventurers of England attempted the North-West Passage, as it is called, to China, and between 1550 and 1578, Sir H. Willoughby, Frobisher, and Sir H. Gibbon all made remarkable voyages.

Between 1585 and 1615, Davis, Hudson, and Baffin were sent by merchant companies to the polar seas, and their discoveries are handed down by the straits and bays which they discovered, and which bear their names.

In 1580 Drake took the first English vessels into the Pacific Ocean. Drake was not only a bold and successful navigator, but he was also a commander of men, in which he showed rare tact and ability.

In 1588 the merchants of Exeter established a trade with the West African coast, and the Senegal Company was formed.

In 1553 the first effort to reach India was made *viâ* the Cape of Good Hope. It was not, however, till the year 1660 that any progress was made in the East. In that year the East India Company was formed, and it is to the establishment of this Company that we owe our great Indian Empire. The year 1669 saw the formation of the Hudson Bay Company—a Company which exists at the present day. And so the record goes on down to our own times. Not the least amongst the trading corporations of Great Britain were the merchant adventurers of this city in which we are now assembled; and they, too, contributed in no small degree, not only in the past but in the present, to the extension of our geographical knowledge and its application as a science. No doubt the spirit and energy of our Scandinavian forefathers has been fostered and encouraged until it has now found its development in the enterprise and prosperity of this great mercantile centre of the north of England. And the old churches of Jarrow and Monkwearmouth bear further testimomy to the fact that, as commerce drew together communities which became centres of maritime energy and progress, religion was not forgotten, and the seed of knowledge and truth thus sown in the early history of the past has spread itself throughout the length and breadth of the great colonial empire of Greater Britain.

Following on the discoveries of the sixteenth and seventeenth centuries, and the marvellous results to which they have given birth, the story of our own times, from a geographical point of view, is quite as wonderful. As I remarked at the beginning of this paper, the discovery of steam as a motive power has brought the world into an extraordinary condition of contactiveness, and quite recently several new companies have been formed in the same spirit and on the same lines as those followed by the old merchant adventurers. These later creations are being started under more favourable conditions than their predecessors, for they have all the advantages which modern science and modern appliances can afford. The English Government have wisely encouraged and promoted the formation of these trading corporations. In countries where climate and circumstances of environment are not favourable to colonization by white men, our colonial system of government progresses somewhat slowly. It has not the elasticity, nor the adaptability, to provide for the many contingencies which must naturally arise when a few white men maintain the position of rulers over large areas, peopled by savage and uncivilized races.

In the Island of Borneo there is the North Borneo Company trading, governing, and civilizing a large portion of territory with marked success.

On the west coast of Africa, the Royal Niger Company is developing the great natural resources of that magnificent river, and its tributary the Binué.

On the east coast there is the Imperial British East African Company, operating in what is known as the British sphere of influence north of Zanzibar. Though not a twelvemonth has passed since they commenced their work, their initiatory proceedings have been remarkably successful, and there is every prospect of an early and rapid development of the territory committed to their charge. In the south-eastern portion of Central Africa, the African Lakes Company have fairly established themselves; and a new company is now being formed to open up and civilize a further portion of that section of the African continent.

The establishment of these great trading and governing centres is likely to exercise most important influences. They are, as I have before pointed out, from their organization and objects, better adapted at the outset to compete with and overcome the obstacles which present themselves to established forms of bureaucratic government; at the same time the Government of this country can interfere in cases of necessity, by the grants that have been made to them of Royal Charters, under which they carry on their operations.

A wise control and judicious administration combined with the introduction of commerce and civilization will, at no distant date, open these territories to the markets of the world, to the missionary, and to the scientific explorer. The commercial element of geography also enters very largely into their promotion and prosperity because of the fields they open to our home manufactures. It is important here to observe that, if these territories had passed into the hands of other nationalities, but a very limited quantity of British goods would ever have entered into them, and their value, as a market for the industries of the nation, would have been lost.

The establishment of a Geographical Society in this city is of real importance. Its objects should be the collection of information, and the study of applied geography in all its varied branches and aspects. It should aim to furnish complete information concerning the geography of all parts of the globe. In Chambers of Commerce our large trade centres have, no doubt, means of guiding and controlling some of our most important mercantile operations, but they afford no opportunities to the student, they are not teaching bodies; and there are instances where considerable risks have been incurred and heavy losses sustained in some of their ventures, simply from a want of knowledge of geographical data.

I should like to see a Geographical Society in every large city of this Empire, conducted on the lines I have briefly suggested, because the study of, and interest in, the commercial geography of this great Empire and the world is too much neglected amongst us. Past prosperity, and a tendency to run in the same groove, narrow our commercial horizon. Slowly, but surely, other nations, competing with us in many parts of the world, are doing so successfully because of the study they make of commercial geography.

It is for this reason I have in my address dwelt strongly upon the question and study of geography as an applied science, and it is for a greater reason I urge its importance, viz. that we may hand down to our children unimpaired the heritage bequeathed us by our forefathers; a heritage gained by courage, energy, perseverance, and patriotism—qualities which, under God's blessing, have made this nation the head of the commerce of the world.

SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

OPENING ADDRESS BY PROF. F. Y. EDGEWORTH, M.A., F.S.S., PRESIDENT OF THE SECTION.

Points at which mathematical reasoning is applicable to political economy—

A.—Perfect competition—
1. Simplest type of market.
2. Complex system of markets; simplified by certain abstractions.
3. The more concrete problem of an exchange and distribution.

B.—Monopoly—
1. Transactions between a single monopolist and a competing public.
2. Transactions between two monopolists or combinations.

The use of these applications of mathematics to political economy illustrated by comparison with—
1. Applied mathematics generally.
2. The mathematical theory of statistics.

Conclusion.

AT the meeting of the British Association which was held at Cambridge about a quarter of a century ago, Jevons submitted to this Section a "general mathematical theory of political economy," which, as he himself records, was "received without a word of interest or belief." I propose to consider the justice of the unfavourable verdict which our predecessors appear to have passed on the mathematical method introduced by Jevons.

There is some difficulty in discussing so abstruse a subject in this place. It is as if one should discourse on the advantages of classical education on an occasion on which it might seem pedantic to cite the learned languages. I shall evade this difficulty by addressing to students some appended notes,[1] which, like the boy of proverb, are to be seen, not heard.

The cardinal article of Jevons's theory is that the value in exchange of a commodity measures, or corresponds to, the utility of the least useful portion of that commodity. What a person pays per month or year for a sack or ton of coal is not what he would be willing to give for the same rather than be without fuel altogether. Rather the price is proportioned to the advantage which the consumer expects from the portion which he could best dispense with—to the "final utility," in Jevons's happy phrase.

I shall not be expected here to dwell on a subject which has been elucidated in treatises of world-wide reputation, such as those of Profs. Marshall, Sidgwick, Walker, and I would add Prof. Nicholson's article on "Value" in the "Encyclopædia Britannica." Those writers seem to present what I may call the economical kernel of Jevons's theory divested of the mathematical shell in which it was originally inclosed; whereas my object is to consider the use of that shell—whether it is to be regarded as a protection or an encumbrance.

I may begin by removing an objection which the mere statement of the question raises. The idea of reducing human actions to mathematical rule may present itself to common-sense as absurd. One is reminded of Swift's "Laputa," where the beef was cut into rhomboids and the pudding into a cycloid, and the tailor constructed a very ill-fitting suit of clothes by means of rule and compasses. It should be understood, however, that the new method of economical reasoning does not claim more precision than what has long been conceded to another department of science applied to human affairs—namely, statistics. It is now a commonplace that actions such as suicide or marriage, springing from the most capricious motives, and in respect of which the conduct of individuals most defies prediction, may yet, when taken in the aggregate, be regarded as constant and uni-

[1] The appended notes are referred to by letters of the alphabet, thus: (a).

form. The advantage of what has been called the law of large numbers may equally be enjoyed by a theory which deals with markets and combinations.

But, indeed, even the limited degree of arithmetical precision which is proper to statistical generalizations need not be claimed by our mathematical method rightly understood. It is concerned with quantity, indeed, but not necessarily with number. It is not so much a political arithmetic as a sort of economical algebra, in which the problem is not to find x and y in terms of given quantities, but rather to discover loose quantitative relations of the form: x is greater or less than y, and increases or decreases with the increase of z.

Such is the character of what may be called perhaps the leading proposition in this calculus—namely, the mathematical theory of supply and demand. The use of a curve introduced by Cournot to represent the amount of a commodity offered, or demanded, at any particular price, supplemented by Jevons's theory of final utility (*a*), does not indeed determine what price will rule in any market. But it assists us in conjecturing the direction and general character of the effect which changes in the condition or requirements of the parties will produce. For example, in the case of international trade the various effects of a tax or other impediment, which most students find it so difficult to trace in Mill's laborious chapters, are visible almost at a glance by the aid of the mathematical instrument (*b*). It takes Prof. Sidgwick a good many words to convey by way of a particular instance that it is possible for a nation by a judiciously regulated tariff to benefit itself at the expense of the foreigner. The truth in its generality is more clearly contemplated by the aid of diagrams such as those employed by the eminent mathematical economists Messrs. Auspitz and Lieben (*c*).

There seems to be a natural affinity between the phenomena of supply and demand and some of the fundamental conceptions of mathematics, such as the relation between function and variable,[1] between the ordinate of a curve and the corresponding abscissa,[2] and the first principle of the differential calculus; especially in its application to the determination of *maxima* and *minima*. The principle of equilibrium is almost as dominant in what Jevons called the mechanics of utility as in natural philosophy itself. In so many instances does mathematical science supply to political economy what Whewell would have called "appropriate and clear" conceptions. Their use might, perhaps, be illustrated by comparing—however fancifully, and *si parva licet componere magnis*—the advance in economics which Jevons initiated or continued to the advance in mathematics which the new and sublime method invented by Sir William Hamilton appears to have effected. Algebra and geometry are to ordinary language in political economy somewhat as quaternions are to ordinary algebraic geometry in mathematical physics, if we accept the view of the latter relation which has been given by a very competent judge, Clerk Maxwell. "I am convinced," he says, "that the introduction of the ideas as distinguished from the operations and methods of quaternions will be of great use in the study of all parts of our subject, and especially . . . . where we have to deal with a number of physical quantities, the relations of which to each other can be expressed far more simply by a few expressions of Hamilton's than by the ordinary equations."[3] This is the spirit in which the economist should employ mathematics—"the ideas as distinguished from the operations and methods."

In considering the above-given, and indeed any concrete instances, it is hardly possible to keep to what may be called the simplest type of supply and demand, the ideal market in which we contemplate only two groups of competitors and only two articles of exchange; say, gold for corn, or any other *quid pro quo*. In general, and especially when considering what rates of exchange tend to rule in an average of transactions, it is proper to take into account that the dealings in one market will affect those in another. If the *entrepreneur* has less to pay for machinery, *cæteris paribus*, he will be able to offer more on the labour market. Thus we obtain the idea of a system of markets mutually dependent. In a general view of this correlation it is not necessary to distinguish whether the state of one part is connected as cause or effect with the other parts of the system. As Prof. Marshall[1] says:—"Just as the motion of every body in the solar system affects and is affected by the motion of every other, so it is with the elements of the problem of political economy" (*e*).

This conception of mutually dependent positions is one in which minds disciplined in mathematical physics seem peculiarly apt to acquiesce. In other quarters there may be observed a restless anxiety to determine which of the variables in a system of markets is to be regarded as determining or regulating the others. In one of the principal economic journals there has lately been a pretty stiff controversy on the question which of the parties in the distribution of the national produce may be regarded as "residual claimants upon the product of industry" (*Quarterly Journal of Economics*, 1887, p. 287; 1888, p. 9); whether it is the working class which occupies this preferential position, or if the "real keystone of the arch" is interest. Such questions certainly admit of a meaning, and probably of an answer. But they will probably appear of secondary importance to those who accept, as the first approximation to a correct view of the subject, the principle of mutual dependence—what may be called the Copernican theory of distribution, in which one variable is not more determined by another than the other is by that one (*f*).

Among the factors of this economic equilibrium I have not as yet explicitly included cost of production. Rather, the system of markets which so far I have had in view is that which would arise if the articles of exchange were periodically rained down like manna upon the several proprietors, and each individual sought to maximize his advantage according to the law of final utility. But now we must observe that self-interest does not operate in this fashion. We must take account of efforts and sacrifices.

Here, again, the language of symbol and diagram is better suited than the popular terminology to express the general idea that all things are in flux, and that the fluxions are interdependent. In Prof. Marshall's words, "As a rule, the cost of production of a thing is not fixed; the amount produced and its normal value are to be regarded as determined simultaneously under the action of economic laws. It, then, is incorrect to say, as Ricardo did, that cost of production alone determines value; but it is no less incorrect to make utility alone, as others have done, the basis of value" ("Economics of Industry," p. 148). Among those who may have gone astray in the latter sense, who, in their recoil from Scylla, are at least sailing dangerously near Charybdis, may be placed the important Austrian school who have rediscovered and restated the theory of final utility without the aid of mathematical expression. To amplify a figure suggested by one of them,[2] let us figure the hard conditions of industrial life by the austerity of a schoolmaster, who, in order to cultivate patience and fortitude in his scholars, should distribute among them certain rewards—it might be toys and sweets—in return for certain amounts of fatigue and pain endured. Thus, the cost of procuring a marble might be writing out twenty lines; the cost of a top, standing half an hour in the stocks. Supposing exchange to be set up among the members of the youthful population, free competition being assumed, there would theoretically arise an equilibrium of trade in which the value of each article would correspond to its final utility. That is, if a top exchanged for ten marbles, it might be expected that each boy would prize the last top about as highly as the last decade of marbles which he thought fit to purchase. So far, final utility may be regarded as the regulating principle.

But it is equally true that the final *dis*-utilities of the exchanged articles will be equal. If a top is worth ten marbles, we are entitled to expect such an adjustment of trade that each and every boy would as soon stand in the stocks half an hour as

[1] The treating as constant what is variable—e.g. *supply*, *margin*, *wages fund*, is the source of most of the fallacies in political economy.

[2] For instance, the two meanings of increased demand—which Mr. Sidgwick has contrasted as the *rise* and the extension of demand—are most easily and with least liability to logomachy distinguished as the variation of an ordinate (1) due to the displacement of the curve, the abscissa not varying, or (2) corresponding to an increment of the abscissa, the curve being undisturbed.

[3] Clerk Maxwell, "Electricity and Magnetism." Art. He says in the context: "As the methods of Descartes are still the most familiar to students of science, and as they are really the most useful for purposes of calculation, we shall express all our results in the Cartesian form." Compare Prof. Marshall's dictum with respect to the use of the vulgar tongue in "Economic Reasonings," cited below, p. 9.

[1] In a remarkable review of Jevons's theory in the *Academy* of April 1, 1872.

[2] Cf. Prof. Böhm Bawerk: "Es kann ein Erzieher einem Knaben, um ihn gegen Weheleidigkeit abzuhärten, für die tapfere, freiwillige Erduldung von Schmerzen ein sehnlich begehrtes Spielzeug in Aussicht stellen. So untergeordnet das Vorkommen solcher Fälle auch sein mag, so wichtig ist es für die Theorie festzustellen, dass Arbeit und Arbeitsplage doch nicht der einzige Umstand ist, auf den sich . . . die Wertschätzung gründen kann."—*Konrad's Jahrbuch*, 1886, p. 43.

write out two hundred lines—the cost of ten marbles at twenty lines per marble.

To be sure, final utility may be conceived as operating by itself without reference to cost of production, as we tacitly assumed in our first paragraphs. Whereas the converse conception of a traffic in discommodities[1] has less place in real life.

But it is not worth while weighing the two principles against each other, *in vacuo*, so to speak, and abstracting the real circumstances by which each is differently modified. As these are introduced, the balance will oscillate now in favour of one side, now of the other; perhaps leaving it ultimately uncertain whether cost of production or final utility is the more helpful in the explanation of economic phenomena.

For instance, in our allegory let us introduce the supposition that there is only one variety of cost—say, the common labour of writing out verses. If, now, the authorities fix twenty lines as the cost of a marble, and 200 as the cost of a top, it is predictable that a top will be worth ten marbles. It is equally true indeed, now as before, that the final utility of a top will be equal to the final utility of ten marbles. But the latter proposition, though equally true, is not equally useful. For it does not afford the simple and exact method of prediction which is obtained by the Ricardian view upon the supposition made. But then the supposition that there is only one variety of sacrifice is not always appropriate. And even if that were appropriate, it might not be helpful when we introduce the condition that the cost of procuring each article is not fixed definitely, but varies increasingly or decreasingly with the amount procured. Thus, the cost of the first marble given out might be twenty lines; of the next marble, twenty-one lines; with an equally varying scale for tops. Upon this supposition the two propositions that value corresponds to final utility and also final disutility might be equally true, but equally useless for the purpose of prediction.

Again, it may be that a man is freer to vary the extent of his expenditure than the duration of his work (*g*). The final disutility experienced by the Secretary of this Association during its meetings must be fearful. For it is not open to him to terminate at pleasure his day's work, as if he were employed by the piece. He would not, however, have accepted the office unless the advantages, less by all the trouble, were at least as great as in any other position open to him. Now this equation of the net advantages in different occupations is—co-ordinately and (in a mathematical sense) *simultaneously* with the equation of final utility for different kinds of expenditure—a condition of normal economic equilibrium (*h*). Yet again, the free play of this tendency is impeded by the existence of "non-competing groups."

I cannot be expected here to enumerate all the conditions of economic equilibrium. For a complete exposition of the complexities at which I have thought it necessary to glance, I must refer to the second book of Prof. Sidgwick's "Political Economy." It will be evident to his readers[2] that what may be called the general economic problem of several trading bodies distributing and exchanging *inter se* under the influence of self-interest and in a *régime* of competition is much more hopelessly difficult than the as yet imperfectly solved dynamical problem of several material bodies acting on each other *in vacuo*. When Gossen, the predecessor of Jevons as an exponent of the law of final utility, compares that principle to the law of gravitation, and the character of our science to that of astronomy, he betrays a too parental partiality. A truer, though still too flattering, comparison would be afforded by some very immature and imperfect specimens of physics—say the theory of fluid motion applied to the problems of house ventilation.

There is a certain resemblance between the uniformity of pressure to which the jostling particles of a gas tend and the unity of price which is apt to result from the play of competition. As the architect is guided by studying the laws according to which air flows, so it will help the builder of economic theory to have mastered the principle of movement towards equilibrium. But even in the material constructions practice is apt to lag far behind theory, as every reader in the British Museum knows. Much less are we able to predict what currents will flow between the different compartments of the industrial system. We know so imperfectly the coefficient of fluid friction, and the other conditions of the general problem: what compartments may be regarded as completely isolated and hermetically sealed, which partitions are porous and permeable.

Moreover, there is one operation of competition, which it does not seem easy or helpful to represent by physical analogies—the transference from one occupation to another, the equation of net advantages or total utilities in different employments; industrial as distinguished by Cairnes from commercial competition. The latter operation appears to me to admit much better of mathematical expression than the former, which is not so well represented by the equilibrium of a physical system.[1] Accordingly, the equation of net advantages has been judiciously omitted by Jevons in his formulation of the cost of production. And the Helvetian Jevons, as we may call Prof. Walras, appears to have altogether made abstraction of the cost of production considered as importing sacrifice and effort.

Prof. Walras, illustrating the operation of a simple market, supposes each dealer, before going to market, to write down his scale of requirements—how much he would be willing to buy or to sell at each price. From these data it would be easy to calculate beforehand the rate of exchange which would prevail in the market formed by those individuals. But, when we advance from the simplest type of market to the complexities introduced by division of labour, it is seen to be no longer a straightforward problem in algebra or geometry, given the natures of all the parties, to find the terms to which they will come. Here, even if we imagine ourselves in possession of numerical data for the motives acting on each individual, we could hardly conceive it possible to deduce *a priori* the position of equilibrium towards which a system so complicated tends.

Accordingly, it may be doubted whether the direct use of mathematical formulæ extends into the region of concrete phenomena much below the height of abstraction to which Jevons has confined himself. However, the formulation of more complicated problems has still a negative use, as teaching the Socratic lesson that no exact science is attainable. As Dupuit, one of the greatest of Jevons's mathematical predecessors, points out, "Quand on ne peut savoir une chose, c'est déjà beaucoup que de savoir qu'on ne sait rien" (*Annales des Ponts et Chaussées*, 1844, p. 372). If, he says, the early theorists, instead of formulating the balance of trade, had confined themselves to declaring the question above their powers, they would probably have done a greater service than the successors who refuted them. So Cournot, referring to his own mathematical treatment of economics, "Aussi nos modestes prétensions étaient-elles non d'accroître de beaucoup la domaine de la science proprement dite, mais plutôt de montrer (ce qui a bien aussi son utilité) tout ce que nous manque pour donner la solution vraiment scientifique de questions que la polémique quotidienne tranche hardiment" ("Revue Sommaire"). Similarly Jevons says ("Theory of Political Economy," p. 157, second edition), "One advantage of the theory of economics, carefully studied, will be to make us very careful in our conclusions when the matter is not of the simplest possible nature."

In the vineyard of science, to perform the part of a pruning-hook is an honourable function; and a very necessary one in this age of luxuriant speculation, when novel theories teem in so

[1] Suppose our allegorical schoolmaster should discontinue the system of rewards, and prefer to cultivate diligence by requiring each boy from time to time to bring up a certain number of lines, written out—whether by himself or another would not be scrutinized—or to be responsible for the cleaning of a window, after the manner of Mr. Squeers's practical method. In the traffic of discommodities which would be set up on this supposition, the (negative) value of each article of exchange would be measured solely by its disutility. However, it must be admitted, I think, that this latter hypothesis is rather more absurd than the former abstraction—with reference to real life at least; for, as it happens, the traffic in impositions more nearly resembles what is said to occur in actual schools.

[2] There occurs to me only one point at which the use of mathematical illustrations more complicated than those which I have referred to in my first two headings would conduce to the apprehension of Mr. Sidgwick's theorems. I allude to his repeated statement that, not only in international trade, as Mill pointed out, but also in trade in general, there may be several rates of exchange at which the supply just takes off the demand. This statement, taken without reservation, goes the length of destroying the prestige which is now attached to competition. Prof. Marshall, in an important passage, recommends arbitrators and combinations to imitate the method of a celebrated engineer, who, in order to make a breakwater, first ascertained the slope at which a bank of stones would naturally be arranged under the action of the waves, and then let down stones so as to form such a slope ("Economics of Industry," p. 215). Now, if gravitation acted sometimes vertically and sometimes at an angle of 45°, if the forces of competition tended to two distinct positions of equilibrium, the construction of the economic breakwater would become arbitrary. It is important, therefore, to show the limits of Prof. Sidgwick's theory. See the appended note (*j*).

[1] Commercial competition might be likened to a system of lakes flowing into each other; industrial competition to a system of vessels so communicating by means of valves, that when the level of one exceeded that of another to a certain extent, then *per saltum* a considerable portion of the contents of that one (a finite difference as compared with the differentials of the open system) is discharged into the other.

many new economic journals. I give in the appended notes an example of this corrective process applied to a theory of great worth and authority, and concerning the most vital interests, such as the relations of employer and employed, and the Socialist attack on capital (*i*). In directing this weapon of criticism against Prof. Walker, I act upon the Miltonic rule for selecting an adversary—

> "Best with the best, more glory will be won,
> Or less be lost."

In the preceding remarks I have had in view, as presumably most favourable to computation, the case of bargains in which there is competition on both sides. It is now to be added that the mathematical method is nearly as applicable to a *régime* of monopoly. Here Cournot, rather than Jevons, is our guide. Cournot's masterly analysis of the dealings between a monopolist seller and a number of buyers competing against each other has been copied out of mathematics into the vulgar tongue by many well-known writers, and need not here be repeated (*k*).

It is in this department, perhaps, that we can best answer Cairnes's challenge to Jevons to produce any proposition discovered by the mathematical method which is not discoverable by ordinary reasoning. Not, indeed, that the economist is bound to answer that challenge; any more than, in order to prove the advantages of international trade, he is concerned to deny that claret may be produced in Scotland.

The following proposition is a particular case of a more general theorem given by Cournot. Let there be a railway and a line of steamers, each forming part of a certain through journey, and separately useless; the fares will be lower when both means of transport belong to a single company than where there is less monopoly, the two services being in the hands of two companies, each seeking its own gain independently of the other.

The *rationale* of this somewhat paradoxical proposition is not easily discerned without the aid of symbols. Cournot, in a popular redaction ("Revue Sommaire") of the theories which he first conceived in a mathematical form, suggests, as a generally intelligible explanation, that it is better to be at the mercy of a single master than of several petty tyrants. But this seems to be a commonplace of the sort which, in the absence of rigid reasoning, has so often deceived the amateur economist. Might it not be applied to the case of monopoly in general?

It would be hard to say how much this remarkable proposition may add to the arguments in favour of the Government monopolizing railways. Nor would I undertake to estimate the practical significance of Cournot's numerous mathematical theorems on the taxation of monopolists. We might perhaps compare the function of the sovereign science with respect to the theory of monopolies to the duty of Government as to their management—to exercise a general supervision without attempting to control details.

We have in the last few paragraphs been supposing monopoly on one side of the market, on the other side a public competing with each other. Let us now consider the bargain between two monopolists, whether individuals, or rather corporate trading-bodies, combinations in the most general sense of the term. The mathematical analysis of this case brings very clearly into view the important property, which is not very prominent in writings of the pre-Jevonian era, that the bargain between two self-interested co-contractors is not determinate in the same sense as in a *régime* of perfect competition.

No doubt, if we take a very simple case—such as that imagined by De Quincey, of the bargain between the owner of a musical-box and a colonist already on his way to a distant region where no luxuries can be purchased—it is easy to see that the bargain may settle down at any point between certain limits. But where both the amount of commodity to be sold and money to be paid are variable, as in the momentous case of a bargain between a combination of employers on the one hand and *employés* on the other, it is a less familiar truth that the terms of the contract are in general to some extent indeterminate. For instance, the bargain may be either all in the interest of the one party, say long hours and small pay, or, on the other hand, high wages with much leisure.

The significance of this proposition has been missed by many of those who have treated the subject without the aid of the appropriate apparatus. Some fail to see that there is any peculiarity in the bargain between isolated units. Another discerns the indeterminateness of the bargain only in the special case in which the article exchanged is a large indivisible object, like a house. Another limits the difficulty to the case of a single negotiation as distinguished from a contract which, as in the actual labour market, may be modified from time to time. Another tells us that in such a bargain the most anxious party gains least.

All these phrases seem to obscure the cardinal distinction that perfect competition tends to a determinate settlement, whereas in a *régime* of combination a principle of adjustment is still to seek. What is that principle?

At a former meeting of the British Association, on the occasion of a discussion on sliding scales, I stated the difficulty which there might be, in the absence of competition, in defining fair wages and reasonable terms, and I asked the eminent Professor who introduced the subject in what direction one should look for a solution of this difficulty. His reply imported, as I understood, that no other general rule can be given but this: to obtain a full knowledge of, and bring a candid judgment to bear on, all the circumstances relevant to each case. To which I would add that one circumstance relevant to this whole class of cases is just the fact that there is in the abstract such a marked difference between combination and competition.

Possibly the dry light of abstract science may enable us to see a little further into this difficulty. Analysis strongly suggests that the right solution is what may be called the utilitarian arrangement, that which is productive of the greatest sum total of advantage for all concerned. The utilitarian determination is clearly discerned to be by no means necessarily coincident with the settlement towards which competition tends. For instance, the *vrai prix*, in Condillac's sense, as determined by the play of supply and demand in the labour market, might be such that the *entrepreneur* class should take the lion's share, leaving the labourer a bare and painful subsistence; but there is no ground to believe that this is the best possible arrangement. From an abstract point of view it is by no means evident that a free labour market "is the only way to equity, that any interference with it must involve injustice" (Danson). Nor need it appear "a great fundamental principle—as inevitable in its action as gravitation—that a fair day's wages for a fair day's labour is determined by the proportion which the supply in the market bears to the demand" (Rupert Kettle on "Arbitration"). It may be true indeed, in a practical sense, that perfect competition is "not less harmonious and beneficent in its operation than gravity" (Walker, "Political Economy"); but theoretically it is tenable that there is an adjustment of contracts more beneficent than that which the mechanical play of competition tends to establish (*l*).

To introduce these philosophical conceptions of utilitarianism will doubtless seem irrelevant to those who are immersed in the details of business. But the practical man should be reminded that in other spheres of action, politics and morals, the principle of utility, however badly received at first, has exercised a great influence—though doubtless not so great as was anticipated by some theorists, and requiring to be largely tempered with common-sense.

Such, I think, are the principal points at which mathematical reasoning is capable of being applied to political economy. In estimating the use of this method it is natural to take as our standard the helpfulness of mathematics in other departments of science.

As compared with mathematical physics, the mathematical theory of political economy shows many deficiencies. First, there is the want of numerical data, which has been already noticed. It is true that there is a faint hope of obtaining what Jevons too confidently expected—statistical data for the relations between supply and price. It is true also that in the higher mathematics conclusions which are quantitative without being numerical are more frequent than is usually supposed. Some political economy is as exact as some mathematical physics. The fields cultivated by Section A and Section F may overlap, but it must be admitted that the best part of our domain corresponds to what is the worst part of theirs. If you inquire as to the products of our inferior soils, we must confess, if we do not wish to conceal the nakedness of the land, that over a large portion of our territory no crop is produced. We are employed only in rooting out the tares which an enemy has planted. Much of our reasoning is directed to the refutation of fallacies, and a great part of our science only raises us to the zero point of nescience from the negative position of error. "*Sapientia prima stultitiâ caruisse.*" In this introductory portion of political economy we have seen that the mathematical method is likely to be serviceable (see above, p. 498).

It is not to be supposed, however, that the work of our Section is wholly destructive; that like the islanders of whom it was said that they earned a precarious livelihood by washing one another's clothes, so we are occupied only in mangling each other's theories. Like imprudent sectaries, by our mutual recriminations we have obscured the virtues common to our profession. What Jevons said of Cairnes, that his own opinions were much more valuable than his objections against other people's opinions, is true of Jevons himself and other controversial economists. Now, this possibility of mutual misunderstanding by persons who are both in the right is connected with a circumstance which it is not irrelevant here to notice. It is that in our subject, unlike physics, it is often not clear what is the prime factor, what elements may be omitted in a first approximation. One writer on rent may emphasize distance from the centres of population as the main attribute, and introduce fertility of soil as a perturbation of the abstract result given by the first view. Another fixes attention on the powers of the soil, and allows for other elements, as for friction. So in the theory of money, the state of credit or the quantity of metal have each been regarded as the prime variable.[1] It need not be pointed out how unfavourable to exact science is such a state of the subject-matter. Imagine an astronomer hesitating whether in the determination of Jupiter's movements the sun or the planet Saturn played the most important part. That is the condition of many of our speculations.

It will not be expected that from such materials any very elaborate piece of reasoning can be constructed. Accordingly another point of contrast with mathematical physics is the brevity of our calculations. The whole difficulty is in the statement of our problems. The purely computative part of the work is inconsiderable. Scarcely has the powerful engine of symbolic language been applied when the train of reasoning comes to a stop. The case is like that of the swell in *Punch*, who, about to enter a hansom, inquires solicitously of the driver whether he has got a good horse. "Yes, sir; very good 'oss." "Aw—then dwive to next door." However, our road, though short, is so slippery as to require every precaution.

It follows that in economics, unlike physics, the use of symbols may perhaps be dispensed with by native intelligence. It must be admitted that the correct theory of value has been rediscovered by Menger, and restated by his follower, Böhm-Bawerk, without the explicit use of mathematics. Without the law, they have done by nature the things contained under the law. Still, under a higher dispensation, they might have attained greater perfection. Nor can equal accuracy be ascribed to all the followers of Menger. Nor is the terseness which comes of mathematical study a characteristic of this Austrian school (*m*).

Another point of contrast between the mathematical science of the physicist and the economist is that the former appeals to a larger public. Mathematics is as it were the universal language of the physical sciences. It is for physicists what Latin used to be for scholars; but it is unfortunately Greek to many economists. Hence the writer who wishes to be widely read—who does not say, with the French author, "*J'imprime pour moi*"—will do well not to multiply mathematical technicalities beyond the indispensable minimum, which we have seen reason to suppose is not very large. The parsimony of symbols, which is often an elegance in the physicist, is a necessity for the economist. Indeed, it is tenable that our mathematical constructions should be treated as a sort of scaffolding, to be removed when the edifice of science is completed. As Prof. Marshall, one of the highest authorities on this subject, says: "When a man has cleared up his mind about a difficult economic question by mathematical reasoning, he generally finds it best to throw aside his mathematics and express what he has to say in language that is understanded of the people" (*Academy*, June 1881). Upon this view mathematical discipline might be compared to grammar or to the study of classical literature, which it is profitable to have learnt thoroughly, while it is pedantic to obtrude one's learning.

From these considerations it may appear that our little branch of science is of quite a rudimentary form. The solid structure and regular ramifications of the more developed mathematical sciences are wanting. A less unfavourable contrast would be presented if we compared our method, not with applied mathematics generally, but with that particular branch of it which comes nearest to ours in its proximity to human interests—the use of the calculus of probabilities in social statistics.

There is really only one theorem in the higher part of the calculus, but it is a very difficult one, the theory of errors, or deviation from averages. The direct applications of this theory to human affairs are not very considerable. Perhaps the most conspicuous example is afforded by an investigation to which, if I had undertaken to review the work done in our subjects during the past year, I ought to have directed particular attention—Mr. Galton's rigid proof of the fact and amount of *regression*, or reversion, in children compared with parents, and other relationships.

But, beyond the isolated instances in which the theory of deviations is applied in social statistics with the same strictness and cogency as in physics, there is a wide zone of cases in which the abstract theory is of use as giving us some idea of the value to be attached to statistical results. Mr. Galton justly complains of the statisticians who "limit their inquiries to averages, and do not revel in the more comprehensive views" of the deviations from averages. "Their souls seem as dull to the charm of variety as that of the native of one of our flat English counties, whose retrospect of Switzerland was that, if its mountains could be thrown into its lakes, two nuisances would be got rid of at once." But great caution is required in transferring the theory of errors to human affairs; and the calculus of probabilities may easily be made, in Mill's phrase, the "opprobrium of mathematics."

Now, in all these respects there is a considerable resemblance between the higher parts of the two branches of science which are cultivated in this Section. It may be said that in pure economics there is only one fundamental theorem, but that is a very difficult one: the theory of bargain in a wide sense. The direct application of mathematical reasoning is, as we have seen, limited—more limited, I think, than the corresponding function of the higher statistics. But, on the other hand, the regulative effect, the educational influence, of studies like those of Cournot and Jevons are probably very extensive.

How extensive, it would be difficult to decide without defining the limits of a province within which our special subject is included—the use of abstract reasoning in political economy. Now, on this vexed question, and with reference to the heated controversy between the historical and the deductive schools, the mathematical economist as such is not committed to any side. It may be dangerous to take wide general views; it may be better to creep from one particular to another rather than ascend to speculative heights. Our only question here is whether, if that ascent is to be made, it is better to proceed by the steep but solid steps of mathematical reasoning, or to beguile the severity of the ascent by the zigzag windings of the flowery path of literature. It is tenable that the former course is safest, as not allowing us to forget at what a dangerous height of abstraction we proceed. As Prof. Foxwell has well said,[1] with reference to the mathematical methods in the hands of Jevons and Prof. Marshall, "It has made it impossible for the educated economist to mistake the limits of theory and practice, or to repeat the confusions which brought the study into discredit and almost arrested its growth."

I trust that I have succeeded in distinguishing the question what is the worth of abstract reasoning in political economy from the much more easily answered question whether, if it is worth doing, it is worth doing well.[2] The mathematical economist is concerned to separate his method from that mathematical and metaphysical reasoning which Burke repudiates as inapplicable to human affairs; from that abstract method which he has in view when he says:—"Nothing can be more hard than the heart of a thoroughbred metaphysician. It comes nearer to the cold malignity of a wicked spirit than to the frailty and passion of a man" ("Letters on a Regicide Peace"). Burke is referring to the Jacobin philosophers; but our withers are unwrung, if similar words should be applied to some of the "sophisters and economists" of a later generation. Just as a political party, if

[1] Compare Cournot: "Ce que l'un néglige dans une première approximation comme un fait secondaire et accessoire, un autre le regardera comme le fait principal et dominant" ("Principes," book iv. chap. vii.).

[1] In his important letter on "The Economic Movement in England" in the *Quarterly Journal of Economics* for October 1888.

[2] Cf. Prof. Foxwell. *loc. cit.*:—'What the new school protest against is first the unscientific and meagre way in which deduction was used. In their view, though it is worth while to study, and therefore worth while to study accurately, the workings of private interest under a system of competition, yet human nature is not all self-interest. . . ."

popularly suspected of complicity with crime, would do well to take every opportunity of clearing themselves from that imputation, so the mathematical economist is called on to disown emphatically all sympathy with the flagrant abuses to which the injudicious use of abstract reasoning is undoubtedly liable.

To continue the comparison which I was instituting between the mathematical theory of economics and the calculus of probabilities, they have one very unpleasant property in common—a liability to slips. As De Morgan says,[1] "Everybody makes errors in probabilities at times, and big ones." He goes on to mention a mistake committed by both Laplace and Poisson, the ineptitude of which he can only parallel by the reasoning of a little girl whom he had called a "daughter of Eve"; to which she retorted, "Then you must be a daughter of Adam." It is not to be concealed that economic reasoning, even in its severest form, is sometimes equally inconsequent. I should have hesitated to assert that Cournot has made some serious mistakes in mathematics applied to political economy, but that the authority of the eminent mathematician Bertrand[2] may be cited in support of that assertion.

Again, the more abstract theories of value and of probabilities seem to resemble each other in their distance from the beaten curriculum. Each forms, as it were, a little isolated field on the rarely crossed frontier and almost inaccessible watershed between the moral and the physical sciences.

The same character of remoteness belongs perhaps to another province, which is also comparable with ours—the mathematical side of formal logic, the symbolic laws of thought which Boole formulated. There was a certain congruity between Jevons's interest in his logical machine and in what he called the "mechanics of industry." But I venture to regard the latter pursuit as much more liberal and useful than any species of syllogism-grinding.

If you accept these parallels, you will perhaps come to the conclusion that the mathematical theory of political economy is a study much more important than many of the curious refinements which have occupied the ingenuity of scientific men; that as compared with a great part of logic and metaphysics it has an intimate relation to life and practice; that, as a means of discovering truth and an educational discipline, it is on a level with the more theoretical part of statistics; while it falls far short of mixed mathematics in general in respect of that sort of pre-established harmony between the subject-matter and the reasoning which makes mathematical physics the most perfect type of applied science.

But we must remember—and the mention of the theory of probabilities may remind us—that any such judgment is liable to considerable error. We cannot hope to measure the utility of a study with precision, but rather to indicate the estimate on either side of which competent judges would diverge—a central point, which will be found, if I mistake not, equally removed from the position of Gossen, who compares the new science to astronomy, and the attitude of Dr. Ingram towards the researches which he regards as nothing more than "academic playthings, and which involve the very real evil of restoring the metaphysical entities previously discarded."[3]

One more general caution is suggested by another of the technical terms which we have employed. What we are concerned to discover is not so much whether mathematical reasoning is useful, but what is its "final utility" as compared with other means of research. It is likely that a certain amount of mathematical discipline—say as much as Mr. Wicksteed imparts in his excellent "Alphabet of Economic Science"—is a more valuable acquisition to a mind already stored with facts than the addition of a little more historical knowledge.

But, in reverting to the subject of final utility, I am reminded that Presidential addresses, like other things, are subject to this law; and that a discourse on method prolonged beyond the patience of the hearers is apt to become what Jevons called a *discommodity*.

[1] Writing to Rowan Hamilton ("Life of Hamilton," by R. Graves, vol. iii.).

[2] *Journal des Savants*, 1883. I hope to show on some future occasion that M. Bertrand's censures of Cournot and Prof. Walras are far too severe.

NOTES.

(*a*) SIMPLE EXCHANGE.—The simplest case of exchange is where there are two large groups of uncombined individuals dealing respectively in two commodities, *e.g.* corn and money. To represent the play of demand and supply, let any abscissa, Ox in Fig. 1, represent a certain price, and let the quantity of commodity demanded at that price be xp. The locus of p may be called the demand-curve. Similarly, xq represents the quantity offered at any price, Ox; and the locus of q is called the supply-curve. The price Oa, at which the demand is just equalled by the supply, is determined by the intersection of these curves. This is Cournot's construction. The converse construction, in which the abscissa stands for quantity of commodity, the ordinate for price, is employed by Mr. Wicksteed in his excellent "Alphabet of Economic Science."

The diagrammatic representation which most closely corresponds to Jevons's formulæ is that which the present writer, after Prof. Marshall, and Messrs. Auspitz and Lieben, independently, has adopted. In this construction the two coordinates respectively and symmetrically represent the quantities

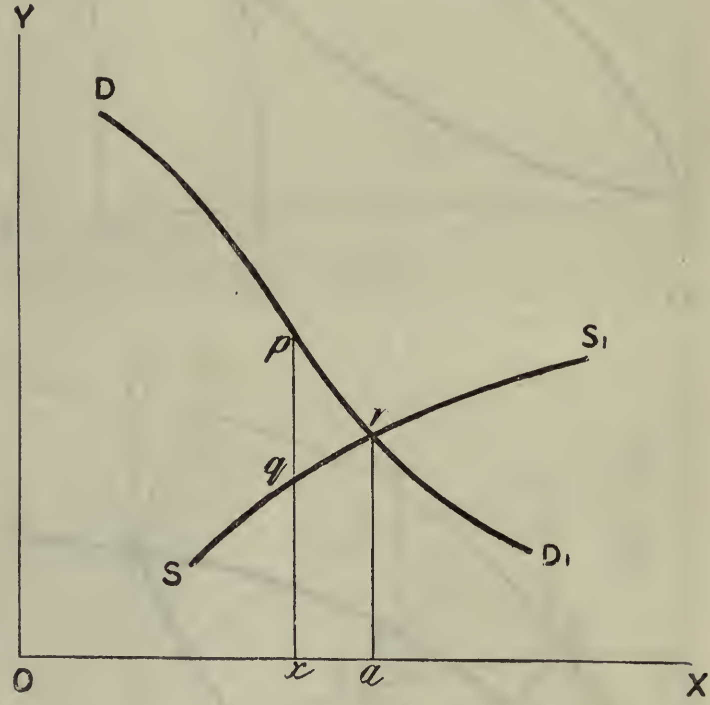

FIG. 1.

of the two commodities exchanged, the *quid* and the *pro quo*. For instance, Fig. 2 may represent the state of supply and demand in the international market between Germany and England. The curve OE denotes that in exchange for any amount of "linen," Oy, England is prepared to supply the quantity of "cloth" yp (= Ox); or, in other words, that in exchange for the quantity Ox of cloth England demands xp (= Oy) of linen. The curve OG is similarly related to Germany's supply and demand. The position of equilibrium is determined by the intersection of these curves.

(*b*) VARIATIONS IN SUPPLY.—Suppose, as Mill supposes ("Pol. Econ.," book iii. ch. xviii. § 5), that there has occurred an improvement in the art of producing Germany's export, linen. The altered conditions of supply may be represented by the displaced curve OG′, Fig. 3, indicating that, whereas before the improvement Germany in exchange for any quantity, Ox, of cloth offered only xq, she now offers xq'. The effect of the improvement on the rate of exchange will depend upon the form of the curve OE beyond the point r. If the intersection of the curve OE is at r; vertically above r, we have the case where, as Mill rather awkwardly says, the demand of England for linen increases "in the same proportion with the cheapness." The other cases in which the demand for linen—and accordingly the price, so to speak, of cloth in linen—are increased more or less than the cheapness, are represented by the points of intersection r_2, r_3.

The same construction may be used to represent the effect on the rate of exchange produced by a tax on exports or imports. Let OG′ now represent the undisturbed condition of supply, and let OG be what this curve becomes when displaced by a tax on Germany's exports. According to the position of the original intersection, whether at r_1, r_2, or r_3, we have the three cases distinguished by Mill (book v. ch. iv. § 6).

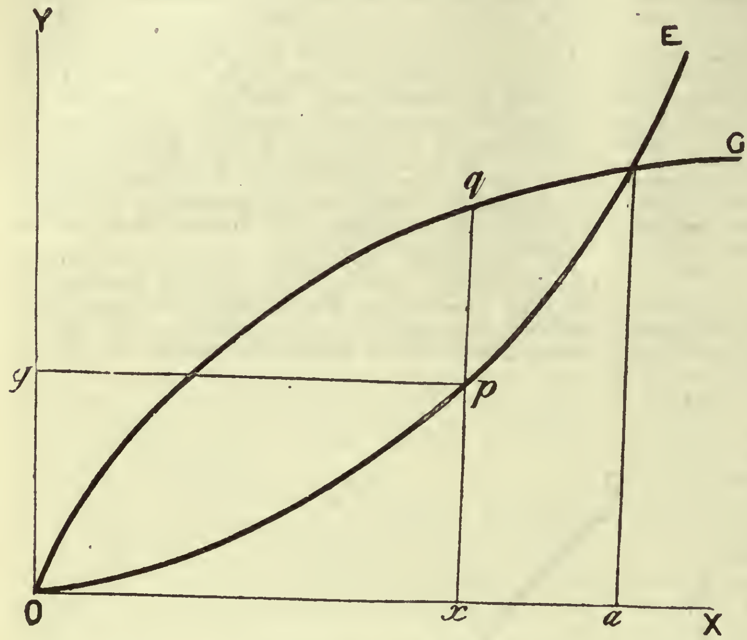

FIG. 2.

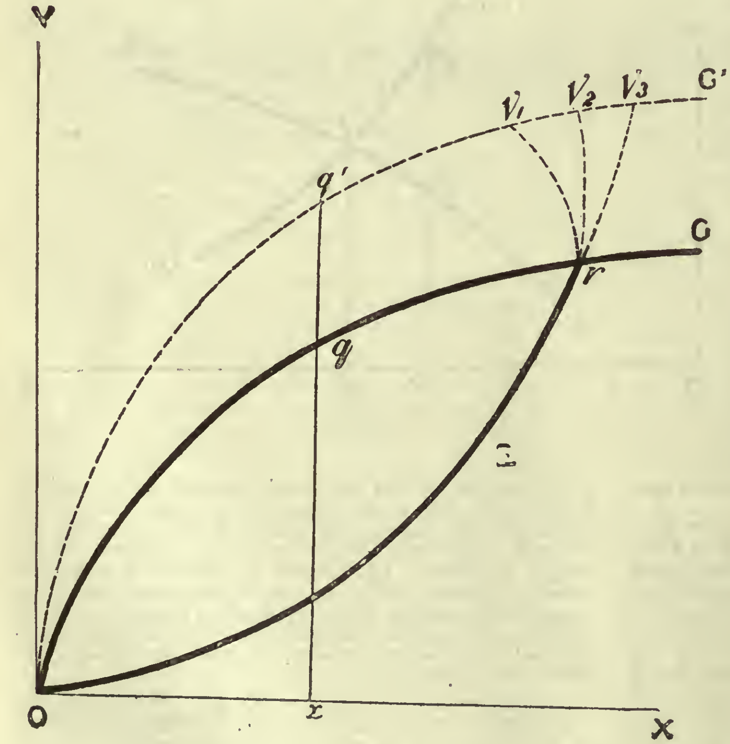

FIG. 3.

Again, the same construction may be used to facilitate the comprehension of international trade which Prof. Sidgwick has recently proposed. Let the curves OE and OG′ represent the conditions of supply and demand, on the hypothesis that cost of transport is annihilated, that England and Germany are in juxtaposition. Now restore the abstracted sea, and the altered conditions of supply and demand *in a market on the English shore* will be represented by the change of OG′ to OG. According to the form of the curve OE the different effects on the rate of exchange are visible at a glance. (Cf. Sidgwick, "Pol. Econ.," book ii. ch. ii. § 3)

(*c*) GAIN OF TRADE.—To measure the variations in the advantage acruing from trade by the variations of price—or more generally, rate of exchange—is a confusion which could hardly have occurred to the mathematical economist. The simplest method of illustrating the gain of trade is that proposed by Messrs. Auspitz and Lieben. In Fig. 4, let On be the *locus* of a point t, such that a certain individual in exchange for the quantity Ox of one commodity will just be willing to give the quantity tx of another commodity, will neither gain nor lose by that bargain. Then, if he obtain Ox in return for only rx, he is a gainer by that bargain to the extent of tr. The curve thus defined is called the *utility-curve*.

Now add properly the utility-curves for all the individuals of a community, and we obtain what may be called a collective utility-curve. There is a peculiar propriety in taking one axis, say the ordinate, to stand for money. Let ON, then, in Fig. 5, be the collective utility-curve, in this sense, for the German community with respect to cloth. Let OG represent the demand of Germany for cloth, as before, except that the ordinate now stands for money, not linen. And let OE represent the supply of cloth in exchange for money on the part of England. Then the gain to Germany of the trade with England is represented by the vertical distance tr.

Now let Germany impose a tax on the import of cloth. The effect of the tax will be to displace the supply-curve in the manner indicated by the dotted curve OE′. Let r' be the new point of intersection between the demand- and (displaced) supply-curve. The gain to Germany in the way of trade is now $t'r'$. To which is to be added the tax r'S accruing to Germany. Since t'S may very well be greater than tr, Germany may gain by the imposition of the tax.

What difficulties the reader may feel about this proposition will disappear on reference to Messrs. Auspitz and Lieben's beautiful and original reasoning ("Theorie der Preise," §§ 80–82). In the light of their constructions it will be at once seen what conditions of supply and demand are favourable to the endeavour of one nation to gain by taxing the imports from (or exports to) another. It will be noticed that the particular supposition entertained by Prof. Sidgwick (book iii. ch. v. § 2)—that the quantity consumed of the taxed import is constant—is not essential.

It may be observed that the *utility-curve* is a particular case of the "*indifference-curve*" employed by the present writer ("Mathematical Psychics," p. 21). Also the lines *tr* and *t'*S are particular cases of the "preference-curve" (*ibid.* p. 22). If these more general conceptions are employed, the demonstration will not require that we should put the ordinate for money, regarded as a constant measure of utility. The interpretation assigned to the curves OG and OE in our second and third figures may still stand.

(*d*) ECONOMIC EQUILIBRIUM.—By analogy with well-known physical principles, economic equilibrium may be regarded as determined by the condition that the advantage of all parties concerned, the integrated utility of the whole economic system, should be a *maximum*. This *maximum* is in general subject, or in technical phrase *relative*, to certain conditions; in particular what Jevons called the "law of indifference," that in a market all portions of a commodity shall be exchanged at the same rate. But occasionally this condition is suspended; as often as we take what may be called a socialistic or utilitarian view as distinguished from that incommensurability of pleasures appertaining to different persons, which Jevons in a remarkable passage of his "Theory" (p. 15) has postulated. It will be found that this postulate must be abandoned when we consider the gain of trade, as in our note (*c*), or the theory of combinations, as in note (*l*), and on other occasions.

In general, the first condition of a maximum, that the first term of variation should vanish, gives the Jevonian equations of exchange, the demand-curves of other writers.

The second condition of a maximum, that the second term of variation should be negative, finds its fulfilment in certain well-known propositions which involve the conception of a decreasing rate of increase, viz. the law of diminishing returns, the law, or laws, of diminishing utility and increasing fatigue.

For some propositions it is proper to take account not only of the sign, but also the magnitude, of the second differential of utility. Thus, when Prof. Walker is contending that in case of "any increase of product resulting from the introduction of any new force into industry," the whole increment will fall to be added to the share of the working class, he argues, quite correctly upon his premises, that if the improvement does not "increase the amount of tools and supplies required in production"—since "there is no greater demand for capital in the case supposed— . . . there can be no increase in the rate or amount of interest" (*Quarterly Journal of Economics*, 1887, pp. 283, 284). Analytically we should find that the variation in the rate of interest due to the disturbance of the equilibrium, say $\Delta\iota$, was indefinitely small as compared with the variation in the rate of wages, say $\Delta\omega$, because the decrease in the rate at which the utility of capital increases is indefinitely great. The argument requires that this second differential should be infinite at the position of equilibrium—a postulate which may perhaps give us pause.

(*e*) COMPLEX EXCHANGE is the general case of simplex exchange above analyzed. We have now several, instead of two, categories of dealers and commodities. In both cases equilibrium is determined upon the principle that each individual seeks to maximize his own advantage, subject to the conditions (1) that in a market there is only one price for any article, and (2) that all which is bought is sold, and all which is sold is bought. Let there be *m* dealers and *n* articles. And the first article being taken as the measure of value, let the prices of the remaining articles be $p_2, p_3, \ldots p_n$. Let the quantities of commodities bought or sold by any individual, say No. *r*, be $x_{r1}, x_{r2}, \ldots x_{rn}$; each variable with its sign: *plus*, if bought, *minus*, if sold. Let the advantage of the individual, regarded as a function of his purchases and sales, be $\psi_r(x_{r1}, x_{r2} \ldots x_{rn})$. There is sought the system of values assigned to the variables for which this function is a maximum, subject (α) to the condition which follows from

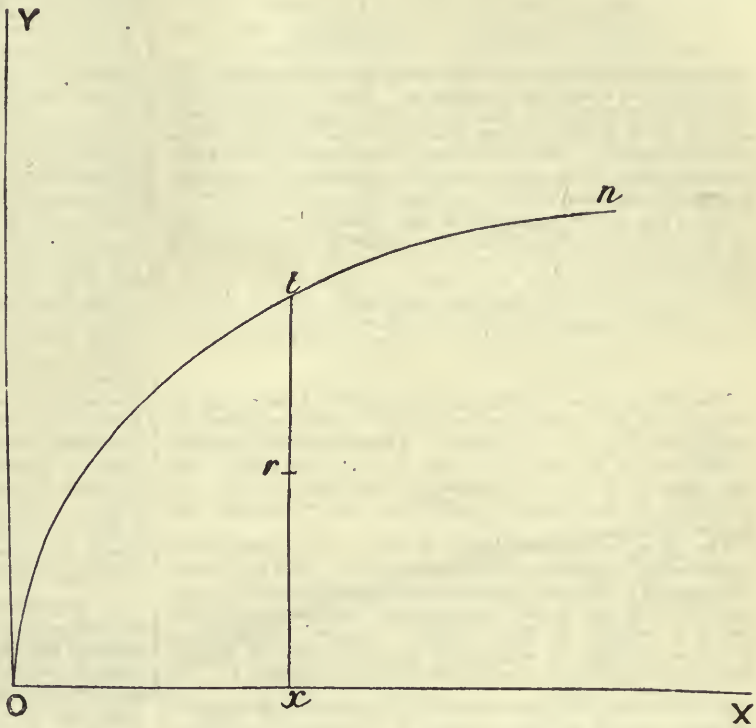

FIG. 4.

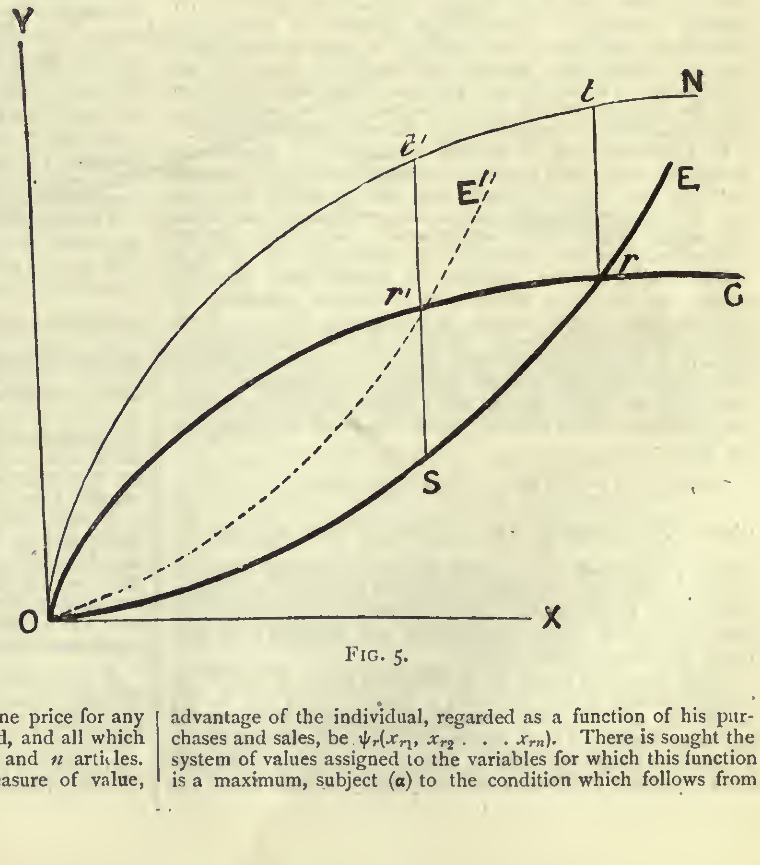

FIG. 5.

the first assumption above made: $x_{r1} + p_2x_{r2} + \&c. + p_nx_{rn} = 0$. In order to determine the maximum of ψ_r subject to this condition, we obtain (β) by the calculus of variations $(n - 1)$ equations of the form—

$$\left(\frac{d\psi_r}{dx_{r1}}\right)=\frac{1}{p_2}\left(\frac{d\psi_r}{dx_{r2}}\right)= \ldots = \frac{1}{p^n}\left(\frac{d\psi_r}{dx_{rn}}\right)$$

(with certain conditions as to the second term of variation). To which is to be added the equation (α). We have thus n equations relating to the rth individual. The same being true of each of the m individuals, we have in all mn equations of the forms (α) and (β). We have also (γ), from the condition that everything which is bought is sold, and conversely, n equations of the following form: $x_{1s} + x_{2s} + \&c. + x_m = 0$.

But of the $(m + n)$ equations of the forms (α) and (γ) only $(m + n - 1)$ are independent. For adding the m equations of the form (α) we have:—

$$\left.\begin{array}{l}(x_{11} + x_{21} + \ldots + x_{m1}) \\ + p_2(x_{12} + x_{22} + \ldots + x_{m2}) \\ + \quad — \quad — \quad — \quad — \\ + p_n(x_{1n} + x_{2n} + \ldots + x_{mn})\end{array}\right\} = 0.$$

Now, if any $(n - 1)$ of the equations of the form γ, say all but the first, are given, then in the last written equation the coefficients of $p_2 \ldots p_n$ vanish. Therefore the first equation of the form (γ), viz. $x_{11} + x_{21} + \&c. + x_{m1}$, is also given. We have thus $mn + (n - 1)$ equations to determine $mn + (n - 1)$ quantities, viz. the x variables, which are mn in number, and the $(n - 1)$ p's.

The great lesson to be learnt is this. The equations are *simultaneous*, and their solutions *determinate*. That the factors of economic equilibrium are simultaneously determined is a conception which few of the literary school have received. The reader is referred to Prof. Walras's "Leçon" 12 ("Econ. Pol.," second ed.) for a lengthier exposition, and for a more accurate one to Messrs. Auspitz and Lieben's Appendix IV.

(*f*) COMMERCIAL COMPETITION.—Abstracting that change of occupations which Cairnes ascribed to "industrial" as distinguished from "commercial" competition (comp. Sidgwick's "Pol. Econ.," book ii. ch. i.), let us suppose that the x's of the last note, which primarily denoted commodities ready for immediate consumption, include also agencies of production: (the use of) land, labour, and capital. We may conceive *entrepreneurs* buying these agencies from landlords, labourers, and capitalists, and selling finished products to the public. We have thus the appropriate idea of rent, wages, interest, and (normal) prices determined *simultaneously* (in the mathematical sense).

In a primary view of complex exchange it is proper, with Jevons, to regard each portion of commodity sold, each negative variable, say $-x_{rs}$, as a deduction from an initial store, say ξ_{rs}. But when we consider production, we regard ξ as a function of the outlay of the *entrepreneur*. Supposing that the *entrepreneur* confines himself to the production of a single article, let the gross produce, in money, after replacing capital, be $f_r(c_r, l_r)$, where f_r is a function depending on the individual's skill, energy, opportunities, &c., c_r is the amount of capital borrowed by him, and l_r the number of acres of a certain quality which he rents. The net produce is obtained by deducting from this quantity the payments $c_r\iota - l_r\rho$, where ι is the rate of interest and ρ is the rent per acre. Thus the advantage which the *entrepreneur* seeks to maximize is of the form—

$$\psi_r(x_{r1}, x_{r2} \ldots [f_r(c_r, l_r) - c_r\iota - l_r\rho] - x_{rr}p_{rr}, \ldots).$$

whence $\frac{df_r}{dc_r} = \iota$ and $\frac{df_r}{dl_r} = \rho$. The first of these equations expresses a well-known proposition regarding the final utility of capital. The second equation expresses a less familiar condition with respect to the number of acres which will be rented on an ideal supposition of the homogeneity and divisibility of land above the margin of cultivation.

What, then, and where, is the Ricardian theory of rent? Its symbolic statement is $l_r\rho = f(c_r, l_r) - f(c_r, o) = f_r(c_r, l_r) - c_r \times \iota$; where $f(c_r, o)$ is the gross produce of c_r capital laid out by the individual numbered r, on land below the margin obtainable for nothing in as large quantities as desired. It will be found that these equations postulate that the quantity of land above the margin is small as compared with the number of applicants, and that $f(c_r, o)$ is identical with $c_r \times \iota$, which are the common Ricardian assumptions. The validity of these assumptions as a first approximation, the need of correction where greater accuracy is required (truths which some minds seem incapable of holding together), have been admirably pointed out by Mr. Sidgwick ("Pol. Econ.," book ii. ch. vii. § 2). The second approximations made by him may be usefully expressed in the symbols which have been proposed, or rather in those which the student may construct for himself. I do not put forward those which occur to me as the best—if, indeed, there is any absolutely best in the matter of expression. For some purposes it would have been proper to take account of the various qualities of land (as I have elsewhere done—"Brit. Assoc. Rep.," 1886). For other purposes it would be well to put labour hired by the *entrepreneur* as an independent variable. When this or any other variable is omitted, we are to understand that there is implied the best possible arrangements with respect to the variables which are not expressed. The nature of this implication is shown in the following note.

(*g*) So far we have been taking for granted that the *entrepreneur* does his best, without reference to the motives acting upon him, the pleasures procurable by the sale of his product. Formally it would be proper to take account that the utility-function ψ_r involves the *effort*, say e_r, explicitly, as fatigue diminishes advantage, and implicitly, as exertion increases production. Corresponding to the new variable we have a new equation, the complete differential of ψ_r with reference to e_r, say $\left(\frac{d\psi_r}{de_r}\right) + \left(\frac{d\psi_r}{df_r}\right)\frac{df_r}{de_r} = 0$. It is a nice question how far effort should be regarded as an independent variable; how far the essential principle of piece-work prevails in modern industry.

(*h*) INDUSTRIAL COMPETITION.—The condition that net advantages should be equal in industries between which there is mobility may thus be contemplated. Let us put the advantage of an individual, say No. r, engaged in the occupation s as a function of his net income, the price of the articles in which his expenditure is made, and the disutility of effort. Say $\phi_{rs}(\mathfrak{f}_{rs}(\pi_1, \pi_2 \ldots e_{rs}), p_1, p_2 \ldots - e_{rs})$; where ϕ_{rs} is a utility-function, not necessarily the same for the same individual in different occupations, since his indulgences may vary with the nature of his employment; $\mathfrak{f}_{rs}$—a symbol not identical with the f of the last but one note—is the individual's net earnings in the business s, involving prices π_1, π_2, &c., of all manner of agents of production, involving also, as stated in note (*g*), the effort e_{rs}; p_1, p_2, &c., are prices of articles of consumption as a function of which the individual's advantage may be obtained by means of the equations (α) and (β) in note (*e*)—eliminating the quantities consumed. The last variable in the function ϕ_{rs}, the explicit e_{rs}, has a negative sign prefixed, to indicate that the direct effect of increased fatigue is diminished advantage.

The equation of net advantages imports that the advantage, ϕ_{rr}, of the occupation which the individual chooses is not less than ϕ_{rs}, the advantage of any other occupation open to him. It is important to observe that for all occupations the complete differential with regard to e is zero; in symbols $\left(\frac{d\phi}{d\mathfrak{f}}\right)\frac{d\mathfrak{f}}{de} + \left(\frac{d\phi}{de}\right) = 0$.

But this equation conveys no presumption that the final disutility in different occupations is the same that $\left(\frac{d\phi_{rs}}{de_{rs}}\right) = \left(\frac{d\phi_{rt}}{de_{rt}}\right)$.

The equation of final disutility holds only where efforts and sacrifices are capable of being applied in "doses" to any number of occupations. The latter is the only case, I think, contemplated by Jevons in his analysis of cost of production ("Theory," ch. v.). The inquiry, what is meant in general by saying that the cost of production of two articles is equal, must start from right conceptions about final and total utility. But this is not the place to follow up the difficult investigation. I do not attempt here to discuss any matter fully, but only to illustrate the suitability of the subtle language of mathematics to economical discussions.

(*i*) PROF. WALKER'S THEORY OF BUSINESS PROFITS.—Prof. Walker's theory as stated in the *Quarterly Journal of Economics* for April 1887, involves the proposition that the remuneration of the lowest, the least gifted employers, is on a level with that of the labouring class. Concerned as we are here with methods rather than results, it is allowable to posit this premise without expressing an opinion as to its accuracy. It is fortunate not to have to take sides on an issue concerning which the highest authorities are divided, and statistical demonstration is hardly possible.

But, though the expositor of method is not called to dispute the truth of this proposition, he has something to say against the evidence which has been adduced in proof of it. He must enter a protest against the form of the following argument :—

"Let our hypothesis be clearly understood. We assume, first, that there is in a given community a number of employers, more or fewer, who alone are, by law or by custom, permitted to do the business of that community, . . . or else who are so exceptionally gifted and endowed by Nature for performing this industrial function that no one not of that class would aspire thereto, or would be conceded any credit or patronage should he so aspire. Secondly, we assume that neither in point of ability nor opportunity has any one member of this class an advantage as against another, . . . all being, we might say, the exact copies of the type taken, whether that should involve a very high or a comparatively low order of industrial power.

"Now, in the case assumed, what would be true of business profits, the remuneration of the employing class? I answer, that if the members of this class were few, they might conceivably effect a combination among themselves, and . . . fix a standard for their own remuneration. . . . If, however, the community were a large one, and if the business class . . . were numerous, such a combination . . . would be impracticable, . . . the members of the business class would begin to compete with each other. From the moment competition set in it would find no natural stopping-place until it had reduced profits to that minimum which, for the purposes of the present discussion, we call *nil*.

"What, in the case supposed, would be the minimum of profits? I answer: This would depend upon an element not yet introduced into our problem. The ultimate minimum would be the amount of profits necessary to keep alive a sufficient number of the employing class to transact the business of the community. Whether, however, competition would force profits down to this low point would depend on the ability or inability of the employing class to escape into the labouring class. We have supposed that labourers could not become employers; but it does not follow that employers might not become labourers and earn the wages of labourers. . . ." (*Quarterly Journal of Economics*, 1887, p. 270 and context).

This reasoning will puzzle those who have received the abstract theory of supply and demand as formulated by the mathematical section [above, notes (*a*) and (*d*)]. Because the dealers on one side of a market, as the employers in the labour market, compete against each other without combination, it does not follow that the advantage which they obtain from their bargains is *nil*. The minimum to which the play of competition tends is not necessarily small in the sense of a bare subsistence. It is a minimum only in the mathematical sense in which every position of equilibrium is a minimum (of potential energy in physics; in psychics, may we say, of potential utility). See note (*d*).

Representing the *entrepreneur's* demand for work by the curve OG (Fig. 5), where the abscissa measures work done, and the ordinate money payable out of the wages and profit fund, and putting OE for the offer of the workmen, we see that the point *r* may differ to any extent from the utility-curve ON, which indicates the advantage of a transaction [see note (*d*)]. As far as abstract theory, without specific data, carries us, the competing *entrepreneurs* may make very good bargains. They may be ever so prosperous; they may be, in Burke's fine phrase, "gambolling in an ocean of superfluity."

So far, on the hypothesis that neither in point of ability nor opportunity has any one member of this class an advantage as against another. The heterogeneity of faculty will, of course, introduce a graduation of gain. But in this flight of steps it is not necessary that the lowest should be on a level with the grade of common labour. The scale of profits may be a sort of Jacob's ladder, culminating in a paradise of luxury, and having its lowest rung suspended high above the plain of ordinary wages.

Let us suppose, however, that the writer has tacitly made some assumption as to the numbers of the "numerous" business class relatively to the "large" community (compare the parallel passages in his "Political Economy," Arts.). Still, what does the consideration of business profits as rent do more than the received principle of supply and demand? If the workmen, believing that in the distribution regulated by competition too much has been assigned to brain and too little to muscle, determine to reduce profits by means of a combination, should they stay their hand because they are told that profits (above the lowest grade) are of the nature of rent? The terms "rent" and "margin" may indeed suggest that the extra profits of the abler *entrepreneurs* exactly correspond to their greater ability. It might seem that if, so to speak, we pushed down all the higher faculties to the level of the lowest grade of business power, the diminution of

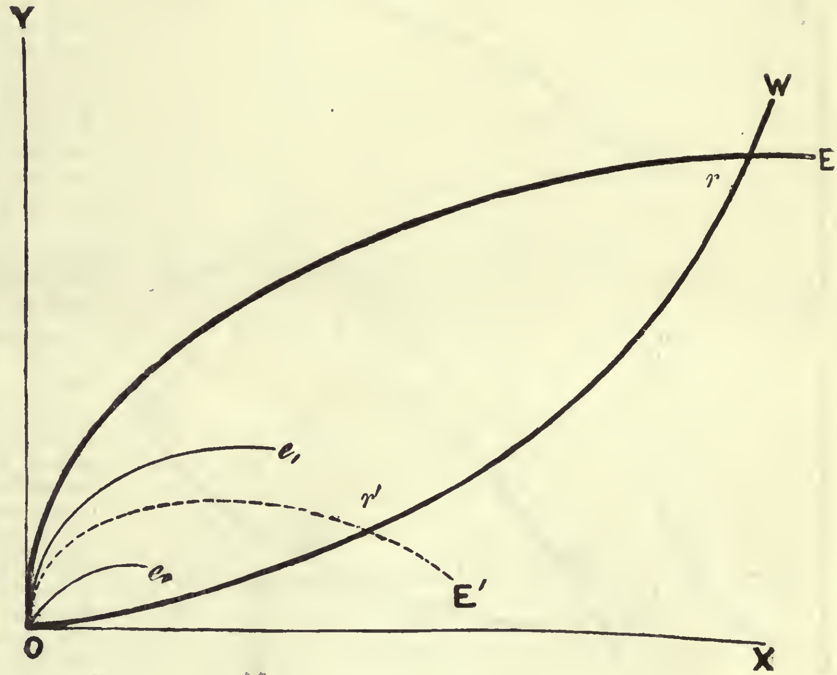

Fig. 6.

the total distributed to the wages and profits fund would exactly correspond to the subtraction from the earnings of the degraded *entrepreneurs*, while everything else remained constant. Conversely, it might be argued that the increment of produce due to the existence of superior ability may justly be assigned as extra profit.

But how little appropriate is this precise conception will at once appear from the annexed diagram. Let OE in Fig. 6 represent the *entrepreneur's* demand, OW the workmen's offer of labour, the abscissa representing work done, and the ordinate wages payable out of the wages and profits funds (abstraction being made of interest and rent for land). Let OE be formed by the superposition of Oe_0, the demand-curve for the lowest collective *entrepreneurs*, and one or more curves, such as Oe_1, appertaining to the *entrepreneurs* of higher ability. Now let us shrink these higher natures to the zero of business ability. The individual demand-curve for each degraded *entrepreneur* will become identical with that from which Oe_0 was formed (by the combination of all the demand curves for the lowest grade). The new demand-curve will therefore be of the form OE′ intersecting with OW at the point r'. (Whether the disturbance will stop there will depend upon the nature of the communication between the departments of employer and workman; whether the mobility is one-sided, like that of fluid allowed by a valve to escape from one vessel to another, but not back again—see the end of the passage cited on p. 505 from the *Quarterly Journal of Economics*—or whether the permeation is perfect.) If Oe_0 is small, if the part played in production by the marginal employers is insignificant, it is probable that the annihilation of the higher grades will result in the destruction of the greater part not only of profits, but also of wages.

Accordingly it appears, in general, inexact to say that the "surplus which is left in the hands of the higher grades of employers . . . is of their own creation" (*Quarterly Journal of Economics*, April 1887, p. 274); if we define their own creation as the difference between the actual produce and that which would have existed if their superior faculties had not been exercised. In that sense (and what other sense is there?) the surplus of the higher grades is likely to be much *less* than their own creation (especially in the case where the marginal employers are relatively few). We seem to have proved too much. But may we not deduce the *quod est demonstrandum*, that actual profits are deserved, from the larger proposition that the *entrepreneurs'* "own creation" is by a certain amount greater than their profits? No; for that larger proposition is blocked by the antinomy that the workmen (or the higher grades of them may by parity claim the greater part of the produce as *their* "own creation"—what would not have existed but for the exertion of their faculties.

In short, we know no more than we knew at first—viz. that the distribuend is produced jointly by the owners of brain and muscle, that the terms of the distribution are determined by supply and demand, and that in this, as in every other market, each more favoured nature enjoys a *rent*, or differential advantage [the nature of which is well illustrated by Messrs. Auspitz and Lieben's construction indicated in our note (*c*)]. That the surplus earning of the superior *entrepreneur* is his own creation is true of the individual, but not of the class; in division, but not in composition.

However, Prof. Walker may have tacitly made some specific assumptions as to the quantities involved (*e.g.* the proportion of produce with which the marginal *entrepreneurs* are concerned); or I may have misinterpreted his statements. Even so, the liability to such misconstruction is a defect in the purely literary method.

It would be easy in the case of less eminent writers to exemplify the part which the mathematical *organon* may play in lopping the excrescences of verbal dialectics. But I must content myself with briefly adverting to one of Prof. Walker's critics, Mr. Sidney Webb. His able paper on the "Rate of Interest and the Laws of Distribution" appears to me to contain several points deserving of attention; with respect to which mathematical conceptions may assist the reader in distinguishing the original from the familiar, and the true from the misleading.

(1) Mr. Webb restates the theory formulated by Jevons, that capital is ideally distributed according to the law of "equal returns to the last increments" ("Rate of Interest and Laws of Distribution," by S. Webb, pp. 10, 11, 21 of paper reprinted from *Quarterly Journal of Economics*, January 1888).

In symbols [see above, note (*f*), p. 504] let the net earning of any individual be $f_r(c_r) - \iota c_r$; where f_r is a function differing for different individuals according to their faculties and opportunities, c_r is the amount of borrowed capital employed by the individual; ι is the rate of interest; land and labour are not expressed. In equilibrium,

$$\frac{df_r(c_r)}{dc_r} = \iota = \frac{df_s(c_s)}{dc_s} = \frac{df_t(c_t)}{dc_t} = \dots$$

(2) Again, Mr. Webb discerns that the "law of diminishing returns" is applicable to capital as well as to land (*ibid.*, pp. 9, 20, &c.). This is probably a new truth to the literary economist, who will have some difficulty in reconciling it with the *law of increasing returns* received into the text-books. To the mathematician it is evident that, in order to maximize the net earnings $f(c) - \iota c$, not only must the first differential of this expression vanish, but also the second differential, $\frac{d_2 f}{dc^2}$, must be negative, which is the *law of diminishing returns* It is quite consistent with the supposition that for certain values of the variable, not admissible as a solution of the problem, $\frac{df}{dc}$ should be positive, agreeably to the *law of increasing returns*.

Diagrammatically, let us represent the conditions under which capital is applied by a certain individual, according as the scale of production is large or small, by the curves pq and $p'q'$ in Fig. 7; where the abscissa denotes quantity of capital, and the ordinate the increment of (gross) produce due to an increment of capital. There cannot be equilibrium, unless the increment denoted by the ordinate is just balanced by the sacrifice thereby incurred—in the case which I have supposed, the payment of interest. There cannot, then, on this supposition, be stable equilibrium, unless the curve is ascending. The descending (dotted) branches correspond to the law of increasing returns. (The explanation of other features in the figure is given in the next note.)

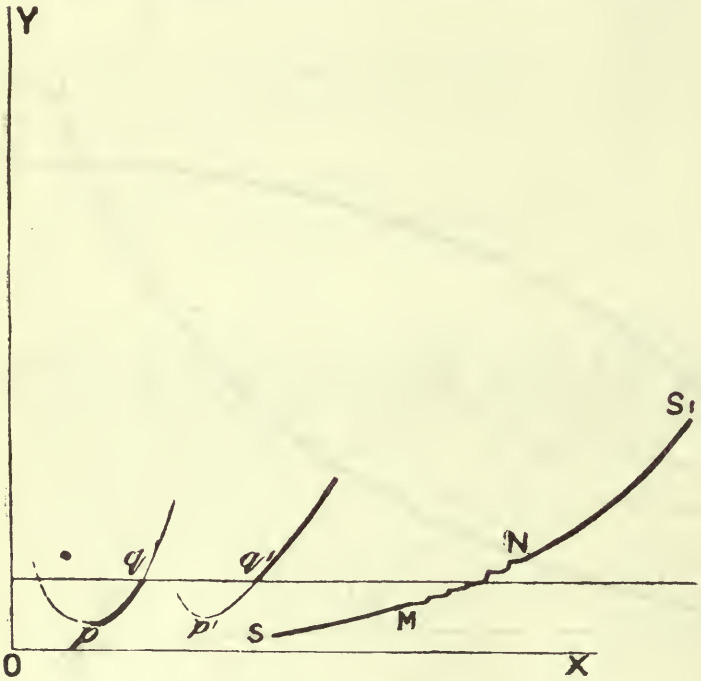

FIG. 7.

(3) Mr. Webb dwells much on "the special industrial advantages not due to superiority of site or skill" which are enjoyed by some individuals. The use of an expression for the product like our f_r may serve at least to keep in mind the existence of such specialities. It also brings into view a difficulty which has not been sufficiently noticed by those who use *rent* in its metaphorical or secondary sense.

Suppose the extra produce is a function involving several variables (or parameters) like land, ability, opportunity. Say, $f_r = F(\lambda, \alpha, \omega \dots)$, where F is a form common to the community, and λ, α, ω denote the quality of land, ability, and opportunity peculiar to the individual. If the extra produce is $F(\lambda, \alpha, \omega) - F(o, o, o)$; is $F(\lambda, o, o) - F(o, o, o)$ the "economic rent" of land; $F(o\ \alpha\ o) - F(o, o, o)$ the rent of ability; $F(o\ o\ \omega) - F(o\ o\ o)$ the extra produce due to opportunity? (*ibid.*, pp. 16, 17). If so, the three parts do not make up the whole.

(4) Anyway, to call the third extra produce *interest* is very unhappy. Its affinities are evidently with rent (cf. Sidgwick, "Pol. Econ.," book ii. ch. vii. § 4).

(5) I should not have complained about the use of a term, but that it is connected with Mr. Webb's main contention against Prof. Walker, to which I am unable to attach significance:

that "this, not the 'rent of ability,' is the real keystone of the arch" (*ib.*, p. 17). From the point of view here taken (above, p. 497) this search for the "keystone" among the factors of distribution is nearly as hopeless as the speculation of the ancients about the real *up* or *down*.

(*j*) DETERMINATENESS OF ECONOMIC EQUILIBRIUM.—To investigate the possibility of there being more than one rate of exchange at which the supply is just carried off by the demand, let us consider the most favourable or, at least, the most familiar case in which there may be two scales of production, and therefore two series of terms on which the producer is willing to deal—two supply-curves. Let the two branches in Fig. 7 represent such a double supply-curve, the ordinate denoting price, and the abscissa the quantity of product which is offered at that price by a certain individual. Now, the essential idea or leading property of an individual supply-curve is that it represents the quantity which the individual will prefer to offer at any given price. Hence the *descending* part of the branches, dotted in the figure, cannot form a genuine supply-curve. For at any point on that part of the *locus* it is evidently the interest of the individual to increase his production, price being constant. Stable equilibrium, therefore, can exist only on the ascending, the unbroken branches. The thick curve lines in the figure indicate the *locus* of *greatest possible*, as distinguished from *maximum*, utility. Suppose that at and above the price, corresponding to the point q, it is the interest of the producer to adopt the larger scale of production. Up to that price his industrial dispositions will be represented by the inner curve; on reaching that point he will jump from q to q' and ascend along the outer curve. The *locus* of greatest possible utility may be called the genuine or effective supply-curve. A similarly shaped supply-curve may exist for other producers. Suppose, now, all these individual effective supply-curves superposed, and we have the effective supply-curve for the community, SS^1, which continually trends outwards. This character is not annulled by the existence of steps in the tract MN, corresponding to the prices at which the leap of each individual occurs. *A fortiori* the demand-curve continually trends outwards like that in Fig. 1 (cp. Auspitz and Lieben). It should seem, therefore, that theoretically on the supposition of enlightened self-interest there is only one rate of exchange at which supply is just equal to demand. No doubt there is something to be said on the other side. Suppose the jump from q to q', or from q' to q, involves a breach of habit, the inconvenience which the "economic man" will not neglect. A little attention will show that in this case the tract MN′ of the collective-curve might break up in two separate branches. Moving from M upwards we should not be on the same *locus* as from N downwards.

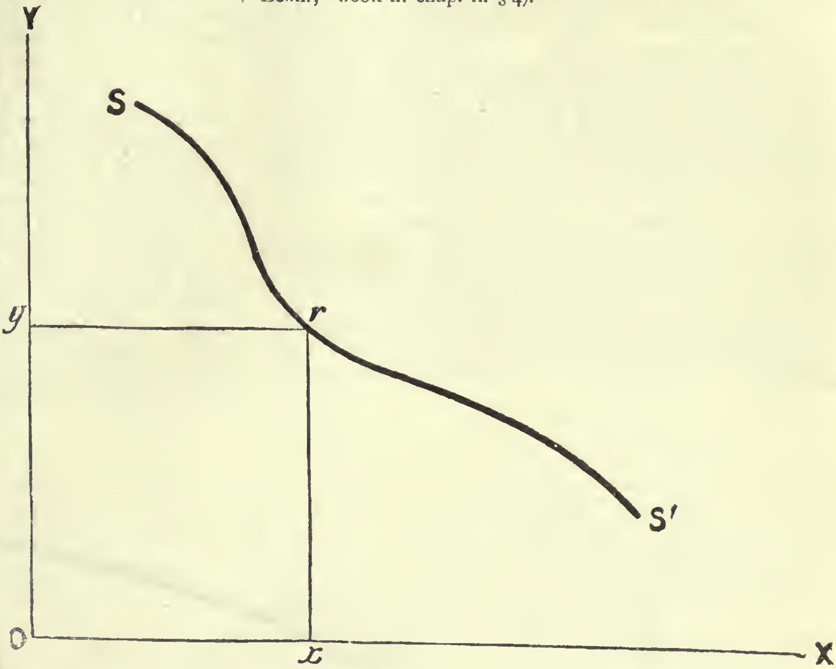

FIG. 8.

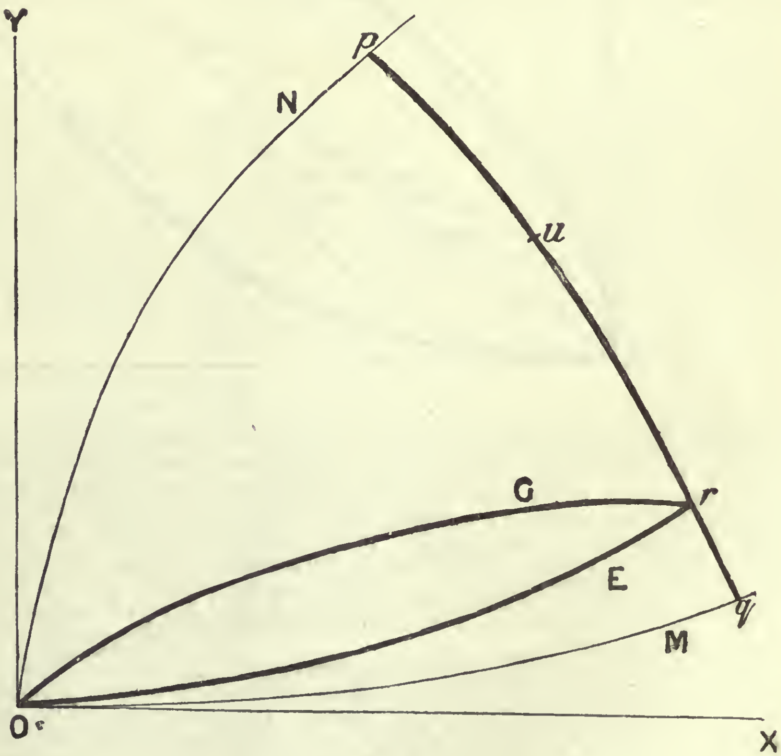

FIG. 9.

(*k*) ONE-SIDED MONOPOLY.—In Fig. 8 let the curve SS′ represent the demand of the public for a monopolized article, the abscissa denoting price, the ordinate quantity. Then, as Cournot shows, it is the interest of the monopolist that the rectangle $Oy_r rx$ should be a *maximum* ("Recherches," Art. 25), or rather the *greatest possible*. The solution is not likely to be indeterminate, except in the particular case where the demand-curve is an equilateral hyperbola (contrast Sidgwick, "Pol. Econ.," book ii. chap. ii. § 4).

(*l*) TWO-SIDED MONOPOLY.—In Fig. 9 let Op and Oq represent the curves of constant satisfaction, or indifference-curves [above, note (*d*); "Theorie der Preise," Appendix II.; "Mathematical Psychics," p. 21] drawn through O for two individuals or combinations respectively. Then the *locus* of bargains which it is not the interest of both parties to disturb is the *contract-curve, pq* ("Math. Psych.," *loc. cit.*). At what point, then, on this curve will the transaction settle down? If we assume that the conditions of a market are retained, the required point is at the intersection of the supply- and demand-curves, which is on the contract-curve. That is the solution of Messrs. Auspitz and Lieben ("Theorie," p. 381). It corresponds to the principle laid down by Prof. Marshall for the action of arbitrators (referred to above in note). But Prof. Menger, who has a numerical scheme equivalent to a rudimentary contract-curve ("Grundsätze," pp. 176–78), and Prof. Böhm-Bawerk, referring to the "*Spielraum*" afforded by the indeterminates of bargain, recommend to "split the difference." Instead of "equal," "*equitable*" division has been proposed by the present writer—namely, that adjustment which produces the maximum of utility to all concerned; not subject to the conditions of a market, but irrespectively thereof [equations (β) and (γ), without equation (α) in note (*e*) above], the utilitarian arrangement, which also is represented by a point in the contract-curve, say *u* in Fig. 9. Such might seem to be the ideally most desirable arrangement; but very likely the practically best, the πρακτόν ἀγαθόν, is in the neighbourhood indicated by Prof. Marshall and Messrs. Auspitz and Lieben.

(*m*) THE AUSTRIAN SCHOOL.—Prof. Menger and his followers have expressed the leading propositions of the economic calculus—the law of diminishing utility, the law of demand and supply, and so forth—by means of particular numerical examples, supplemented with copious verbal explanation. Their success is such as to confirm the opinion that the mathematical method is neither quite indispensable nor wholly useless, *nec nihil nec omnia*, like most scientific appliances. Conceding that in the main they impart a saving knowledge of the true theory of value, it may still be maintained that they occasionally emphasize the accidents of a particular example as if they formed the essence of the general rule; that their explanations are excessively lengthy; and yet their meaning sometimes is obscure. For instance, Prof. Böhm-Bawerk may seem to attach undue importance to his conception of the *Grenzpaar*. He illustrates the play of demand and supply by supposing a market in which on the one hand there are a number of dealers each with a horse to sell, and on the other hand a number of would-be buyers (*Konrad's Jahrbuch*, 1886; "Kapital," p. 211; cp. Mr. James Bonar's excellent article in the *Quarterly Journal of Economics*, 1888). The latter are arranged in the order of their strength: first, the one who is prepared to give most for a horse, the highest price which the second can afford is less, and so on. Parallel to this

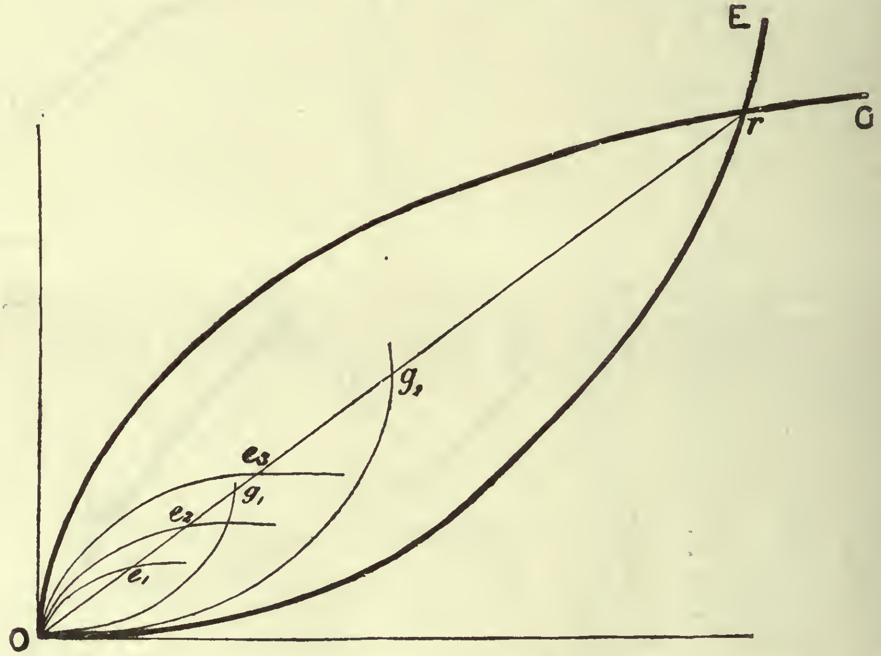

FIG. 10.

arrangement is that of the would-be sellers: first, he who can sell cheapest, and so on. Upon this hypothesis it might happen that the fifth would-be buyer is willing to give a little more than the lowest figure which the fifth would-be seller will take; while the sixth on the side of the buyers is not willing to give quite as much as the sixth horse-dealer stands out for. In this case five horses only will be sold; and the couple who are the last between whom a bargain is possible—buyer No. 5 and seller No. 5—enjoy a mighty distinction as the *Grenzpaar*; an honour which is to some extent shared with No. 6, the first couple between whom a bargain is impossible.

Now this attention to a particular couple is not always appropriate. How if the weakest actual buyer should prove to be, not buyer No. 5 but buyer No. 1, as to a *second* horse? Prof. Böhm-Bawerk, indeed, has thought of this case, and called attention to it in a note to his later redaction ("Kapital," p. 218). So far—although the whole simplicity of the scheme is destroyed when we permit second and third horses to the different buyers and sellers—the conception of a "limiting couple" may still be retained. It will be found, however, that this idea is not appropriate to the general case of a divisible commodity, which a single individual on one side of the market may buy from or sell to a large number on the other side. That general case is much more clearly represented by a diagram like Fig. 10, where the inner thin-lined curves represent the dispositions of the individual dealer, the outer thick curves the collective supply and demand (cp. Auspitz and Lieben, "Theorie der Preise"). No doubt Prof. Böhm-Bawerk's conception is appropriate to a particular case, that in which the *kleinste marktübliche Mengeneinheit*, in the phrase of Messrs. Auspitz and Lieben (*ibid.*, p. 123), is considerable. But it is better, with those eminent theorists, to begin with the general or, at least, the simple case.

As an instance of the excessive circumlocution in which the purely literary method is liable to be entangled, we may notice the doctrine of objective and subjective value, which occupies many pages in the works which we have cited. I have been unable to find more in the distinction than what is visible on a glance at the appropriate diagram. The individual's subjective estimate of worth is expressed by his particular demand- or supply-curve, Oe_1, Oe_2, &c., Og_1, Og_2, &c., in Fig. 10. The proper combination of those individual curves gives the collective demand- and supply-curves, of which the intersection represents the "objective" value.

Moreover, verbal circumlocutions are so little adapted to express mathematical conceptions that we are sometimes left in uncertainty as to our author's meaning. When Prof. Böhm-Bawerk remarks that there is something special in the labour-market, in that the buyer will vary his arrangements according to the price of the article, the rate of interest ("Kapital," p. 407), does he specify the property which Messrs. Auspitz and Lieben have stated as general—that the utility function [our ψ, note (*e*) above] is discontinuous, being different for large and small values of the variable under consideration?

These deficiencies are more conspicuous in other writings of the Austrian school. A glance at Fig. 10, an intuition of the corresponding algebraic formulæ, will show that the notion of an *average* imported into the doctrine of value by Dr. Emil Sax ("Staatswirthschaft") is not quite appropriate. As an instance in which great abridgment would be effected by mathematical expression, we might notice the last three chapters of Dr. Zuckerkandl's "Theorie der Preise." Again the difficulty of conveying technical propositions without the proper phraseology may be illustrated by Prof. Wieser's "Der natürliche Werth," when he speaks of value and final utility having place in a Communistic or Socialistic State (p. 26, note, and *passim*). May his meaning thus be formulated? In an economical *régime* distribution and exchange are regulated by the condition that the final utility of all concerned should be zero, the total utility a minimum, *subject to the law that there should be only one rate of exchange in a market.* In a communistic or utilitarian *régime* the limitation which the last italicized clause expresses is removed. In terms employed in our note (*e*) the economical adjustment is determined by the equations (α), (β), and (γ); the utilitarian adjustment is determined by (β) and (γ) only—in short, the distinction between the points *r* and *u* in our Fig. 9 referring to note (*e*).

In offering these too brief criticisms I regret that my limits impose a curtness which is hardly consistent with courtesy.

SECTION G.

MECHANICAL SCIENCE.

Opening Address by William Anderson, M.Inst.C.E., President of the Section.

I have had considerable difficulty in selecting a subject which should form the main feature of my address. This meeting being held in Newcastle, it seemed almost imperative that I should dwell upon two industries which may be said to have had their genesis here: that I should direct your attention to the extraordinary development of the system of transmitting power by hydraulic agency, and the use of the same agency for lifting enormous weights and exerting mighty pressures; and that I should not neglect to notice a manufacture of specially national importance—that of heavy artillery, and of ships of war sent forth fully equipped and ready to take their places in our first line of defence.

The desire which I felt of treating of these subjects was heightened by the opportunity which it would have afforded of paying a tribute of respect and admiration to the distinguished citizen of this town, who, by his genius and perseverance, created the Elswick Works, raised the character of British engineering, and rendered his country services so eminent that Her Majesty has seen fit to recognize them by bestowing honours higher than any which an engineer has hitherto been able to achieve.

But I felt that the themes mentioned, important as they are, have been frequently treated of by able men, and that I would perhaps render more service to Mechanical Science if I drew your attention to a subject which appears to me to be bearing with daily augmenting force on the practical manipulation of the materials used in construction. I allude to the molecular structure of matter. This branch of science has, up to the present time, been left very much in the hands of the chemist and the physicist, and I dare say that many engineers may think that it is by no means desirable to change the arrangement; but I hope to show that the progress of engineering, the more exact methods of dealing with the properties of materials, the increased demands on their powers of endurance, render it imperatively necessary that mechanics should interest themselves more deeply in their internal structures and the true meaning of the laws by which their properties are defined.

Five years ago, at Montreal, in his address to the Mathematical Section, Sir William Thomson took for his subject the ultimate constitution of matter, and discussed, in a most suggestive manner, the very structure of the ultimate atoms or molecules. He passed in review the theories extant on the subject, and pointed out the progress which had been made in recent years by the labours of Clausius, of Clerk Maxwell, of Tait, and of others, among whom his own name, I may add, stands in unrivalled prominence.

I will not presume to enter into the field of scientific thought and speculation traversed by Sir William Thomson, because I am only too conscious that both my mathematical knowledge and my acquaintance with the natural sciences is too limited to entitle the views which I may have formed to any respect; I propose to draw attention only to some general considerations, and to point out to what extent they practically interest the members of this Section.

In a lecture delivered at the Royal Institution last May, Prof. Mendeleeff attempted to show that there existed an analogy between the constitution of the stellar universe and that of matter as we know it on the surface of the earth, and that from the motions of the heavenly bodies down to the minutest interatomic movements in chemical reactions the third law of Newton held good, and that the application of that law afforded a means of explaining those chemical substitutions and isomerisms which are so characteristic, especially of organic chemistry.

Examined from a sufficient distance, the planetary system would appear as a concrete whole, endowed with invisible internal motions, travelling to a distant goal. Taken in detail, each member of the system may be involved in movements connected with its satellites, and again each planet and satellite is instinct with motions which, there is good reason to believe, extend to the ultimate atoms, and may even exist, as Sir W. Thomson has suggested, in the atoms themselves. The total result is complete equilibrium, and, in many cases, a seeming absence of all motion, which is, in reality, the consequence of dynamic equilibrium, and not the repose of immobility or inertness.

The movements of the members of the stellar universe are, many of them, visible to the eye, and their existence needs no demonstration; but the extension of the generalization just mentioned to substances lying, to all appearances, inert on the earth's surface is not so apparent. In the case of gases, indeed, it is almost self-evident that they are composed of particles, so minute as to be invisible, in a condition of great individual freedom. The rapid penetration of odours to great distances, the ready absorption of vapour and of other gases, and the phenomena connected with diffusion, compression, and expansion seem to demonstrate this. One gas will rapidly penetrate another and blend evenly with it, even if the specific gravities be very different. The particles of gases are, as compared with their own diameters, separated widely from each other; there is plenty of room for additional particles; hence any gas which would, by virtue of its molecular motion, soon diffuse itself uniformly through a vacuum will also diffuse itself through one or more other gases, and once so diffused, it will never separate again. A notable example of this is the permanence of the constitution of the atmosphere, which is a mere mixture of gases. The oxygen and the nitrogen, as determined by the examination of samples collected all over the world, maintain sensibly the same relative proportions, and even the carbonic acid, though liable to slight local accumulations, preserves, on the whole, a constant ratio; and yet the densities of these gases differ very greatly.

Liquids, though to a much less degree than gases, are also composed of particles separated to a considerable relative distance from each other, and capable of unlimited motion where no opposing force, such as gravity, interferes; for under such circumstances their energy of motion is not sufficient to overcome the downward attraction of the earth; hence they are constrained to maintain a level surface.

The occlusion of gases without sensible comparative increase of volume shows that the component particles are widely separated. Water, for example, at the freezing-point occludes above one and three-quarter times its own volume of carbonic oxide, and about 480 times its volume of hydrochloric acid, with an increase of volume, in the latter case, of only one-third; and sulphuric acid absorbs as much as 600 times its bulk of methylic ether. The quantity of gas occluded increases directly as the pressure, which seems to indicate that the particles of the occluded gas are as free in their movements among the particles of the liquid as they would be in an otherwise empty containing vessel.

Liquids, therefore, are porous bodies whose constituent particles have great freedom of motion. It is no wonder, consequently, that two dissimilar liquids, placed in contact with each other, should interpenetrate one another completely, if time enough be allowed; and this time, as might be expected, is considerably greater than that required for the blending of gases, because of the vastly greater mobility of the particles of the latter. The diffusion of liquids takes place not only when they are in actual contact, but even when they are separated by partitions of a porous nature, such as plaster of Paris, unglazed earthenware, vegetable or animal membranes, and colloidal substances, all of which may be perfectly water-tight in the ordinary sense of the term, but yet powerless to prevent the particles of liquids making their way through simultaneously in both directions.

The rate of diffusion increases with the temperature; but an increase of temperature, we know, is synonymous with increased molecular motion of the body, and with increased activity of this kind we would naturally look for more rapid interchanges of the moving atoms. Such phenomena are only conceivable on the supposition that active molecular motion is going on in an apparently still and inert mass.

When we come to solid substances the same phenomena appear.

The volumes of solids do not differ greatly from the volumes of the liquids from which they are congealed, and the solid volumes are generally greater. The volume of ice, for example, is one tenth greater than that of the water from which it separates. Solid cast-iron just floats on liquid iron, and most metals behave in the same way; consequently, if the liquids be porous the solids formed from them must be so also; hence, as might be expected, solids also occlude gases in a remarkable manner. Platinum will take up five and a half times its own volume of hydrogen, palladium nearly 700 times, copper 60 per cent., gold 29 per cent., silver 21 per cent. of hydrogen and 75 per cent. of oxygen, iron from eight to twelve and a half times its volume of a gaseous mixture chiefly composed of carbonic oxide.

Not only are gases occluded, but they are also transpired under favourable conditions of temperature and pressure, and even liquids can make their way through. Red-hot iron tubes will permit the passage of gases through their substance with great readiness, common coal-gas under high pressure transpires through the steel of the containing vessel, and it is well known that mercury will penetrate tin and other metals with great rapidity, completely altering their structure, their properties, and even their chemical compositions.

The evidence of the mobility of the atoms or molecules of solid bodies is overwhelming. Substances when reduced to powder, may, even at ordinary temperatures, be restored to the homogeneous solid condition by pressure only. Thus, Prof. W. Spring, some ten years ago, produced from the powdered nitrates of potassium and sodium, under a pressure of thirteen tons to the square inch, homogeneous transparent masses of slightly greater specific gravity than the original crystals, but not otherwise to be distinguished from them. More than that, from a mixture of copper filings and sulphur he produced, under a pressure of thirty-four tons per square inch, perfectly homogeneous cuprous sulphide, Cu_2S, the atoms of the two elements having been brought, by pressure, into so intimate a relation to each other that they were able to arrange themselves into molecules of definite proportion; and, still more remarkable, the carefully dried powders of potash, saltpetre, and acetate of soda were, by pressure, caused to exchange their metallic bases and form nitrate of soda and acetate of potash.

The same movements and changes have taken place, and are still going on, in Nature's laboratory. During the countless ages with which geology deals, and under the enormous pressures of superincumbent masses, stratified sedimentary rocks become crystallized and assume the appearance of rocks of igneous origin, and not only so, but rocks of whatever origin, crushed and ground to pieces by irresistible geological disturbances, reconstruct themselves into new forms by virtue of the still more irresistible and constant action of molecular forces and movements. Those who had the privilege of hearing Prof. A. Geikie's brilliant lecture at the Royal Institution last session will remember the striking series of microscopic slides which he exhibited, and by the aid of which he illustrated the changes of structure to which I have alluded.

At high temperatures the same effects are more easily produced on account of the greater energy of motion of the atoms or molecules. In the process of the manufacture of steel by cementation, or in case-hardening, the mere contact of iron with solid substances rich in carbon is sufficient to permit the latter to work its way into the heart of the former, while in the formation of malleable cast-iron the carbon makes its way out of the castings with equal facility; it is a complete case of diffusion of solid substances through each other, but, on account of the inferior and restricted mobility of the particles at ordinary temperatures, a higher degree of heat and longer time are needed than with liquids or gases.

Again, when, by the agency of heat, molecular motion is raised to a pitch at which incipient fluidity is obtained, the particles of two pieces brought into contact will interpenetrate or diffuse into each other, the two pieces will unite into a homogeneous whole, and we can thus grasp the full meaning of the operation known as "welding." By the ordinary coarse methods but few substances unite in this way, because the nature of the operation prevents, or at any rate hinders, the actual contact of the two substances; but when molecular motion is excited to the proper degree by a current of electricity, the faces to be joined can be brought into actual contact, the presence of foreign substances can be excluded, and many metals not hitherto considered weldable, such as tool steel, copper, and aluminium are readily welded, as many of us witnessed at the hands of Prof. Ayrton in the highly instructive lecture on electricity delivered last year at our Bath meeting. Again, a mere superficial union of different metals takes place readily under the influence of high temperature and moderate pressure, as we see in the operations of tinning, soldering, and brazing. The surfaces of the metals must be made as clean as possible; the solder, which melts at a lower temperature than the metal to be soldered or brazed, is applied, and at a comparatively moderate temperature and under very slight pressure the particles interpenetrate each other; the two metals unite and form an alloy, by the intervention of which the two surfaces are joined. This effect is very well illustrated by the action which takes place at the surface of contact of two dissimilar liquids. If brine, for example, be placed in the lower part of a glass tube, and ordinary water, coloured in some way, be carefully poured on the top, a sharp plane of demarcation will appear, but in a short time the plane of separation will become blurred, and will ultimately disappear, a local blending of the two waters will take place, and will thus present a case of fluid-welding.

It seems plain, therefore, that apparently inert solid masses are also built up of moving particles in dynamic equilibrium, for without such an assumption it would be hard to explain the phenomena to which I have alluded. But in addition to this evidence we can adduce the effects of other forms of energy, which we recognize under the names of radiant heat, light, and electricity. These we know to be forms of motion which can be communicated and converted from one to the other, from the invisible to the visible. The movement which we term radiant heat, acting through the instrumentality of the luminiferous ether which is believed, on the strongest grounds, to pervade all space and all matter, is competent to augment the quantity of movement in the particles of substances, and generally to cause an enlargement of volume. Conversely, when the particles, by contact or by radiation, part with their heat, either to surrounding objects or to space, the quantity of motion is reduced, the body contracts, and this contraction goes on down to temperatures far below those at which we have to work in practice, and consequently at all ordinary temperatures there must be abundant room for molecular motion.

Again, energy in the form of light operates changes in the surface of bodies, causing colours to fade, and giving to photography the marvellous power which it possesses. Light decomposes the carbonic acid of the atmosphere in the chlorophyll of green leaves, and determines chemical combinations, such as chlorine with hydrogen to form hydrochloric acid, or carbonic oxide with chlorine to form chlorocarbonic acid. It is inconceivable that these effects could be produced unless the undulations of light were competent to modify the molecular motions already existing in the solid liquid and gaseous bodies affected.

Electricity exerts a similar influence. Generated by the molecular movements caused by chemical activity, whether directly, as in the primary battery, or indirectly, as in the dynamo, it is competent to increase the molecular movements in bodies so as to produce the effects of heat directly applied; it is capable of setting up motions of such intensity as to produce chemical changes and decompositions, to say nothing of the whole series of phenomena connected with magnetism, with induction, or the action through space and through non-conducting bodies, which, as in the case of radiant heat and light, seems to imply the existence of an interatomic ether. Conversely, changes of molecular equilibrium, brought about by the action of external forces, produce corresponding changes in electrical currents: witness the effects of heat, for example, on conductivity and the wondrous revelations of molecular change obtained by the aid of Prof. Hughes' induction balance. The behaviour of explosives illustrates also, and in a striking manner, the effects of disturbing molecular equilibrium. An explosive is a substance which contains in itself, in a solid or liquid form, all the elements necessary to produce a chemical change by which it is converted into the gaseous state. The application of heat, of pressure, or of impact, causes, as in Prof Spring's experiments, chemical union to take place, first at the spot where the equilibrium is disturbed by the application of external force, and afterwards, with great rapidity, throughout the mass, the disturbance being propagated either by the air surrounding the particles or by the luminiferous ether with all the rapidity of light; the chemical reaction is accelerated by the pressure which may arise, for example, if the explosive be confined in the chamber of a gun or in the borehole of a blast. High explosives, as they are termed, are comparatively inert to ordinary ignition; but when the molecular equilibrium is suddenly disarranged throughout the mass by the detonation of a percussion fuse, combination takes place instantly throughout, and violent explosion follows. In a similar manner some gases, such as acetylene, cyanogen, and others, can be decomposed by detonation and reduced to their solid constituents. Prof. Thorpe has devised a very beautiful lecture experiment, in which carbon disulphide is caused to fall asunder into carbon and sulphur by the detonation of fulminate of mercury fired by an electric spark. In these cases a reverse action takes place, but illustrates equally well the conversion of one form of energy into others, and the consequent disturbance of molecular equilibrium in the substances affected. It seems to me clear, therefore, that the time has come when the conception of dynamic equilibrium in the ultimate particles of matter in all its forms must take the place of the structural system of inert particles. I cannot conceive how the phenomena which I have enumerated can be explained on the supposition that matter is built up of motionless particles—how, for example, a stack of red and yellow bricks could ever change the order of arrangement without being completely pulled asunder and built up again, in which case an intermediate state of chaos would exist; but I can easily comprehend how a dense crowd of people may appear as a compact mass, streaming, it may be, in a definite direction, and yet how each member of that mass is endowed with limited motion, by virtue of which he may push his way through without disturbing the general appearance; how the junction of two crowds would form one whole, though, perchance, altered in character; and how even Prof. Spring's experiments may be explained by the supposition that bystanders on the edge of a crowd would be forced, by external pressure, to form part of it and partake of its general movements.

It is a suggestive fact that the product of the atomic weight of certain groups of substances and their specific heats is a constant quantity which, for the greater number of the elements, does not differ much from 6·5. This implies that the quantity of heat necessary to raise the temperature of the atoms of any one of the groups to any given extent is the same; hence these atoms will be endowed with the same amount of energy at any given temperature, and therefore would be competent to replace each other without disturbing the general dynamic equilibrium.

When it is conceded that molecular motion pervades matter in all its forms, and that the solid passes, often insensibly, into the fluid, or even direct into the gaseous, it follows, almost of necessity, that there must be a border-land, the limits of which are determined by temperature and pressure, in which substances are constantly changing from one state to another. This is observable in fusion, but to a more marked degree in evaporation, where the particles are being incessantly launched into space as gas and return as constantly to the liquid state. Henri Ste. Claire Deville has investigated similar phenomena in chemical reactions; he has found that at certain temperatures and pressures substances fall asunder and combine much in the way in which evaporation takes place, and has given the name of "dissociation" to this property of matter Prof. Mendeleeff and others have extended the great French chemist's observations, and have formulated the general law that substances are capable of dissociation at all temperatures, not only in the case of chemical unions, but also in that of solutions.

If steel be looked upon as a solution of carbon and iron, then the hardening of steel is explained by the theory that dissociation has taken place at the temperature at which it is suddenly cooled, the sudden cooling fixing the molecular motion at such an amplitude or phase that it gives a characteristic structure, one of the properties of which is extreme hardness. In tempering, the gradual communication of heat causes dissociation again to take place, the molecular equilibrium is modified by the increased energy imparted to the particles, and when suddenly cooled at any point there remains again a distinct substance, composed of iron and carbon, partly in various degrees of solution and partly free, and again possessing special mechanical qualities. That steel, and probably other alloys, differ in the nature of their composition according to the way in which they are worked, both with respect to heat and mechanical pressure, has been abundantly proved by many eminent metallurgists, and especially by Sir Frederick Abel, in the extended researches which he has recently carried out, on the hardening of steel, for the Institution of Mechanical Engineers, and it would appear as a natural sequence that the properties of steel would be greatly affected by the manner in which its temperature was changed, as we indeed find that it is when these changes are produced by baths of melted metals, by oil, or by water at different temperatures. The action which takes place may be illustrated by what would happen supposing that a complicated dance, such as the lancers, were suddenly stopped in various phases of the figures. The component parts would always remain the same, but the relative distribution of the partners would vary continually, and analysis would show that at one time each gentleman was associated with a particular lady; at another, that two ladies were attached to a single gentleman, while a number of gentlemen had no partners at all; and yet again, at another, that the movements which were once rectilinear have become circular. In each case the groups would assume a totally distinct appearance.

In support of these views it may be stated that, as far as I know, no pure element is capable of being hardened or tempered, the reason being that no chemical change can take place when there is only one substance; the effect of heat or pressure, however suddenly applied, produces merely a change of form which does not appear to carry with it any corresponding alteration of mechanical properties.

It may be urged, however, that it is unlikely that alloys or solutions could be affected in a manner so marked merely by small changes at comparatively low temperatures; but I would observe that "great and little" are relative terms, and we have abundant evidence of the immense effects produced by what would be called "little" causes. Sir Frederick Bramwell, in his address last year, drew attention to the importance of the "next to nothing." It is not so very long ago that anyone would have been considered a dreamer for propounding a theory that the presence of the fraction of a per cent. of carbon, phosphorus, or sulphur would totally alter the character of iron; it is known that the addition of one two-thousandth part of aluminium to molten iron makes the pasty ma s as fluid as water; that the presence of the smallest impurity in copper has a disastrous effect on its powers of conducting electricity; and that the addition of one-thousandth part of antimony converts the "best selected" copper into the worst conceivable. I need hardly allude to the great part played in Nature by microscopic organisms, and how much of the beauty of our seas and rivers is derived from substances so minute that nothing but the electric beam of Prof. Tyndall is capable of revealing their presence.

There is one more circumstance connected with my subject to which I must draw your attention, because, though its application to the mechanical properties of substances is very recent, it promises to be of great importance. I allude to the periodic law of Dr. Mendeleeff. According to that law, the elements, arranged in the order of their atomic weights, exhibit an evident periodicity of properties, and, as Prof. Carnelley has observed, the properties of the compounds of the elements are a periodic function of the atomic weights of their constituent elements. Acting on these views, Prof. Roberts-Austen has recently devoted much time and labour to testing their exactness with reference to the mechanical properties of metals. The investigation is surrounded by extraordinary difficulties, because one of the essential features of the inquiry is that the metals operated on should be absolutely pure. For chemical researches a few grains of a substance are all that is needed, and the requisite purity can be obtained at a moderate cost of time and labour; but when mechanical properties have to be determined considerable masses are needed, and the funds necessary for obtaining these are beyond the reach of most private individuals. I cannot help suggesting that wealthy institutions, such as many of those connected with our profession, could not employ their resources more wisely than in giving the means of following up the researches which Prof. Roberts-Austen has inaugurated.

In view of the difficulty of obtaining metals of sufficient purity, he selected gold as his base, because that metal can be more readily brought to a state of purity than any other, and is not liable to oxidation. In a communication to the Royal Society, made last year, he shows that the metals alloyed with gold which diminish its tenacity and extensibility have high atomic volumes, while those which increase these properties have either the same atomic volumes as gold or have lower ones. The inquiry has only just been commenced, but it appears to me to promise results which, to the engineer, will prove as important and as fruitful of progress as the great generalization of Mendeleeff has been to chemists. A law which can not only indicate the existence of unknown elements but which can also define their properties before they are discovered, if capable of application to metallurgy, must surely yield most valuable results, and will make the compounding of alloys a scientific process instead of the lawless and haphazard operation which it is now.

The practical importance of the views I have enunciated are, I think, sufficiently obvious. Everyone will admit that an external force cannot be applied to a system in motion without affecting that motion; consequently matter, in whatever state, cannot be touched without changes taking place, which will be more or less permanent. The application of heat will cause a change of volume, and, at last, a change of condition; the application of external stresses will also produce a change of volume; and it is natural to infer that there must be some relation between the two, and, accordingly, Prof. Carnelley has drawn attention to the fact that the most tenacious metals have high melting-points, though here again there is a great want of exactness, partly on account of the difficulty of measuring high temperatures, and partly by reason of the scarcity of pure materials.

Again, long-continued stresses, or stresses frequently applied, may be expected to produce permanent changes of form, and so we arrive at what is termed the fatigue of substances. Stretched beyond their elastic limits, which limits I do not suppose to exist except when stresses are applied quickly, substances are permanently deformed, and the same effects follow the long application of heat. The constant recurrence of stresses, even of those within the elastic limit, causes changes in the arrangement of the molecules of substances which slowly alter the properties of the latter, and in this way pieces of machinery, which theoretically were abundantly strong for the work they had to perform, have failed after a more or less extended period of use. The effect is intensified if the stresses are applied suddenly, if they reach nearly to the elastic limit, and if they are imposed in two or more directions at once, for then the molecular disturbance becomes very intense, the internal equilibrium is upset, and a tendency to rupture follows. Such cases occur in artillery, in armour-plates, in the parts of machinery subject to impact; and, as might be expected, the destructive effects do not always appear at once, but often after long periods of time.

When considerable masses of metal have to be manipulated by forging or by pressure in a heated condition, the subsequent cooling of the mass imposes restrictions on the free movement of some, if not all, of the particles; internal stresses are developed which slowly assert themselves, and often cause unexpected failures. In the manufacture of dies for coining purposes, of chilled rollers, of shot and shell hardened in an unequal manner, spontaneous fractures take place without any apparent cause, and often after long delay, the reason being that the constrained molecular motion of the inner particles gradually extends the motion of the outer ones until a solution of continuity is caused.

Similar stresses occur in such masses as crank shafts, screw shafts, gun hoops, &c. The late General Kalakoutsky, some seventeen years ago, commenced a systematic investigation into the internal stresses in the tubes and hoops of guns and in armour-piercing shells. The method he pursued was to cut disks or rings about half an inch thick off the hoops and shells, to divide the metal of each disk into from four to six rings, to fix by means of silver plugs, on which very finely marked cross-lines were drawn, from four to eight points on the surface of each ring, and then to measure, with extreme exactness, the changes in diameter produced in every ring by the successive cutting out of the rings. Knowing by direct tests the mechanical properties of his material, he was able, from the changes in the diameters, to calculate what the tangential stresses in every part of each disk were, and to draw inferences as to their fitness for the work they were intended to perform. The same method of investigation has been pursued by Captain Noble of the Elswick Works, and by Lieutenant Crozier of the United States Artillery, with the practical result that probably much more attention will be paid in future to the principles on which the annealing and hardening of steel is carried on. A gun hoop or tube, to be in the best condition to resist a bursting stress, should have its inner surface in a state of compression, and its outer in a state of tension, and the hoops should be shrunk on to the tubes or on to each other with but very little pressure. General Kalakoutsky proposed, in order to set up beneficial internal stresses, that tubes which were being annealed should be cooled from the inside by a jet of steam, of air, of water, or of oil; and he advocated the practice of testing the effects of each new method of manufacture or of treatment by the careful measurements of slices of the finished material instead of working at random, as is still very much the practice. It is evident, also, that a sample of steel cut out of a gun hoop or crank shaft, and tested, can afford no indication of the available tenacity of the same sample *in situ*. When released from the constraint of its surroundings, the particles must, of necessity, change their condition, for the disturbing forces have been removed; and the probability is that, if the steel be good, the test will prove satisfactory, especially if some time be allowed to elapse between cutting out the sample and testing it, and a false security will be engendered such as has often led to disastrous results.

The influence of time on steel seems to be well established: the highest qualities of tool steel are kept in stock for a considerable period; and it seems certain that bayonets, swords, and guns are liable to changes which may account for some of the unsatisfactory results which have manifested themselves at tests repeated after a considerable interval of time. As all these things have been hardened and tempered, there must necessarily have been considerable constraint put upon the freedom of motion of the particles, this constraint has gradually been overcome, but at the expense of the particular quality of the steel which it was originally intended to secure.

I have now laid before you the views respecting the constitution of matter which I think are gaining ground, which explain many phenomena with which we are familiar, and which will serve as guides in our treatment of metals, and especially of alloys; but I must admit that the subject is still by no means clear, that a great deal more definition is wanted, and that we are still awaiting the advent of the man who shall do for molecular physics what Newton did for astronomy in explaining the structure of the universe.

One of the most remarkable features of the last thirty years is the introduction of petroleum, and the wonderful development to which the trade in it has attained.

Under the generic name of petroleum are embraced a vast variety of combinations of carbon and hydrogen, each of which is distinguished by some special property. At ordinary temperatures and pressures some are gaseous, some are liquid, and some solid, and most are capable of being modified by suitable treatment under various temperatures and pressures. The employment of petroleum in the arts is still extending rapidly. Used originally for illuminating purposes, it is now employed as fuel for heating furnaces and steam-boilers; as a working agent in heat-engines; valuable medicinal properties have been discovered; and as a lubricant it stands unrivalled.

As an illuminant, even in this country, it is, to a large extent, superseding every other in private houses, and even in public lamps, because it gives a cheaper and more brilliant light than ordinary gas, and leaves the consumer free from the tyranny of great and privileged companies.

As fuel it is especially convenient, cleanly, and economical. Stored in tanks of suitable construction, it is sprayed into the furnace without labour and without creating dust and dirt; it is especially convenient in locomotive and marine work on account of the rapidity, ease, and cleanliness with which it can be run into the tender or into the oil-bunkers of a ship. As a working agent in heat-engines it is employed in two ways. First as vapour, generated from the liquid petroleum contained in a boiler, very much in the same way as the vapour of water is used in an engine with surface condenser, the fuel for producing the vapour being also petroleum. Very signal success has been obtained by Mr. Yarrow and others in this mode of using mineral oil, especially for marine purposes and for engines of small power; there seems to be no doubt that by using a highly volatile spirit in the boiler a given amount of fuel will produce double the power obtainable by other means. and at the same time the machinery will be lighter and will occupy less space than if steam were the agent used. The other method is to inject a very fine spray of hot oil, associated with the proper quantity of air, into the cylinder of an ordinary gas-engine, and ignite it there by means of an electric spark or other suitable means. Attempts to use oil in this way date back many years, but it was not till 1888 that Messrs. Priestman Brothers exhibited at the Nottingham Show of the Royal Agricultural Society an engine which worked successfully with oil, the flashing-point of which was higher than 75° F., and was therefore within the category of safe oils. The engine exhibited was very like an ordinary Otto gas-engine, and worked in exactly the same cycle. A pump at the side of the engine forced air into a small receiver at a few pounds' pressure to the square inch. The compressed air, acting by means of a small injector, carried with it the oil in the form of fine spray, which issued into a jacketed chamber heated by the exhaust, in which the oil was vaporized. The mingled air and oil was thus raised to a temperature of about 300°, and was then drawn, with more air, into the cylinder, where, after being compressed by the return stroke of the piston, it was exploded by an electric spark, and at the end of the cycle the products of combustion were discharged into the air after encircling the spray chamber and parting with most of their heat to the injected oil. The results of careful experiments made by Sir William Thomson and by myself on different occasions were, that 1·73 pound of petroleum was consumed per brake-horse power per hour; but the combustion was by no means perfect, for a sheet of paper held over the exhaust-pipe was soon thickly spattered with spots of oil.

At the Windsor Show of the Royal Agricultural Society this year, Messrs. Priestman again exhibited improved forms of their engine; the consumption of oil fell to 1·25 pound per brake-horse power per hour, and a sheet of paper held over the exhaust remained perfectly clean. They also showed a portable engine of very compact construction, and quite adapted to agricultural use; the ordinary water cart, which has, in any case, to attend a portable steam-engine, being adapted to supply the water necessary to keep the working cylinder of the engine cool.

It is hardly necessary to state that the use of petroleum for furnace purposes of all kinds is increasing very rapidly, and the demand has naturally reacted on the supply in promoting improved means of transport; and Newcastle, again, has led the van in this matter, for Sir William Armstrong, Mitchell, and Co., Messrs. Palmer, and others have sent out a fleet of steamers constructed to carry the oil in bulk with perfect safety, both as regards the stowage of a cargo so eminently shifting, and with respect to risk from fire and from explosion.

The enormous consumption of petroleum and of natural gases frequently raises the question as to the probability of the proximate exhaustion of the supply; and, without doubt, many fear to adopt the use of oil, from a feeling that if such use once becomes general the demand will exceed the production, the price will rise indefinitely, and old methods of illumination, and old forms of fuel, will have to be reverted to From this point of view it is most interesting to inquire what are the probabilities of a continuous supply; and such an investigation leads at once to the question, "What is the origin of petroleum?" In the year 1877, Prof. Mendeleeff undertook to answer this question; and as his theory appears to be very little known, and has never been fully set forth in the English language, I trust you will forgive me for laying a matter so interesting before you. Dr. Mendeleeff commences his essay by the statement that most persons assume, without any special reason—excepting, perhaps, its chemical composition—that naphtha, like coal, has a vegetable origin. He combats this hypothesis, and points out, in the first place, that naphtha must have been formed in the depths of the earth. It could not have been produced on the surface, because it would have evaporated; nor over a sea bottom, because it would have floated up and been dissipated by the same means. In the next place, he shows that naphtha must have been formed beneath the very site on which it is found; that it cannot have come from a distance, like so many other geological deposits, and for the reasons given above—namely, that it could not be water-borne, and could not have flowed along the surface, while in the superficial sands in which it is generally found no one has ever discovered the presence of organized matter in sufficiently large masses to have served as a source for the enormous quantity of oil and gas yielded in some districts; and hence it is most probable that naphtha has risen from much greater depths under the influence of its own gaseous pressure, or floated up upon the surface of water, with which it is so frequently associated.
